The most precise individual γ/ϕ_3 measurement with an uncertainty of $\sim 5^\circ$ results from LHCb's amplitude model-independent study of $D_{B^-} \to K^0_S\pi^+\pi^-$ and $D_{B^-} \to K^0_SK^+K^-$ [119], using input from the charm threshold [80, 87]. LHCb's analysis of $D_{B^-} \to K^+\pi^-\pi^+\pi^-$ decays leads to the second most precise individual γ/ϕ_3 measurement with $\gamma/\phi_3 = 55.8^{\circ\,+6.0^\circ}_{-5.8^\circ} \pm 0.6^{\circ\,+6.7^\circ}_{-4.3^\circ}$ [113]. Here, the first uncertainty is due to $B^\pm \to DK^\pm$ statistics, the second systematic, and the third due to the uncertainty on charm-threshold input. This illustrates the importance of charm-threshold data, and the need for the analysis of larger threshold datasets to keep pace with the sharp increase in $B^\pm \to DK^\pm$ data

expected at the upgraded LHCb detector and Belle II. Further improvements in this mode are expected from including information on relative phases between D^0 and $\overline{D}^0$ amplitudes obtained from charm mixing [85, 94, 116].

The current world average on γ/ϕ_3 is dominated by LHCb who finds, combining its results with input from CLEO–c and BESIII in an amplitude-model independent approach, $\gamma = 63.8^{\circ}{}^{+3.5^{\circ}}_{-3.7^{\circ}}$ [111, 120]. Belle II, which is expected to reach excellent precision in γ/ϕ_3, recently released its first γ/ϕ_3 result, based on Belle, Belle II and charm threshold data [100].

The interference between mixing and decay in $B^0 \to D^0 h^0$ with $h^0 = \pi^0, \eta, \omega$ provides sensitivity to β, which can be extracted from the Dalitz plot of the subsequent $D^0 \to K^0_S \pi^+ \pi^-$ decay [38, 121–124]. The combined BaBar/Belle analysis based on this technique resolved the ambiguity in β present in other measurements [38].

Further details on *CP* violation in beauty and charm can be found in [125, 126].

69.4.2 *Charm Mixing and CP violation*

Time-dependent amplitude analyses in decays to final states that are accessible to both D^0 and $\overline{D}^0$ have unique sensitivity to mixing parameters. A Dalitz plot analysis of a self-conjugate final state, such as $K^0_S \pi^+ \pi^-$ and $K^0_S K^+ K^-$, allows a direct measurement of x and y, the normalized mass and width difference of the $D^0 - \overline{D}^0$ system's mass eigenstates [127]. This is in contrast to decays like $D^0 \to K^+ \pi^-$ which only provide access to decay-specific parameters x'^2, y'.

The phase differences between D^0 and $\overline{D}^0$ amplitudes across the Dalitz plot affect these measurements in the same way as those of γ/ϕ_3 in $B^+ \to DK^+$, and can be taken into account in an amplitude model-independent way using the same charm threshold results [65, 70–75, 125]. This approach recently resulted in the first observation of a non-zero mass difference between the neutral charm mass eigenstates by LHCb [128], using a model-independent analysis of $D^0 \to K^0_S \pi^+ \pi^-$. The "bin flip" technique applied in this measurements exploits that *CP*-conjugate regions of the $D^0 \to K^0_S \pi^+ \pi^-$ Dalitz plot have near-identical experimental efficiencies [129]. This measurement is also sensitive to *CP* violation in mixing and in the interference between mixing and decay, which is discussed further in [125, 126].

69.4.3 *Everything, Everywhere, All at Once*

The discussion above shows how closely related the measurements of γ/ϕ_3, charm mixing, and the analysis of charm threshold data are, due to the shared charm parameters. While above, the emphasis was on the importance of charm as input to γ/ϕ_3, and threshold data as input to charm mixing and γ/ϕ_3, these relationships are in fact omnidirectional. This is demonstrated by LHCb's combined γ/ϕ_3 fit to γ/ϕ_3-sensitive beauty decays to charm such as $B^- \to DK^-$, charm mixing, and charm threshold data. This combined analysis has a notable effect on charm parameters due to the input from beauty decays to charm [111].

69.4.4 *Searches for time-integrated CPV in charm*

The recent observation of direct *CP* violation in LHCb's analysis of $D^0 \to \pi^+ \pi^-$ and $D^0 \to K^+ K^-$ decays [130, 131], and the open question as to its Standard Model or beyond the Standard Model nature, add renewed interest in the search for *CP* violation in other decays.

Multibody decays, with their rich structure and varying strong phase across phase space, could potentially have particularly high sensitivity to *CP* violation. Comparing the results of amplitude fits for *CP*-conjugate decay modes provides a measure of *CP* violation, as for example done for $D^0 \to K^0_S K^{\pm} \pi^{\mp}$, $D^0 \to K^+ K^- \pi^+ \pi^-$, and $D^0 \to \pi^+ \pi^- \pi^+ \pi^-$ using LHCb and CLEO–c data [32, 132–134]. A widely-used amplitude model-independent technique to search for local *CP* violation in multibody phase space is based on performing a χ^2 comparison of *CP*-conjugate phase-space distributions. This method was pioneered by BaBar [135] and developed further in [136–138] with results reported by BaBar [135, 139] and LHCb in $D^{\pm} \to K^+ K^- \pi^{\pm}$ [140, 141], CDF in $D^0 \to K^0_S \pi^+ \pi^-$ [142], and LHCb in $D^+_{(s)} \to K^+ K^- K^+$, $D^+ \to \pi^- \pi^+ \pi^+$, $D^0 \to K^+ K^- \pi^+ \pi^-$, $D^0 \to \pi^+ \pi^- \pi^+ \pi^-$, and $\Xi^+_c \to p K^- \pi^+$ [138, 143–145]. Unbinned methods can increase sensitivity [146, 147] and have been applied by LHCb to $D^+ \to \pi^- \pi^+ \pi^+$, $D^0 \to \pi^+ \pi^- \pi^0$, $D^0 \to \pi^+ \pi^- \pi^+ \pi$, and $\Xi^+_c \to p K^- \pi^+$ [144, 145, 148–150].

An alternative model-independent approach is based on observables in four body decays that are odd under motion reversal ("naïve T") [151–159], which is equivalent to P for scalar particles [159]. One such observable is $C_T = \vec{p}_2 \cdot (\vec{p}_3 \times \vec{p}_4)$ where $\vec{p}_i$ are the decay products' three momenta in the decay's center of mass frame. Comparing the P violating asymmetry $A_T \equiv \frac{\Gamma(C_T>0)-\Gamma(C_T<0)}{\Gamma(C_T>0)+\Gamma(C_T<0)}$ with its C-conjugate provides sensitivity to *CP* violation. Additional variables are proposed in [159], which also provides an excellent review of this topic. Searches for *CP* violation using P-odd variables have been carried out by BaBar, Belle, FOCUS, and LHCb in $D^0 \to K^+ K^- \pi^+ \pi^-$ [160–163], $D^+ \to K^+ K^0_S \pi^+ \pi^-$, $D^+_s \to K^+ K^0_S \pi^+ \pi^-$ [164], $D^0 \to K^0_S \pi^+ \pi^- \pi^0$ [165], and $D^0 \to \pi^+ \pi^- \pi^+ \pi^-$ [149].

Recently, LHCb performed the first full angular analysis of the rare decays $D^0 \to \pi^+ \pi^- \mu^+ \mu^-$ and $D^0 \to K^+ K^- \mu^+ \mu^-$. From this, several observables with sensitivity to physics beyond the Standard Model are constructed, including *CP*-violating ones. The results are in agreement with Standard-Model predictions [166, 167].

All results of analyses mentioned in this section are compatible with *CP* conservation. The observation of *CP* violation in two body charm decays [130, 131], and the vast data samples about to be collected, provide grounds for optimism that this may change in the foreseeable future.

69.5 Summary

Multibody charm decays offer a rich phenomenology, including unique sensitivity to *CP* violation and charm mixing. This is a highly dynamic field with many new results (some of which we presented here) and rapidly increasing, high quality datasets. These datasets constitute a huge opportunity, but also a challenge to improve the theoretical descriptions of soft hadronic effects in multibody decays. For some measurements, model-independent methods, many relying on input from the charm threshold, provide a way of removing model-induced uncertainties. At the same time, substantial progress in the theoretical description of multibody decays is being made.

70. D^0-$\overline{D}^0$ Mixing

Revised September 2023 by D.M. Asner (BNL) and A.J. Schwartz (U. of Cincinnati).

The formalism for D^0-$\overline{D}^0$ mixing is closely related to that for CP violation; for further details on the latter, see the note "CP Violation in the Quark Sector" in this *Review*. The time evolution of the D^0–$\overline{D}^0$ system is described by the Schrödinger equation

$$i\frac{\partial}{\partial t}\begin{pmatrix}D^0(t)\\ \overline{D}^0(t)\end{pmatrix} = \left(\mathbf{M}-\frac{i}{2}\mathbf{\Gamma}\right)\begin{pmatrix}D^0(t)\\ \overline{D}^0(t)\end{pmatrix}, \tag{70.1}$$

where the $\mathbf{M}$ and $\mathbf{\Gamma}$ matrices are Hermitian, and CPT invariance requires that $M_{11} = M_{22} \equiv M$ and $\Gamma_{11} = \Gamma_{22} \equiv \Gamma$. The off-diagonal elements of $\mathbf{M}$ and $\mathbf{\Gamma}$ are referred to as the dispersive and absorptive parts, respectively, of the mixing. The mass eigenstates D_1 and D_2 of the Hamiltonian $\mathbf{M}$ - $i\mathbf{\Gamma}/2$ are defined as

$$|D_{1,2}\rangle \;\equiv\; p|D^0\rangle \pm q|\overline{D}^0\rangle\,, \tag{70.2}$$

where normalization imposes $|p|^2 + |q|^2 = 1$. If $p = \pm q$, then the mass eigenstates are CP eigenstates and CP is conserved in mixing. Our phase convention is $CP|D^0\rangle = -|\overline{D}^0\rangle$ and $\mathrm{Arg}(q/p) \in [-\pi/2, \pi/2]$, which imply that, in the absence of CP violation in mixing, D_2 is CP-even and D_1 is CP-odd.

The eigenvalues of $\mathbf{M}$ - $i\mathbf{\Gamma}/2$ are

$$\omega_{1,2} \;=\; \left(M-\frac{i}{2}\Gamma\right) \pm \frac{q}{p}\left(M_{12}-\frac{i}{2}\Gamma_{12}\right) \;\equiv\; m_{1,2}-\frac{i}{2}\Gamma_{1,2}\,, \tag{70.3}$$

where $m_{1,2}$ and $\Gamma_{1,2}$ are real and correspond to the masses and decay widths, respectively, of the $D_{1,2}$ mass eigenstates. As the trace $\Gamma_{11} + \Gamma_{22} = 2\Gamma$ is unchanged by diagonalizing $\mathbf{\Gamma}$, Γ must equal $(\Gamma_1 + \Gamma_2)/2$, the mean decay width. Solving for the eigenstates of the eigenvalues yields

$$\left(\frac{q}{p}\right)^2 = \frac{M_{12}^* - \frac{i}{2}\Gamma_{12}^*}{M_{12} - \frac{i}{2}\Gamma_{12}}\,. \tag{70.4}$$

If CP is conserved in mixing, then $(q/p)^2 = 1$ and M_{12} and Γ_{12} must be real. In this case, the difference in eigenvalues is $\Delta m \equiv m_2 - m_1 = 2M_{12}$ and $\Delta\Gamma \equiv \Gamma_2 - \Gamma_1 = 2\Gamma_{12}$. The signs of Δm and $\Delta\Gamma$ are difficult to predict from theory and thus must be determined experimentally.

We define dimensionless mixing parameters x and y as

$$x \equiv \frac{\Delta m}{\Gamma} \tag{70.5}$$

$$y \equiv \frac{\Delta\Gamma}{2\Gamma}\,. \tag{70.6}$$

These parameters are measured in several ways. The most precise values are obtained by measuring the time dependence of D^0 decays. For all methods, the initial flavor of the D^0 or $\overline{D}^0$ when produced must be determined. The most common method used for this is to reconstruct $D^{*+} \to D^0\pi^+$ or $D^{*-} \to \overline{D}^0\pi^-$ decays; the charge of the accompanying pion (which has low momentum in the lab frame and is often referred to as the "soft" pion) determines the flavor of the neutral D. BABAR and LHCb have also identified the flavor of the neutral D by reconstructing the semileptonic decays $B^+ \to \overline{D}^0\ell^+\nu$, $B^0 \to D^{*-}\ell^+\nu$, $B^- \to D^0\ell^-\nu$, and $\overline{B}^0 \to D^{*+}\ell^-\nu$; in this case the charge of the accompanying lepton determines the D flavor. Both experiments have used both tags together to select "double-tagged" $B \to D^{*\pm}\ell^{\mp}\nu$, $D^{*\pm} \to (D^0, \overline{D}^0)\pi^{\pm}$ decays, which have especially high purity. At e^+e^- collider experiments such as Belle, BABAR, and BESIII, the D flavor can also be determined by fully reconstructing a flavor-specific D decay on the "opposite side" of an event, i.e., recoiling against the signal-side D decay.

At BESIII, where $D\overline{D}$ pairs are produced near their threshold via $e^+e^- \to \psi(3770) \to D^0\overline{D}^0$, there is relatively little background and the purity of opposite-side tagging is equivalent to that achieved using $D^{*\pm}$ decays. However, BESIII operates at a symmetric e^+e^- collider, and the $D\overline{D}$ pairs are produced almost at rest in the lab frame. As a consequence, the D's do not travel any appreciable distance before decaying, and time-dependent analyses are not possible. To overcome this, measurements of mixing at BESIII utilize the quantum coherence of the initial $\psi(3770) \to D^0\overline{D}^0$ state and time-integrated measurements [1–5].

70.1 Time-Dependent Analyses

Our notation is as follows: Cabibbo-favored (CF) decay amplitudes are denoted $\overline{A}_f \equiv \langle f|H|\overline{D}^0\rangle$ and $A_{\overline{f}} \equiv \langle \overline{f}|H|D^0\rangle$; i.e, the final state is $f = K^+\ell^-\nu$, $K^+\pi^-$, $K^+\pi^-\pi^0$, etc. Doubly-Cabibbo-suppressed (DCS) decay amplitudes are denoted $A_f \equiv \langle f|H|D^0\rangle$ and $\overline{A}_{\overline{f}} \equiv \langle \overline{f}|H|\overline{D}^0\rangle$. When discussing decay rates, we neglect constant phase-space factors, which divide out in ratios of rates to common final states.

Starting from a pure $|D^0\rangle$ or $|\overline{D}^0\rangle$ state at $t = 0$, the time-dependent decay rates to "wrong-sign" final states can be written

$$r(t) \equiv \left|\langle f|H|D^0(t)\rangle\right|^2 = \left|\overline{A}_f\right|^2\left|\frac{q}{p}\right|^2\left|g_+(t)\,\lambda_f^{-1} + g_-(t)\right|^2 \tag{70.7}$$

$$\overline{r}(t) \;\equiv\; \left|\langle \overline{f}|H|\overline{D}^0(t)\rangle\right|^2 = \left|A_{\overline{f}}\right|^2\left|\frac{p}{q}\right|^2\left|g_+(t)\,\lambda_{\overline{f}} \;+\; g_-(t)\right|^2, \tag{70.8}$$

where

$$\lambda_f \;\equiv\; \frac{q}{p}\frac{\overline{A}_f}{A_f}\,, \quad \lambda_{\overline{f}} \;\equiv\; \frac{q}{p}\frac{\overline{A}_{\overline{f}}}{A_{\overline{f}}}\,, \tag{70.9}$$

and

$$g_\pm(t) \;=\; \frac{1}{2}\left(e^{-i\omega_1 t} \pm e^{-i\omega_2 t}\right). \tag{70.10}$$

A change in convention for the relative phase of D^0 and $\overline{D}^0$ would cancel between q/p and $\overline{A}_f/A_f$ or $\overline{A}_{\overline{f}}/A_{\overline{f}}$, leaving λ_f and $\lambda_{\overline{f}}$ unchanged. For multibody final states, these equations apply separately to each point in phase-space. Integrating over regions of phase-space can lead to enhanced sensitivity to CP violation; see the discussion below on multibody decays and the note "Review of Multibody Charm Analyses" in this *Review*. As the mixing parameters x and y are very small, $r(t)$ and $\overline{r}(t)$ are usually expanded to second order in x and y.

70.2 Semileptonic decays

Consider the final state $f = K^+\ell^-\bar{\nu}_\ell$, where $A_f = \overline{A}_{\overline{f}} = 0$ is an excellent approximation in the Standard Model. The final state f is accessible from a D^0 only via mixing,[1] and the decay rate is

$$r(t) = \left|\overline{A}_f\right|^2\left|\frac{q}{p}\right|^2|g_-(t)|^2 \;\approx\; \left|\overline{A}_f\right|^2\left|\frac{q}{p}\right|^2\left(\frac{x^2+y^2}{4}\right)(\Gamma t)^2\,e^{-\Gamma t}\,. \tag{70.11}$$

For $\overline{r}(t)$, q/p is replaced by p/q. In the Standard Model, CP violation in charm mixing is small and $|q/p| \approx 1$. In the limit of CP conservation, $r(t) = \overline{r}(t)$, and the time-integrated mixed decay rate relative to the time-integrated unmixed decay rate for semileptonic decays is

$$\frac{\displaystyle\int_0^\infty r(t)\,dt}{\displaystyle\int_0^\infty \left|\overline{A}_f\right|^2 e^{-\Gamma t}\,dt} \;=\; \frac{x^2+y^2}{2} \;\equiv\; R_M\,. \tag{70.12}$$

Table 70.1 summarizes results for R_M from semileptonic decays. The world average from the Heavy Flavor Averaging Group (HFLAV) [6] is $R_M = (1.30 \pm 2.69) \times 10^{-4}$.

[1] There exists a doubly Cabibbo-suppressed amplitude in which the c and $\bar{u}$ quarks exchange a W, and then the resulting d quark (from c) decays semileptonically. We neglect this second-order process.

Table 70.1: Results for $R_M = (x^2+y^2)/2$ in D^0 semileptonic decays. The HFLAV average assumes statistical and systematic uncertainties are uncorrelated. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded and thus are not included in the HFLAV average.

Year	Experiment	Final state(s)	R_M ($\times 10^{-3}$)	90% C.L. ($\times 10^{-3}$)
2008	Belle (492 fb^{-1}) [7]	$K^{(*)+}e^-\overline{\nu}_e$	$0.13\pm0.22\pm0.20$	< 0.61
2007	BABAR (344 fb^{-1}) [8]	$K^{(*)+}e^-\overline{\nu}_e$	$0.04\,^{+0.70}_{-0.60}$	$(-1.3, 1.2)$
2005	CLEO (9.0 fb^{-1}) [9]	$K^{(*)+}e^-\overline{\nu}_e$	$1.6\pm2.9\pm2.9$	< 7.8
1996	E791 (2×10^{10} evts) [10]	$K^+\ell^-\overline{\nu}_\ell$	$1.1\,^{+3.0}_{-2.7}\,^{+0.0}_{-0.1}$	< 5.0
	HFLAV Average [6]		$\mathbf{0.130 \pm 0.269}$	
2005*	Belle (253 fb^{-1}) [11]	$K^{(*)+}e^-\overline{\nu}_e$	$0.02\pm0.47\pm0.14$	< 1.0
2004*	BABAR (87 fb^{-1}) [12]	$K^{(*)+}e^-\overline{\nu}_e$	$2.3\pm1.2\pm0.4$	< 4.2

70.3 Wrong-sign decays to hadronic non-CP eigenstates

Consider the final state $f = K^+\pi^-$, i.e., $A_{\bar{f}}$ and $\overline{A}_f$ are CF, A_f and $\overline{A}_{\bar{f}}$ are DCS. Because CF and DCS decays proceed via tree-level amplitudes, and such amplitudes involve only the first two quark generations, direct CP violation is negligible[2]. The ratios of decay amplitudes can be written

$$\frac{A_f}{\overline{A}_f} = -\sqrt{R_D^+}\,e^{-i\delta_f} \qquad \frac{\overline{A}_{\bar{f}}}{A_{\bar{f}}} = -\sqrt{R_D^-}\,e^{-i\delta_f}\,, \quad (70.13)$$

where δ_f is the strong phase difference between the DCS and CF amplitudes. The minus sign originates from the weak phase difference between the amplitudes, specifically, the relative minus sign between V_{us} and V_{cd} (which produces a relative minus sign between $V_{cs}^*V_{ud}$ and $V_{us}^*V_{cd}$). The parameters R_D^+ and R_D^- are the ratios of the DCS decay rate to the CF decay rate. From the relevant CKM matrix elements, one estimates R_D^+, $R_D^- \sim \tan^4\theta_c$, where θ_c is the Cabibbo angle.

With the parameterization of Eq. (70.13), Eq. (70.9) becomes

$$\lambda_f^{-1} = \frac{p}{q}\frac{A_f}{\overline{A}_f} = -\sqrt{R_D^+}\left|\frac{p}{q}\right| e^{-i(\delta_f+\phi)} \quad (70.14)$$

$$\lambda_{\bar{f}} = \frac{q}{p}\frac{\overline{A}_{\bar{f}}}{A_{\bar{f}}} = -\sqrt{R_D^-}\left|\frac{q}{p}\right| e^{-i(\delta_f-\phi)}\,, \quad (70.15)$$

where $\phi = \mathrm{Arg}(q/p)$. The weak phase ϕ is independent of the final state f and is often referred to as "universal." For convenience, we define the mean decay rate $R_D \equiv (R_D^+ + R_D^-)/2$, and the decay rate asymmetry $A_D \equiv (R_D^+ - R_D^-)/(R_D^+ + R_D^-)$.

With these definitions, we expand the decay rates in Eqs. (70.7) and (70.8) to second order in the small mixing parameters x and y to obtain [13,14]:

$$r(t) = \left|\overline{A}_{\bar{f}}\right|^2 e^{-\Gamma t}\,[\,R_D(1+A_D) + \sqrt{R_D(1+A_D)}\left|\frac{q}{p}\right| y'_+(\Gamma t) + \left|\frac{q}{p}\right|^2 \frac{(x'^2_+ + y'^2_+)}{4}(\Gamma t)^2\Bigg] \quad (70.16)$$

and

$$\overline{r}(t) = \left|A_{\bar{f}}\right|^2 e^{-\Gamma t}\,[\,R_D(1-A_D) + \sqrt{R_D(1-A_D)}\left|\frac{p}{q}\right| y'_-(\Gamma t) + \left|\frac{p}{q}\right|^2 \frac{(x'^2_- + y'^2_-)}{4}(\Gamma t)^2\Bigg]\,, \quad (70.17)$$

where

$$x'_\pm = x\cos(\delta_f \pm \phi) + y\sin(\delta_f \pm \phi) \quad (70.18)$$

$$y'_\pm = y\cos(\delta_f \pm \phi) - x\sin(\delta_f \pm \phi)\,. \quad (70.19)$$

[2]For two quark generations, the weak phases can be defined to eliminate all weak-phase differences.

Defining the "strong-phase-rotated" mixing parameters

$$x' \equiv x\cos\delta_f + y\sin\delta_f \quad (70.20)$$

$$y' \equiv y\cos\delta_f - x\sin\delta_f \quad (70.21)$$

gives

$$x'_\pm = x'\cos\phi \pm y'\sin\phi \quad (70.22)$$

$$y'_\pm = y'\cos\phi \mp x'\sin\phi\,, \quad (70.23)$$

i.e., $x'_\pm$ and $y'_\pm$ are obtained from x', y' via an additional "weak-phase rotation." To summarize, parameters (x', y') are the mixing parameters (x, y) rotated by the strong phase δ_f, and parameters $(x'_\pm, y'_\pm)$ are the parameters (x', y') rotated by the weak phase $+\phi$ for D^0 decays and $-\phi$ for $\overline{D}^0$ decays. Note that $x'^2_+ + y'^2_+ = x'^2_- + y'^2_- = x'^2 + y'^2 = x^2 + y^2$. In Eqs. (70.16) and (70.17), a fourth term $R_D(1 \pm A_D)(x_\pm^2 - y_\pm^2)(\Gamma t)^2/4$ has been dropped, as it is negligible relative to the other terms for the range of decay times measured by experiments.

Comparing Eqs. (70.16) and (70.17), one sees that $r(t) \neq \overline{r}(t)$ and CP is violated if either $A_D \neq 0$, $|q/p| \neq 1$, or $\phi \neq 0$. These three inequalities correspond, respectively, to the three types of CP violation: in the decay amplitudes ($R_D^+ \neq R_D^-$); in the mixing; and due to interference between a mixed decay amplitude (i.e., mixing is followed by decay) and an unmixed decay amplitude. Whereas CP violation in the decay amplitudes is parameterized by A_D, CP violation in mixing is parameterized by $A_M \equiv (|q/p| - |p/q|)/(|q/p| + |p/q|)$.

In the limit of CP conservation, $A_D = 0$, $|q/p| = 1$, and $\phi = 0$. In this case

$$r(t) = \overline{r}(t) = \left|A_{\bar{f}}\right|^2 e^{-\Gamma t}\left[R_D + \sqrt{R_D}\,y'(\Gamma t) + \frac{x'^2 + y'^2}{4}(\Gamma t)^2\right], \quad (70.24)$$

and the total number of $D^0 \to f$ decays divided by the total number of $D^0 \to \bar{f}$ decays is

$$R = \frac{\displaystyle\int_0^\infty r(t)\,dt}{\displaystyle\int_0^\infty \left|A_{\bar{f}}\right|^2 e^{-\Gamma t}\,dt} = R_D + \sqrt{R_D}\,y' + \frac{x'^2 + y'^2}{2}\,. \quad (70.25)$$

The ratio R is more straightforward to measure than $r(t)$ or $\overline{r}(t)$, as there is no decay-time dependence. In Table 70.2 we report measurements of R, R_D, and A_D in $D^0 \to K^+\pi^-$ decays normalized to $D^0 \to K^-\pi^+$ decays, and results from HFLAV [15] obtained from a global fit to all relevant data that allows for both mixing and CP violation (see Section 70.7). The experiments typically perform a single fit for parameters R_D, x'^2, and y'; results for x'^2 and y' are listed in Table 70.3. Allowing for CP violation, the experiments measure parameters (R_D^+, x'^2_+, y'_+) and (R_D^-, x'^2_-, y'_-) [or equivalently (R_D, A_D) instead of (R_D^+, R_D^-)] by

Table 70.2: Results for R, R_D, and A_D as measured using $D^0 \to K^\pm\pi^\mp$ decays. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded and thus are not included in the HFLAV global fit (Section 70.7). The measurements with a dagger (†) are not included in the HFLAV global fit due to much poorer precision.

separately fitting the $D^0 \to K^+\pi^-$ and $\overline{D}^0 \to K^-\pi^+$ event samples.

Extraction of the mixing parameters x and y from measurements of x' and y' requires knowledge of the strong phase difference $\delta_{K\pi}$. This can be determined from the decay rates of $D_\pm \to K^+\pi^-$, where D_+ (D_-) denotes the CP-even (CP-odd) eigenstate. Since $|D_\pm\rangle = (|D^0\rangle \mp |\overline{D}^0\rangle)/\sqrt{2}$,

$$\sqrt{2}\,A(D_\pm \to K^+\pi^-) \;=\; A(D^0 \to K^+\pi^-) \mp A\left(\overline{D}^0 \to K^+\pi^-\right). \tag{70.26}$$

Squaring this amplitude and using Eq. (70.13) yields the relation

$$\cos\delta_{K\pi} \;=\; \frac{|A(D_+ \to K^+\pi^-)|^2 - |A(D_- \to K^+\pi^-)|^2}{2\,|A(D^0 \to K^+\pi^-)|\,|A(\overline{D}^0 \to K^+\pi^-)|}\,. \tag{70.27}$$

Measuring the right-hand side is possible if one can identify pure D_+, D_-, D^0, and $\overline{D}^0$ initial states. This is accomplished at CLEOc and BESIII utilizing the processes $e^+e^- \to \psi(3770) \to \overline{D}^0 D^0 \to (f_{CP})(K^+\pi^-)$, or $\psi(3770) \to \overline{D}^0 D^0 \to (f_{\overline{D}^0})(K^+\pi^-)$, where f_{CP} denotes a CP-specific final state, and $f_{\overline{D}^0}$ denotes a $\overline{D}^0$-flavor-specific final state. In the first case, quantum coherence and CP symmetry ensures that the $K^+\pi^-$ state originates from a neutral D with CP opposite that of f_{CP}. In the second case, at the time when the $\overline{D}^0$ decays, the opposite side is D^0. However, it can potentially mix to $\overline{D}^0$ before decaying to $K^+\pi^-$, and this introduces some dependence on the mixing parameters x and y. This dependence is seen explicitly in the observable

$$A_{K\pi}^{CP} \;\equiv\; \frac{|A(D_- \to K^-\pi^+)|^2 - |A(D_+ \to K^-\pi^+)|^2}{|A(D_- \to K^-\pi^+)|^2 + |A(D_+ \to K^-\pi^+)|^2}\,. \tag{70.28}$$

To lowest order in the mixing parameters [28],

$$A_{K\pi}^{CP} \;=\; \frac{2\sqrt{R_D}\cos\delta_{K\pi} + y}{1+R}\,, \tag{70.29}$$

where R is defined in Eq. (70.25). Such measurements are discussed in Section 70.5.

70.3.1 *Wrong-sign decays to multibody final states*

For multibody final states, Eqs. (70.13)-(70.25) apply to each point in phase-space.[3] Although x and y do not vary across phase-space, knowledge of the resonant substructure is needed to determine the strong phase difference δ from point to point to extract x and y. Alternatively, experimental knowledge of the strong phase difference between D^0 and $\overline{D}^0$ decay amplitudes across phase space [29] allow one to determine x and y independent of a decay model of resonant substructure. This phase information can be measured at the charm threshold, where CLEO-c and BESIII took data.

A time-dependent analysis at BABAR [30, 31] of $D^0 \to K^+\pi^-\pi^0$ decays, relative to CF $\overline{D}^0 \to K^+\pi^-\pi^0$ decays, determined the strong phase variation across the Dalitz plot and reported $x'' = (2.61\,^{+0.57}_{-0.68}\pm 0.39)\%$ and $y'' = (-0.06\,^{+0.55}_{-0.64}\pm 0.34)\%$. These mixing parameters are defined as

$$x'' = x\cos\delta_{K\pi\pi^0} + y\sin\delta_{K\pi\pi^0} \tag{70.30}$$

$$y'' = y\cos\delta_{K\pi\pi^0} - x\sin\delta_{K\pi\pi^0}\,, \tag{70.31}$$

in analogy with x', y', and $\delta_{K\pi}$ of Eqs. (70.20) and (70.21). Here, $\delta_{K\pi\pi^0}$ is the strong phase difference between the amplitudes $A(D^0 \to K^+\rho^-)$ and $A(\overline{D}^0 \to K^+\rho^-)$. The phase difference $\delta_{K\pi\pi^0}$ can be determined in a manner similar to that for $\delta_{K\pi}$: by using Eq. (70.27) and quantum-correlated measurements of the branching fractions $B(D_+ \to K^+\rho^-)$, $B(D_- \to K^+\rho^-)$, $B(D^0 \to K^+\rho^-)$, and $B(\overline{D}^0 \to K^+\rho^-)$ in $e^+e^- \to \psi(3770)$ events.

For the decay modes D^0 and $\overline{D}^0 \to K^+\pi^-\pi^+\pi^-$, Belle measured $R = (0.324 \pm 0.008 \pm 0.007)\%$ [32]. Subsequently, a phase-space-integrated analysis from LHCb [33] measured the product of a "coherence factor" $R_D^{K3\pi}$ and the strong-phase-rotated mixing parameter $y''_{K3\pi}$. This measurement resulted in an observation of charm mixing with 8.2σ significance.

Both the sign and magnitude of x and y without strong phases entering or sign ambiguity can be determined by measuring the time-dependent resonant substructure of multibody D^0 decays to self-conjugate final states [34, 35]. For such decays, e.g., $D^0 \to K^0_S\,\pi^+\pi^-$, the DCS and CF decay amplitudes populate the same Dalitz plot, which allows for direct measurement of the strong phase difference. Belle [35, 36], BABAR [37], and CLEO [38] have measured the overall phase difference between $D^0 \to K^*(892)^-\pi^+$ and $D^0 \to K^*(892)^+\pi^-$ to be $[173.9 \pm 0.7$ (stat. only)]°, $[177.6 \pm 1.1$ (stat. only)]°, and $[189\pm 10 \pm 3\,^{+15}_{-5}]$°, respectively. These results are close to the 180° expected from Cabibbo factors, i.e., the relative minus sign between $V^*_{cs}V_{ud}$ and $V^*_{us}V_{cd}$; thus they indicate a small strong phase. Four LHCb measurements [39–42] of x, y using $D^0 \to K^0_S\pi^+\pi^-$ decays are decay-model independent, as the model of resonances in the intermediate state is replaced by strong-phase measurements from CLEO-c [43] and BESIII [44]. Table 70.4 summarizes results from time-dependent analyses of self-conjugate multibody final states. World average values for the measurements listed are given later, as a result of the HFLAV global fit.

With regard to resonant substructure in $D^0 \to K^0_S\,\pi^+\pi^-$ decays, Belle [35, 36] measured the relative strong phase (statistical errors only) and the ratio R (central values only) of the DCS fit

[3] However, if the decay amplitudes involve the third generation, then $A_f/\overline{A}_f$ and $\overline{A}_{\overline{f}}/A_{\overline{f}}$ in Eq. (70.13) also have weak phase differences. However, this phase difference is estimated to be negligible for the sensitivity of current and foreseeable future experimental measurements.

Table 70.3: Results for x'^2 and y', as measured using $D^0 \to K^\pm\pi^\mp$ decays. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded and thus are not included in the HFLAV global fit. The measurements with a dagger (†) are not included in the HFLAV global fit due to much poorer precision. All confidence limits and intervals correspond to 95% C.L. The Belle 2006 results restrict x'^2 to the physical region. The BABAR confidence intervals are obtained from the fit, whereas Belle uses a Feldman-Cousins method, and CDF uses a Bayesian method.

‡This result allows for all types of CP violation and is superseded by Ref. [36], which assumes no direct CP violation in CF or DCS decays.

fraction relative to the CF fit fraction for five excited K states: $K^*(892)^+\pi^-$, $K_0^*(1430)^+\pi^-$, $K_2^*(1430)^+\pi^-$, $K^*(1410)^+\pi^-$, and $K^*(1680)^+\pi^-$. Similarly, BABAR [37, 47, 48] reported central values of R for $K^*(892)^+\pi^-$, $K_0^*(1430)^+\pi^-$, and $K_2^*(1430)^+\pi^-$. The systematic uncertainties on R are not evaluated. Large differences in R are observed among these final states, which indicates significant hadronic effects.

70.4 Decays to CP Eigenstates

When the final state f is a CP eigenstate, there is no distinction between f and $\overline{f}$. Thus $A_f = A_{\overline{f}}$ and $\overline{A}_{\overline{f}} = \overline{A}_f$. We denote final states with CP eigenvalues ±1 by $f_\pm$. Decays to CP eigenstates proceed mainly via singly Cabibbo-suppressed amplitudes. Such amplitudes can contain internal loops and thus involve the third quark generation; in this manner a weak phase would appear in

Table 70.5: Results for y_{CP} and A_Γ from D^0 decays to CP eigenstates. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been superseded.

‡This measurement has sufficient precision that y_{CP} for the normalization channel $D^0 \to K^-\pi^+$ must be accounted for. Thus, the measurement is $y_{CP}(h^+h^-) - y_{CP}(K^-\pi^+)$. HFLAV accounts for this small correction in their global fit.

§This result for y_{CP} is not superseded, but it is not included in the HFLAV average due to having some correlations with the result of Ref. [52] but much worse precision.

the decay amplitude, leading to direct CP violation. However, such internal loop amplitudes are suppressed, and the presence of a weak phase is often neglected.

The mixing parameter y may be measured by comparing the rate for D^0 decays to CP eigenstates such as K^+K^- with the rate to flavor eigenstates such as $K^-\pi^+$ [14]. If decays to K^+K^- have a shorter effective lifetime than those to $K^-\pi^+$, then $\Gamma_+ > \Gamma_-$, or, since CP violation is very small, $\Gamma_2 > \Gamma_1$ and y is positive. For small mixing ($x, y \ll 1$), the decay rates for $D^0 \to f_\pm$ and $\overline{D}^0 \to f_\pm$ have an approximately exponential time dependence:

$$r_\pm(t) \propto \exp(-\Gamma_\pm\, t) \tag{70.32}$$

$$\overline{r}_\pm(t) \propto \exp(-\overline{\Gamma}_\pm\, t)\,, \tag{70.33}$$

where the effective decay widths are given by

$$\Gamma_\pm = \Gamma\left(1 \pm \left|\frac{q}{p}\right| (y\cos\phi - x\sin\phi)\right) \tag{70.34}$$

$$\overline{\Gamma}_\pm = \Gamma\left(1 \pm \left|\frac{p}{q}\right| (y\cos\phi + x\sin\phi)\right)\,. \tag{70.35}$$

Thus, the effective decay rate to a CP eigenstate combining equal numbers of D^0 and $\overline{D}^0$ decays (e.g., an untagged sample with no production asymmetry) is

$$r_\pm(t) \;+\; \overline{r}_\pm(t) \;\propto\; e^{-(1\pm y_{CP})\Gamma t}\,, \tag{70.36}$$

where

$$y_{CP} = \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) y\cos\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) x\sin\phi \tag{70.37}$$

$$\approx y\cos\phi - A_M\, x\sin\phi\,. \tag{70.38}$$

If CP is conserved, $y_{CP} = y$. Most measurements of y_{CP} have used $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays, which are CP-even, measured relative to $D^0 \to K^-\pi^+$. Belle measured y_{CP} also using $D^0 \to K^0_S\,\omega$ decays [51], which are CP-odd, and $D^0 \to K^0_S\,K^+K^-$ decays [59], which are dominated by the CP-odd final state $K^0_S\,\phi$. Table 70.5 summarizes the current status of measurements.

In addition to y_{CP}, Belle [54], BABAR [58], CDF [57], and LHCb [50, 66] have reported measurements of the decay-rate asymmetry for CP-even final states:

$$A_\Gamma \equiv \frac{\Gamma_+ - \overline{\Gamma}_+}{\Gamma_+ + \overline{\Gamma}_+} \;=\; \frac{(1/\tau_+) - (1/\overline{\tau}_+)}{(1/\tau_+) + (1/\overline{\tau}_+)} \;=\; \frac{\overline{\tau}_+ - \tau_+}{\overline{\tau}_+ + \tau_+} \tag{70.39}$$

$$\approx \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) y\cos\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) x\sin\phi \tag{70.40}$$

$$\approx A_M\, y\cos\phi - x\sin\phi\,. \tag{70.41}$$

If CP is conserved, $A_\Gamma = 0$.

There is a contribution to Eq. (70.41) from direct CP violation, i.e., $|\overline{A}_f/A_f| \neq 1$ [72,73]. For $f = K^+K^-$ and $\pi^+\pi^-$, this contribution can be estimated from measurements of $A_{CP}(K^+K^-)$ and $A_{CP}(\pi^+\pi^-)$ (see below) and is much smaller than the current uncertainty on A_M; thus we neglect it here. We note that, when averaging A_Γ measurements over K^+K^- and $\pi^+\pi^-$ final states, the contribution from direct CP violation cancels, as it has the same magnitude but opposite signs for K^+K^- and $\pi^+\pi^-$ due to U-spin symmetry [73].

The asymmetry A_Γ is an asymmetry in the full decay widths. An asymmetry in partial widths is referred to as A_{CP} and is final-state dependent:

$$A_{CP} \equiv \frac{\Gamma(D^0 \to f) - \Gamma(\overline{D}^0 \to \overline{f})}{\Gamma(D^0 \to f) + \Gamma(\overline{D}^0 \to \overline{f})}\,. \tag{70.42}$$

Unlike A_Γ, which is measured by fitting decay time distributions, A_{CP} is measured by fitting for signal yields and (aside from acceptance effects) does not require measuring decay times. For neutral D decays, A_{CP} receives contributions from both direct (in the decay amplitudes) and indirect (due to mixing) processes: $A_{CP}(D^0 \to f) = A_{CP}^f + A_{CP}^{\rm indirect}$. The latter indirect contribution depends on the mixing parameters x and y:

$$\begin{aligned} A_{CP}^{\rm indirect} &= \frac{1}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right) x \sin\phi - \frac{1}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right) y \cos\phi \\ &= -A_\Gamma\,. \end{aligned} \tag{70.43}$$

Numerous measurements of A_{CP} for decays to CP eigenstates are listed in this *Review* [74]. Table 70.6 summarizes the current status of measurements of the *difference* in A_{CP} for $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays: $\Delta A_{CP} \equiv A_{CP}(K^+K^-) - A_{CP}(\pi^+\pi^-)$. Within the Standard Model, $A_{CP}^{KK} \approx -A_{CP}^{\pi\pi}$ [75], and ΔA_{CP} essentially doubles any direct CP violation present. The difference is also advantageous experimentally, as several systematic uncertainties cancel. As $A_{CP}^{\rm indirect}$ is independent of final state, it subtracts out of ΔA_{CP}. However, at hadron experiments such as LHCb, there is a difference in efficiencies between K^+K^- and $\pi^+\pi^-$ such that $\langle t \rangle_{KK} \neq \langle t \rangle_{\pi\pi}$, i.e., the mean decay times slightly differ. This difference leads to a small contribution to ΔA_{CP} from $A_{CP}^{\rm indirect}$ [72]. The most recent ΔA_{CP} result from LHCb [76], based on 8.9 fb^{-1} of data, differs from zero with a statistical significance of 5.3σ. Thus, this measurement constitutes the first observation of CP violation in charm decays. These CP asymmetries are included in HFLAV's global fit for charm mixing parameters discussed below.

Table 70.6: Results for the difference in time-integrated CP asymmetries ΔA_{CP} between $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays. When a single uncertainty is listed, that corresponds to statistical and systematic uncertainties combined. The measurements with an asterisk (*) have been either superseded or combined with subsequent results and thus are not included in the HFLAV global fit.

Year	Experiment	ΔA_{CP} ($\times 10^{-3}$)
2019	LHCb (8.9 fb^{-1} B, D^* tags) [76]	-1.54 ± 0.29

2012*	LHCb (0.62 fb^{-1} D^* tag) [83]	$-8.2 \pm 2.1 \pm 1.1$
2012‡	Belle (976 fb^{-1}) [84]	$-8.7 \pm 4.1 \pm 0.6$

‡This preliminary result was not published and thus is not included in the HFLAV global fit.

70.5 Quantum-correlated $D^0\overline{D}^0$ Analyses

Measurements of R_D, $\cos\delta_{K\pi}$, $\sin\delta_{K\pi}$, x, and y can be obtained from a combined fit to time-integrated yields of single-tagged (ST) and double-tagged (DT) $D^0\overline{D}^0$ events produced at the $\psi(3770)$ resonance. Single-tagged events are those in which either the D^0 or $\overline{D}^0$ decay is reconstructed (identified), and the other neutral D decays generically. Double-tagged events are those in which both the D^0 and $\overline{D}^0$ decays are identified. Due to quantum correlations, the decay of a D^0, $\overline{D}^0$, D_+, or D_- projects the other neutral D into a state $\overline{D}^0$, D^0, D_-, or D_+, respectively. The CP-specific D_- and D_+ decays (or, neglecting CP violation, D_1 and D_2 decays) include interference between D^0 and $\overline{D}^0$ amplitudes, and this provides sensitivity to R_D and $\cos\delta_{K\pi}$. The flavor-specific D^0 and $\overline{D}^0$ decays include interference between D_1 and D_2 amplitudes, and this provides sensitivity to x and y. For details of this method, see Refs. [1–5].

BESIII has reported results using 2.9 fb^{-1} of $e^+e^- \to \psi(3770)$ data, where the quantum-correlated $D^0\overline{D}^0$ pairs are produced in a $C=-1$ state. They measure $y_{CP} = (-2.0 \pm 1.3 \pm 0.7)\%$ [56] from DT yields using a CP-eigenstate tag for one D and a flavor-specific semileptonic tag for the other; and they measure $A_{K\pi}^{CP} = (13.2 \pm 1.1 \pm 0.7)\%$ [85] from DT yields using a CP tag for one D and a $K^\pm\pi^\mp$ tag for the other. For y_{CP}, the CP eigenstates used are K^-K^+ (f_+), $\pi^+\pi^-$ (f_+), $K^0_S\,\pi^0\pi^0$ (f_+), $K^0_S\,\pi^0$ (f_-), $K^0_S\,\eta$ (f_-), and $K^0_S\,\omega$ (f_-). For $A_{K\pi}^{CP}$, seven additional CP eigenstates are included: $\pi^0\pi^0$ (f_+), $K^0_S\,\eta'$ (f_-), $K^0_S\,\phi$ (f_-), $K^0_L\,\pi^0$ (f_+), $K^0_L\,\omega$ (f_+), $K^0_L\,\pi^0\pi^0$ (f_-), and $\pi^+\pi^-\pi^0$ (mixed CP). Using Eq. (70.29) and external inputs for the CP-even fraction of $D^0 \to \pi^+\pi^-\pi^0$ (from Ref. [86]) and values of R_D and y (from HFLAV [87]), BESIII obtains $\delta_{K\pi} = (7.6\,^{+10.4}_{-11.6})^\circ$ [85].

CLEO-c has reported results using 0.82 fb^{-1} of $e^+e^- \to \psi(3770)$ data [88–90]. The values for y, R_M, $\cos\delta_{K\pi}$, and $\sin\delta_{K\pi}$ are obtained from a combined fit to the ST (hadronic only) and DT yields. The DT yields include events in which one D is reconstructed in a hadronic mode and the other D is partially reconstructed in flavor-specific $D \to K^\mp e^\pm \nu$ and $D \to K^\mp \mu^\pm \nu$ modes. The CLEO-c analysis obtains $\cos\delta_{K\pi} = 0.81\,^{+0.22\,+0.07}_{-0.18\,-0.05}$ and $\sin\delta_{K\pi} = -0.01 \pm 0.41 \pm 0.04$. These fits allow $\cos\delta_{K\pi}$ and $\sin\delta_{K\pi}$ (and also x^2) to be unphysical. Constraining $\cos\delta_{K\pi}$ and $\sin\delta_{K\pi}$ to the physical range $[-1,+1]$ (i.e., interpreting $\delta_{K\pi}$ as an angle) and also using external inputs for x, y, and y_{CP} from HFLAV 2012 [91], CLEO-c obtains $\delta_{K\pi} = (18\,^{+11}_{-17})^\circ$ [90].

70.6 Summary of Experimental Results

The first evidence for D^0-$\overline{D}^0$ mixing was obtained in 2007 by Belle [69] and BABAR [20]. These results were confirmed by CDF [92] and, much later, by LHCb [22]. There are now numerous measurements of D^0-$\overline{D}^0$ mixing with various levels of sensitivity. For $D^0 \to K^+\pi^-$ decays, LHCb [21,22], CDF [19], and Belle [18] each exclude the no-mixing hypothesis by more than five standard deviations. LHCb [33] reported the observation of charm mixing in $D^0 \to K^+\pi^-\pi^+\pi^-$ decays with 8.2σ significance. However, the strong phase difference for this decay is not known, and thus the mixing parameters x and y cannot be extracted. The most precise measurements of x and y are obtained from a time-dependent Dalitz plot analysis of $D^0 \to K^0_S\,\pi^+\pi^-$ decays. This method was developed at CLEO [93] and subsequently used at Belle [35,36] and BABAR [37] with much higher statistics. BABAR has applied this method also to $D^0 \to K^0_S\,K^+K^-$ decays [37]. It has recently been used by LHCb with very high statistics [41,42] to obtain the most precise values of x and y to date. This measurement resulted in the first observation ($> 5\sigma$ significance) of dispersive mixing ($x \neq 0$).

The experimental measurements establish that D^0 and $\overline{D}^0$ mesons mix. This mixing is presumably dominated by long-distance amplitudes, which are difficult to calculate. Under the assumption that the observed mixing is due entirely to non-Standard Model processes, significant constraints on new physics models can be obtained [94]. A significant limitation to interpreting charm mixing in terms of new physics is the theoretical uncertainty on Standard Model predictions [95,96]. We note that the HFLAV global fit results for x and y (see below) indicate that

Table 70.7: HFLAV global fit results (see text) [15].

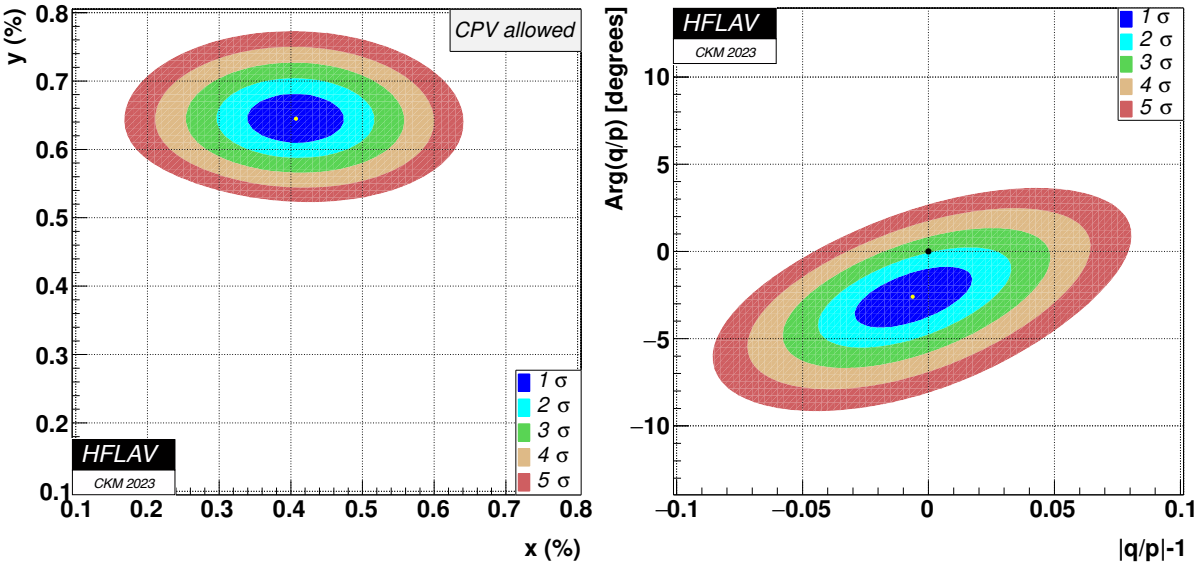

Figure 70.1: Two-dimensional 1σ-5σ contours for (x, y) (left) and for ($|q/p|$, Arg(q/p)) (right) as obtained by HFLAV [15]. In the right plot, the black dot denotes the no-CP-violation point $(0, 0)$.

charm mixing is at the upper end of the range of these predictions. The current situation would benefit from knowledge of the strong phase difference $\delta_{K\pi\pi}$ between $\overline{D}^0 \to K^+\pi^-\pi^0$ and $D^0 \to K^+\pi^-\pi^0$ decays, and similarly the strong phase difference $\delta_{K\pi\pi\pi}$ between $\overline{D}^0 \to K^+\pi^-\pi^+\pi^-$ and $D^0 \to K^+\pi^-\pi^+\pi^-$ decays. Such knowledge would allow one to extract x and y from measurements of (x''^2, y'') and $(x''_{K3\pi}, y''_{K3\pi})$ for these three- and four-body decays.

With regard to CP violation, by combining four separate measurements from two data sets totalling 8.9 fb^{-1} of data, LHCb observed CP violation in D decays for the first time [76]. The observable measured is the difference $\Delta A_{CP} = A_{CP}(K^+K^-) - A_{CP}(\pi^+\pi^-)$, which is dominated by *direct* CP violation, i.e., the potential contributions from indirect CP violation mostly cancel. The amount of direct CP violation observed is small: $\Delta A_{CP} = (-0.154 \pm 0.029)\%$. A theory calculation indicates this value is consistent with Standard Model expectations [97]; however, new physics contributions cannot be excluded. A subsequent LHCb measurement of $A_{CP}(K^+K^-) = (0.068 \pm 0.056)\%$ differs from zero by only 1.2σ [98]; thus, the ΔA_{CP} result is interpreted as indicating direct CP violation in $D^0 \to \pi^+\pi^-$ decays.

70.7 HFLAV Global Fit for Charm Mixing Parameters

The Heavy Flavor Averaging Group (HFLAV) performs global fits to all relevant mixing measurements to obtain world average values for the following parameters: mixing parameters x and y; strong phase differences $\delta_{K\pi}$ and $\delta_{K\pi\pi^0}$; the ratio R_D of $D^0 \to K^+\pi^-$ and $\overline{D}^0 \to K^+\pi^-$ partial widths; direct CP-violating parameters $A_D(K^+\pi^-)$, $A_{CP}^{KK} \equiv A_K$, and $A_{CP}^{\pi\pi} \equiv A_\pi$; and indirect CP-violating parameters $|q/p|$, Arg$(q/p) \equiv \phi$, ϕ_{12}, ϕ_2^M, and ϕ_2^Γ. Four separate fits are performed: *(a)* assuming no CP violation; *(b)* assuming no subleading amplitudes for indirect CP violation; *(c)* assuming no subleading amplitudes in Cabibbo-favored and doubly Cabibbo-suppressed decays; and *(d)* allowing for all CP violation. Fits *(b)* and *(c)* correspond to theory expectations [73,99,100], with the latter being less restrictive. For fit *(b)*, four fitted parameters are reduced to three using the relationship $\tan\phi = (x/y) \cdot (1 - |q/p|^2)/(1 + |q/p|^2)$ [99–101]; alternatively, one can fit for the three parameters $x_{12} \equiv 2|M_{12}|/\Gamma$,

$y_{12} \equiv |\Gamma_{12}|/\Gamma$, and $\phi_{12} \equiv \text{Arg}(M_{12}/\Gamma_{12})$, from which x, y, $|q/p|$, and ϕ can be derived. Details of these fits are given in Ref. [87].

The fits use Belle, BABAR, CDF, and LHCb measurements of $D^0 \to K^{(*)+}\ell^-\overline{\nu}$, K^+K^-, $\pi^+\pi^-$, $K^+\pi^-$, $K^+\pi^-\pi^0$, $K^+\pi^-\pi^+\pi^-$, $K^0_S\pi^+\pi^-$, $K^0_SK^+K^-$, and $\pi^+\pi^-\pi^0$ decays, as well as CLEO-c and BESIII measurements of $\cos\delta$, $\sin\delta$, and $A_{CP}(K^+\pi-)$ obtained from quantum-correlated branching fractions measured in $e^+e^- \to \psi(3770) \to D^0\overline{D}^0$ reactions. Correlations among observables are taken into account by using the error matrices provided by the experiments. Three observables input to the fit are themselves world average values calculated by HFLAV: $R_M = (x^2 + y^2)/2$ from $D^0 \to K^{(*)+}\ell^-\overline{\nu}$ decays (Table 70.1), and y_{CP} and A_Γ from $D^0 \to f_{CP}$ decays (Table 70.5). A measurement by LHCb of R_M using $D^0 \to K^+\pi^-\pi^+\pi^-$ decays is input separately.

The results of the fit as of September, 2023 are listed in Table 70.7. Confidence contours in the two dimensions (x, y) and $(|q/p|, \phi)$ resulting from the fit are plotted in Fig. 70.1. These contours are obtained by allowing, for any point in the two-dimensional plane, all other fitted parameters to take their preferred values. The 1σ–5σ boundaries drawn are the loci of points in which the χ^2 has risen above the minimum by 2.30, 6.18, 11.83, 19.33, and 28.67 units. The fit excludes the no-mixing point $x = y = 0$ at more than 11.5σ. The fit is consistent with CP conservation ($|q/p| = 1$, $\phi = 0$) at the 2σ level. The χ^2 of the all-CP-violation-allowed fit is 65.4 for 63−10 = 53 degrees of freedom, which is satisfactory. One-dimensional likelihood functions for parameters are obtained by allowing, for any value of the parameter, all other fitted parameters to take their preferred values. The resulting likelihood functions give central values, 68.3% C.L. intervals, and 95% C.L. intervals as listed in Table 70.7.

From the results of the HFLAV global fit, we conclude the following: (1) Since CP violation is small and y_{CP} is positive, the CP-even state is shorter-lived, as in the $K^0\overline{K}^0$ system. (2) Since x is positive, the CP-even state is heavier, unlike in the $K^0\overline{K}^0$ system. (3) The strong phase difference $\delta_{K\pi}$ is small but probably nonzero: the 95% C.L. interval is $3.7^\circ < \delta_{K\pi} < 18.2^\circ$. (4) While direct CP violation has been observed in D decays, there is still no evidence for indirect CP violation, i.e., $|q/p| \neq 1$ or $\phi \neq 0$. Observing such CP violation at the current level of sensitivity would indicate new physics.

70.8 Future Data

Current results are based primarily upon CLEO-c (0.82 fb^{-1} of $e^+e^- \to \psi(3770)$ data), Belle and BABAR (∼1.4 ab^{-1} of $e^+e^- \to \Upsilon(4S)$ data), CDF (9.6 fb^{-1} of $p\overline{p}$ collision data at $\sqrt{s}$ = 1.96 TeV), and LHCb Runs 1 and 2 (3.0 fb^{-1}+5.9 fb^{-1} of pp collision data at $\sqrt{s}$ = 7, 8, 13 TeV).

BESIII has accumulated 8 fb^{-1} of $e^+e^- \to \psi(3770)$ data and plans to collect a total of 20 fb^{-1} by 2025. These data should provide strong phase measurements that would enable improved model-independent determinations of mixing parameters from Belle II and LHCb. In 2019, Belle II began accumulating 50 ab^{-1} of $e^+e^- \to \Upsilon(4S)$ data [102], which is expected to take approximately ten years to collect. At LHCb, Run 2 was completed in 2018, Run 3 is now in progress, and Run 4 is planned for 2027-30 [103]. The goal for Runs 3 + 4 is to accumulate an additional 50 fb^{-1} of pp data at $\sqrt{s} \approx$ 14 TeV [104]. These data, along with the large e^+e^- dataset from Belle II, should provide more precise measurements of D^0-$\overline{D}^0$ mixing and direct CP violation, and might possibly uncover indirect CP violation in the neutral D system.

71. D_s^+ Branching Fractions

Revised September 2021 by J.L. Rosner (Chicago U.) and C.G. Wohl (LBNL).

Figure 71.1 shows a partial breakdown of the D_s^+ branching fractions. The rest of this note is about how the figure was constructed. The values shown make heavy use of CLEO measurements of inclusive branching fractions [1]. For references to other data cited in the following, see the Listings. An addendum updates branching fractions to two-body final states reported by the BESIII Collaboration in 2020 [2], and the conclusion stresses modes still to be identified.

71.1 Modes with leptons

The bottom (18.0±1.0)% of Fig. 71.1 shows the fractions for the modes that include leptons. The measured $K^0e^+\nu_e$ and $K^{*0}e^+\nu_e$ fractions have been doubled to take account of the corresponding $\mu^+\nu_\mu$ fractions. The sum of the exclusive $Xe^+\nu_e$ fractions is (6.0± 0.3)%, consistent with an inclusive semileptonic measurement of (6.5 ± 0.4)%. There seems to be little missing here.

71.2 Inclusive hadronic $K\overline{K}$ fractions

The Cabibbo-favored $c \to s$ decay in D_s^+ decay produces a final state with both an s and an $\bar{s}$; and thus modes with a $K\overline{K}$ pair or with an η, ω, η', or ϕ predominate (as may already be seen in Fig. 71.1 in the semileptonic fractions). We consider the $K\overline{K}$ modes first. A complete picture of the exclusive $K\overline{K}$ charge modes is not yet possible, because branching fractions for many of those modes have not yet been measured. However, CLEO has measured the inclusive K^+, K^-, K_S^0, K^+K^-, $K^+K_S^0$, $K^-K_S^0$, and $2K_S^0$ fractions (these include modes with leptons) [1]. And each of these inclusive fractions with a K_S^0 is equal to the corresponding fraction with a K_L^0: $f(K^+K_L^0) = f(K^+K_S^0)$, $f(2K_L^0) = f(2K_S^0)$, *etc.* Therefore, of all-inclusive fractions pairing a K^+, K_S^0, or K_L^0 with a K^-, K_S^0, or K_L^0, we know all but $f(K_S^0K_L^0)$.

We can get that fraction. The total K_S^0 fraction is

$$f(K_S^0) = f(K^+K_S^0) + f(K^-K_S^0) + 2f(2K_S^0) + f(K_S^0K_L^0) + f(\text{single } K_S^0) \ ,$$

where $f(\text{single } K_S^0)$ is the sum of the branching fractions for modes such as $K_S^0\pi^+2\pi^0$ with a K_S^0 and no second K. The $K_S^0\pi^+2\pi^0$ mode is in fact the only unmeasured single-K_S^0 mode (throughout, we shall assume that fractions for modes with a K or $K\overline{K}$ and more than three pions are negligible), and we shall take its fraction to be the same as for the $K_S^0 2\pi^+\pi^-$ mode, (0.30 ± 0.11)%. Any reasonable deviation from this value would be too small to matter much in the following. Adding the several small single-K_S^0 branching fractions, including those from semileptonic modes, we get $f(\text{single } K_S^0) = (1.7 \pm 0.2)$%. Using this, we have:

$$\begin{aligned} f(K_S^0K_L^0) &= f(K_S^0) - f(K^+K_S^0) - f(K^-K_S^0) \\ &\quad - 2f(2K_S^0) - f(\text{single } K_S^0) \\ &= (19.0 \pm 1.1) - (5.8 \pm 0.5) - (1.9 \pm 0.4) \\ &\quad - 2 \times (1.7 \pm 0.3) - (1.7 \pm 0.2) \\ &= (6.2 \pm 1.4)\% \ . \end{aligned}$$

Here and below we treat the errors as uncorrelated, although often they are not. However, our main aim is to get numbers for Fig. 71.1; errors are secondary.

There is a check on our result: The ϕ inclusive branching fraction is (15.7 ± 1.0)%, of which 34%, or (5.34 ± 0.34)% of D_s^+ decays, produces a $K_S^0K_L^0$. Our $f(K_S^0K_L^0) = (6.2 \pm 1.4)$% has to be at least this large—and it is, within the sizable error.

We now have all the inclusive $K\overline{K}$ fractions. We use $f(K^+\overline{K}^0) = 2\,f(K^+K_S^0)$, and likewise for $f(K^-K^0)$. For K^+K^- and $K_S^0K_L^0$, we subtract off the contributions from $\phi\ell^+\nu$ decay to get the purely hadronic $K\overline{K}$ inclusive fractions:

$$\begin{aligned} f(K^+K^-, \text{hadronic}) &= (15.8 \pm 0.7) - (2.1 \pm 0.3) \\ &= (13.7 \pm 0.8)\% \\ f(K^+\overline{K}^0, \text{hadronic}) &= (11.6 \pm 1.0)\% \\ f(K^-K^0, \text{hadronic}) &= (3.8 \pm 0.8)\% \\ f(2K_S^0 + 2K_L^0, \text{hadronic}) &= (3.4 \pm 0.6)\% \\ f(K_S^0K_L^0, \text{hadronic}) &= (6.2 \pm 1.4) - (1.5 \pm 0.2) \\ &= (4.7 \pm 1.4)\% \ . \end{aligned}$$

The fractions are shown in Fig. 71.1. They total (37.2 ± 2.2)% of D_s^+ decays.

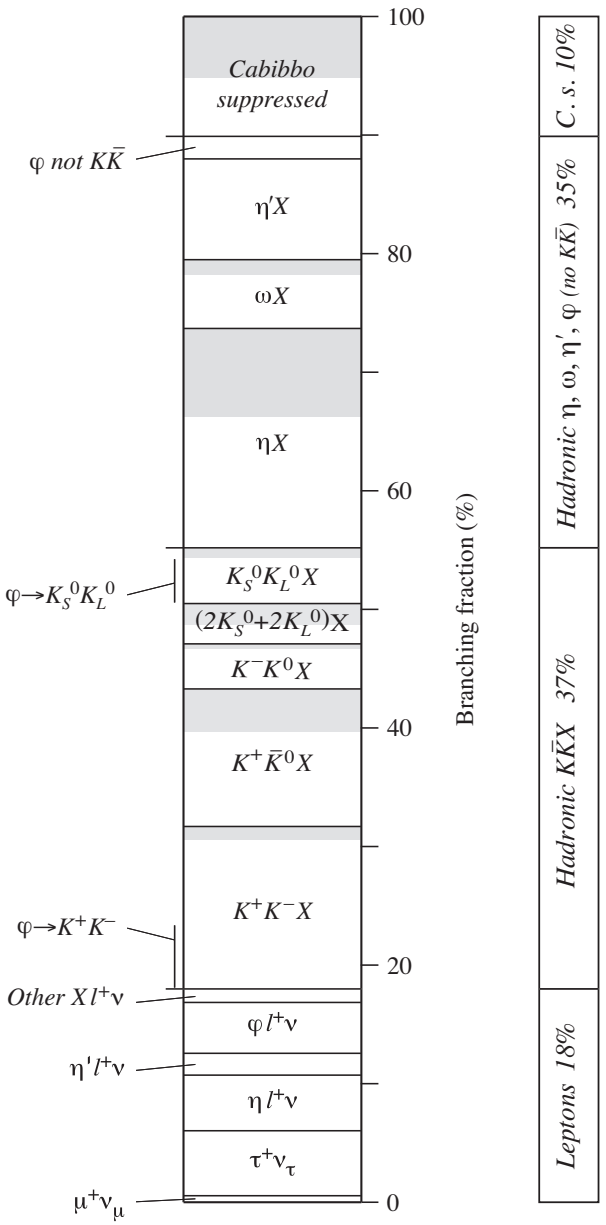

Figure 71.1: A partial breakdown of D_s^+ branching fractions. The hadronic bins in the left column show inclusive fractions. Shading within a bin shows how much of the inclusive fraction is not yet accounted for by adding up all the relevant exclusive fractions. The inclusive hadronic ϕ fraction is spread over three bins, in proportion to its decay fractions into K^+K^-, $K_S^0K_L^0$, and no-$K\bar{K}$ modes.

We can add more information to the figure by summing up measured branching fractions for exclusive modes within each bin:

K^+K^- *modes*—The sum of measured $K^+K^-\pi^+$, $K^+K^-\pi^+\pi^0$, and $K^+K^-2\pi^+\pi^-$ branching fractions is $(12.6 \pm 0.6)\%$. That leaves $(1.1 \pm 1.0)\%$ for the $K^+K^-\pi^+2\pi^0$ mode, which is the only other K^+K^- mode with three or fewer pions. In Fig. 71.1, this unmeasured part of the K^+K^- bin is shaded.

$K^+\overline{K}^0$ *modes*—Two times the sum of the measured $K^+K_S^0$, $K^+K_S^0\pi^0$, and $K^+K_S^0\pi^+\pi^-$ branching fractions is $(8.0 \pm 0.5)\%$. This leaves $(3.6 \pm 1.1)\%$ for the unmeasured $K^+\overline{K}^0$ modes (there are three such modes with three or fewer pions). This is shaded in the figure.

K^-K^0 *modes*—Twice the $K^-K_S^0 2\pi^+$ fraction is $(3.4 \pm 0.2)\%$, which leaves about $(0.4 \pm 0.8)\%$ for $K^-K^0 2\pi^+\pi^0$, the only other K^-K^0 mode with three or fewer pions.

$2K_S^0$+$2K_L^0$ *modes*—The $2K_S^0\pi^+$ and $2K_S^0 2\pi^+\pi^-$ fractions sum to $(0.86 \pm 0.07)\%$; this times two (for the corresponding $2K_L^0$ modes) is $(1.72 \pm 0.14)\%$. This leaves about $(1.7 \pm 0.7)\%$ for other $2K_S^0 + 2K_L^0$ modes.

$K_S^0K_L^0$ *modes*—Most of the $K_S^0K_L^0$ fraction is accounted for by ϕ decays (see below).

71.3 Inclusive hadronic η, ω, η', and ϕ fractions

These are easier. We start with the inclusive branching fractions, and then, to avoid double counting, subtract: (1) fractions for modes with leptons; (2) η mesons that are included in the inclusive η' fraction; and (3) K^+K^- and $K_S^0K_L^0$ from ϕ decays:

$$\begin{aligned} f(\eta \text{ hadronic}) &= f(\eta \text{ inclusive}) - 0.65\, f(\eta' \text{ inclusive}) \\ &\quad - f(\eta\ell^+\nu) = (18.5 \pm 3.0)\% \\ f(\omega \text{ hadronic}) &= f(\omega \text{ inclusive}) - 0.026\, f(\eta' \text{ inclusive}) \\ &= (5.8 \pm 1.4)\% \\ f(\eta' \text{ hadronic}) &= f(\eta' \text{ inclusive}) - f(\eta'\ell^+\nu) \\ &= (8.5 \pm 1.5)\% \\ f(\phi \text{ hadronic}, \not\to K\overline{K}) &= 0.17 \left[f(\phi \text{ inclusive}) - f(\phi\ell^+\nu) \right] \\ &= (1.9 \pm 0.2)\% \ . \end{aligned}$$

The factors 0.65, 0.026, and 0.17 are the $\eta' \to \eta$, $\eta' \to \omega$, and $\phi \not\to K\overline{K}$ branching fractions. Figure 71.1 shows the results; the sum is $(34.7 \pm 3.6)\%$, which is about equal to the hadronic $K\overline{K}$ total.

Note that the bin marked ϕ near the top of Fig. 71.1 includes neither the $\phi\ell^+\nu$ decays nor the 83% of other ϕ decays that produce a $K\overline{K}$ pair. There is twice as much ϕ in the $K_S^0K_L^0$ bin, and nearly three times as much in the K^+K^- bin. These contributions are indicated in those bins.

Again, we can show how much of each bin is accounted for by measured exclusive branching fractions: η *modes*—The sum of $\eta\pi^+$, $\eta\pi^+\pi^0$ (nearly all $\eta\rho^+$), and ηK^+ branching fractions is $(11.1 \pm 1.2)\%$, which leaves a good part of the inclusive hadronic η fraction, $(18.5 \pm 3.0)\%$, to be accounted for. This is shaded in the figure. ω *modes*—The sum of $\omega\pi^+$, $\omega\pi^+\pi^0$, and $\omega 2\pi^+\pi^-$ fractions is $(4.6 \pm 0.9)\%$, which is nearly as large as the inclusive hadronic ω fraction, $(5.8 \pm 1.4)\%$. η' *modes*—The sum of $\eta'\pi^+$, $\eta'\rho^+$, and $\eta'K^+$ fractions is $(9.9 \pm 1.5)\%$, which is larger than but not in serious disagreement with the inclusive hadronic η' fraction, $(8.5 \pm 1.5)\%$.

71.4 Cabibbo-suppressed modes

The sum of the fractions for modes with a $K\bar{K}$, η, ω, η', or leptons is $(89.9 \pm 4.4)\%$. The remaining $(10.1 \pm 4.4)\%$ is to Cabibbo-suppressed modes, mainly single-K+ pions and multiple-pion modes (see below). However, it should be noted that some small parts of the modes already discussed are Cabibbo-suppressed. For example, the $(1.1 \pm 0.2)\%$ of D_s^+ decays to $K^0\ell\nu$ or $K^{*0}\ell\nu$ is already in the $X\ell\nu$ bin in Fig. 71.1. And the inclusive measurements of η, ω, and η' fractions do not distinguish between (and therefore include both) Cabibbo-allowed and -suppressed modes. We shall not try to make a separation here.

K^0 + *pions*—Above, we found that $f(\text{single } K_S^0) = (1.7 \pm 0.2)\%$. Subtracting semileptonic fractions with a K_S^0 leaves $(1.3 \pm 0.2)\%$. The hadronic single-K^0 fraction is twice this, about $(2.6 \pm 0.4)\%$. The sum of measured $K^0\pi^+$, $K^0\pi^+\pi^0$, and $K^0 2\pi^+\pi^-$ fractions is $(1.8 \pm 0.3)\%$, about two-thirds as much.

K^+ + *pions*—The $K^+\pi^0$ and $K^+\pi^+\pi^-$ fractions sum to $(0.72 \pm 0.05)\%$. The total K^+ fraction wanted here is probably in the 1-to-2% range.

Multi-pions—The $2\pi^+\pi^-$, $\pi^+2\pi^0$, and $3\pi^+2\pi^-$ fractions total $(2.5 \pm 0.2)\%$. Modes not measured might double this.

The sum of the actually measured fractions is, including the semileptonics, $(4.9 \pm 0.3)\%$. The error on our Cabibbo-suppressed total, $(10.1 \pm 4.4)\%$ is too large to know how much we might be missing.

71.5 Addendum: Improved precision in some measurements

The Table compares measurements of branching fractions to pairs of two pseudoscalar mesons used in our 2019 update of the 2018 PDG review with values available in 2021 [2]. They have not changed much but are much better known.

Final state	2019 PDG avg or fit (%)	New BESIII entry in 2021 PDG (%)	2021 PDG avg or fit (%)
$K^+\eta'$	0.18±0.06	0.268±0.025	0.265±0.025
$K^+\eta$	0.177±0.035	0.162±0.012	0.160±0.011
$\eta\pi^+$	1.70±0.09	1.741±0.063	1.68±0.10
$K^+K_S^0$	1.50±0.05	1.502±0.055	1.46±0.04
$K_S^0\pi^+$	0.122±0.006	0.1109±0.005	0.110±0.005
$K^+\pi^0$	0.063±0.021	0.0748±0.0057	0.074±0.0057

Other recent BESIII additions include the measurements $\mathcal{B}(D_s \to \omega\pi^+, \omega K^+) = (1.77 \pm 0.32 \pm 0.13,\ 0.87 \pm 0.24 \pm 0.08) \times 10^{-3}$ [3] and $\mathcal{B}(D_s \to K_{S,L}K^+) = (1.425 \pm 0.038 \pm 0.031,\ 1.485 \pm 0.039 \pm 0.046)\%$ [4].

71.6 Concluding remarks

The shaded bands in the figure imply that about eight percent of the total D_s decay rate is into ηX, with X still to be accounted for. Unidentified Cabibbo-suppressed modes and the modes $K^+\overline{K}^0X$ and $(2K_S^0 + 2K_L^0)X$ respectively correspond to $\sim (5, 3, 2)\%$ of the total. However, one can consider the vast majority of D_s decays to be represented by exclusive final states.

72. Leptonic Decays of Charged Pseudoscalar Mesons

Updated Aug. 2023 by R. A. Briere (Carnegie Mellon U.); written with J. L. Rosner (Chicago U.), S. L. Stone (Syracuse U.) and R. Van de Water (FNAL)

72.1 Introduction

This review updates one in Ref. [1]. Extensive use is made of results of the Flavor Lattice Averaging group (FLAG 21 and the 2023 online update), Ref. [2, 3].

Charged mesons formed from a quark and antiquark can decay to a lepton-neutrino pair when these objects annihilate via a virtual W boson. Figure 72.1 illustrates this process for the purely leptonic decay of a D^+ meson.

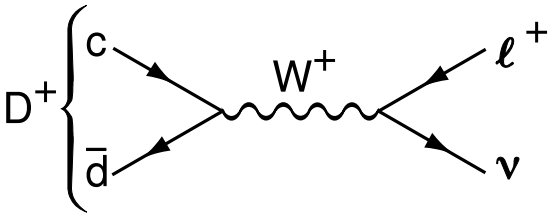

Figure 72.1: The annihilation process for pure D^+ leptonic decays in the standard model.

Similar quark-antiquark annihilations via a virtual W^+ to the $\ell^+\nu$ final states occur for the π^+, K^+, D_s^+, and B^+ mesons. (Whenever pseudoscalar-meson charges are specified in this article, use of the charge-conjugate particles and corresponding decays are also implied.) Let P be any of these pseudoscalar mesons. To lowest order, the decay width is

$$\Gamma^{(0)}(P \to \ell\nu) = \frac{G_F^2}{8\pi} f_P^2 \; m_\ell^2 M_P \left(1 - \frac{m_\ell^2}{M_P^2}\right)^2 |V_{q_1 q_2}|^2 \; . \quad (72.1)$$

Here M_P is the P mass, m_ℓ is the ℓ mass, $V_{q_1 q_2}$ is the Cabibbo-Kobayashi-Maskawa (CKM) matrix element between the quarks $q_1\bar{q}_2$ in P, and G_F is the Fermi coupling constant. The decay constant f_P is proportional to the matrix element of the axial current between the one-P-meson state and the vacuum:

$$\langle 0|\bar{q}_1\gamma_\mu\gamma_5 q_2|P(p)\rangle = ip_\mu f_P \, , \quad (72.2)$$

and can be thought of as proportional to the "wave function overlap" of the quark and antiquark. In this article, we use the convention in which $f_\pi \approx 130$ MeV. For brevity, we will often denote the purely leptonic decay width in Eq. (72.1) by $\Gamma^{(0)}$.

The decay of $P^\pm$ starts with a spin-0 meson, and ends up with a left-handed neutrino or right-handed antineutrino. By angular momentum conservation, the $\ell^\pm$ must then also be left-handed or right-handed, respectively. In the $m_\ell = 0$ limit, the decay is forbidden, and can only occur as a result of the finite ℓ mass. This helicity suppression is the origin of the m_ℓ^2 factor in the decay width.

Experimentally, it is difficult to isolate events in which there are *only* a lepton and neutrino in the final state from those with a lepton, neutrino, and soft photon. Thus, radiative contributions must be removed from the experimental measurements *a posteriori* to obtain $\Gamma^{(0)}$. The radiative contributions can be broken into three pieces: the short-distance contribution to leptonic and semileptonic decays mediated by a $W^\pm$ boson that accounts for electroweak corrections not included in the definition of G_F, the long-distance internal bremsstrahlung (IB) contribution, and the contribution from photon emission that depends upon the hadron's structure. The universal electroweak correction was calculated at $\mathcal{O}(\alpha)$ by Sirlin [4], and increases the purely leptonic decay rate by ~ 1.8–2.2% depending on the decaying meson. The $\mathcal{O}(\alpha)$ IB contribution was calculated by Kinoshita [5], and again is universal for all leptonic decays at this order. Numerically, this universal long-distance contribution lowers the purely leptonic decay rate by ~ 0.4–2.4%, where the correction is smallest for pions and largest for $D_{(s)}$ mesons. The structure-dependent contributions have been estimated within various effective theories to increase the purely leptonic rate by one to a few percent [6–11].

In this review, we treat the radiative corrections differently for the light, charm, and bottom meson systems for several reasons. First, the experimental uncertainties on the decay widths vary substantially Thus, while the inclusion of radiative corrections is essential for the pion, kaon, and $D_{(s)}$-meson decay widths, which have been measured to (sub)-percent precision, radiative corrections can be neglected (for now) for $B \to \tau\nu$ decay. Second, the photons are treated differently on the experimental side for the different decay processes. For pions and kaons, the experimental measurements of $\Gamma_{P\ell 2[\gamma]}$ are fully inclusive, while for $D_{(s)}$ mesons, the experiments impose cuts on the energy of any neutral cluster deposited in the calorimeter, which reduce the soft-photon background substantially. Some experiments also remove the QED bremsstrahlung in the leading-logarithmic approximation using the PHOTOS Monte-Carlo generator [12]. Third, the theoretical knowledge of the structure-dependent corrections varies for each meson system.

Once radiative corrections have been accounted for, measurements of purely leptonic decay branching fractions and lifetimes allow an experimental determination of the product $|V_{q_1 q_2}|\, f_P$. If the decay constant f_P is known to sufficient precision from theory, one can obtain the corresponding CKM element within the standard model. If, on the other hand, one takes the value of $|V_{q_1 q_2}|$ assuming CKM unitarity, one can infer an "experimental measurement" of the decay constant that can then be compared with theory.

The importance of measuring $\Gamma(P \to \ell\nu)$ depends on the particle being considered. Leptonic decays of charged pseudoscalar mesons occur at tree level within the standard model. Thus one does not expect large new-physics contributions to measurements of $\Gamma(P \to \ell\nu)$ for the lighter mesons $P = \pi^+, K^+$, and these processes, in principle, provide clean standard-model determinations of $|V_{ud}|$ and $|V_{us}|$. The situation is different for leptonic decays of charm and bottom mesons. The presence of new heavy particles such as charged Higgs bosons or leptoquarks could lead to observable effects in $\Gamma(P \to \ell\nu)$ for $P = D_{(s)}^+, B^+$ [13–17]. Thus, the determination of $|V_{ub}|$ from $B^+ \to \tau\nu$ decay, in particular, should be considered a probe of new physics. More generally, the ratio of leptonic decays to $\tau\nu$ over $\mu\nu$ final states probes lepton universality [13, 18].

The determinations of CKM elements from leptonic decays of charged pseudoscalar mesons provide complementary information to those from other decay processes. The decay $P \to \ell\nu$ proceeds in the standard model via the axial-vector current $\bar{q}_1\gamma_\mu\gamma_5 q_2$, whereas semileptonic pseudoscalar meson decays $P_1 \to P_2\ell\nu$ proceed via the vector current $\bar{q}_1\gamma_\mu q_2$. Thus the comparison of determinations of $|V_{q_1 q_2}|$ from leptonic and semileptonic decays tests the $V - A$ structure of the standard-model electroweak charged-current interaction. More generally, a small right-handed admixture to the standard-model weak current would lead to discrepancies between $|V_{q_1 q_2}|$ obtained from leptonic pseudoscalar-meson decays, exclusive semileptonic pseudoscalar-meson decays, exclusive semileptonic baryon decays, and inclusive semileptonic decays [19, 20].

Both measurements of the decay rates $\Gamma(P \to \ell\nu)$ and theoretical calculations of the decay constants f_P for $P = \pi^+, K^+, D_{(s)}^+$ from numerical lattice-QCD calculations are now quite precise. As a result, the elements of the first row of the CKM matrix $|V_{ud}|$ and $|V_{us}|$ can be obtained to sub-percent precision from $\pi^+ \to \ell\nu$ and $K^+ \to \ell\nu$, where the limiting error is from continuum theory radiative corrections. The elements of the second row of the CKM matrix $|V_{cd(s)}|$ can be obtained from leptonic decays of charmed pseudoscalar mesons to few-percent precision, where here the limiting error is from experiment. These enable stringent tests of the unitarity of the first and second rows of the CKM matrix.

This review is organized as follows. Because the experimental and theoretical issues associated with measurements of pions and kaons, charmed mesons, and bottom mesons differ, we discuss each one separately. We begin with the pion and kaon sys-

tem in Sec. 72.2. First, in Sec. 72.2.1, we review current measurements of the experimental decay rates. We provide tables of branching-ratio measurements and determinations of the product $|V_{ud(s)}|f_{\pi^+(K^+)}$, as well as average values for these quantities including correlations and other effects needed to combine results. Then, in Sec. 72.2.2, we summarize the status of theoretical calculations of the decay constants. We provide tables of recent lattice-QCD results for f_{π^+}, f_{K^+}, and their ratio from calculations including dynamical u, d, s, and (in some cases c) quarks, along with averages including correlations and strong SU(2)-isospin breaking corrections as needed. We next discuss the charmed meson system in Sec. 72.3, again reviewing current experimental rate measurements in Sec. 72.3.1 and theoretical decay-constant calculations in Sec. 72.3.2. Last, we discuss the bottom meson system in Sec. 72.4, following the same organization as the two previous sections. For almost all of the decay constants presented in Secs. 72.2.2, 72.3.2, and 72.4.2, we take as our preferred values the four-flavor averages from the FLAG 21 review [2] as updated online in 2023 [3]. This 2023 web update contains only one relevant new result since the 2021 version, on f_{K^+}/f_{π^+} from ETM 21 [21].

After having established the status of both experimental measurements and theoretical calculations of leptonic charged pseudoscalar-meson decays, we discuss some implications for phenomenology in Sec. 72.5. For each process discussed in Secs. 72.2–72.4, we combine the average $\mathcal{B}(P \to \ell\nu)$ with the decay constant f_P to infer the associated CKM matrix element. We then compare these results with determinations of the same CKM elements from other processes. We also use the CKM elements obtained from leptonic decays to test the unitarity of the first and second rows of the CKM matrix. Further, as in previous reviews, we combine the experimental $\mathcal{B}(P \to \ell\nu)$s with the associated CKM elements obtained from CKM unitarity to infer "experimental" values for the decay constants. The comparison of these values with theory provides a test of lattice and other QCD approaches, assuming that new-physics contributions to these processes are not significant.

72.2 Pions and kaons

72.2.1 *Experimental rate measurements*

Experimental rate measurements of pion and kaon leptonic decays are fully radiation inclusive. Following Refs. [22, 23], and references therein, we combine the $\mathcal{O}(\alpha)$ radiative corrections to the purely leptonic rate as follows:

$$\Gamma(P \to \ell\nu[\gamma]) = \Gamma^{(0)}(P \to \ell\nu)\left[1 + \frac{\alpha}{\pi}C_P\right], \tag{72.3}$$

where $P = \pi, K$. The full expressions for C_π and C_K are given in Eq. (114) of Ref. [8]. In addition to the universal short- [4] and long-distance [5] corrections, C_π and C_K include hadronic-structure dependent contributions [6] through $\mathcal{O}(\alpha p^4)$ in chiral perturbation theory (χPT), where p is the pion or kaon momentum. The inclusion of radiative corrections to the purely leptonic rates is numerically important given the level of precision achieved on the experimental measurements of the $\pi^\pm \to \mu^\pm\nu$ and $K^\pm \to \mu^\pm\nu$ decay widths.

We evaluate $\delta_P \equiv (\alpha/\pi)C_P$ using experimentally-measured meson and lepton masses and coupling constants from the Particle Data Group [24], and taking the low-energy constants (LECs) that parametrize the hadronic contributions from Refs. [8, 25, 26]. Because the finite non-logarithmic parts of the LECs were estimated within the large-N_C approximation assuming that contributions from the lowest-lying resonances dominate, we conservatively assign a 100% uncertainty to the LECs, which leads to a ± 0.9 error in $C_{\pi,K}$.[1] We obtain the following correction factors to the individual charged pion and kaon decay widths:

$$\delta_\pi = 0.0176(21) \quad \text{and} \quad \delta_K = 0.0107(21)\,. \tag{72.4}$$

The error on the ratio of kaon-to-pion leptonic decay widths is under better theoretical control because the hadronic contributions from low-energy constants estimated within the large-N_c framework cancel at lowest order in the chiral expansion. For the ratio, we use the correction factor

$$\delta_{K/\pi} = -0.0069(17)\,, \tag{72.5}$$

where we take the estimated error due to higher-order corrections in the chiral expansion from Ref. [28].

There have been no new measurements of the pion leptonic decay rate since the review of Ref. [29]. The sum of branching fractions for $\pi^- \to \mu^-\bar{\nu}$ and $\pi^- \to \mu^-\bar{\nu}\gamma$ is 99.98770(4)% [1]. Together with the lifetime 26.033(5) ns [1] this implies $\Gamma(\pi^- \to \mu^-\bar{\nu}[\gamma]) = 3.8408(7) \times 10^7\ \text{s}^{-1}$. We then subtract the estimated radiative correction factor δ_π in Eq. (72.4) to obtain the purely leptonic rate $\Gamma^{(0)}(\pi^- \to \mu^-\bar{\nu})$. Using this rate and the masses from the 2022' PDG review [1] in Eq. (72.1) gives

$$f_{\pi^+}|V_{ud}| = (127.13 \pm 0.01 \pm 0.13)\ \text{MeV}\,, \tag{72.6}$$

where the errors are from the experimental rate measurement and the radiative correction factor, respectively.

The uncertainty on $f_{\pi^-}|V_{ud}|$ is dominated by that from theoretical estimate of the hadronic structure-dependent radiative corrections. The first direct lattice-QCD calculation of the radiative corrections to the pion and kaon leptonic decay rates was performed by the RM123-Soton Collaboration [11]. The results for both $\delta_\pi = 0.0153(19)$ and $\delta_K = 0.0088(9)$, which are given in the Gasser-Rusetsky-Scimemi scheme for separating strong and electromagnetic effects [30], are compatible with our chiral-perturbation-theory estimates above and have smaller quoted uncertainties, especially for δ_K. While independent confirmation of these results is needed, they demonstrate a promising approach for reducing the theoretical uncertainties on the pion and kaon leptonic decay rates in the future.

The world average for the $K \to \mu\nu$ decay rate was previously obtained from a global fit of several kaon-decay branching ratios and lifetime measurements by the FlaviaNet Working Group on Kaon Decays in 2014 [41]; we have now updated to the PDG [1]. The radiation-inclusive branching ratio $\mathcal{B}(K^+ \to \mu^+\nu[\gamma]) = 63.56(11)\%$ and lifetime $\tau_{K^\pm} = 12.380(20)$ ns are now used; this is a very small change. These measurements imply $\Gamma(K^+ \to \mu^+\nu[\gamma]) = 5.134(12) \times 10^7\ \text{s}^{-1}$. As before, we subtract δ_K in Eq. (72.4) from the radiation-inclusive decay width to obtain $\Gamma^{(0)}(K^+ \to \mu^+\nu)$. We then use Eq. (72.1) to obtain

$$f_{K^+}|V_{us}| = (35.083 \pm 0.042 \pm 0.037)\ \text{MeV}\,, \tag{72.7}$$

where the errors are from the experimental rate measurement and the radiative correction factor, respectively.

Short-distance radiative corrections cancel in the ratio of pion-to-kaon decay rates [42]:

$$\frac{\Gamma_{K_{\ell 2[\gamma]}}}{\Gamma_{\pi_{\ell 2[\gamma]}}} = \frac{|V_{us}^2|f_{K^-}^2}{|V_{ud}|^2 f_{\pi^-}^2}\frac{m_K(1 - m_\ell^2/m_K^2)^2}{m_\pi(1 - m_\ell^2/m_\pi^2)^2}(1 + \delta_{K/\pi})\,, \tag{72.8}$$

where $\delta_{K/\pi}$ is given in Eq. (72.5). The left-hand side of Eq. (72.8) is 1.3367(32), which implies

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27599 \pm 0.00033 \pm 0.00024\,, \tag{72.9}$$

where the first uncertainty is from the branching fractions and the second is from $\delta_{K/\pi}$. Here, the estimated error on the hadronic structure-dependent radiative corrections is commensurate with the experimental error.

[1] This uncertainty on $C_{\pi,K}$ is smaller than the error estimated by Marciano and Sirlin in Ref. [27], which predates the calculations of the hadronic-structure contributions in Refs. [6, 8, 25, 26]. The hadronic LECs incorporate the large short-distance electroweak logarithm discussed in Ref. [27], and their dependence on the chiral renormalization scale cancels the scale-dependence induced by chiral loops, thereby removing the dominant scale uncertainty of the Marciano–Sirlin analysis [27].

Table 72.1: Recent published lattice-QCD results for f_{π^+}, f_{K^+}, and their ratio. The upper and lower panels show $(2+1+1)$-flavor and $(2+1)$-flavor determinations, respectively. When two errors are shown, they are statistical and systematic, respectively. Results for f_π and f_K in the isospin symmetric limit $m_u = m_d$ are noted with a ‡; they are corrected for isospin breaking via Eq. (72.13) before computing the averages. The 2+1+1 FLAG 23 averages are dominated by the Fermilab/MILC values.

*PDG 2014 value of $f_{\pi^+} = 130.41(21)$ MeV used to set absolute lattice scale.
†Superseded by f_{K^+}/f_{π^+} from Fermilab/MILC 17.

In summary, the main experimental results pertaining to charged pion and kaon leptonic decays are

$$|V_{ud}|f_{\pi^+} = (127.13 \pm 0.01 \pm 0.13)\ \text{MeV}\,, \tag{72.10}$$

$$|V_{us}|f_{K^+} = (35.083 \pm 0.042 \pm 0.037)\ \text{MeV}\,, \tag{72.11}$$

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27599 \pm 0.00033 \pm 0.00024\,, \tag{72.12}$$

where the errors are from the experimental uncertainties in the branching fractions and the theoretical uncertainties in the radiative correction factors δ_P, respectively. These values contain small changes from earlier reviews [29, 43, 44].

72.2.2 *Theoretical decay-constant calculations*

Table 72.1 presents recent published results for the charged pion and kaon decay constants and their ratio from numerical lattice-QCD calculations with three ($N_f = 2+1$) or four flavors ($N_f = 2+1+1$) of dynamical quarks. The uncertainties on both the individual decay constants and their ratio are at the sub-percent level. The SU(3)-breaking ratio f_{K^+}/f_{π^+} can be obtained with especially small errors because statistical errors associated with the Monte Carlo calculations are correlated between the numerator and denominator, as are some systematics. The results in Table 72.1 were obtained using several independent sets of gauge-field configurations, and a variety of lattice fermion actions that are sensitive to different systematic uncertainties.[2] Thus, the good agreement between them indicates that the lattice-QCD uncertainties are controlled and the associated error estimates are reliable.[3]

Table 72.1 also shows the three- and four-flavor averages for the pion and kaon decay constants and their ratio from the FLAG 23 review [2, 3] in the lines labeled "FLAG 23 average." There is no four-flavor average for the pion decay constant in Table 72.1 because all of the four-flavor calculations use the quantity $f_{\pi^+} = 130.41(20)$ MeV [24] as an input to fix the absolute lattice scale needed to convert from lattice-spacing units to GeV [10, 33, 34].

All of the results in Table 72.1 were obtained using isospin-symmetric gauge-field configurations, *i.e.*, the dynamical up and down quarks have the same mass. Fortunately, however, the dominant effect of strong-isospin breaking is easily included in lattice-QCD calculations as follows. Because the up-down mass difference $\Delta m_{ud} \equiv (m_u - m_d) \sim -2.5$ MeV [50,52] is much less than typical hadronic scales, the strong-isospin breaking corrections to physical observables can be systematically expanded in the small parameter $\delta m_{ud} \equiv \Delta m_{ud}/\Lambda_{\rm QCD}$. The leading strong-isospin-breaking corrections to pseudoscalar-meson decay constants arise from the light *valence* quarks in the initial- and final-state hadrons. (See, *e.g.,* the discussion in Ref. [53], for a detailed discussion of isospin-breaking effects in pion and kaon observables.) Thus, to include the effect of non-degenerate up- and down-quark masses, most recent lattice-QCD calculations of f_{π^+} and f_{K^+} evaluate the masses of the valence quarks in the pion at the physical m_u and m_d, and the mass of the valence light quark in the kaon at the physical m_u. This procedure yields a correction to the kaon decay constant below 0.5%. Consequently, strong-isospin breaking corrections from the light sea-quark masses — which are suppressed by an additional power of δm_{ud} — can be neglected given present uncertainties.

Some earlier lattice-QCD calculations, however, only provide the decay constants and their ratio in the $SU(2)$ isospin-symmetric limit [37,39,40]. The Flavour Lattice Averaging Group corrects these results for strong-isospin breaking using chiral perturbation theory before including them in the averages. The leading strong-isospin-breaking corrections to the pion and kaon decay constants in χPT can be parametrized as [28, 60]

$$f_{\pi^+} = f_\pi\,, \qquad f_{K^+} = f_K\sqrt{1+\delta_{\rm SU(2)}}\,, \tag{72.13}$$

where f_π and f_K denote the values of the decay constants in the isospin-symmetric limit. The pion decay constant does not receive corrections linear in $m_u - m_d$ because of the G-parity symmetry[4] of the pion triplet, so at first order the δm_{ud} expansion, strong-isospin breaking corrections are characterized by a single parameter, $\delta_{\rm SU(2)}$. Next-to-leading order χPT yields numerical values for $\delta_{\rm SU(2)}$ of approximately -0.004. Recent direct lattice-QCD calculations of $\delta_{\rm SU(2)}$ give larger values of around -0.005 to -0.008 [11, 32–34, 53, 61], but further studies are needed. Thus, to be conservative, FLAG includes an uncertainty of 100% on the χPT estimate for $\delta_{\rm SU(2)}$ when correcting those decay-constant values that are quoted in the isospin-symmetric limit.

[2] See the PDG mini-review on "Lattice Quantum Chromodynamics" [45–47] for a general review of numerical lattice-QCD calculations. Details on the different methods used in modern lattice-QCD calculations are provided in Appendix A of the FLAG "Review[s] of lattice results concerning low energy particle physics" [2, 48–50].

[3] See the review by Kronfeld [51] for a summary of the large body of evidence validating the methods employed in modern lattice-QCD calculations.

[4] This is a combination of charge conjugation, C, and an $e^{i\pi I_2}$ rotation in isospin space that maps the triplet onto itself.

Table 72.2: Experimental results for $\mathcal{B}(D^+ \to \mu^+\nu[\gamma])$, $\mathcal{B}(D^+ \to \tau^+\nu[\gamma])$, and $|V_{cd}|f_{D^+}$. The systematic errors on the inferred values of $|V_{cd}|f_{D^+}$ include those from the D^+ lifetime and mass. The error from radiative corrections is only included in the entries labeled "our average." In the second CLEO line the τ^+ decays to $\mu^+\nu_\mu\bar{\nu}_\tau$.

Experiment	Mode	$\mathcal{B}$	$\lvert V_{cd}\rvert f_{D^+}$ (MeV)
CLEO-c [54, 55]	$\mu^+\nu$	$(3.93 \pm 0.35 \pm 0.09) \times 10^{-4}$	$46.80 \pm 2.08 \pm 0.55$
CLEO-c [54, 55]	$\mu^+\nu{+}\tau^+\nu$	$(3.82 \pm 0.32 \pm 0.09) \times 10^{-4}$	$46.14 \pm 1.93 \pm 0.56$
BESIII [56]	$\mu^+\nu$	$(3.71 \pm 0.19 \pm 0.06) \times 10^{-4}$	$45.47 \pm 1.16 \pm 0.38$
Our average	Lines 2+3	$(3.74 \pm 0.17) \times 10^{-4}$	45.65 ± 1.19
CLEO-c [57, 58]	$\tau^+\nu$ $(\pi^+\overline{\nu})$	$< 1.2 \times 10^{-3}$	
BESIII [59]	$\tau^+\nu$ $(\pi^+\overline{\nu})$	$(1.20 \pm 0.24 \pm 0.12) \times 10^{-3}$	50.08 ± 5.62
Our average	$\mu^+\nu + \tau^+\nu$		45.82 ± 1.10

The errors on the decay-constant results in Table 72.1 obtained from $(2+1)$-flavor lattice-QCD calculations do not include an estimate of the systematic uncertainty from the omission of charm sea quarks in the calculation. Consequently, when the uncertainty on the $(2+1+1)$-flavor FLAG average is comparable to or better than that on the $(2+1)$-flavor FLAG average, we simply use the four-flavor average as our preferred value. This is not possible, however, for the pion decay constant. To account for this, we first estimate the systematic uncertainty on pseudoscalar-meson decay constants associated with the omission of charm sea quarks. We then add this estimate in quadrature to the quoted error on the (2+1)-flavor FLAG average for f_{π^+} to obtain our preferred value.

The error introduced by omitting charm sea quarks can be roughly estimated by expanding the charm-quark determinant in powers of $1/m_c$ [62]; the resulting leading contribution is of order $\alpha_s \left(\Lambda_{\rm QCD}/2m_c\right)^2$ [63]. Taking the $\overline{\rm MS}$ values $\overline{m}_c(\overline{m}_c) = 1.275$ GeV, $\overline{\Lambda}_{\rm QCD} \sim 340$ MeV from FLAG [48], and $\overline{\alpha}_s(\overline{m}_c) \sim 0.4$, leads to an estimate of about 0.7% for the contribution to the decay constants from charm sea quarks. We can compare this power-counting estimate of charm sea-quark contributions with the observed differences between the (2+1)- and (2+1+1)-flavor lattice-QCD averages for kaon, $D_{(s)}$-meson, and $B_{(s)}$-decay constants in Tables 72.1, 72.4, and 72.6. Looking at Table 72.1, the three- and four-flavor averages for f_{K^+} agree to much better than our simple power-counting estimate. Inspection of Tables 72.4 and 72.6 shows, however, that charm sea-quark effects of this size are still allowed for both $D_{(s)}$-meson and $B_{(s)}$-meson decay constants.

Our final preferred theoretical values for the charged pion and kaon decay constants are

$$f_{\pi^+} = 130.2(1.2)\,\text{MeV}\,, \quad f_{K^+} = 155.7(3)\,\text{MeV}\,, \quad \frac{f_{K^+}}{f_{\pi^+}} = 1.193(2)\,, \tag{72.14}$$

where f_{K^+} and f_{K^+}/f_{π^+} are simply the four-flavor FLAG 2023 averages [2, 3], and f_{π^+} is the three-flavor FLAG 2023 average with the error increased by the estimated 0.7% charm sea-quark contribution.

72.3 Charmed mesons

72.3.1 *Experimental rate measurements*

Measurements have been made of the branching fractions for D^+ and D_s^+ mesons decaying to both $\mu^+\nu$ and $\tau^+\nu$ final states. The CLEO-c and BESIII experiments have made measurements of D^+ decays using e^+e^- collisions at the $\psi(3770)$ resonant energy where D^-D^+ pairs are copiously produced. They fully reconstruct one of the D mesons; for concreteness, we will take this to be the D^-. Counting the number of these events provides the normalization for the branching fraction measurement. The experimental analyses then proceed by identifying a candidate μ^+ and forming the missing-mass squared, $MM^2 = (E_{\rm CM} - E_{D^-})^2 - \left(\overrightarrow{p}_{\rm CM} - \overrightarrow{p}_{D^-} - \overrightarrow{p}_{\mu^+}\right)^2$, where $E_{\rm CM}$ and $p_{\rm CM}$ are the center-of-mass energy (which is known) and momentum (which equals zero in e^+e^- collisions). A peak at zero MM^2 implies the existence of a missing neutrino, and hence the $\mu^+\nu$ decay of the D^+. CLEO-c does not explicitly identify the muon, so their data consists of a combination of $\mu^+\nu$ and $\tau^+\nu$, $\tau^+ \to \pi^+\nu$ events. This permits them to do two fits: in one they fit for the individual components, and in the other they fix the ratio of $\tau^+\nu/\mu^+\nu$ events to be that given by the standard-model expectation. Thus, the former measurement should be used for new-physics searches, and the latter for standard-model predictions. Our average uses the fixed-ratio value; this ratio is implied by Eq. 72.1 which is necessary to extract $|V_{cd}|f_{D^+}$.

Table 72.2 shows the available measurements of $D^+ \to \mu^+\nu$, an upper limit on $D^+ \to \tau^+\nu$ from CLEO-c, and the first measurement of this decay from BESIII. To extract the values of $|V_{cd}|f_{D^+}$ via Eq. (72.1), we use [1] the mass $m_{D^+} = 1.86966(5)$ GeV and the lifetime $\tau_{D^+} = 1.033(5)$ ps, and apply radiative corrections as described below. For calculating the average $\mu^+\nu$ number, we use the CLEO-c result from $\mu^+\nu{+}\tau^+\nu$. Since the last review the D^+ lifetime is updated and the propagated uncertainties on $|V_{cd}|f_{D^+}$ from the last measurement [59] are corrected.

To obtain the purely leptonic rates $\Gamma^{(0)}(D^+ \to \mu^+(\tau^+)\nu)$, we subtract the radiative contributions as in Sec. 72.2.1, but use numerical values for the corrections appropriate for D mesons. First, we reduce both the $\mu^+\nu$ and $\tau^+\nu$ branching fractions in Table 72.2 by 1.8%, which is the universal short-distance electroweak contribution of Sirlin [4] evaluated using the D-meson mass for the factorization scale. We do not adjust the experimental rates by the universal long-distance correction [5]. This is because QED bremsstrahlung contributions have already been subtracted at leading-log order from the measurements in Table 72.2 using Monte-Carlo estimates computed with PHOTOS [12]. The $\mu^+\nu$ rates should also be reduced by the 1% estimate of the structure-dependent contributions from Dobrescu and Kronfeld [17]. This correction accounts for tree-level radiative processes in which the D meson decays into a real photon and an off-shell vector meson, which subsequently decays weakly to a charged lepton and neutrino. It is estimated using Eq. (12) of Burdman *et al.* [7] with the CLEO-c cut on the photon energy from Ref. [74], which is typical of all the measurements. We do not need to apply the structure-dependent correction to the $\mu^+\nu$ branching fractions in Table 72.2, however, because the experiments have already included it in their quoted results. Therefore, in summary, we reduce both the $D^+ \to \mu^+\nu$ and the $D^+ \to \tau^+\nu$ rates by 1.8% to account for radiative corrections. It is worth noting, however, that the universal long-distance electromagnetic contribution estimated for point-like charged mesons by Kinoshita [5], which we are not including because IB contributions are already subtracted from the measurements via PHOTOS, would *increase* both rates by about 2.5%.

We now discuss the D_s^+ decay process; there is no change since our previous review [1]. Measurements of D_s^+ leptonic decay branching fractions by several groups are listed in Table 72.3. We exclude older values obtained by normalizing to D_s^+ decay modes that are not well-defined. Many measurements, for example, used the $\phi\pi^+$ mode. This decay is a subset of the $D_s^+ \to K^+K^-\pi^+$ channel which has interferences from other modes populating the K^+K^- mass region near the ϕ, the most prominent of which is the $f_0(980)$. Thus, the extraction of the effective $\phi\pi^+$ rate is sensitive to the mass resolution of the experiment and the cuts used

Table 72.3: Experimental results for $\mathcal{B}(D_s^+ \to \mu^+\nu[\gamma])$, $\mathcal{B}(D_s^+ \to \tau^+\nu[\gamma])$, and $|V_{cs}|f_{D_s^+}$. The systematic errors on the inferred values of $|V_{cs}|f_{D_s^+}$ include those from the D_s^+ lifetime and mass. The entries labeled "our average" take into account correlations between systematic errors common to the experiments, and also include errors from radiative corrections.

Experiment	Mode	$\mathcal{B}(\%)$	$\lvert V_{cs}\rvert f_{D_s^+}$ (MeV)
CLEO-c [57, 58]	$\mu^+\nu$	$0.565 \pm 0.045 \pm 0.017$	$247.6 \pm 9.9 \pm 4.1$

BESIII [73]	$\tau^+\nu$ ($\pi^+\pi^0\overline{\nu}$)	$5.29 \pm 0.25 \pm 0.20$	$242.7 \pm 5.7 \pm 4.0$
Our average	$\tau^+\nu$	5.33 ± 0.13	244.0 ± 3.1
Our average	$\mu^+\nu + \tau^+\nu$		243.5 ± 2.7

*We do not use a previous unpublished BaBar result from a subsample of data that uses a different technique for obtaining the branching fraction normalization [64].

to define the ϕ mass region [75].[5]

To find D_s decays in the $\mu^+\nu$ signal channels, the experiments rely on fully reconstructing all of the final state particles except for the neutrino and use a missing-mass technique to infer the existence of the neutrino. CLEO and BESIII use $e^+e^- \to D_sD_s^*$ collisions at 4170 MeV, while BaBar and Belle use $e^+e^- \to DKn\pi D_s^*$ collisions at energies near the $\Upsilon(4S)$. CLEO and BESIII do a similar analysis as was done for the D^+ above. BaBar and Belle do a similar MM^2 calculation by using the reconstructed hadrons, the photon from the D_s^{*+} decay and a detected μ^+. To get the normalization they do a MM^2 fit without the μ^+ and use the signal at the D_s^+ mass squared to determine the total D_s^+ yield.

When selecting the $\tau^+ \to \pi^+\bar{\nu}$ and $\tau^+ \to \rho^+\bar{\nu}$ decay modes, CLEO uses both the calculation of the missing-mass and the fact that there should be no extra energy in the event beyond that deposited by the measured tagged D_s^- and the τ^+ decay products. The $\tau^+ \to e^+\nu\bar{\nu}$ mode, however, uses only extra energy. BaBar and Belle also use the extra energy to discriminate signal from background in their $\tau^+\nu$ measurements. BESIII uses $\tau^+ \to \pi^+\overline{\nu}$ decays, where they calculate the MM^2 and discriminate against μ^+ from $D_s^+ \to \mu^+\nu$ decays, and more recently $\tau^+ \to e^+\nu\overline{\nu}$ and $\tau^+ \to \pi^+\pi^0\overline{\nu}$ decays.

When extracting $|V_{cs}|f_{D_s^+}$ via Eq. (72.1), we first apply the -1.8% universal electroweak correction [4] to all of the $\mu^+\nu$ and $\tau^+\nu$ branching fractions in Table 72.3; this is the same as for D^+ mesons. We also decrease the BaBar and Belle $\mu^+\nu$ branching fractions by the 1% structure-dependent correction [17]. This correction was already included in CLEO and BESIII results for the $\mu^+\nu$ branching fractions in Table 72.3. We use the masses and lifetimes $m_{D_s^+} = 1.96834(7)$ GeV, $m_{\tau^+} = 1.77686(12)$ GeV, and $\tau_{D_s^+} = 0.504(4)$ ps [43]. The inferred values for $f_{D_s^+}|V_{cs}|$ are in good agreement for the $\mu^+\nu$ and $\tau^+\nu$ decay modes.

It is clear from the discussion of radiative corrections in this section that they are less well understood theoretically for D^+ and D_s^+ meson decays than for pions and kaons. We therefore assign a 1.4% systematic uncertainty to the purely leptonic decay rates, which is half the size of the applied radiative corrections. This translates to a 0.7% error on the products of the decay constant times CKM matrix element. Putting everything together, the main experimental results pertaining to charmed meson leptonic decays are (see the bottom lines of Tables 72.2 and 72.3):

$$|V_{cd}|f_{D^+} = \quad 45.82 \pm 1.05 \pm 0.32 = 45.82 \pm 1.10 \text{ MeV} \quad (72.15)$$

$$|V_{cs}|f_{D_s^+} = 243.5 \ \pm 2.1 \pm 1.7 = 243.5 \pm 2.7 \text{ MeV}\,, \quad (72.16)$$

where the errors are from the measured branching fractions and the applied radiative corrections, respectively.

72.3.2 *Theoretical decay-constant calculations*

Table 72.4 presents recent theoretical calculations of charmed heavy-light meson decay constants and their ratio in the isospin-symmetric limit $m_u = m_d$. (As in Sec. 72.2.2, we denote the physical D^+-meson decay constant by f_{D^+}, and use f_D for the isospin-symmetric value.) The upper two panels show results from lattice-QCD calculations with three ($N_f = 2+1$) or four flavors ($N_f = 2+1+1$) of dynamical quarks. Although there are fewer available results than for the pion and kaon sector, both f_D and f_{D_s} have been obtained using multiple sets of gauge-field configurations with different lattice fermion actions, providing independent confirmation. For comparison, the bottom panel of Table 72.4 shows QCD-model calculations of the D- and D_s-meson decay constants for which uncertainty estimates are provided. The lattice and non-lattice results agree, but numerical lattice-QCD calculations have now reached significantly greater precision than other approaches.

The lattice-QCD decay-constant results in Table 72.4 were all obtained using isospin-symmetric gauge-field configurations. As discussed in Sec. 72.2.2, however, the leading strong-isospin breaking corrections to heavy-light pseudoscalar-meson decay constants can be accounted for by using the physical down (or up) quark in the D (or B) meson. Strong-isospin breaking corrections to heavy-strange meson decay constants are roughly an order-of-magnitude smaller because there are no light valence quarks involved. Re-

[5] We have not included the BaBar result for $\mathcal{B}(D_s^+ \to \mu^+\nu)$ reported in Ref. [76] because this measurement determined the ratio of the leptonic decay rate to the hadronic decay rate $\Gamma(D_s^+ \to \ell^+\nu)/\Gamma(D_s^+ \to \phi\pi^+)$.

Table 72.4: Recent theoretical determinations of f_D, f_{D_s}, and their ratio in the isospin-symmetric limit. The upper panels show results from lattice-QCD calculations with $(2+1+1)$ and $(2+1)$ dynamical quark flavors, respectively. Statistical and systematic errors are quoted separately. The bottom panel shows estimates from QCD sum rules (QCD SR). These are not used to obtain our preferred decay-constant values. The 2+1+1 averages are dominated by the Fermilab/MILC values.

*Ref. [32] provides values for f_D and f_{D_s} in the isopsin-symmetric limit, but not for their ratio. Here we infer the central value from those of the individual decay constants, and take the statistical and systematic errors to be the same as for the physical ratio f_{D_s}/f_{D^+}.

†Slight difference from preliminary value quoted in 2019 FLAG review.

‡Obtained using $m_c^{\overline{\rm MS}}$; results using $m_c^{\rm pole}$ are also given in the paper.

cently, the Fermilab Lattice and MILC Collaborations used this approach to calculate directly the dominant strong-isospin breaking corrections to both f_D and f_B, finding [32]

$$\begin{aligned} f_{D^+} - f_D &= +0.58(1)_{\rm stat}(7)_{\rm syst}(1)_{\rm EM\ scheme}\ {\rm MeV}\,, \\ f_{B^+} - f_B &= -0.53(5)_{\rm stat}(7)_{\rm syst}(0)_{\rm EM\ scheme}\ {\rm MeV}\,. \end{aligned} \tag{72.17}$$

These results agree with independent estimates of the strong-isospin-breaking corrections to heavy-light meson decay constants from QCD sum rules [89]. Combined with the determinations of f_D and f_B from the same work, Eq. (72.17) implies that the corrections to the SU(3)-flavor breaking ratios are

$$\frac{f_{D_s}}{f_{D^+}} = \frac{f_{D_s}}{f_D}\Big(1 - 0.0027(3)\Big)\,, \qquad \frac{f_{B_s}}{f_{B^+}} = \frac{f_{B_s}}{f_B}\Big(1 + 0.0028(5)\Big)\,. \tag{72.18}$$

These estimated strong-isospin-breaking corrections to f_D and f_{D_s}/f_D above are commensurate with the uncertainties on the (2+1+1)-flavor FLAG averages in Table 72.4. Consequently, it is important to account for isospin-breaking effects before combining the theoretical decay constants with the corresponding experimental decay rates.

To obtain the charged D^+-meson decay constant, we apply the correction in Eq. (72.17) to the (2+1+1)-flavor 2021 FLAG average for the D-meson decay constant in the isospin-symmetric limit. Similarly we use Eq. (72.18) to correct the (2+1+1)-flavor 2021 FLAG average for f_{D_s}/f_D. We take the four-flavor FLAG 2021 average for f_{D_s} directly. Our final preferred theoretical values for the charmed pseudoscalar-meson decay constants are

$$\begin{aligned} f_{D^+} &= 212.0(7)\ {\rm MeV}\,, \\ f_{D_s} &= 249.9(5)\ {\rm MeV}\,, \\ \frac{f_{D_s}}{f_{D^+}} &= 1.1783(16)\,. \end{aligned} \tag{72.19}$$

72.4 Bottom mesons

72.4.1 *Experimental rate measurements*

The Belle and BaBar collaborations have found evidence for $B^- \to \tau^-\overline{\nu}$ decay in $e^+e^- \to B^-B^+$ collisions at the $\Upsilon(4S)$ energy. The analysis relies on reconstructing a hadronic or semileptonic B decay tag, finding a τ candidate in the remaining track and photon candidates, and examining the extra energy in the event which should be close to zero for a real τ^- decay to $e^-\nu\bar{\nu}$ or $\mu^-\nu\bar{\nu}$ opposite a B^+ tag. The results are listed in Table 72.5. These are unchanged since the previous review [1].

Table 72.5: Experimental results for $\mathcal{B}(B^- \to \tau^-\overline{\nu})$ and $|V_{ub}|f_{B^+}$. To extract the values of $|V_{ub}|f_{B^+}$ via Eq. (72.1), we use the PDG values of the B^+ lifetime of 1.638±0.004 ps, and the τ^+ and B^+ masses of 1.77686 and 5.27934 GeV, respectively.

Experiment	Tag	$\mathcal{B}$ (units of 10^{-4})	$\lvert V_{ub}\rvert f_{B^+}$ (MeV)
Belle [90]	Hadronic	$0.72^{+0.27}_{-0.25} \pm 0.11$	
Belle [91]	Semileptonic	$1.25 \pm 0.28 \pm 0.27$	
Belle [91]	Average	0.91 ± 0.22	0.72 ± 0.09
BaBar [92]	Hadronic	$1.83^{+0.53}_{-0.49} \pm 0.24$	
BaBar [93]	Semileptonic	$1.7 \pm 0.8 \pm 0.2$	
BaBar [92]	Average	1.79 ± 0.48	1.01 ± 0.14
Our average		1.06 ± 0.20	0.77 ± 0.07

Because there are large backgrounds under the signals for these measurements, as well as substantial systematic errors, the significances of the individual results are still below the 5σ discovery threshold. Belle quotes 4.6σ for their combined hadronic and semileptonic tags, while BaBar quotes 3.3σ and 2.3σ, for hadronic and semileptonic tags. Greater precision is necessary to determine if any effects beyond the standard model are present.

We do not correct the measured branching ratios in Table 72.5 for radiative corrections because the experimental uncertainties are so large. The relative radiative corrections are expected to be larger, however, for $B \to \mu\nu$ leptonic decays because the corrections are no longer helicity suppressed [9], and may be a significant fraction of the purely leptonic rate. More theoretical work is needed to understand radiative corrections to leptonic B decays in anticipation of future measurements with greater precision, and of new decay channels.

72.4.2 *Theoretical decay-constant calculations*

Table 72.6 presents recent theoretical calculations of bottom heavy-light meson decay constants and their ratio in the isospin-symmetric limit $m_u = m_d$. The upper two panels show results from lattice-QCD calculations with three ($N_f = 2+1$) or four flavors ($N_f = 2+1+1$) of dynamical quarks. For all decay constants, calculations using different gauge-field configurations, light-quark actions, and b-quark actions provide independent confirmation. For comparison, the bottom panel of Table 72.6 shows QCD-model calculations of the B- and B_s-meson decay constants

Table 72.6: Recent theoretical determinations of f_B, f_{B_s}, and their ratio in the isospin-symmetric limit. The upper panels show results from lattice-QCD calculations with $(2+1+1)$ and $(2+1)$ dynamical quark flavors, respectively. When available, statistical and systematic errors are quoted separately. The bottom panel shows estimates from the relativistic potential model (RPM) and QCD sum rules (QCD SR), which are not used to obtain our preferred decay-constant values. The 2+1+1 FLAG 23 averages are dominated by the Fermilab/MILC values.

*Average of new HPQCD 17 and previous HPQCD 13 results allowing for correlations between the two sets of results.
†Obtained with static b quarks (*i.e.*, $m_b \to \infty$).
‡Ref. [98] does not provide results in the isospin-symmetric limit, so we show f_{B^+} and f_{B_s}/f_{B^+} for this work.
§Obtained using $m_b^{\overline{\rm MS}}$; results using $m_b^{\rm pole}$ are also given in the paper.

for which uncertainty estimates are provided. These are consistent with the lattice values, but with much larger uncertainties.

The lattice-QCD decay-constant results in Table 72.6 were all obtained using isospin-symmetric gauge-field configurations. Some calculations, however, account for the dominant effect of strong-isospin-breaking by using the correct value for the valence light-quark mass in the B meson (m_u for f_{B^+} and m_d for f_{B^0}). Early estimates of the strong-isospin-breaking correction obtained $f_{B^+} - f_B \sim -2$ MeV [96, 98], which would be significant given the present lattice-QCD uncertainties. It turns out, however, that these calculations inadvertently introduced a spurious sea-quark contribution, and therefore overestimated the size of the effect. A more recent calculation by the Fermilab/MILC Collaboration finds very little evidence for isospin violation ($f_{B^+} - f_B \sim -0.5$ MeV) [32], which is more than two times smaller than the total uncertainties on present lattice-QCD calculations. For this reason, we quote isospin averages in the current review. Our preferred theoretical values for the bottom pseudoscalar-meson decay constants are

$$\begin{aligned} f_B &= 190.0(1.3)\ \text{MeV}\,, \\ f_{B_s} &= 230.3(1.3)\ \text{MeV}\,, \\ \frac{f_{B_s}}{f_B} &= 1.209(5)\,, \end{aligned} \tag{72.20}$$

which are simply the $N_f = 2+1+1$ FLAG 2023 averages [3]. Because the uncertainties on the three-flavor results in Table 72.6 are substantially larger than those on the four-flavor results, including them in the average leaves the central values unchanged, and decreases the errors only slightly.

72.5 Phenomenological implications

72.5.1 $|V_{ud}|$, $|V_{us}|$, *and status of first-row unitarity*

Using the average values for $f_{\pi^+}|V_{ud}|$, $f_{K^+}|V_{us}|$, and their ratio from Eqs. (72.10)–(72.12) and for f_{π^+}, f_{K^+}, and their ratio from Eq. (72.14), we obtain the following determinations of the CKM matrix elements $|V_{ud}|$, $|V_{us}|$, and their ratio from leptonic decays within the standard model:

$$\begin{aligned} &|V_{ud}| = 0.9763(1)(90)(10)\,, \quad |V_{us}| = 0.2253(3)(4)(2), \\ &\frac{|V_{us}|}{|V_{ud}|} = 0.2313(3)(4)(2)\,, \end{aligned} \tag{72.21}$$

where the errors are from the experimental branching fraction(s), the pseudoscalar decay constant(s), and radiative corrections, respectively. These results enable a test of the unitarity of the first row of the CKM matrix from leptonic decays alone (the contribution from $|V_{ub}|$ is negligible). Using the values of $|V_{ud}|$ and $|V_{us}|$ from Eq. (72.21), we find

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 - 1 = 0.004(18)\,, \tag{72.22}$$

which is consistent with three-generation unitarity at the few-percent level.

The determinations of $|V_{ud}|$ and $|V_{us}|$ from leptonic decays in Eq. (72.21) can be compared to those obtained from other processes. The result above for $|V_{ud}|$ agrees with the determination from super-allowed β-decay (a previous value of $|V_{ud}| = 0.97420(21)$ [104] has been updated to $|V_{ud}| = 0.97373(31)$ [105]) but has a considerably larger error, primarily due to the uncertainty in the theoretical determination of f_{π^+}.

The CKM element $|V_{us}|$ can be determined from semileptonic $K^+ \to \pi^0 \ell^+ \nu$ decay. Here experimental measurements provide a value for the product $f_+^{K\pi}(0)|V_{us}|$, where $f_+^{K\pi}(0)$ is the form factor at zero four-momentum transfer between the initial state kaon and the final state pion. We quote a recent analysis by Seng *et al.* [106] which finds $|V_{us}|f_+^{K\pi}(0) = 0.21635(38)(3)$, with the first error denoting experiment and the second reflecting uncertainty in higher order corrections. Choosing the 2021 2+1+1-flavor FLAG average for $f_+(0)^{K\pi} = 0.9698(17)$ [2] based on the calculations of ETM [107] and Fermilab/MILC [108] gives $|V_{us}| = 0.22309(39)_{\rm exp}(39)_{\rm LQCD}(3)_{\rm HO}$ from semileptonic decay. The determinations of $|V_{us}|$ from leptonic and semileptonic kaon decays are both quite precise, with comparable errors, but the central values differ by 2.8σ.

Finally, the combination of the ratio $|V_{us}|/|V_{ud}|$ from leptonic decays [Eq. (72.21)] with $|V_{ud}|$ from β decay implies an alternative determination of $|V_{us}| = 0.2252(5)$ which agrees with the value from leptonic kaon decay, but again disagrees with the semileptonic-decay result at the 2.8σ level.

Given the roughly 3σ tension between $|V_{us}|$ from leptonic and semileptonic kaon decays, it is important to scrutinize the uncertainties on the theoretical and experimental inputs to $|V_{us}|$ and other elements of the first row of the CKM matrix. Seng *et al.* have introduced a new approach for calculating radiative corrections to neutron and nuclear beta decays using dispersion relations [109–112]. These calculations imply a value of $|V_{ud}| = 0.97395(23)$, consistent with the updated analysis of Ref. [105]. An independent calculation of the radiative corrections by Czarnecki and Marciano using QCD sum rules yields similar results [113]. Using this value of $|V_{ud}|$ with the determination of $|V_{us}|$ from leptonic kaon decays in Eq. (72.21), we obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 - 1 = -0.0007(5)$, again consistent with first-row unitarity.

Last, we combine the experimental measurement of $f_{\pi^+}|V_{ud}|$ in Eq. (72.10) with $|V_{ud}|$ from super-allowed β-decay [105] to infer an "experimental" value for the pion decay constant:

$$f_{\pi^-}^{\text{"exp"}} = 130.56(2)(4)(13)\ \text{MeV}\,, \tag{72.23}$$

where the uncertainties are from the errors on Γ, $|V_{ud}|$, and higher-order corrections, respectively. Many recent (2+1+1)-flavor lattice-QCD calculations use this quantity to set the overall physical scale in their simulations, *e.g.*, Refs. [10, 32–34]. Conversely, comparing $f_{\pi^-}^{\text{"exp"}}$ with the 2021 FLAG (2+1)-flavor average $f_{\pi^+} = 130.2(8)$ MeV, which only includes lattice-QCD results that employ other observables to set the scale [35–40], provides a test of lattice-QCD methods. The values are in good agreement within present uncertainties. We do not quote an "experimental" value for the kaon decay constant because the value of $|V_{us}|$ is less clear given the approximately 3σ tension between the values of $|V_{us}|$ obtained from leptonic and semileptonic kaon decays.

72.5.2 $|V_{cd}|$, $|V_{cs}|$, *and status of second-row unitarity*

Using the average values for $|V_{cd}|f_{D^+}$ and $|V_{cs}|f_{D_s^+}$ from Eqs. (72.15) and (72.16), and for f_{D^+} and $f_{D_s^+}$ from Eq. (72.19), we obtain the following determinations of the CKM matrix elements $|V_{cd}|$ and $|V_{cs}|$ from leptonic decays within the standard model:

$$|V_{cd}| = 0.2161(50)(15)(7) \quad \text{and} \quad |V_{cs}| = 0.9744(84)(16)(20)\,, \tag{72.24}$$

where the errors are from the measured branching fractions, radiative corrections, and decay constants, respectively. These results enable a test of the unitarity of the second row of the CKM matrix. Taking $|V_{cb}| = 40.8(1.4) \times 10^{-3}$ [1], we obtain

$$|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 - 1 = -0.002(22)\,, \tag{72.25}$$

in agreement with three-generation unitarity.

The uncertainty on $|V_{cd}|$ in Eq. (72.24) is limited by the measurement error on the $D^+ \to \mu^+\nu$ decay rate. For $|V_{cs}|$, however, the experimental and radiative-correction errors are commensurate. The value of $|V_{cs}|$ from leptonic D_s decays decreased substantially from the value of 1.007(17) in an earlier version of this review [29, 114], and is now below unity as expected in the three-generation CKM framework. This change is due to our more consistent treatment of the radiative corrections, which lower the purely leptonic decay rates for $D_s^+ \to \mu^+\nu$ and $D_s^+ \to \tau^+\nu$. We emphasize, however, that we have taken a generous uncertainty on these estimates, and that more theoretical work is needed to really pin down the sizes of the radiative corrections to $D_{(s)}$-meson leptonic decays.

The CKM matrix elements $|V_{cd}|$ and $|V_{cs}|$ can also be obtained from semileptonic $D^+ \to \pi^0\ell^+\nu$ and $D_s^+ \to K^0\ell^+\nu$ decays, respectively. Here experimental measurements determine the product of the form factor times the CKM element, and theory provides the value for the form factor at zero four-momentum transfer between the initial $D_{(s)}$ meson and the final pion or kaon.

The latest experimental averages (2023, with data as of 2021) from the Heavy Flavor Averaging Group (HFLAV) are $f_+^{D\pi}(0)|V_{cd}| = 0.1426(18)$ and $f_+^{DK}(0)|V_{cs}| = 0.7180(33)$ [115]. There were not enough published lattice-QCD calculations of the zero-momentum D-meson semileptonic form factors with $N_f \geq 3$ to permit an average by the FLAG Collaboration; instead, we summarize the 2+1+1 flavor results here. The newest calculation, from the Fermilab Lattice and MILC Collaborations [116] appeared after the FLAG 2023 online update [3]. They report $f_+^{D\pi}(0) = 0.6300(51)$ and $f_+^{DK}(0) = 0.7452(31)$; these results are the most precise and include both decay modes. For the decay $D \to K\ell\nu$, the HPQCD Collaboration [117] calculates $f_+^{DK}(0) = 0.7380(44)$, about 1.3σ lower. An update from HPQCD [118] gives $f_+^{DK}(0) = 0.7441(40)$, in agreement with Fermilab-MILC. Note that the two HPQCD results and Fermilab-MILC all share MILC gauge configurations and are hence not independent. The ETM Collaboration [119], has results for both decays, obtaining $f_+^{D\pi}(0) = 0.612(35)$ and $f_+^{DK}(0) = 0.765(31)$, which are consistent but less precise. A naive combination of the HFLAV $f(0)|V|$ products and the new Fermilab-MILC results gives results for $|V_{cd}|$ and $|V_{cs}|$ consistent with the leptonic decays in Eq. (72.24). However, as with the leptonic case, one must exercise some care with corrections; this is beyond the scope of the present review. We note that Ref. [116] presents a detailed discussion of CKM element extractions using their LQCD results, including consideration of QED, electroweak and isospin corrections; a comparison of leptonic and semileptonic results and unitarity tests are also included.

We can combine the experimental measurements of $f_{D^+}|V_{cd}|$ and $f_{D_s^+}|V_{cs}|$ from Tables 72.2 and 72.3 with $|V_{cd}| = 0.22486(67)$ and $|V_{cs}| = 0.97349(16)$ from the PDG 2022 global unitarity-triangle analysis [1] to infer "experimental" values for the decay constants within the standard model. We take the CKM elements from the global fit because they are based on many input quantities, thereby reducing the sensitivity to any one outlying measurement or calculation. We obtain for the decay constants

$$\begin{aligned} f_{D^+}^{\text{"exp"}} &= 203.8(4.7)(0.6)(1.4)\ \text{MeV}\,, \\ f_{D_s^+}^{\text{"exp"}} &= 250.1(2.2)(0.04)(1.8)\ \text{MeV}\,, \\ (f_{D_s^+}/f_{D^+})^{\text{"exp"}} &= 1.228(30)(4)(9)\,. \end{aligned} \tag{72.26}$$

where the uncertainties are from the errors on $\Gamma^{(0)}$, CKM matrix elements, and radiative corrections, respectively. Here, the third uncertainty on the ratio is taken as 0.7%, the same as on the first two results, due to presumed partial cancellation. Possible further cancellation is not very relevant given the current statistical uncertainty. The "experimental" values f_{D^+} ($f_{D_s^+}/f_{D^+}$) are consistent within 1σ with the (2+1+1)-flavor lattice-QCD averages in Eq. (72.19). The CKM matrix element $|V_{cd}|$ is approximately equal to $|V_{us}|$, as first shown by Wolfenstein [120, 121]. Thus, resolving the inconsistencies between determinations of $|V_{us}|$ from leptonic and semileptonic decays discussed in Sec. 72.5.1 may benefit from the constraints observed here.

Last, we can test lepton-flavor universality in charm meson decays by checking the following relationship derived from Eq. (72.1):

$$\frac{\Gamma(D_s^+ \to \tau^+\nu)}{\Gamma(D_s^+ \to \mu^+\nu)} = \frac{m_\tau^2\left(1 - m_\tau^2/M_{D_s}^2\right)^2}{m_\mu^2\left(1 - m_\mu^2/M_{D_s}^2\right)^2} = 9.75\,, \tag{72.27}$$

where the uncertainties from the masses are negligible to the number of digits quoted. The measured ratio of $\tau^+\nu$ to $\mu^+\nu$ rates is 9.82 ± 0.40, consistent with this standard-model expectation.

72.5.3 $|V_{ub}|$ *and other applications*

Using the average value for $|V_{ub}|f_{B^+}$ from Table 72.5, and for f_{B^+} from Eq. (72.20), we obtain the following determination of the CKM matrix element $|V_{ub}|$ from leptonic decays within the standard model:

$$|V_{ub}| = 4.05(37)(3) \times 10^{-3}\,, \tag{72.28}$$

where the errors are from experiment and theory, respectively. One should bear in mind when interpreting Eq. (72.28) that none of the experimental measurements of the branching fractions that enter the average for $|V_{ub}|f_{B^+}$ have individually reached the 5σ discovery level (see Sec. 72.4.1). Further, decays involving the third generation of quarks and leptons may be particularly sensitive to new physics associated with electroweak symmetry breaking due to their larger masses [13,15], so Eq. (72.28) is more likely to be influenced by new physics than the determinations of the elements of the first and second rows of the CKM matrix in the previous sections.

The CKM element $|V_{ub}|$ can also be obtained from semileptonic B-meson decays. A long-standing 2-3σ tension between the determinations of $|V_{ub}|$ from exclusive $B \to \pi\ell\nu$ decay and from inclusive $B \to X_u\ell\nu$ decay has diminished somewhat; here, X_u denotes all hadronic states populated by the $b \to u$ weak transition [24, 122–126]. The currently most precise determination of $|V_{ub}|^{\rm excl} = 3.73(14) \times 10^{-3}$ is obtained from a joint z-fit by FLAG [2] of the vector and scalar form factors $f_+^{B\pi}(q^2)$ and $f_0^{B\pi}(q^2)$ calculated in (2+1)-flavor lattice QCD [127–129] and experimental measurements of the differential decay rate from BaBar [130, 131] and Belle [132, 133]. This is consistent with the value of $|V_{ub}|^{\rm excl} = 3.70(16) \times 10^{-3}$ obtained in the 2022 PDG review on semileptonic determinations of V_{cb}, V_{ub} [134]. On the other hand, the inclusive determination in that same review, obtained using the theoretical frameworks in Refs. [135–137], is $|V_{ub}|^{\rm incl} = 4.13(26) \times 10^{-3}$ [1, 134]. This value is significantly lower than the $4.49(28)\times10^{-3}$ value from the corresponding PDG 2018 review [134], reducing the exclusive-inclusive tension to less than 2σ. The value of $|V_{ub}|$ from leptonic $B \to \tau\nu$ decay in Eq. (72.28) lies between these inclusive and exclusive determinations, and is compatible (within large uncertainties) with both.

Given the large uncertainties on the experimental measurements of $\mathcal{B}(B^- \to \tau^-\overline{\nu})$, and the lingering tension between $|V_{ub}|$ obtained from inclusive and exclusive semileptonic B decays, we do not present an "experimental" value of the decay constant f_{B^+}.

72.6 Concluding remarks

The increasing precision of measurements of leptonic decays of charged pseudoscalar mesons has begun to require control over radiative corrections at a level superior to that presented here. Improvements will be called for both in theory and in experiment (for example, by BESIII and Belle II).

Unitarity of the CKM matrix is in reasonable shape. However, there is a lingering almost 3σ tension between the values of V_{us} determined by semileptonic and leptonic kaon decays. It will be interesting to follow experimental and theoretical developments on this quantity.

73. Production and Decay of b-flavored Hadrons

Revised March 2024 by P. Eerola (Research Council of Finland), M. Kreps (Warwick U.) and Y. Kwon (Yonsei U., Seoul).

The b quark belongs to the third generation of quarks and is the weak–doublet partner of the t quark. The existence of the third–generation quark doublet was proposed in 1973 by Kobayashi and Maskawa [1] in their model of the quark mixing matrix ("CKM" matrix), and confirmed four years later by the first observation of a $b\bar{b}$ meson [2]. In the KM model, CP violation is explained within the Standard Model (SM) by an irreducible phase of the 3×3 unitary matrix. The regular pattern of the three lepton and quark families is one of the most intriguing puzzles in particle physics. The existence of families gives rise to many of the free parameters in the SM, including the fermion masses, and the elements of the CKM matrix.

Since the b quark is the lighter element of the third–generation quark doublet, the decays of b-flavored hadrons occur via generation-changing processes through CKM matrix. Because of this, and the fact that the CKM matrix is close to a 3×3 unit matrix, many interesting features such as loop and box diagrams, flavor oscillations, as well as large CP asymmetries, can be observed in the weak decays of b-flavored hadrons.

The CKM matrix is parameterized by three real parameters and one complex phase. This complex phase is the source of CP violation in B meson decays in the Standard Model. A crucial milestone was the first observation of CP violation in the B meson system in 2001, by the BaBar [3] and Belle [4] collaborations. They measured a large value for the parameter $\sin 2\beta$ $(= \sin 2\phi_1)$ [5], almost four decades after the discovery of a small CP asymmetry in neutral kaons. A more detailed discussion of the CKM matrix and CP violation can be found elsewhere in this *Review* [6, 7].

The structure of this mini-review is organized as follows. After a discussion of b-quark production and current results on spectroscopy, we discuss lifetimes of b-flavored hadrons. We then discuss some basic properties of B-meson decays, followed by summaries of dominant hadronic, rare hadronic, and electroweak penguin decays of B-mesons. There are separate mini-reviews for B^0–$\overline{B}^0$ mixing [8] and the extraction of the CKM matrix elements V_{cb} and V_{ub} from B-meson decays [9] in this *Review*.

73.1 Production and spectroscopy

The bound states of a $\bar{b}$ antiquark and a u, d, s, or c quark are referred to as the B_u (B^+), B_d (B^0), B_s (B_s^0), and B_c (B_c^+) mesons, respectively. The B_c^+ is the heaviest of the ground–state b-flavored mesons, and the most difficult to produce: it was observed for the first time in the semileptonic mode by CDF in 1998 [10], but its mass was accurately determined only in 2006, from the fully reconstructed mode $B_c^+ \to J/\psi\pi^+$ [11]. Many exclusive decay channels can now be used for the accurate mass measurements, given the large statistics available at the LHC. Currently the most precise measurement is made by LHCb and yields $m(B_c^+) = 6274.47 \pm 0.27 \pm 0.17$ MeV/c^2 [12], combining $B_c^+ \to J/\psi\pi^+$, $B_c^+ \to J/\psi\pi^+\pi^-\pi^+$, $B_c^+ \to J/\psi p\bar{p}\pi^+$, $B_c^+ \to J/\psi D_s^+$, $B_c^+ \to J/\psi D^0 K^+$ and $B_c^+ \to B_s^0\pi^+$ decay modes.

The first excited meson is called the B^* meson, while B^{**} is the generic name for the four orbitally excited $(L = 1)$ B-meson states that correspond to the P-wave mesons in the charm system, D^{**}. Excited states of the B_s^0 meson are similarly named B_s^* and B_s^{**}.

Of the possible bound $\bar{b}b$ states, the $\Upsilon(nS)$ and $\chi_{bJ}(nP)$ states are well studied. The pseudoscalar ground state η_b has been observed for the first time by BaBar [13] indirectly through the decay $\Upsilon(3S) \to \gamma\eta_b$, and then confirmed by Babar in $\Upsilon(2S)$ decays [14] and CLEO in $\Upsilon(3S)$ decays [15]. The most accurate mass and width measurements come now from Belle, using decays $\Upsilon(5S) \to h_b(1P)\pi^+\pi^-$, $h_b(1P) \to \gamma\eta_b(1S)$ [16], $\Upsilon(4S) \to \eta h_b(1P)$, $h_b(1P) \to \gamma\eta_b(1S)$ [17], and $\Upsilon(2S) \to \gamma\eta_b(1S)$ [18]. Belle has also reported first evidence for the $\eta_b(2S)$ in the $h_b(2P) \to \eta_b(2S)\gamma$ transition [16]. In addition, Belle has observed $T_{b\bar{b}1}(10610)$ (was $Z_b(10610)$) and $T_{b\bar{b}1}(10650)$ (was $Z_b(10650)$) states in the processes $\Upsilon(5S) \to \Upsilon(nS)\pi^+\pi^-$ $(n = 1, 2, 3)$ and $\Upsilon(5S) \to h_b(mP)\pi^+\pi^-$ $(m = 1, 2)$ [19]. These $T_{b\bar{b}1}$ states are observed to decay to $\Upsilon(nS)\pi^\pm$ and $h_b(mP)\pi^\pm$, hence electrically charged and do not belong to ordinary $q\bar{q}$ mesons. For classification and naming of these and other states, see Ref. [20].

Experimental studies of b decays have been performed in e^+e^- collisions at the $\Upsilon(4S)$ (ARGUS, CLEO, Belle, BaBar) and $\Upsilon(5S)$ (CLEO, Belle) resonances. The $e^+e^- \to b\bar{b}$ production cross-section at the $\Upsilon(4S)$ $(\Upsilon(5S))$ resonance is about 1.1 nb (0.3 nb). The full data samples of BaBar and Belle are 560 fb^{-1} and 1020 fb^{-1}, respectively, of which 433 fb^{-1} and 710 fb^{-1} are at the $\Upsilon(4S)$ resonance. Since the $\Upsilon(4S)$ decays dominantly to a pair of B mesons (either B^+B^- or $B^0\overline{B}^0$), a precise knowledge of the energy-momentum of one B meson (the 'tagging B') enables deducing the properties of the other B (the 'signal B'). This property has been exploited by both BaBar and Belle, in particular, to measure inclusive decay modes as well as final states with missing neutrinos. The Belle II experiment at SuperKEKB has started recording data in 2019, and the experiment has so far collected about 428 fb^{-1} of data by summer 2022, when their long shutdown 1 started. Of collected data, 363 fb^{-1} is at the $\Upsilon(4S)$ resonance. At the Z resonance (SLC, LEP) all species of b-flavored hadrons could be studied for the first time. The $e^+e^- \to b\bar{b}$ production cross-section at the Z resonance is about 6.6 nb.

High-energy $p\bar{p}$ (Tevatron) and pp collisions (LHC) produce b-flavored hadrons of all species with large cross-sections. At the Tevatron ($\sqrt{s} = 1.96$ TeV) the visible cross section $\sigma(p\bar{p} \to bX, |\eta| < 1)$ is about 30 μb. CDF and D0 experiments at the Tevatron have accumulated by the end of their running about 10 fb^{-1} each.

At the LHC pp collider at $\sqrt{s} = 7 - 13$ TeV, the visible b-hadron cross section at the LHCb experiment with pseudorapidity acceptance $2 < \eta < 5$ has been measured to be ~ 72 μb at 7 TeV and ~ 144 μb at 13 TeV [21] (cross section at 13 TeV corrected in Erratum). LHCb has collected about 1 fb^{-1} at 7 TeV, 2 fb^{-1} at 8 TeV, and close to 5.9 fb^{-1} at 13 TeV during LHC Runs 1 and 2. CMS and ATLAS have collected each about 5 fb^{-1} of data at $\sqrt{s} = 7$, 20 fb^{-1} at 8 TeV and about 150 fb^{-1} at 13 TeV during LHC Runs 1 and 2. The latest LHC Run 3 at 13.6 TeV started in summer 2022, with upgraded detectors. By the time of the writing (March 2024), LHC has delivered about 70 fb^{-1} to ATLAS and CMS experiments, and about 300 pb^{-1} to the LHCb experiment with major detector upgrades.

In hadron collisions, production happens as $b\bar{b}$ pairs via leading order flavor creation or higher order processes such as gluon–splitting. Single b-quarks can be produced by flavor excitation. The total b-production cross section is an interesting test of our understanding of leading and higher order QCD processes. With a wealth of measurements at LHC and at Tevatron (see Ref. [21] and references therein), and improved calculations [22], there is a reasonable agreement between measurements and predictions.

Each quark of a $b\bar{b}$ pair produced in hadron collisions hadronizes separately and incoherently from the other, but it is still possible to obtain a statistical indication of the charge of a produced $b/\bar{b}$ quark ("flavor tag" or "charge tag") from the accompanying particles produced in the hadronization process, or from the decay products of the other quark. The momentum spectrum of produced b-quarks typically peaks near the b-quark mass, and extends to much higher momenta, dropping by about a decade for every ten GeV. Typical decay lengths are of the order of a centimeter at 13 TeV pp collisions; the resolution for the decay vertex must be more precise than this to resolve the fast oscillations of B_s^0 mesons.

In e^+e^- colliders, since the B mesons are very slow in the $\Upsilon(4S)$ rest frame, asymmetric beam energies are used to boost the decay products to allow time-dependent measurements that are crucial for the study of CP violation. At KEKB, the boost was $\beta\gamma = 0.43$, while PEP-II used a slightly larger boost, $\beta\gamma = 0.55$. The typical B-meson decay length is dilated from ≈ 20 μm to ≈ 200 μm. At SuperKEKB the boost is lower, $\beta\gamma = 0.28$, which puts more demanding requirements on the track reconstruction precision at Belle II to reach a resolution in decay time measurements similar to Belle. The two B mesons produced in $\Upsilon(4S)$ decay are in

a coherent quantum state, which makes it easier than in hadron collisions to infer the charge state of one B meson from observation of the other; however, the coherence also requires determination of the decay time of both mesons, rather than just one, in order to perform time–dependent CP–violation measurements. For B_s^0, which can be produced at $\Upsilon(5S)$ the situation is less favourable, as boost is not high enough to provide sufficient time resolution to resolve the fast B_s^0 oscillations.

For the measurement of branching fractions, the initial composition of the data sample must be known. The $\Upsilon(4S)$ resonance decays predominantly to $B^0\overline{B}^0$ and B^+B^-; the current experimental upper limit for non-$B\overline{B}$ decays of the $\Upsilon(4S)$ is less than 4% at the 95% confidence level (CL) [23]. The observed modes of this category are decays to lower Υ states and a pion pair, η, or η', measured branching fractions being of order $10^{-4} - 10^{-5}$ [24], and decays to $h_b(1P)\eta$ with branching fraction of order 10^{-3} [17].

The ratio f_+/f_0 of the fractions of charged to neutral B productions from $\Upsilon(4S)$ decays has been measured by CLEO, BaBar, and Belle in various ways. They typically use pairs of isospin-related decays of B^+ and B^0, such that it can be assumed that $\Gamma(B^+ \to x^+) = \Gamma(B^0 \to x^0)$. In this way, the ratio of the number of events observed in these modes is proportional to $(f_+\tau_+)/(f_0\tau_0)$ [25]. BaBar has also performed an independent measurement of f_0 with a different method that does not require isospin symmetry or the value of the lifetime ratio, based on the number of events with one or two reconstructed $B^0 \to D^{*-}\ell^+\nu$ decays [26]. The combined result, from the current average of τ_+/τ_0, is $f_+/f_0 = 1.058 \pm 0.024$ [27]. The result is consistent within 2.4σ with equal production of B^+B^- and $B^0\overline{B}^0$ pairs, and we assume $f_+/f_0 = 1$ in this mini-review except where explicitly stated otherwise. This assumption is also supported by the near equality of the B^+ and B^0 masses: our fit yields $m(B^0) = 5279.72 \pm 0.08$ MeV/c^2, $m(B^+) = 5279.41 \pm 0.07$ MeV/c^2, and $m(B^0) - m(B^+) = 0.31 \pm 0.05$ MeV/c^2.

Data collected at the $\Upsilon(5S)$ resonance gave CLEO, Belle and BaBar access to B_s^0 decays. In $\Upsilon(5S)$ decays there are seven possible final states including a pair of non-strange B mesons and 0, 1 or 2 pions, and three final states with a pair of strange B mesons ($B_s^{*0}\overline{B}_s^{*0}$, $B_s^{*0}\overline{B}_s^0$, and $B_s^0\overline{B}_s^0$). The fraction of events with a pair of B_s^0 mesons over the total number of events with a pair of b-flavored hadrons has been measured to be $f_s[\Upsilon(5S)] = 0.199^{+0.030}_{-0.029}$ [28], of which 88% is $B_s^{*0}\bar{B}_s^{*0}$ events. However, the small boost of B_s^0 mesons produced in this way prevents resolution of their fast oscillations for time-dependent measurements; these are only accessible in hadron collisions (or at the Z peak).

In high-energy collisions, the produced b or $\bar{b}$ quarks can hadronize with different probabilities into the full spectrum of b-hadrons, either in their ground or excited states. The hadronization does not have to be identical in $p\overline{p}$ or pp collisions and in Z decay, because of the different momentum distributions of the b-quark in these processes; the sample used in the $p\overline{p}$ measurements has momenta close to the b mass, rather than $m_Z/2$ in Z decay. The available data from Tevatron and LHC show that the production fractions f_d, f_u, f_s, and $f_{\rm baryon}$ of B^0, B^+, B_s^0, and b baryons, respectively, of weakly decaying b hadrons depend on the kinematics of the produced b hadron. Recently LHCb experiment found evidence for dependence of b-quark hadronization on multiplicity in pp collisions [29]. The production fractions of b hadrons are discussed in more detail in the $B^0 - \overline{B}^0$ mixing section in this *Review* [8].

Excited B-meson states have been thoroughly studied by CLEO, LEP, CUSB, D0 and CDF (an admixture of B mesons) and LHCb (B^{*+}-meson). The current world average of the B^*–B mass difference is 45.21 ± 0.21 MeV/c^2. Excited B_s^*-meson states have observed in $\Upsilon(5S)$ decays by CUSB, CLEO and Belle.

For orbitally excited $B_{(s)}$ meson states, with relative angular momentum L=1 of the two quarks, there exist four states $(J, j_q) = (0, 1/2), (1, 1/2), (1, 3/2), (2, 3/2)$, where j_q is the total angular momentum of the light u, d or s quark and J is the total angular momentum of the B meson. These states are collectively called as $B_{(s)}^{**}$ mesons. The $j_q = 1/2$ states are named $B_{(s)0}^*$ ($J = 0$) and $B_{(s)1}$ ($J = 1$) mesons, while the states with $j_q = 3/2$ are named $B_{(s)1}$ ($J = 1$) and $B_{(s)2}^*$ ($J = 2$) mesons. The states with $j_q = 1/2$ can decay through an S-wave transition and are expected to have a large width, but the $j_q = 3/2$ states are narrow D-wave decays. Evidence for B^{**} production has been initially obtained at LEP as a broad $B\pi$ resonance [30] or a B^+K^- enhancement [31]. Detailed results have been obtained for the narrow states $B_1(5721)^{0,+}$ and $B_2(5747)^{0,+}$ at the Tevatron and by LHCb, and clear enhancements compatible with the higher mass states $B_J(5840)^{0,+}$ and $B_J(5970)^{0,+}$ have been observed [32]. Also the narrow B_s^{**} states $B_{s1}(5830)^0$ and $B_{s2}(5840)^0$ have been measured at the CDF [32], LHCb [33], and CMS [34].

Excited states of B_c^+ mesons will provide important information about the strong potential. A $B_c^+\pi^+\pi^-$ resonance has been observed for the first time by ATLAS [35]. The mass of the resonance has been measured precisely by CMS and LHCb as 6871.2 ± 1.0 MeV/c^2 [36]. The resonance may be interpreted as the second S-wave state of the B_c^+ meson, $B_c^+(2S)$, but the quantum numbers are to be confirmed.

Baryon states containing a b quark are labeled according to the same scheme used for non-b baryons, with the addition of a b subscript [20]. The first observed b baryon was the Λ_b^0 (quark composition udb). Thanks to the large samples accumulated at the Tevatron and specially at the LHC many new b baryons have been found. The masses of all these new baryons have been measured to a precision of a few MeV/c^2, and found to be in agreement with predictions from Heavy Quark Effective Theory (HQET).

Clear signals of four strongly–decaying baryon states, Σ_b^+, Σ_b^{*+} (uub), Σ_b^-, Σ_b^{*-} (ddb) have been obtained by CDF [37] and LHCb [38]. LHCb has also observed two new mass peaks in the $\Lambda_b^0\pi^\pm$ systems, consistent with single resonances and named as $\Sigma_b^\pm(6097)$ [38]. The nature of these resonances is, however, not yet clear. The isodublet of strange b baryons Ξ_b^0 (usb) and $\Xi_b^\pm$ (dsb) has been observed by CDF and D0 [39]. Masses, lifetimes, and branching ratios have been accurately measured by LHCb [40–42] and CDF [43]. LHCb has also measured several parameters sensitive to P and CP violation [42,44]. Other observed Ξ_b baryons are spin-3/2 states $\Xi_b(5945)^0$ (Ξ_b^{*0}) [45,46], $\Xi_b^*(5955)^-$ [46,47] and $\Xi_b(6100)^-$ [46,48], a spin-1/2 state $\Xi_b'(5935)^-$ [46,47], and resonance states $\Xi_b^-(6227)$ [41,49], $\Xi_b^0(6327)$ [50] and $\Xi_b^0(6333)$ [50]. The doubly–strange bottom baryon Ω_b^- has been observed first by D0 and CDF [51]. Mass and mean life have been measured precisely by LHCb [52] and CDF [43]. LHCb has also observed four excited Ω_b^- states $\Omega_b^-(6316)$, $\Omega_b^-(6330)$, $\Omega_b^-(6340)$ and $\Omega_b^-(6350)$ [53].

The so-called exotic states have raised a lot of interest recently. While many exotic states were seen in the charm sector, in bottom sector there are fewer seen. The D0 Collaboration claimed a narrow state $X(5568)$ decaying into a $B_s^0\pi^\pm$ final state [54]. While this would be an interesting addition to the observed states as the first exotic state with constituent quarks with four different flavours (b, s, u, d), analysis by LHCb yields negative result [55]. Also CMS finds no such a state [56].

73.2 Lifetimes

Precise lifetimes are key in extracting the weak parameters that are important for understanding the role of the CKM matrix in CP violation, such as the determination of V_{cb} and B_s^0–$\overline{B}_s^0$ mixing parameters. In the naive spectator model, the heavy-flavored hadrons can decay only via the external spectator mechanism, and thus, the lifetimes of all mesons and baryons containing b quarks would be equal. Non–spectator effects, such as the interference between contributing amplitudes, modify this simple picture and give rise to a lifetime hierarchy for b-flavored hadrons similar to the one in the charm sector. However, since the lifetime differences are expected to scale as $1/m_Q^2$, where m_Q is the mass of the heavy quark, the variations in the b system are expected to be only 10% or less [57,58]. We expect:

$$\tau(B^+) \geq \tau(B^0) \approx \tau(B_s^0) > \tau(\Lambda_b^0) \gg \tau(B_c^+) \,. \qquad (73.1)$$

For the B_c^+, both quarks decay weakly, so the lifetime is much shorter.

Measurements of the lifetimes of the different b-flavored hadrons thus provide a means to determine the importance of non-spectator mechanisms in the b sector. Availability of large samples of fully–reconstructed decays of different b-hadron species has resulted in precise measurements with small statistical and systematic uncertainties (∼1%). The world averages given in Table 73.1 have been determined by the Heavy Flavor Averaging Group (HFLAV) [59].

Table 73.1: Summary of the world-average b-hadron lifetime measurements. For the B_s^0 lifetimes, see text below.

Particle	Lifetime [ps]
B^+	1.638 ± 0.004
B^0	1.517 ± 0.004
B_s^0	1.520 ± 0.005
B_{sL}^0	1.429 ± 0.006
B_{sH}^0	1.623 ± 0.008
B_c^+	0.510 ± 0.009
Λ_b^0	1.471 ± 0.009
Ξ_b^-	1.572 ± 0.040
Ξ_b^0	1.480 ± 0.030
Ω_b^-	$1.64^{+0.18}_{-0.17}$

The B_s^0 lifetime in Table 73.1 is defined as $1/\Gamma_s$, where Γ_s is the average width of the light (L) and heavy (H) mass eigenstates, $(\Gamma_L+\Gamma_H)/2$. In the absence of CP violation, the light (heavy) B_s^0 mass eigenstate is the CP-even (CP-odd) eigenstate. Thus, the lifetime of the light (heavy) mass eigenstate can be measured from CP-even (odd) final states. The lifetimes can also be obtained from time-dependent angular analysis of $B_s^0 \to J/\psi\phi$ decays.

The short B_c^+ lifetime is in good agreement with predictions [60]. With large samples of B_c^+ mesons at the LHC precision on the lifetimes can still improve. The measurement using semileptonic decays gives $\tau_{B_c^+} = 0.509 \pm 0.008 \pm 0.012$ ps [61] while using decays $B_c^+ \to J/\psi\pi^+$ yields $\tau_{B_c^+} = 0.5134 \pm 0.0110 \pm 0.0057$ ps [62]. Each of these is more precise than the combination of all previous experiments.

The recent Λ_b^0 lifetime measurements from LHC experiments and CDF are precise and favour lifetime close to the lifetime of B^0 meson, in agreement with theory.

For precision comparisons with theory, lifetime ratios are more sensitive. Experimentally it is found [59]:

$$\frac{\tau_{B^+}}{\tau_{B^0}} = 1.076 \pm 0.004\,, \quad \frac{\tau_{B_s^0}}{\tau_{B^0}} = 1.002 \pm 0.004\,,$$

$$\frac{\tau_{\Lambda_b^0}}{\tau_{B^0}} = 0.969 \pm 0.006\,,$$

while recent Heavy Quark Expansion (HQE) predictions give [58]:

$$\frac{\tau_{B^+}}{\tau_{B^0}} = 1.04^{+0.05}_{-0.01} \pm 0.02 \pm 0.01\ , \quad \frac{\tau_{B_s^0}}{\tau_{B^0}} = 1.001 \pm 0.002\ ,$$

$$\frac{\tau_{\Lambda_b^0}}{\tau_{B^0}} = 0.935 \pm 0.054.$$

The ratio of B^+ to B^0 lifetimes has a precision of better than 1%, and is significantly different from 1.0, in agreement with predictions [57]. The ratio of B_s^0 to B^0 lifetimes is expected to be very close to 1.0.

For a detailed discussion on neutral B^0 and B_s^0 oscillation and relevant CP violation measurements see Ref. [8].

73.3 Features of decays

The ground states of b-flavored hadrons decay via weak interactions. In most decays of the b-flavored hadrons, where the b-quark is accompanied by lighter partner quarks (d, u, s, or c), the decay modes are well described by the decay of the b quark (spectator model) [63]. The dominant decay mode of a b quark is $b \to cW^{*-}$ (referred to as a "tree" or "spectator" decay), where the virtual W materializes either into a pair of leptons $\ell\bar{\nu}$ ("semileptonic decay"), or into a pair of quarks which then hadronizes. The transition $b \to u$ is suppressed by $|V_{ub}/V_{cb}|^2 \sim (0.1)^2$ relative to $b \to c$ transitions. The decays in which the spectator quark combines with one of the quarks from W^* to form one of the final state hadrons are suppressed by a factor $\sim (1/3)^2$, because the colors of the two quarks from different sources must match ("color–suppression").

Semileptonic B decays $B \to X_c\ell\nu$ and $B \to X_u\ell\nu$ provide an excellent way to measure the magnitude of the CKM elements $|V_{cb}|$ and $|V_{ub}|$ respectively, because the strong interaction effects are much simplified due to the two leptons in the final state. Both exclusive and inclusive decays can be used with dominant uncertainties being complementary. For exclusive decay analysis, knowledge of the form factors for the exclusive hadronic system $X_{c(u)}$ is required. For inclusive analysis, it is usually necessary to restrict the available phase-space of the decay products to suppress backgrounds; subsequently uncertainties are introduced in the extrapolation to the full phase-space. Moreover, restriction to a small corner of the phase-space may result in breakdown of the operator-product expansion scheme, thus making theoretical calculations unreliable. A more detailed discussion of B semileptonic decays and the extraction of $|V_{cb}|$ and $|V_{ub}|$ is given elsewhere in this *Review* [9]. While traditionally B^0 and B^+ decays were used, over time also other B hadron studies became available. Most notably, determination of of $|V_{ub}|$ using $\Lambda_b^0 \to p\mu^-\bar{\nu}_\mu$ decays by LHCb [64] was more precise than expected. Besides, there have been measurements of inclusive semileptonic decay rates of B_s^0 [65] and B_c^+ [66] mesons. One of the latest additions in this area is the observation of the $B_s^0 \to K^-\mu^+\nu_\mu$ decays by LHCb using only a fraction of their available data [67].

On the other hand, hadronic B decays are complicated because of strong interaction effects caused by the surrounding cloud of light quarks and gluons. While this complicates the extraction of CKM matrix elements, it also provides a great opportunity to study perturbative and non-perturbative QCD, hadronization, and Final State Interaction (FSI) effects.

Many aspects of B decays can be understood through the Heavy Quark Effective Theory (HQET) [68]. This has been particularly successful for semileptonic decays. For further discussion of HQET, see for instance Ref. [69]. For hadronic decays, one typically uses effective Hamiltonian calculations that rely on a perturbative expansion with Wilson coefficients. In addition, some form of the factorization hypothesis is commonly used, where, in analogy with semileptonic decays, two-body hadronic decays of B mesons are expressed as the product of two independent hadronic currents, one describing the formation of a charm meson (in case of the dominant $b \to cW^{*-}$ decays), and the other describing the hadronization of the remaining $\overline{u}d$ (or $\overline{c}s$) system from the virtual W^-. Qualitatively, for B decays with a large energy release, e.g. $b \to uW^{*-}$ transitions, the $\overline{u}d$ pair (produced as a color singlet) travels fast enough to leave the interaction region without influencing the meson containing the spectator quark. This is known to work well for the dominant spectator decays [70]. There are several common implementations of these ideas for hadronic B decays, the most common of which are QCD factorization (QCDF) [71], perturbative QCD (pQCD) [72], and soft collinear effective theory (SCET) [73].

The transitions $b \to s$ and $b \to d$ are flavor-changing neutral-current (FCNC) processes. Although they are not allowed in the SM as a tree-process, they can occur via loop diagrams (denoted "penguin" decays). The rates for $b \to s$ penguin decays are comparable to the CKM-suppressed $b \to u$ tree processes. Pure-penguin decays were first established by the observation of $B \to K^*(892)\gamma$ [74]. Penguin processes involving $b \to d$ transitions are further suppressed by CKM, and have been observed for $B \to (\rho/\omega)\gamma$ decays [75, 76]. LHCb has observed a $b \to d$ penguin transition in the $B^+ \to \pi^+\mu^+\mu^-$ mode and measured its branching fraction to be $(1.83 \pm 0.24 \pm 0.05) \times 10^{-8}$ [77].

Other decay processes discussed in this *Review* include W–exchange (a W is exchanged between initial–state quarks), penguin annihilation (the gluon from a penguin loop attaches to

the spectator quark, similar to an exchange diagram), and pure–annihilation (the initial quarks annihilate to a virtual W, which then decays). Some observed decay modes such as $B^0 \to D_s^- K^+$, may be interpreted as evidence of a W-exchange process [78]. The evidence for the purely leptonic decay $B^+ \to \tau^+\nu$ from Belle [79] and BaBar [80] is the first sign of a pure annihilation decay. The average branching fraction is $(1.09 \pm 0.24) \times 10^{-4}$, which is somewhat larger than, though consistent with, the value expected in the SM. A substantial region of parameter space of charged Higgs mass vs. $\tan\beta$ is excluded by the measurements of this mode. A dedicated discussion of purely leptonic decays of charged pseudoscalar mesons is given elsewhere in this *Review* [81].

73.4 Dominant hadronic decays

Most of the hadronic B decays involve $b \to c$ transition at the quark level, resulting in a charmed hadron or charmonium in the final state. Other types of hadronic decays are very rare and will be discussed separately in the next section. The experimental results on hadronic B decays have steadily improved over the years, and the measurements have reached sufficient precision to challenge our understanding of the dynamics of these decays. With good particle detection and hadron identification capabilities of B-factory detectors, a substantial fraction (roughly on the order of a few per mill) of hadronic B decay events can be fully reconstructed. In particular, good performances for detecting π^0 and other neutral particles helped Belle and BaBar to make comprehensive measurements of the decays $\overline{B}^0 \to D^{(*)0}h^0$ [82], where h^0 stands for light neutral mesons such as $\pi^0, \eta^{(\prime)}, \rho^0, \omega$. The measurements are being complemented by LHCb, in decays like $\overline{B^0} \to D^0\pi^+\pi^-$ [83], where no neutral particles reconstruction is needed. These decays proceed through color-suppressed diagrams, hence they provide useful tests on the factorization models.

Because of the kinematic constraint of $\Upsilon(4S) \to B\bar{B}$, the energy sum of the final-state particles of a B meson decay is always equal to one half of the total energy in the center of mass frame. As a result, the two variables, ΔE (energy difference) and M_B (B candidate mass with a beam-energy constraint) are very effective for reducing combinatorial background both from $\Upsilon(4S)$ and $e^+e^- \to q\bar{q}$ continuum events. In particular, the energy-constraint in M_B improves the signal resolution by almost an order of magnitude.

The kinematically clean environment of B meson decays provides an excellent opportunity to search for new states. For instance, quark-level $b \to c\bar{c}s$ decays have been used to search for new charmonium and charm-strange mesons and study their properties in detail. While narrow charm-strange states $D_{s0}^*(2317)$ [84] and $D_{s1}(2460)$ [85] were discovered by BaBar and CLEO, respectively, the properties of these new states were revealed by studying the B meson decays, $B \to DD_{s0}^*(2317)$ and $B \to DD_{s1}(2460)$ by Belle [86] and BaBar [87]. Another example is Dalitz plot analysis of decay $B_s^0 \to \bar{D}^0 K^-\pi^+$ in which the decay to spin-3 resonance was observed for the first time [88]. One of the most significant improvements in the past decade is establishment of decays $B^+ \to D^0K^+$ and $B^+ \to D^0K^*(892)^+$ with D^0 decaying to final state common to D^0 and $\overline{D}^0$ [89]. This allows direct determination of CKM angle $\gamma(= \phi_3)$ to be $65.9^{+3.3}_{-3.5}$.

Information on B_s^0, B_c^+ and Λ_b^0 decays have been remarkably improved with recent studies of large samples from LHCb. Noticeable additions in B_s include decay modes to $D_s^{(*)+}D_s^{(*)-}$, $\bar{D}^0\bar{K}^0$, and $J/\psi\bar{K}^*(892)^0$. The $B_s^0 \to D_s^{(*)+}D_s^{(*)-}$ decays were first observed by CDF [90], followed by Belle [91]. LHCb has improved the precision with $\mathcal{B}(B_s^0 \to D_s^{(*)+}D_s^{(*)-}) = (3.07 \pm 0.22 \pm 0.33)\%$ [92], which suggests that $B_s^0 \to D_s^{(*)+}D_s^{(*)-}$ decays do not saturate the CP-even modes of the B_s decays. The $B_s^0 \to \bar{D}^0\bar{K}^0$ decay occurs mostly via a color-suppressed tree diagram, and has a small theoretical uncertainty in the SM, thus this mode can significantly improve the determination of the CP-violation angle ϕ_s. LHCb has observed this decay and the branching fraction is $(4.3 \pm 0.5 \pm 0.7) \times 10^{-4}$ [93]. The $B_s^0 \to J/\psi\bar{K}^*(892)^0$ decay can be used to constrain the penguin pollution in determining ϕ_s. LHCb has updated the branching fraction and measured the CP asymmetries of this decay, thereby constraining the penguin pollution in ϕ_s [94], although a much more stringent constraint on penguin pollution can come from $B^0 \to J/\psi\rho^0$ which has been observed by BaBar [95] and LHCb [96]. The $B_c^+ \to B_s^0\pi^+$ decay is unique as the only observed mode of b-flavored hadron decays where the partner quark decays (c in this case) while the b quark remains a spectator. LHCb has observed this mode [97] and measured $\mathcal{B}(B_c^+ \to B_s^0\pi^+)/\mathcal{B}(B_c^+ \to J/\psi\pi^+) = (91 \pm 10 \pm 8 \pm 3)$ [98]. In addition, LHCb [99] and ATLAS [100] have measured $B_c^+ \to J/\psi D_s^{(*)+}$, which, by comparing with $B_c^+ \to B_s^0\pi^+$, provides a ratio of exclusive $b \to c$ and $c \to s$ decays of B_c^+. For $\Lambda_b^0 \to \Lambda_c^+\pi^+\pi^-\pi^-$ [101], not only the total rate is measured, but also structure involving decays through excited Λ_c and Σ_c baryons.

In addition, a variety of exotic particles that do not fit the conventional meson spectroscopy have been discovered in B decays. Belle found the $X(3872)$ state by studying $B^+ \to J/\psi\pi^+\pi^-K^+$ [102], which was confirmed by CDF [103], D0 [104] and BaBar [105]. Production of $X(3872)$ has been studied by the LHC experiments, LHCb [106], CMS [107] and ATLAS [108].

A charged charmonium-like state $X(4430)^\pm$ that decays to $\psi(2S)\pi^\pm$ was observed by Belle in $B \to \psi(2S)K\pi^\pm$ [109]. Since it is charged, it could not be an ordinary charmonium state. A high-statistics study by LHCb confirmed the existence of the $X(4430)^\pm$ in decays $B \to \psi(2S)K\pi^\pm$ [110], demonstrated its resonance character by studying the phase motion, unambiguously determined its spin-parity, and saw evidence for another state. In a Dalitz plot analysis of $\bar{B}^0 \to J/\psi K^-\pi^+$ [111], Belle has found another state, labeled as $X(4200)^+$ in this *Review*, adding to the list of exotic charged charmonium-like states. In an amplitude analysis of the decay $\Lambda_b^0 \to J/\psi pK^-$, LHCb observed exotic structures, labeled as $P_c(4380)^+$ and $P_c(4450)^+$ in this *Review*, in the $J/\psi p$ channel [112]. The subsequent analysis with significantly increased statistics observed additional state and resolved the peak at 4450 MeV/c^2 as being due to the two states close in the mass [113]. The structure in the $J/\psi p$ channel was also seen in the $B_s^0 \to J/\psi p\overline{p}$ decays [114] and in the $J/\psi\Lambda$ channel in $B^+ \to J/\psi\Lambda p$ and $\Xi_b^- \to J/\psi\Lambda K^-$ decays [115]. They are referred to as charmonium-pentaquark states. More detailed discussions of exotic meson-like states and pentaquarks are given elsewhere in this *Review* [116].

73.5 Rare hadronic decays

All B-meson decays that do not occur through the $b \to c$ transition are usually called rare B decays. These include both semileptonic and hadronic $b \to u$ decays that are suppressed at leading order by the small CKM matrix element V_{ub}, as well as higher-order $b \to s(d)$ processes such as electroweak and gluonic penguin decays. In this section, we review hadronic rare B decays, while electroweak penguin decays and others are discussed in the next.

Charmless B meson decays into two-body hadronic final states such as $B \to \pi\pi$ and $K\pi$ are experimentally clean, and provide good opportunities to probe new physics and search for indirect and direct CP violations. Since the final state particles in these decays tend to have larger momenta than average B decay products, the event environment is cleaner than for $b \to c$ decays. Branching fractions are typically around 10^{-5}. Over the past decade, many such modes have been observed not only by e^+e^- collider experiments such as BaBar and Belle, but also by hadron collider experiments such as CDF ($p\bar{p}$) and LHCb (pp). In the latter cases, huge data samples of the modes with all charged final-state particles have been reconstructed by triggering on the impact parameter of the charged tracks. This has also allowed observation of charmless decays of the B_s, in final states such as $\phi\phi$ [117], K^+K^- [118,119], and $K^-\pi^+$ [119,120], and of charmless decays of the Λ_b^0 baryon [120]. The large samples available at LHCb experiment allow to perform also time-dependent CP violation measurements [121]. Charmless B_s modes are related to corresponding B^0 modes by U-spin symmetry, and are determined by similar amplitudes. Combining the observables from B_s^0 and B^0 modes is a further way of eliminating hadronic uncertainties and extracting relevant CKM information [122].

Because of relatively high-momenta for final state particles, the dominant source of background in e^+e^- collisions is $q\bar{q}$ contin-

uum events; sophisticated background suppression techniques exploiting event shape variables are essential for these analyses. In hadron collisions, the dominant background comes from QCD or partially reconstructed heavy flavors, and is similarly suppressed by a combination of kinematic and isolation requirements. The results are in general consistent among the experiments.

Most rare decay modes including $B^0 \to K^+\pi^-$ have contributions from both $b \to u$ tree and $b \to sg$ penguin processes. If the size of the two contributions are comparable, the interference between them may result in direct CP violation, seen experimentally as a charge asymmetry in the decay rate measurement. BaBar [123], Belle [124], CDF [118], and LHCb [121, 125] have measured the direct CP violating asymmetry in $B^0 \to K^+\pi^-$ decays. Direct CP violation has been observed in this decay with a significance of more than 5σ. The world average value of the asymmetry is now rather precise, $A_{CP}(K^+\pi^-) = -0.0834 \pm 0.0032$. The CP asymmetry in $B^+ \to K^+\pi^0$ mode has been measured by BaBar [126], *Belle [124] and LHCb [127] with the average value $A_{CP}(K^+\pi^0) = 0.030 \pm 0.013$. These two asymmetries differ significantly, in contrast to a naive expectation based on simplified picture in the SM. For more detailed tests, there are sum rules [128] that relate the decay rates and decay-rate asymmetries between the four $K\pi$ charge states. A crucial ingredient of the sum rule test is $A_{CP}(K^0\pi^0)$. Currently, measured values are reported by both BaBar [129] and Belle [130]. Using the $A_{CP}(K^0\pi^0)$ value of Ref. [130], Belle reports the sum rule test result that is consistent with zero within 1.9σ [124]. With the future improvements via Belle II and upgraded LHCb, the measurements are expected to become precise enough to shape a definite conclusion. The CP asymmetry in the π^+K^- mode has also been measured in B_s^0 decays, by CDF [118] and LHCb [121, 125]. The combined value is $A_{CP}(B_s^0 \to \pi^+K^-) = 0.224 \pm 0.012$.

In addition to $B_{(s)} \to K\pi$ modes, significant ($> 3\sigma$) non-zero CP asymmetries have been measured in several other rare decay modes: $A_{CP}(B^+ \to \rho^0K^+) = 0.37 \pm 0.10$ [131], $A_{CP}(B^+ \to \eta K^+) = -0.37 \pm 0.08$ [132], $A_{CP}(B^0 \to \eta K^{*0}) = 0.19 \pm 0.05$ [133], and $A_{CP}(B^+ \to f_2(1270)K^+) = -0.68^{+0.19}_{-0.17}$ [131]. In at least the first two cases, a large direct CP violation might be expected since the penguin amplitude is suppressed so the tree and penguin amplitudes may have comparable magnitudes. There are also measurements by LHCb of CP asymmetries in several 3-body modes: $A_{CP}(B^+ \to \pi^+\pi^-\pi^+) = 0.057 \pm 0.013$, $A_{CP}(B^+ \to K^+\pi^-\pi^+) = 0.027 \pm 0.008$, $A_{CP}(B^+ \to K^+K^-\pi^+) = -0.122 \pm 0.0021$, and $A_{CP}(B^+ \to K^+K^-K^+) = -0.033 \pm 0.008$ [134]. Many of these analyses now include Dalitz plot treatments with many intermediate resonances.

BaBar [135] and Belle [124, 136] have observed the decays $B^+ \to \overline{K}^0K^+$ and $B^0 \to K^0\overline{K}^0$. The world-average branching fractions are $\mathcal{B}(B^0 \to K^0\overline{K}^0) = (1.21 \pm 0.16) \times 10^{-6}$ and $\mathcal{B}(B^+ \to \overline{K}^0K^+) = (1.31 \pm 0.17) \times 10^{-6}$. These are the first observations of hadronic $b \to d$ transitions, with significance bigger than 5σ for all four measurements. CP asymmetries have been measured for these modes, but with large errors. LHCb has observed $B^0 \to K^+K^-$ mode which occurs via a weak-annihilation process and is the rarest hadronic B-meson decay thus far observed, with $\mathcal{B}(B^0 \to K^+K^-) = (7.80 \pm 1.52) \times 10^{-8}$ [137]. $B_s^0 \to K^+K^-$ decay mode, which occurs mostly via $b \to s$ penguin process, has been observed by Belle [138], CDF [139] and LHCb [119]. The average branching fraction is $\mathcal{B}(B_s^0 \to K^+K^-) = (26.6 \pm 2.2) \times 10^{-6}$. Belle has also observed $B_s^0 \to K^0\overline{K}^0$ [140] which also occurs via $b \to s$ penguin transition in the SM. This was recently confirmed by LHCb [141]. The average branching fraction is $(1.76 \pm 0.31) \times 10^{-5}$.

The decay $B^0 \to \pi^+\pi^-$ can be used to extract the CKM angle α (for details see elsewhere in this *Review* [142]). This is complicated by the presence of significant contributions from penguin diagrams. An isospin analysis [143] can be used to untangle the penguin complications. The decay $B^0 \to \pi^0\pi^0$ is crucial in this analysis. Both BaBar and Belle have observed $B^0 \to \pi^0\pi^0$, with a mild tension in the measured branching fractions: $(1.83 \pm 0.25) \times 10^{-6}$ for BaBar [123] and $(1.31 \pm 0.26) \times 10^{-6}$ for Belle [144]. It turns out that the amount of penguin pollution in the $B \to \pi\pi$ system is rather large. In the past few years, measurements in the $B^0 \to \rho\rho$ system have produced more precise values of α, since penguin amplitudes are generally smaller for decays with vector mesons. An important ingredient in the analysis is the $B^0 \to \rho^0\rho^0$ branching fraction. The average of measurements from BaBar [145] and Belle [146] yields a branching fraction of $(0.96 \pm 0.15) \times 10^{-6}$. This is only 3% of the $\rho^+\rho^-$ branching fraction, much smaller than the corresponding ratio ($\gtrsim 20\%$) in the $\pi\pi$ system.

Since $B \to \rho\rho$ has two vector mesons in the final state, the CP eigenvalue of the final state depends on the longitudinal polarization fraction f_L for the decay. Therefore, a measurement of f_L is needed to extract the CKM angle α. Both BaBar and Belle have measured f_L for the decays $\rho^+\rho^-$ [147] and $\rho^+\rho^0$ [148] and in both cases the measurements show $f_L > 0.9$, making a complete angular analysis unnecessary. In $B^0 \to \rho^0\rho^0$, f_L is measured by BaBar [145], Belle [146] and LHCb [149], with the average value being $0.71^{+0.08}_{-0.09}$.

By analyzing the angular distributions of the B decays to two vector mesons, we can learn a lot about both weak- and strong-interaction dynamics in B decays. Decays that are penguin-dominated surprisingly have values of f_L near 0.5. The list of such decays has now grown to include $B \to \phi K^*(892)$, $B \to \rho K^*(892)$, and $B \to \omega K^*(892)$. The reasons for this "polarization puzzle" are not fully understood. A detailed description of the angular analysis of B decays to two vector mesons can be found in a separate mini-review [150] in this *Review* .

73.6 Electroweak penguin decays

Electroweak penguin decays are one-loop FCNC decays proceeding through penguin or box Feynman diagrams with final state including real photon or pair of leptons. Such decays were first observed by CLEO experiment when it observed decay $B \to K^*(892)\gamma$ [74]. Since then significant amount of experimental information was obtained. Branching fractions for these decays are 10^{-5} or less, which makes them excellent candidates for searches for new physics beyond SM. Often several observables are available, which allows for stringent tests of the SM.

Starting with radiative decays, experimentally easiest to study are exclusive decays with a fully reconstructed final state. The best studied decay in this class is $B \to K^*(892)\gamma$ seen by CLEO, Belle, BaBar experiments [151, 152] with world average branching fraction $\mathcal{B}(B^0 \to K^*(892)^0\gamma) = (41.8 \pm 2.5) \times 10^{-6}$. Decays through several other kaon resonances such as $B \to K_1(1270)\gamma$, $K_2^*(1430)\gamma$, *etc.* were studied at B-factories [153,154]. It is worth to mention decay $B^+ \to K^+\pi^+\pi^-\gamma$ for which besides measurements of the branching fraction [154, 155] one can also use the angular distribution to access photon polarization. Such a measurement was done by the LHCb experiment, which was able to clearly demonstrate that the photon in $B^+ \to K^+\pi^+\pi^-\gamma$ decay is polarized [156]. Unfortunately given non-trivial hadronic structure, more work is needed before turning this into test of the SM. The exclusive radiative decays $B_s^0 \to \phi\gamma$ was seen by the Belle and LHCb experiments [157] with an average branching fraction of $(3.4 \pm 0.4) \times 10^{-5}$ and more recently also decay $\Lambda_b \to \Lambda\gamma$ was observed by LHCb [158].

Compared to $b \to s\gamma$, the $b \to d\gamma$ transitions such as $B \to \rho\gamma$, are suppressed by the CKM elements ratio $|V_{td}/V_{ts}|^2$. Both Belle and BaBar have observed these decays [75,76]. The world average $\mathcal{B}(B \to (\rho,\omega)\gamma) = (1.30 \pm 0.23) \times 10^{-6}$. This can be used to calculate $|V_{td}/V_{ts}|$ [159]; the measured values are $0.195^{+0.025}_{-0.024}$ from Belle [75] and $0.233^{+0.033}_{-0.032}$ from BaBar [76].

The observed radiative penguin branching fractions can constrain a large class of SM extensions [160]. However, due to the uncertainties in the hadronization, only the inclusive $b \to s\gamma$ rate can be reliably compared with theoretical calculations. This rate can be measured from the endpoint of the inclusive photon spectrum in B decay. By combining the measurements of $B \to X_s\gamma$ from the CLEO, BaBar, and Belle experiments [161,162], HFLAV obtains the average: $\mathcal{B}(B \to X_s\gamma) = (3.49 \pm 0.19) \times 10^{-4}$ [59] for $E_\gamma \geq 1.6$ GeV, averaging over B^+ and B^0. Consistent but less precise results have been reported by ALEPH for inclusive b–hadrons produced at the Z, which includes also contribution from B_s^0 and Λ_b^0 hadrons. Using the sum of seven exclusive final

states, the BaBar experiment measured the branching fraction of inclusive $b \to d\gamma$ decays to be $(9.2 \pm 2.0 \pm 2.3) \times 10^{-6}$ [163]. The measured branching fraction can be compared to theoretical calculations. Recent calculations of $\mathcal{B}(b \to s\gamma)$ at NNLO level predict for the $E_\gamma \geq 1.6$ GeV values of $(3.36 \pm 0.23) \times 10^{-4}$ for $b \to s\gamma$ and $(1.68 \pm 0.17) \times 10^{-5}$ for $b \to d\gamma$ decays [164].

The CP asymmetry in $b \to s\gamma$ is extensively studied theoretically both in the SM and beyond [165]. According to the SM, the CP asymmetry in $b \to s\gamma$ is smaller than 1%, but some non-SM models allow significantly larger CP asymmetry ($\sim$ 10%) without altering the branching fraction. The current world average is $A_{CP} = 0.015 \pm 0.011$, again dominated by BaBar and Belle [166, 167]. In addition to the CP asymmetry, BaBar and Belle also measured the isospin asymmetry $\Delta_{0-} = -0.005 \pm 0.020$ in $b \to s\gamma$ measured using sum of exclusive decays [166, 168]. An alternative measurement using full reconstruction of the companion B in the hadronic decay modes yields a consistent, but less precise result [169]. Both Belle and BaBar experiments measured the isospin asymmetry in exclusive $B \to K^*(892)\gamma$ decay with average of $6.3 \pm 1.7\%$ [152] and therefore providing evidence for the non-zero isospin asymmetry.

In addition, experiments have measured the inclusive photon energy spectrum for $b \to s\gamma$, and by analyzing the shape of the spectrum they obtain the first and second moments for photon energies. Belle has measured these moments covering the widest range in the photon energy ($1.7 < E_\gamma < 2.8$ GeV) [162]. The measurement by BaBar has slightly smaller range with lower limit at 1.8 GeV [170]. These results can be used to extract non-perturbative HQET parameters that are needed for precise determination of the CKM matrix element V_{ub} (see further discussion elsewhere in this *Review* [171]).

Additional information on FCNC processes can be obtained from $b \to s\ell^+\ell^-$ decays. These processes are studied as a function of dilepton invariant mass squared, q^2. Different q^2 regions are sensitive to different physics. Starting at the very low q^2 decays exhibit sensitivity to the same physics as the radiative decays. Then for the q^2 in region 1.1 to 6.0 GeV$^2/c^4$ the SM and new physics have best chance to compete. At the high q^2 above the $\psi(2S)$ mass, the interference of SM and new physics is to some extend complementary to that in lower q^2. Regions around J/ψ and $\psi(2S)$ is normally excluded from measurements as these are dominated by the $b \to c$ transitions to charmonia. For exclusive decays, theory predictions require calculations of hadronic form factors. With current theory predictions, the most useful are measurements within the q^2 regions 1.1 to 6.0 GeV$^2/c^4$ and from 16.0 GeV$^2/c^4$ up to the kinematic limit. From this reason in the listing we provide results mainly in those two regions.

Similar as for radiative decays, also for the $b \to s\ell^+\ell^-$ decays the inclusive measurements provide some benefits. Both Belle and BaBar performed such measurement without reconstructing hadronic part exclusively and measure a branching fraction of $(5.8 \pm 1.3) \times 10^{-6}$ [172]. Unfortunately this measurement is not trivially possible at hadron colliders and also does not easily allow the angular distributions of the decay products to be exploited. One alternative is to extract information on the inclusive decay as sum of exclusive decays. Such a measurement was performed by Belle [173], but in this case the difficulty lies in extrapolation for the missing hadronic states.

Turning to the exclusive decays, the initial measurements performed by B-factories typically averaged between charged and neutral B mesons as well as between e^+e^- and $\mu^+\mu^-$ finals states. The experiments CDF, LHCb, ATLAS and CMS are much better suited for the $\mu^+\mu^-$ finals states compared to the e^+e^- final states. As such most measurements at hadron colliders are done only with $\mu^+\mu^-$ pairs and by separating charged and neutral B mesons. Recently, however, with much increased statistics, LHCb measured several final states with e^+e^-, to make a series of tests of e/μ universality in $B \to K^{(*)}\ell^+\ell^-$ decays. At hadron colliders other b hadrons are produced and as such CDF and LHCb experiments did observe also $B_s^0 \to \phi\mu^+\mu^-$ [174, 175], $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ [174, 176] and $\Lambda_b^0 \to pK^-\mu^+\mu^-$ decays [177]. The averages of the total branching fractions integrated over whole q^2 regions are $(5.6 \pm 0.6) \times 10^{-7}$ for $B^+ \to K^+e^+e^-$, $(4.53 \pm 0.35) \times 10^{-7}$ for $B^+ \to K^+\mu^+\mu^-$, $(1.03^{+0.19}_{-0.17}) \times 10^{-6}$ for $B^0 \to K^*(892)^0e^+e^-$ and $(0.94 \pm 0.05) \times 10^{-6}$ for $B^0 \to K^*(892)^0\mu^+\mu^-$ decays [178–182]. The total branching fractions for $B_s^0 \to \phi\mu^+\mu^-$ and $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ decays are $(8.4 \pm 0.4) \times 10^{-7}$ [174, 175, 183] and $(1.08 \pm 0.28) \times 10^{-6}$ [174, 176] respectively. With increased precision of $B^0 \to K^*(892)^0\ell^+\ell^-$ decay, there is a question on what fraction of the seen branching fraction is due to the $K^*(892)^0$ resonance and what fraction is due to the $K\pi$ in s-wave. This has been studied by LHCb which found that the $K\pi$ in s-wave fraction varies between 1% and about 10% depending on the q^2 region [182]. It should be noted, that for all relevant B meson decays the branching fractions so far studied are consistently below the SM expectation.

In the $b \to s\ell^+\ell^-$ decays angular distributions offer rich source of information. The full angular analysis was performed for decays $B^+ \to K^+\ell^+\ell^-$, $B^0 \to K^0\ell^+\ell^-$, $B^+ \to K^*(892)^+\ell^+\ell^-$, $B^0 \to K^*(892)^0\ell^+\ell^-$, $B_s^0 \to \phi\mu^+\mu^-$ and $\Lambda_b^0 \to \Lambda\mu^+\mu^-$ decays [184–192]. An attempt to increase sensitivity to the NP was made by constructing observables, which have reduced theory uncertainties and measurements of these are done. Most notably the observable called P_5' [193] shows a discrepancy with the SM in the q^2 region which is highly sensitive to new physics [186–188]. Measurements of the CP asymmetries [177, 178, 181, 194, 195] and the isospin asymmetry [179–181, 194] were also performed. All these measurements are well consistent with the small A_{CP} and small isospin asymmetry expected in the SM [196]. With statistics available at the LHC, the measurement of phase difference between long- and short-distance contribution in $B^+ \to K^+\mu^+\mu^-$ decays became possible [197].

With the data samples available at LHC, the lepton universality in $b \to s\ell^+\ell^-$ can be tested. While in the SM decays to electron-positron and muon pairs are expected to be same up to small corrections due to the different masses of leptons, in extensions of the SM this does not have to hold. The angular analysis of $B^0 \to K^*(892)^0e^+e^-$ decays was performed by LHCb at low dilepton invariant masses [198] and Belle in several regions over whole q^2 range [188]. The LHCb measurement yields the most stringent constraint on the photon polarization. The result on lepton universality test which over past few years attracted most attention is the ratio of branching fractions between $B^+ \to K^+\mu^+\mu^-$ and $B^+ \to K^+e^+e^-$ and between $B^0 \to K^*(892)^0\mu^+\mu^-$ and $B^0 \to K^*(892)^0e^+e^-$ decays [179, 199]. The measurements by LHCb showed mild discrepancy from the SM, with significance of $3.1\,\sigma$ for $B^+ \to K^+\ell^+\ell^-$ and about $2.4\,\sigma$ for $B^0 \to K^*(892)^0\ell^+\ell^-$. The latest analysis in Ref. [200] identified previously missed hadronic misidentification background. With better handling of such background the results are now consistent with the SM. LHCb experiment performed similar test with $\Lambda_b^0 \to pK^-\ell^+\ell^-$ decays [201], $B^0 \to K_S^0\ell^+\ell^-$ and $B^+ \to K^*(892)^+\ell^+\ell^-$ [202].

While $b \to d\ell^+\ell^-$ decays are further suppressed, they recently became accessible. Signals were observed for $B^+ \to \pi^+\mu^+\mu^-$ [77], $B^0 \to \pi^+\pi^-\mu^+\mu^-$ [203] and $\Lambda_b^0 \to p\pi^-\mu^+\mu^-$ [204] decays. Search for the $B_s^0 \to \overline{K}^*(892)^0\mu^+\mu^-$ at LHCb is complicated by large background from $B^0 \to K^*(892)^0\mu^+\mu^-$ and current significance for the decay is 3.4σ [205]. The total branching fractions are only quantities measured and these are about 2×10^{-8} for the meson decays and about 7×10^{-8} for the Λ_b^0 decay.

A closely related process is $B \to X_s\nu\overline{\nu}$. Since the neutrinos are not detected, the final state is a strange hadron system X_s plus missing energy-momentum. Depending on X_s, the SM branching fraction is $\mathcal{O}(10^{-6})$. New physics effects beyond SM, e.g. those from dark sector models can greatly enhance the yield of X_s plus missing energy. BaBar [206], Belle [207], and Belle II [208] have searched for these decays and determined the upper limits in the range $\mathcal{O}(10^{-5})$.

Finally the decays $B_{(s)}^0 \to e^+e^-$ and $\mu^+\mu^-$ are interesting since they only proceed at second order in weak interactions in the SM, but may have large contributions from supersymmetric loops, proportional to $(\tan\beta)^6$. First limits were published more than 30 years ago and since then experiments at Tevatron, B-factories and LHC gradually improved those and effectively ex-

cluded whole models of new physics and significantly constrained allowed parameter space of others. For the decays to $\mu^+\mu^-$, Tevatron experiments pushed the limits down to roughly factor of 5-10 above the SM expectation [209]. The long journey in the search for these decays culminated in 2012, when first evidence for $B_s^0 \to \mu^+\mu^-$ decay was seen [210]. Subsequently, LHC experiments ATLAS [211], CMS [212] and LHCb [213] observed statistically significant signal for $B_s^0 \to \mu^+\mu^-$ decay. The average branching fraction is found to be $(3.01 \pm 0.435) \times 10^{-9}$. In experiments at hadron colliders searches for $B^0 \to \mu^+\mu^-$ decays are performed at the same time. The $B(B^0 \to \mu^+\mu^-)$ is extracted in simultaneously with $B(B_s^0 \to \mu^+\mu^-)$ and is found to be $(0.07^{+0.13}_{-0.11}) \times 10^{-9}$. The limits for the e^+e^- modes are: $< 9.4 \times 10^{-9}$ and $< 2.5 \times 10^{-9}$, respectively, for B_s^0 and B^0 [214]. The searches for decays to $\tau^+\tau^-$ are more challenging with current best limits of $B(B^0 \to \tau^+\tau^-) < 2.1 \times 10^{-3}$ and $B(B_s^0 \to \tau^+\tau^-) < 6.8 \times 10^{-3}$ at 95% C.L. [215]. All existing measurements of B^0 and B_s^0 decays to same flavour dilepton pair is consistent with SM expectation [216]. With $B_s^0 \to \mu^+\mu^-$ decay observed, it was suggested that the effective lifetime is useful further test of the decay [217]. Attempt was made by LHCb and CMS experiments, but its precision is not yet sufficient to provide test of the SM [212, 213]. It will take couple of years until interesting precision is reached. The searches were also performed for lepton flavour violating decays to two leptons with best limits in $e^\pm\mu^\mp$ channel, where limits are $< 1.3 \times 10^{-9}$ for B^0 and $< 6.3 \times 10^{-9}$ for B_s^0, at 95% confidence level [218].

Several theory groups performed global analysis of electroweak decays concluding that significant tension between data and SM is present [219]. The tension can be relieved by new physics beyond SM. For more detailed reviews see e.g. Ref. [220].

73.7 Summary and Outlook

The study of B mesons continues to be one of the most productive fields in particle physics. With the two asymmetric B-factory experiments Belle and BaBar, we now have a combined data sample of well over 1 ab^{-1}. CP violation has been firmly established in many decays of B mesons. Evidence for direct CP violation has been observed. Many rare decays resulting from hadronic $b \to u$ transitions and $b \to s(d)$ penguin decays have been observed, and the emerging pattern is still full of surprises. Despite the remarkable successes of the B-factory experiments, many fundamental questions in the flavor sector remain unanswered.

At Fermilab, CDF and D0 each has accumulated about 10 fb^{-1}, which is the equivalent of about 10^{12} b-hadrons produced. In spite of the low trigger efficiency of hadronic experiments, a selection of modes have been reconstructed in large quantities, giving a start to a program of studies on B_s and b-flavored baryons, in which a first major step has been the determination of the B_s oscillation frequency.

As Tevatron and B-factories finished their data taking few year ago, the experiments at the LHC have become very active. LHCb has collected about 1 fb^{-1} at 7 TeV, 2 fb^{-1} at 8 TeV, and close to 5.9 fb^{-1} at 13 TeV during LHC Runs 1 and 2. CMS and ATLAS have collected each about 5 fb^{-1} of data at $\sqrt{s} = 7$ TeV, 20 fb^{-1} at 8 TeV and about 150 fb^{-1} at 13 TeV during LHC Runs 1 and 2. The latest LHC Run 3 at 13.6 TeV started in summer 2022, with upgraded detectors. By the time of the writing (summer 2023), LHC has delivered about 70 fb^{-1} to ATLAS and CMS experiments. LHCb, which is dedicated to the studies of b- and c-hadrons, has a data sample that is for many decays larger than the sum of all previous experiments. With it, we are entering to regime of precision physics even for many rare decays, which allows much more detailed measurements.

The Belle II experiment at the SuperKEKB has started recording data in 2019 and has by summer 2022 collected about 428 fb^{-1} of data, when their long shutdown 1 started. The aim to increase sample to ~ 50 ab^{-1} will make it possible to explore the indirect evidence of new physics beyond the SM in the heavy-flavor particles (b, c, and τ), in a way that is complementary to the LHC. The LHCb Collaboration is commissioning upgrade of its detector and is planning on nominal running from 2024. The aim of the upgrade was to increase flexibility of the trigger, which will allow about a factor of five increase in instantaneous luminosity and of about a factor of two in efficiencies on triggering on purely hadronic decays. The plan is to integrate about 50 fb^{-1} of data during LHC runs 3 and 4.

These experiments promise a rich spectrum of rare and precise measurements that have the potential to fundamentally affecting our understanding of the SM and CP-violating phenomena.

74. Polarization in B Decays

Revised July 2023 by A.V. Gritsan (Johns Hopkins U.).

We review the notation used in polarization measurements in particle production and decay, with a particular emphasis on the B decays and the CP-violating observables in polarization measurements. We look at several examples of vector-vector and vector-tensor B meson decays, while more details about the theory and experimental results in B decays can be found in a separate mini-review [1] in this *Review*.

Figure 74.1 illustrates angular observables in an example of the sequential process $ab \to X \to P_1P_2 \to (p_{11}p_{12})(p_{21}p_{22})$ [2]. The angular distributions are of particular interest because they are sensitive to spin correlations and reveal properties of particles and their interactions, such as quantum numbers and couplings. In the case of a spin-zero particle X, such as B meson or a Higgs boson, there are no spin correlations in the production mechanism and the decay chain is to be analyzed. The angular distribution of decay products can be expressed as a function of three helicity angles which describe the alignment of the particles in the decay chain. The analyzer of the B-daughter polarization is normally chosen for two-body decays, as the direction of the daughters in the center-of-mass of the parent (*e.g.*, $\rho \to 2\pi$) [3], and for three-body decays as the normal to the decay plane (*e.g.*, $\omega \to 3\pi$) [4]. An equivalent set of transversity angles is sometimes used in polarization analyses [5]. The differential decay width depends on complex amplitudes $A_{\lambda_1\lambda_2}$, corresponding to the X-daughter helicity states λ_i.

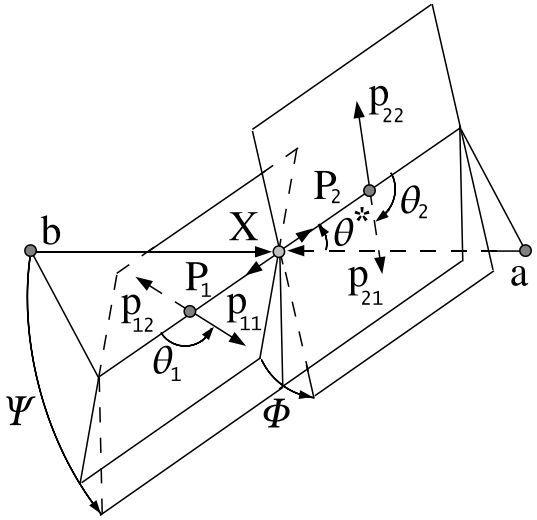

Figure 74.1: Definition of the production and helicity angles in the sequential process $ab \to X \to P_1P_2 \to (p_{11}p_{12})(p_{21}p_{22})$. The three helicity angles include θ_1 and θ_2, defined in the rest frame of the two daughters P_1 and P_2, and Φ, defined in the X frame as the angle between the two decay planes. The two production angles θ^* and Ψ are defined in the X frame, where Ψ is the angle between the production plane and the average of the two decay planes.

In the case of a spin-zero B-meson decay, its daughter helicities are constrained to $\lambda_1 = \lambda_2 = \lambda$. Therefore we simplify amplitude notation as A_λ. Moreover, most B-decay polarization analyses are limited to the case when the spin of one of the B-meson daughters is 1. In that case, there are only three independent amplitudes corresponding to $\lambda = 0$ or ±1 [6], where the last two can be expressed in terms of parity-even and parity-odd amplitudes $A_{\parallel,\perp} = (A_{+1} \pm A_{-1})/\sqrt{2}$. The overall decay amplitude involves three complex terms proportional to the above amplitudes and the Wigner d functions of helicity angles. The exact angular dependence would depend on the quantum numbers of the B-meson daughters and of their decay products, and can be found in the literature [6,7]. When both B-meson daughters are tensor mesons and the smaller of the two daughter spins is $J_1 > 1$, this formalism can be easily extended by introducing the parity-even and parity-odd amplitudes of higher order $A_{\parallel n,\perp n} = (A_{+n} \pm A_{-n})/\sqrt{2}$, with $1 < n \leq J_1$, while the general angular parameterization may be found in Ref. [7]. However, we limit the following discussion to $J_1 = 1$. The differential decay rate would involve six real quantities α_i, including interference terms,

$$\frac{d\Gamma}{\Gamma\, d\cos\theta_1\, d\cos\theta_2\, d\Phi} = \sum_i \alpha_i\ f_i\,(\cos\theta_1,\, \cos\theta_2,\, \Phi)\,, \qquad (74.1)$$

where each $f_i\,(\cos\theta_1, \cos\theta_2, \Phi)$ has unique angular dependence specific to particle quantum numbers, and the α_i parameters are defined as:

$$\alpha_1 = \frac{|A_0|^2}{\Sigma|A_\lambda|^2} = f_L\,, \qquad (74.2)$$

$$\alpha_2 = \frac{|A_\parallel|^2 + |A_\perp|^2}{\Sigma|A_\lambda|^2} = (1 - f_L)\,, \qquad (74.3)$$

$$\alpha_3 = \frac{|A_\parallel|^2 - |A_\perp|^2}{\Sigma|A_\lambda|^2} = (1 - f_L - 2\,f_\perp)\,, \qquad (74.4)$$

$$\alpha_4 = \frac{\Im m(A_\perp A_\parallel^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_\perp(1-f_L-f_\perp)}\,\sin(\phi_\perp - \phi_\parallel)\,, \qquad (74.5)$$

$$\alpha_5 = \frac{\Re e(A_\parallel A_0^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_L\,(1 - f_L - f_\perp)}\,\cos(\phi_\parallel)\,, \qquad (74.6)$$

$$\alpha_6 = \frac{\Im m(A_\perp A_0^*)}{\Sigma|A_\lambda|^2} = \sqrt{f_\perp\, f_L}\,\sin(\phi_\perp)\,, \qquad (74.7)$$

where the amplitudes have been expressed with the help of polarization parameters f_L, $f_\perp$, $\phi_\parallel$, and $\phi_\perp$ defined in Table 74.1. Note that the terms proportional to $\Re e(A_\perp A_\parallel^*)$, $\Im m(A_\parallel A_0^*)$, and $\Re e(A_\perp A_0^*)$ are absent in Eqs. (2-7). However, these terms may appear for some three-body decays of a B-meson daughter, see Ref. [7].

Table 74.1: Rate, polarization, and CP-asymmetry parameters defined for the B-meson decays to mesons with non-zero spin. Numerical examples are shown for the average of the $B^0 \to \varphi K^*(892)^0$ decay measurements obtained from BABAR [8], Belle [9], and LHCb [10]. The first six parameters are defined under the assumption of no CP violation in decay, while they are averaged between the $\overline{B}$ and B parameters in general. The last six parameters involve differences between the $\overline{B}$ and B meson decay parameters. The phase convention δ_0 is chosen with respect to a single A_{00} amplitude from a reference B decay mode, which is $B^0 \to \varphi K_0^*(1430)^0$ for numerical results.

parameter	definition	average
$\mathcal{B}$	$\Gamma/\Gamma_{\rm total}$	$(10.1^{+0.6}_{-0.5}) \times 10^{-6}$
f_L	$\lvert A_0\rvert^2/\Sigma\lvert A_\lambda\rvert^2$	0.497 ± 0.017
$f_\perp$	$\lvert A_\perp\rvert^2/\Sigma\lvert A_\lambda\rvert^2$	0.225 ± 0.015
$\phi_\parallel - \pi$	$\arg(A_\parallel/A_0) - \pi$	-0.712 ± 0.058
$\phi_\perp - \pi$	$\arg(A_\perp/A_0) - \pi$	-0.615 ± 0.056
$\delta_0 - \pi$	$\arg(A_{00}/A_0) - \pi$	-0.26 ± 0.10
A_{CP}	$(\bar\Gamma - \Gamma)/(\bar\Gamma + \Gamma)$	-0.003 ± 0.038
A_{CP}^0	$(\bar{f_L} - f_L)/(\bar{f_L} + f_L)$	-0.007 ± 0.030
$A_{CP}^\perp$	$(\bar{f_\perp} - f_\perp)/(\bar{f_\perp} + f_\perp)$	-0.014 ± 0.057
$\Delta\phi_\parallel$	$(\bar{\phi_\parallel} - \phi_\parallel)/2$	$+0.051 \pm 0.053$
$\Delta\phi_\perp$	$(\bar{\phi_\perp} - \phi_\perp - \pi)/2$	$+0.075 \pm 0.050$
$\Delta\delta_0$	$(\bar{\delta_0} - \delta_0)/2$	$+0.13 \pm 0.08$

Overall, six real parameters describe three complex amplitudes A_0, $A_\parallel$, and $A_\perp$. These could be chosen to be the four polarization

parameters f_L, $f_\perp$, $\phi_\parallel$, and $\phi_\perp$, one overall size normalization, such as decay rate Γ, or branching fraction $\mathcal{B}$, and one overall phase δ_0. The phase convention is arbitrary for an isolated B decay mode. However, for several B decays, the relative phase could produce meaningful and observable effects through interference with other B decays with the same final states, such as for $B \to VK_J^*$ with $J = 0, 1, 2, 3, 4, ...$ The phase could be referenced to the single $B \to VK_0^*$ amplitude A_{00} in such a case, as shown in Table 74.1. Here V stands for any spin-one vector meson.

Moreover, *CP* violation can be tested in the angular distribution of the decay as the difference between the B and $\overline{B}$. Each of the six real parameters describing the three complex amplitudes would have a counterpart *CP*-asymmetry term, corresponding to three direct-*CP* asymmetries in three amplitudes, and three *CP*-violating phase differences, equivalent to the phase measurements from the mixing-induced *CP* asymmetries in the time evolution of B-decays [1]. In Table 74.1 and Ref. [11], these are chosen to be the direct-*CP* asymmetries in the overall decay rate $\mathcal{A}_{CP}$, in the f_L fraction $\mathcal{A}_{CP}^0$, and in the $f_\perp$ fraction $\mathcal{A}_{CP}^\perp$, and three weak phase differences:

$$\Delta\phi_\parallel = \frac{1}{2}\arg(\bar{A}_\parallel A_0 / A_\parallel \bar{A}_0)\,, \tag{74.8}$$

$$\Delta\phi_\perp = \frac{1}{2}\arg(\bar{A}_\perp A_0 / A_\perp \bar{A}_0) - \frac{\pi}{2}\,, \tag{74.9}$$

$$\Delta\delta_0 = \frac{1}{2}\arg(\bar{A}_{00} A_0 / A_{00} \bar{A}_0)\,. \tag{74.10}$$

The $\frac{\pi}{2}$ term in Eq. (74.8) reflects the fact that $A_\perp$ and $\bar{A}_\perp$ differ in phase by π if *CP* is conserved. The two parameters $\Delta\phi_\parallel$ and $\Delta\phi_\perp$ are equivalent to triple-product asymmetries constructed from the vectors describing the decay angular distribution [12]. The *CP*-violating phase difference in the reference decay mode [11] is, in the Wolfenstein CKM quark-mixing phase convention,

$$\Delta\phi_{00} = \frac{1}{2}\arg(A_{00} / \bar{A}_{00})\,. \tag{74.11}$$

This can be measured only together with the mixing-induced phase difference for some of the neutral B-meson decays similar to other mixing-induced *CP* asymmetry measurements [1].

It may not always be possible to have a phase-reference decay mode which would define δ_0 and $\Delta\delta_0$ parameters. In that case, it may be possible to define the phase difference directly similarly to Eq. (74.11):

$$\Delta\phi_0 = \frac{1}{2}\arg(A_0 / \bar{A}_0)\,. \tag{74.12}$$

One can measure the angles of the CKM unitarity triangle, assuming Standard Model contributions to the $\Delta\phi_0$ and B-mixing phases. Examples include measurements of $\beta = \phi_1$ with $B \to J/\psi K^*$ and $\alpha = \phi_2$ with $B \to \rho\rho$.

Most of the B decays that arise from tree-level $b \to c$ transitions have the amplitude hierarchy $|A_0| > |A_+| > |A_-|$ which is expected from analyses based on quark-helicity conservation [13]. The larger the mass of the vector-meson daughters, the weaker the inequality. The B meson decays to heavy vector particles with charm, such as $B \to J/\psi K^*$, $\psi(2S)K^*$, $\chi_{c1}K^*$, $D^*\rho$, D^*K^*, D^*D^*, and $D^*D_s^*$, show a substantial fraction of the amplitudes corresponding to transverse polarization of the vector mesons ($A_{\pm 1}$), in agreement with the factorization prediction. The detailed amplitude analysis of the $B \to J/\psi K^*$ decays has been performed by the BABAR [14], Belle [15], CDF [16], CLEO [17], D0 [18], and LHCb [19] collaborations. Most analyses are performed under the assumption of the absence of direct *CP* violation. The parameter values are given in the particle listing of this *Review*. The difference between the strong phases $\phi_\parallel$ and $\phi_\perp$ deviates significantly from zero. The measurements [14, 15] of *CP*-violating terms similar to those in $B \to \varphi K^*$ [8] shown in Table 74.1 are consistent with zero.

In addition, the mixing-induced *CP*-violating asymmetry is measured in the $B^0 \to J/\psi K^{*0}$ decay [1, 14, 15] where angular analysis allows one to separate *CP*-eigenstate amplitudes. This allows one to resolve the sign ambiguity of the $\cos 2\beta$ ($\cos 2\phi_1$) term that appears in the time-dependent angular distribution due to interference of parity-even and parity-odd terms. This analysis relies on the knowledge of discrete ambiguities in the strong phases $\phi_\parallel$ and $\phi_\perp$, as discussed below. The BABAR experiment used a method based on the dependence on the $K\pi$ invariant mass of the interference between the S- and P-waves to resolve the discrete ambiguity in the determination of the strong phases $(\phi_\parallel, \phi_\perp)$ in $B \to J/\psi K^*$ decays [14]. The result is in agreement with the amplitude hierarchy expectation [13]. The CDF [20], D0 [21], LHCb [22], and ATLAS [23] experiments have studied the $B_s^0 \to J/\psi(K^+K^-)$, $J/\psi(\pi^+\pi^-)$, $\psi(K^+\pi^-)$ decays and provided the lifetime, polarization, and phase measurements.

The amplitude hierarchy $|A_0| \gg |A_+| \gg |A_-|$ was expected in B decays to light vector particles in both penguin transitions [24, 25] and tree-level transitions [13]. There is confirmation by the BABAR and Belle experiments of predominantly longitudinal polarization in the tree-level $b \to u$ transition, such as $B^0 \to \rho^+\rho^-$ [26], $B^+ \to \rho^0\rho^+$ [27], and $B^+ \to \omega\rho^+$ [28]; this is consistent with the analysis of the quark helicity conservation [13]. Because the longitudinal amplitude dominates the decay, a detailed amplitude analysis is not possible with current B samples, and limits on the transverse amplitude fraction are obtained. The small branching fractions of $B^0 \to \rho^0\rho^0, \omega\rho^0, \omega\omega$ [28–31] indicate that $b \to d$ penguin pollution is small in the charmless, strangeless vector-vector B decays. There is a measurement of large longitudinal polarization in $B^0 \to \rho^0\rho^0$ [29–31] decays. The fraction of transverse polarization is large in decays to heavier mesons such as $B^0 \to a_1(1260)^+ a_1(1260)^-$ [32].

The interest in the polarization and *CP*-asymmetry measurements in penguin transition, such as $b \to s$ decays $B \to \varphi K^*$, ρK^*, ωK^*, or $B_s^0 \to \varphi\varphi$, K^*K^*, and $b \to d$ decay $B \to K^*\bar{K}^*$, is motivated by their potential sensitivity to physics beyond the Standard Model. The decay amplitudes for $B \to \varphi K^*$ have been measured by the BABAR, Belle, and LHCb experiments [9–11, 33, 34]. The fractions of longitudinal polarization are $f_L = 0.50 \pm 0.05$ for the $B^+ \to \varphi K^{*+}$ decay and $f_L = 0.497 \pm 0.017$ for the $B^0 \to \varphi K^{*0}$ decay. These indicate significant departure from the naive expectation of predominant longitudinal polarization, suggesting other contributions to the decay amplitude, previously neglected, either within the Standard Model, such as penguin annihilation [35] or QCD rescattering [36], or from physics beyond the Standard Model [37]. The complete set of twelve amplitude parameters measured in the $B^0 \to \varphi K^{*0}$ decay is given in Table 74.1. Several other parameters could be constructed from the above twelve parameters, as suggested in Ref. [38].

The discrete ambiguity in the phase $(\phi_\parallel, \phi_\perp, \Delta\phi_\parallel, \Delta\phi_\perp)$ measurements has been resolved by BABAR in favor of $|A_+| \gg |A_-|$ through interference between the S- and P-waves of $K\pi$. The search for vector-tensor and vector-axialvector $B \to \varphi K_J^{(*)}$ decays with $J = 1, 2, 3, 4$ revealed a large fraction of longitudinal polarization in the decay $B \to \varphi K_2^*(1430)$ with $f_L = 0.90^{+0.06}_{-0.07}$ [11, 39], but large contribution of transverse amplitude in $B \to \varphi K_1(1270)$ with $f_L = 0.46^{+0.13}_{-0.15}$ [40].

Like $B \to \varphi K^*$, the decays $B \to \rho K^*$ and $B \to \omega K^*$ may be sensitive to New Physics. Measurements of the longitudinal polarization fraction in $B \to \rho K^*$ [41] and in both vector-vector and vector-tensor final states of $B \to \omega K_J^*$ [28] by BABAR and Belle reveal a large fraction of transverse polarization, indicating an anomaly similar to $B \to \varphi K^*$ except for a different pattern in vector-tensor final states. An angular analysis of the $B^0 \to \rho^0 K^{*0}$ decay mode by LHCb [42] provides much higher precision and indicates remarkably small longitudinal polarization fraction and a significant direct CP asymmetry observed in angular distributions of $B \to VV$ decays for the first time. A large transverse polarization is also observed in the $B_s^0 \to \varphi\varphi$ decay by CDF [43] and LHCb [44], $B_s^0 \to K^{*0}\bar{K}^{*0}$ decays by LHCb [45], and $B_s^0 \to \varphi K^{*0}$ decays by LHCb [46]. At the same time, measurement of the polarization in the $b \to d$ penguin decays $B \to K^*\bar{K}^*$ indicates a large fraction of longitudinal polarization [45, 47]. The LHCb experiment has also provided the very first polarization results on the tensor-tensor, as well as vector-tensor, decays of the B_s^0 meson in the $(K\pi)(K\pi)$ final state [45]. The polarization pattern in penguin-dominated B-meson decays is not fully understood [35–37].

The three-body semileptonic B-meson decays, such as $B \to V\ell_1\ell_2$, share many features with the two-body $B \to VV$ decays. Their differential decay width can be parameterized with the two helicity angles defined in the V and $(\ell_1\ell_2)$ frames and with the azimuthal angle, as defined in Fig. 74.1. However, since the $(\ell_1\ell_2)$ pair does not come from an on-shell particle, the angular distribution is unique to each point in the dilepton mass $m_{\ell\ell}$ spectrum. The polarization measurements as a function of $m_{\ell\ell}$ provide complementary information on physics beyond the Standard Model, as discussed for $B \to K^*\ell^+\ell^-$ and $B_s \to \phi\ell^+\ell^-$ decays in Ref. [48]. The data in these modes have been analyzed by the BABAR, Belle, CDF, CMS, ATLAS, and LHCb experiments [49–54].

The examples of the angular distributions and observables in $B \to K^*\ell^+\ell^-$ are discussed in Ref. [48]. Two angular observables have been measured in this decay in certain ranges of the dilepton mass $m_{\ell\ell}$. One parameter is the fraction of longitudinal polarization F_L, which is determined by the K^* angular distribution and is similar to f_L defined for exclusive two-body decays. The other parameter is the forward-backward asymmetry of the lepton pair A_{FB}, which is the asymmetry of the decay rate with positive and negative values of $\cos\theta_1$. A complete set of observables and angular terms has been adopted by the LHCb collaboration [54] following Ref. [48] with the F_L, A_{FB}, and $S_3 - S_9$ coefficients in the angular distributions. Additional set of optimized observables $P_i^{(\prime)}$ is derived from those, for example $P_2 = 2A_{FB}/(3-3F_L)$ and $P_5' = S_5/\sqrt{F_L(1-F_L)}$. These observables have the advantage that the leading form-factor uncertainties cancel. There have been hints of deviations from SM in the measurement of P_5' and lepton flavor universality [49–54].

In summary, there has been considerable interest in the polarization measurements of B-meson decays because they reveal both weak- and strong-interaction dynamics [35–37,55]. New measurements will further elucidate the pattern of spin alignment measurements in rare B decays, and further test the Standard Model and strong interaction dynamics, including the non-factorizable contributions to the B-decay amplitudes.

75. B^0–$\overline{B}^0$ Mixing

Revised March 2024 by O. Schneider (EPFL).

There are two neutral B^0–$\overline{B}^0$ meson systems, B^0_d–$\overline{B}^0_d$ and B^0_s–$\overline{B}^0_s$ (generically denoted B^0_q–$\overline{B}^0_q$, $q = s, d$), which exhibit particle-antiparticle mixing [1]. This mixing phenomenon is described in Ref. [2]. In the following, we adopt the notation introduced in Ref. [2], and assume CPT conservation throughout. In each system, the light (L) and heavy (H) mass eigenstates,

$$|B_{\rm L,H}\rangle = p|B^0_q\rangle \pm q|\overline{B}^0_q\rangle, \tag{75.1}$$

have a mass difference $\Delta m_q = m_{\rm H} - m_{\rm L} > 0$, a total decay width difference $\Delta\Gamma_q = \Gamma_{\rm L} - \Gamma_{\rm H}$ and an average decay width $\Gamma_q = (\Gamma_{\rm L} + \Gamma_{\rm H})/2$. In the absence of CP violation in the mixing, $|q/p| = 1$, the differences are given by $\Delta m_q = 2|M_{12}|$ and $|\Delta\Gamma_q| = 2|\Gamma_{12}|$, where M_{12} and Γ_{12} are the off-diagonal elements of the mass and decay matrices [2]. The evolution of a pure $|B^0_q\rangle$ or $|\overline{B}^0_q\rangle$ state at $t = 0$ is given by

$$|B^0_q(t)\rangle = g_+(t)\,|B^0_q\rangle + \frac{q}{p}\,g_-(t)\,|\overline{B}^0_q\rangle, \tag{75.2}$$

$$|\overline{B}^0_q(t)\rangle = g_+(t)\,|\overline{B}^0_q\rangle + \frac{p}{q}\,g_-(t)\,|B^0_q\rangle, \tag{75.3}$$

which means that the flavor states remain unchanged (+) or oscillate into each other (−) with time-dependent probabilities proportional to

$$|g_\pm(t)|^2 = \frac{e^{-\Gamma_q t}}{2}\left[\cosh\left(\frac{\Delta\Gamma_q}{2}\,t\right) \pm \cos(\Delta m_q\, t)\right]. \tag{75.4}$$

In the absence of CP violation, the time-integrated mixing probability $\int |g_-(t)|^2\,dt/(\int |g_-(t)|^2\,dt + \int |g_+(t)|^2\,dt)$ is given by

$$\chi_q = \frac{x_q^2 + y_q^2}{2(x_q^2+1)}\,, \quad \text{where} \quad x_q = \frac{\Delta m_q}{\Gamma_q}\,, \quad y_q = \frac{\Delta\Gamma_q}{2\Gamma_q}\,. \tag{75.5}$$

75.1 Standard Model predictions and phenomenology

In the Standard Model, the transitions $B^0_q \to \overline{B}^0_q$ and $\overline{B}^0_q \to B^0_q$ are due to the weak interaction. They are described, at the lowest order, by box diagrams involving two W bosons and two up-type quarks (see Fig. 75.1), as is the case for $K^0 - \overline{K}^0$ mixing. However, the long range interactions arising from intermediate virtual states are negligible for the neutral B meson systems, because the large B mass is off the region of hadronic resonances. The calculation of the dispersive and absorptive parts of the box diagrams yields the following predictions for the off-diagonal element of the mass and decay matrices [3],

$$M_{12} = -\frac{G_F^2 m_W^2 \eta_B m_{B_q} B_{B_q} f_{B_q}^2}{12\pi^2}\, S_0(m_t^2/m_W^2)\,(V_{tq}^* V_{tb})^2\,, \tag{75.6}$$

$$\Gamma_{12} = \frac{G_F^2 m_b^2 \eta'_B m_{B_q} B_{B_q} f_{B_q}^2}{8\pi} \times \left[(V_{tq}^* V_{tb})^2 + V_{tq}^* V_{tb} V_{cq}^* V_{cb}\,\mathcal{O}\left(\frac{m_c^2}{m_b^2}\right) + (V_{cq}^* V_{cb})^2\,\mathcal{O}\left(\frac{m_c^4}{m_b^4}\right)\right], \tag{75.7}$$

where G_F is the Fermi constant, m_W the W boson mass, and m_i the mass of quark i; m_{B_q}, f_{B_q} and B_{B_q} are the B^0_q mass, weak decay constant and bag parameter, respectively. The known function $S_0(x_t)$ can be approximated very well by $0.784\,x_t^{0.76}$ [4], and V_{ij} are the elements of the CKM matrix [5]. The QCD corrections η_B and η'_B are of order unity. The only non-negligible contributions to M_{12} are from box diagrams involving two top quarks. The phases of M_{12} and Γ_{12} satisfy

$$\phi_M - \phi_\Gamma = \pi + \mathcal{O}\left(\frac{m_c^2}{m_b^2}\right), \tag{75.8}$$

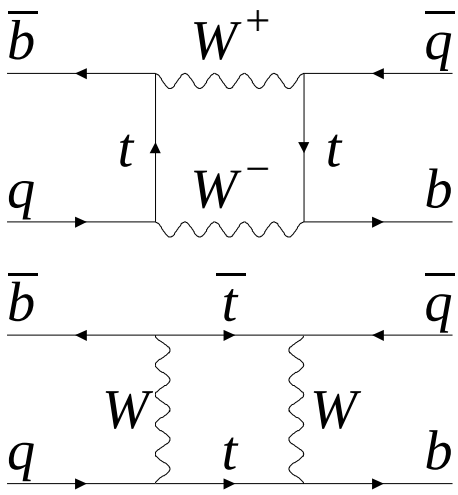

Figure 75.1: Dominant box diagrams for the $B^0_q \to \overline{B_q}^0$ transitions ($q = d$ or s). Similar diagrams exist where one or both t quarks are replaced with c or u quarks.

implying that the mass eigenstates have mass and width differences of opposite signs. This means that, like in the K^0–$\overline{K}^0$ system, the heavy state is expected to have a smaller decay width than that of the light state: $\Gamma_{\rm H} < \Gamma_{\rm L}$. Hence, $\Delta\Gamma_q = \Gamma_{\rm L} - \Gamma_{\rm H}$ is expected to be positive in the Standard Model.

Furthermore, the quantity

$$\left|\frac{\Gamma_{12}}{M_{12}}\right| \simeq \frac{3\pi}{2}\,\frac{m_b^2}{m_W^2}\,\frac{1}{S_0(m_t^2/m_W^2)} \sim \mathcal{O}\left(\frac{m_b^2}{m_t^2}\right) \tag{75.9}$$

is small, and a power expansion of $|q/p|^2$ yields

$$\left|\frac{q}{p}\right|^2 = 1 + \left|\frac{\Gamma_{12}}{M_{12}}\right|\sin(\phi_M - \phi_\Gamma) + \mathcal{O}\left(\left|\frac{\Gamma_{12}}{M_{12}}\right|^2\right). \tag{75.10}$$

Therefore, considering both Eqs. (75.8) and (75.9), the CP-violating parameter

$$1 - \left|\frac{q}{p}\right|^2 \simeq \mathrm{Im}\left(\frac{\Gamma_{12}}{M_{12}}\right) \tag{75.11}$$

is expected to be very small: $\sim \mathcal{O}(10^{-3})$ for the B^0_d–$\overline{B}^0_d$ system and $\lesssim \mathcal{O}(10^{-4})$ for the B^0_s–$\overline{B}^0_s$ system [6].

In the approximation of negligible CP violation in mixing, the ratio $\Delta\Gamma_q/\Delta m_q$ is equal to the small quantity $|\Gamma_{12}/M_{12}|$ of Eq. (75.9); it is hence independent of CKM matrix elements, *i.e.*, the same for the B^0_d–$\overline{B}^0_d$ and B^0_s–$\overline{B}^0_s$ systems. Calculations [7] yield $\sim 5 \times 10^{-3}$ with a $\sim 15\%$ uncertainty. Given the published experimental knowledge [8] on the mixing parameter x_q

$$\begin{cases} x_d = 0.7697 \pm 0.0035 & (B^0_d\text{–}\overline{B}^0_d \text{ system}) \\ x_s = 26.99 \pm 0.09 & (B^0_s\text{–}\overline{B}^0_s \text{ system}) \end{cases}, \tag{75.12}$$

the Standard Model thus predicts that $\Delta\Gamma_d/\Gamma_d$ is very small (below 1%), but $\Delta\Gamma_s/\Gamma_s$ considerably larger ($\sim 10\%$). These width differences are caused by the existence of final states to which both the B^0_q and $\overline{B}^0_q$ mesons can decay. Such decays involve $b \to c\bar{c}q$ quark-level transitions, which are Cabibbo-suppressed if $q = d$ and Cabibbo-allowed if $q = s$.

A complete set of Standard Model predictions for all mixing parameters in both the B^0_d–$\overline{B}^0_d$ and B^0_s–$\overline{B}^0_s$ systems can be found in Ref. [7].

75.2 Experimental issues and methods for oscillation analyses

Time-integrated measurements of B^0–$\overline{B}^0$ mixing were published for the first time in 1987 by UA1 [9] and ARGUS [10], and since then by many other experiments. These measurements are typically based on counting same-sign and opposite-sign lepton pairs from the semileptonic decay of the produced $b\overline{b}$ pairs. Such analyses cannot easily separate the contributions from the different b-hadron species, therefore, the clean environment of $\Upsilon(4S)$ machines (where only B^0_d and charged B_u mesons are produced) is in principle best suited to measure χ_d.

However, better sensitivity is obtained from time-dependent analyses aiming at the direct measurement of the oscillation frequencies Δm_d and Δm_s, from the proper time distributions of B^0_d or B^0_s candidates identified through their decay in (mostly) flavor-specific modes, and suitably tagged as mixed or unmixed. This is particularly true for the B^0_s–$\overline{B}^0_s$ system, where the large value of x_s implies maximal mixing, *i.e.*, $\chi_s \simeq 1/2$. In such analyses, the B^0_d or B^0_s mesons are either fully reconstructed, partially reconstructed from a charm meson, selected from a lepton with the characteristics of a $b \to \ell^-$ decay, or selected from a reconstructed displaced vertex. At high-energy colliders (LEP, SLC, Tevatron, LHC), the proper time $t = \frac{m_B}{p} L$ is measured from the distance L between the production vertex and the B decay vertex, and from an estimate of the B momentum p. At asymmetric B factories (SuperKEKB, KEKB, PEP-II), producing $e^+e^- \to \Upsilon(4S) \to B^0_d\,\overline{B_d}{}^0$ events with a boost $\beta\gamma$ (= 0.28, 0.425, 0.55), the proper time difference between the two B candidates is estimated as $\Delta t \simeq \frac{\Delta z}{\beta\gamma c}$, where Δz is the spatial separation between the two B decay vertices along the boost direction. In all cases, the good resolution needed on the vertex positions is obtained with silicon detectors.

The average statistical significance $\mathcal{S}$ of a B^0_q oscillation signal can be approximated as [11]

$$\mathcal{S} \approx \sqrt{N/2}\, f_{\rm sig}\, (1-2\eta)\, e^{-(\Delta m_q\, \sigma_t)^2/2}\,, \qquad (75.13)$$

where N is the number of selected and tagged candidates, $f_{\rm sig}$ is the fraction of signal in that sample, η is the total mistag probability, and σ_t is the resolution on proper time (or proper time difference). The quantity $\mathcal{S}$ decreases very quickly as Δm_q increases; this dependence is controlled by σ_t, which is therefore a critical parameter for Δm_s analyses. At high-energy colliders, the proper time resolution $\sigma_t \sim \frac{m_B}{\langle p\rangle}\sigma_L \oplus t\frac{\sigma_p}{p}$ includes a constant contribution due to the decay length resolution σ_L (typically 0.04–0.3 ps), and a term due to the relative momentum resolution σ_p/p (typically 10–20% for partially reconstructed decays), which increases with proper time. At B factories, the boost of the B mesons is estimated from the known beam energies, and the term due to the spatial resolution dominates (typically 0.7–1.5 ps because of the much smaller B boost).

In order to tag a B^0_q candidate as mixed or unmixed, it is necessary to determine its flavor both in the initial state and in the final state. The initial and final state mistag probabilities, η_i and η_f, degrade $\mathcal{S}$ by a total factor $(1-2\eta) = (1-2\eta_i)(1-2\eta_f)$. In lepton-based analyses, the final state is tagged by the charge of the lepton from $b \to \ell^-$ decays; the largest contribution to η_f is then due to $\overline{b} \to \overline{c} \to \ell^-$ decays. Alternatively, the charge of a reconstructed charm meson (D^{*-} from B^0_d or D^-_s from B^0_s), or that of a kaon hypothesized to come from a $b \to c \to s$ decay [12], can be used. For fully-inclusive analyses based on topological vertexing, final-state tagging techniques include jet-charge [13] and charge-dipole [14, 15] methods. At high-energy colliders, the methods to tag the initial state (*i.e.*, the state at production), can be divided into two groups: the ones that tag the initial charge of the $\overline{b}$ quark contained in the B^0_q candidate itself (same-side tag), and the ones that tag the initial charge of the other b quark produced in the event (opposite-side tag). On the same side, the sign of a charged pion, kaon or proton from the primary vertex is correlated with the production state of the B^0_q meson if that particle is a decay product of a B^{**} state or the first in the fragmentation chain [16, 17]. Jet- and vertex-charge techniques work on both sides and on the opposite side, respectively. Finally, the charge of a lepton from $b \to \ell^-$, of a kaon from $b \to c \to s$ or of a charm hadron from $b \to c$ [18] can be used as an opposite-side tag, keeping in mind that its performance is degraded due to integrated mixing. At SLC, the beam polarization produced a sizeable forward-backward asymmetry in the $Z \to b\overline{b}$ decays, and provided another very interesting and effective initial state tag based on the polar angle of the B^0_q candidate [14]. Initial state tags have also been combined to reach $\eta_i \sim 26\%$ at LEP [17, 19] or 22% at SLD [14] with full efficiency. In the case $\eta_f = 0$, this corresponds to an effective tagging efficiency $Q = \epsilon D^2 = \epsilon(1-2\eta)^2$, where ϵ is the tagging efficiency, in the range $23 - 31\%$. The equivalent figure achieved by CDF during Tevatron Run I was $\sim 3.5\%$ (see tagging summary on page 160 of Ref. [20]), reflecting the fact that tagging is more difficult at hadron colliders. The CDF and DØ analyses of Tevatron Run II data reached $\epsilon D^2 = (1.8 \pm 0.1)\%$ [21] and $(2.5 \pm 0.2)\%$ [22] for opposite-side tagging, while same-side kaon tagging (for B^0_s analyses) contributed an additional $3.7-4.8\%$ at CDF [21], and pushed the combined performance to $(4.7 \pm 0.5)\%$ at DØ [23]. LHCb, operating in the forward region at the LHC where the environment is different in terms of track multiplicity and b-hadron production kinematics, has reported $\epsilon D^2 = (2.10 \pm 0.25)\%$ [24] for opposite-side tagging, $(1.80 \pm 0.26)\%$ [25] for same-side kaon tagging, and $(2.11 \pm 0.11)\%$ [26] for same-side pion and proton tagging: the combined figure ranges typically between $(3.73 \pm 0.15)\%$ [27] and $(6.3 \pm 0.5)\%$ [28] depending on the mode in which the tagged B^0_s meson is reconstructed, and reaches up to $(8.1 \pm 0.6)\%$ [29] for hadronic B^0_d modes. ATLAS [30] and CMS [31] have reported $\epsilon D^2 \sim 1.75\%$ and $\epsilon D^2 \sim 10\%$ using opposite-side tagging of $B^0_s \to J/\psi\phi$ decays.

At B factories, the flavor of a B^0_d meson at production cannot be determined, since the two neutral B mesons produced in a $\Upsilon(4S)$ decay evolve in a coherent P-wave state where they keep opposite flavors at any time. However, as soon as one of them decays, the other follows a time-evolution given by Eqs. (75.2) or (75.3), where t is replaced with Δt (which will take negative values half of the time). Hence, the "initial state" tag of a B can be taken as the final-state tag of the other B. Effective tagging efficiencies of 30% are achieved by BaBar and Belle [32], using different techniques including $b \to \ell^-$ and $b \to c \to s$ tags. It is worth noting that, in this case, mixing of the other B (*i.e.*, the coherent mixing occurring before the first B decay) does not contribute to the mistag probability.

Before the experimental observation of a decay-width difference, oscillation analyses typically neglected $\Delta\Gamma_q$ in Eq. (75.4), and described the time dependence with the functions $\Gamma_q e^{-\Gamma_q t}(1 \pm \cos(\Delta m_q t))/2$ (high-energy colliders) or $\Gamma_d e^{-\Gamma_d|\Delta t|}(1 \pm \cos(\Delta m_d \Delta t))/4$ (asymmetric $\Upsilon(4S)$ machines). As can be seen from Eq. (75.4), a non-zero value of $\Delta\Gamma_q$ would effectively reduce the oscillation amplitude with a small time-dependent factor that would be very difficult to distinguish from time resolution effects. Measurements of Δm_q are usually extracted from the data using a maximum likelihood fit.

75.3 Δm_d and $\Delta\Gamma_d$ measurements

Many B^0_d–$\overline{B}^0_d$ oscillations analyses have been published [33] by the ALEPH [34], DELPHI [15, 35], L3 [36], OPAL [37, 38], CDF [16], DØ [22], BaBar [39], Belle [40], Belle II [41], and LHCb [42–45] collaborations. Although a variety of different techniques have been used, the individual Δm_d results obtained at LEP and Tevatron have remarkably similar precision. Their average is compatible with the more precise measurements at the asymmetric B factories and the LHC. The systematic uncertainties are not negligible; they are often dominated by sample composition, mistag probability, or b-hadron lifetime contributions. Before being combined, the measurements are adjusted on the basis of a common set of input values, including the b-hadron lifetimes and fractions published in this *Review*. Some measurements are statistically correlated. Systematic correlations arise both from common physics sources (fragmentation fractions, lifetimes, branching ratios of b hadrons), and from purely experimental or algorithmic effects (efficiency, resolu-

tion, tagging, background description). Combining all measurements [15, 16, 22, 34–45] and accounting for all identified correlations yields $\Delta m_d = 0.5069 \pm 0.0016(\text{stat}) \pm 0.0011(\text{syst})$ ps^{-1} [8], a result dominated by the latest LHCb measurement with $B^0 \to D^{(*)-}\mu^+\nu_\mu X$ decays [45].

On the other hand, ARGUS and CLEO have published time-integrated measurements [46–48], which average to $\chi_d = 0.182 \pm 0.015$. Following Ref. [48], the width difference $\Delta\Gamma_d$ could in principle be extracted from the measured value of $1/\Gamma_d$ and the above averages for Δm_d and χ_d (see Eq. (75.5)), provided that $\Delta\Gamma_d$ has a negligible impact on the Δm_d and $1/\Gamma_d$ analyses that have assumed $\Delta\Gamma_d = 0$. However, $\Delta\Gamma_d/\Gamma_d$ is too small and the knowledge of χ_d too imprecise to provide useful sensitivity on $\Delta\Gamma_d/\Gamma_d$. Direct time-dependent studies published by DELPHI [15], BaBar [49], Belle [50], LHCb [51], ATLAS [52] and CMS [53] provide stronger constraints, which can be combined to yield [8]

$$\Delta\Gamma_d/\Gamma_d = +0.001 \pm 0.010\,. \tag{75.14}$$

This determination is compatible both with zero and with the Standard Model prediction of $(4.0 \pm 0.9) \times 10^{-3}$ [54].

Assuming $\Delta\Gamma_d = 0$ and no CP violation in mixing, and using the B^0_d lifetime average of 1.517 ± 0.004 ps [8], the Δm_d and χ_d results are combined to yield the world average

$$\Delta m_d = 0.5069 \pm 0.0019 \text{ ps}^{-1} \tag{75.15}$$

or, equivalently,

$$\chi_d = 0.1860 \pm 0.0011\,. \tag{75.16}$$

This Δm_d value provides an estimate of $2|M_{12}|$, and can be used with Eq. (75.6) to extract $|V_{td}|$ within the Standard Model [55]. The main experimental uncertainties on the result come from m_t and Δm_d, but are still completely negligible with respect to the uncertainty due to the hadronic matrix element $f_{B_d}\sqrt{B_{B_d}} = 225 \pm 9$ MeV [56] obtained from three-flavor lattice QCD calculations.

75.4 Δm_s and $\Delta\Gamma_s$ measurements

After many years of intense search at LEP and SLC, B^0_s–$\overline{B}^0_s$ oscillations were first observed in 2006 by CDF using 1 fb^{-1} of Tevatron Run II data [21]. LHCb then observed B^0_s–$\overline{B}^0_s$ oscillations independently with $B^0_s \to D^-_s\pi^+$ [42, 57], $B^0_s \to D^-_s\mu^+\nu X$ [44] and $B^0_s \to J/\psi K^+K^-$ [27] decays using up to 3 fb^{-1} of LHC Run 1 data. More recently measurements based on additional LHC Run 2 data have been published by CMS with $B^0_s \to J/\psi\phi$ decays [31], and by LHCb with $B^0_s \to D^-_s\pi^+\pi^-\pi^+$ [58], $B^0_s \to D^-_s\pi^+$ [59] and $B^0_s \to J/\psi K^+K^-$ [60] decays. Taking systematic correlations into account, the average [8] of all published measurements of Δm_s [21, 27, 31, 42, 44, 57–60] is

$$\Delta m_s = 17.765 \pm 0.004(\text{stat}) \pm 0.004(\text{syst}) \text{ ps}^{-1}\,, \tag{75.17}$$

with an impressive precision dominated by the most recent $B^0_s \to D^-_s\pi^+$ result [59] (see Fig. 75.2).

The information on $|V_{ts}|$ obtained in the framework of the Standard Model is hampered by the hadronic uncertainty, as in the B^0_d case. However, several uncertainties cancel in the frequency ratio

$$\frac{\Delta m_s}{\Delta m_d} = \frac{m_{B_s}}{m_{B_d}}\,\xi^2\left|\frac{V_{ts}}{V_{td}}\right|^2\,, \tag{75.18}$$

where the SU(3) flavor-symmetry breaking factor $\xi = (f_{B_s}\sqrt{B_{B_s}})/(f_{B_d}\sqrt{B_{B_d}})$ is obtained as 1.206 ± 0.017 from a combination of three-flavor lattice QCD calculations [56] dominated by the results of Ref. [61], or as $1.2014^{+0.0065}_{-0.0072}$ from QCD sum rules [62]. Using the measurements of Eqs. (75.15) and (75.17), one can extract

$$\left|\frac{V_{td}}{V_{ts}}\right| = \begin{cases} 0.2054 \pm 0.0004 \pm 0.0029\,(\text{lattice QCD}) \\ 0.2045 \pm 0.0004^{+0.0011}_{-0.0012}\,(\text{QCD sum rules}) \end{cases}\,, \tag{75.19}$$

in good agreement with (but much more precise than) the value obtained from the ratio of the $b \to d\gamma$ and $b \to s\gamma$ transition rates observed at the B factories [55].

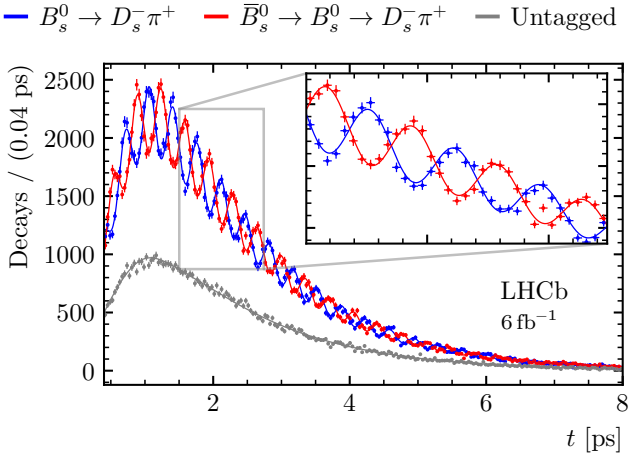

Figure 75.2: Proper decay-time distributions of background-subtracted $B^0_s \to D^-_s\pi^+$ decays tagged as unmixed (blue), tagged as mixed (red) or untagged (grey) in the Run 2 data of the LHCb experiment, displaying B^0_s–$\overline{B}^0_s$ oscillations [59].

The CKM matrix can be constrained using experimental results on observables such as Δm_d, Δm_s, $|V_{ub}/V_{cb}|$, ϵ_K, and $\sin(2\beta)$ together with theoretical inputs and unitarity conditions [55,63,64]. The constraint from our knowledge on the ratio $\Delta m_s/\Delta m_d$ is more effective in limiting the position of the apex of the CKM unitarity triangle than the one obtained from the Δm_d measurements alone, due to the reduced hadronic uncertainty in Eq. (75.18). We also note that the experimental value of Δm_s from Eq. (75.17) is consistent with the Standard Model predictions obtained from CKM fits where no experimental information on Δm_s is used, *e.g.*, 17.89 ± 0.65 ps^{-1} [63] or $17.26^{+0.63}_{-0.41}$ ps^{-1} [64]. It is also consistent with the prediction 18.23 ± 0.62 ps^{-1} from Ref. [7].

Information on $\Delta\Gamma_s$ can be obtained from the study of the proper time distribution of untagged B^0_s samples [65]. In the case of an inclusive B^0_s selection [66], or a flavor-specific (semileptonic or hadronic) B^0_s decay selection [19, 67–69], both the short- and long-lived components are present, and the proper decay-time distribution is a superposition of two exponentials with decay constants $\Gamma_{\text{L,H}} = \Gamma_s \pm \Delta\Gamma_s/2$. In principle, this provides sensitivity to both Γ_s and $(\Delta\Gamma_s/\Gamma_s)^2$. Ignoring $\Delta\Gamma_s$ and fitting for a single exponential leads to an estimate of $1/\Gamma_s$ (called effective lifetime) with a relative bias proportional to $(\Delta\Gamma_s/\Gamma_s)^2$. An alternative approach, sensitive to first order in $\Delta\Gamma_s/\Gamma_s$, is to determine the effective lifetime of untagged B^0_s decays to pure CP eigenstates; measurements exist for $B^0_s \to D^+_s D^-_s$ [68], $B^0_s \to K^+K^-$ [69,70], $B^0_s \to J/\psi\eta$ [71, 72], $B^0_s \to J/\psi f_0(980)$ [73], $B^0_s \to J/\psi\pi^+\pi^-$ [53,74,75], $B^0_s \to J/\psi K^0_S$ [76], and $B^0_s \to \mu^+\mu^-$ [77]. The extraction of $1/\Gamma_s$ and $\Delta\Gamma_s$ from such measurements, discussed in detail in Ref. [78], requires additional information in the form of theoretical assumptions or external inputs on weak phases and hadronic parameters. In what follows, we only use the effective lifetimes of decays to CP-even ($D^+_s D^-_s$, $J/\psi\eta$) and CP-odd ($J/\psi f_0(980)$, $J/\psi\pi^+\pi^-$) final states where CP conservation can be assumed. In addition $\Delta\Gamma_s$ can be extracted from the decay-time distributions of B^0_s decays to CP-even and CP-odd final states, as has been done by LHCb with $B^0_s \to J/\psi\eta'$ and $B^0_s \to J/\psi\pi^+\pi^-$, respectively [79].

The best sensitivity to $1/\Gamma_s$ and $\Delta\Gamma_s$ is achieved by the time-dependent measurements of the $B^0_s \to J/\psi K^+K^-$ (including $B^0_s \to J/\psi\phi$) and $B^0_s \to \psi(2S)\phi$ decay rates performed at CDF [80], DØ [81], ATLAS [30, 82], CMS [31, 83] and LHCb [27, 60, 84–86], where the CP-even and CP-odd amplitudes are separated statistically through a full angular analysis (see Fig. 75.3). The LHCb collaboration analyzes the $B^0_s \to J/\psi K^+K^-$ decay considering that the K^+K^- system can be in a P-wave or S-wave state, and measures the dependence of the strong phase difference between the P-wave and S-wave amplitudes as a function of the K^+K^- invariant mass [27, 60, 87];

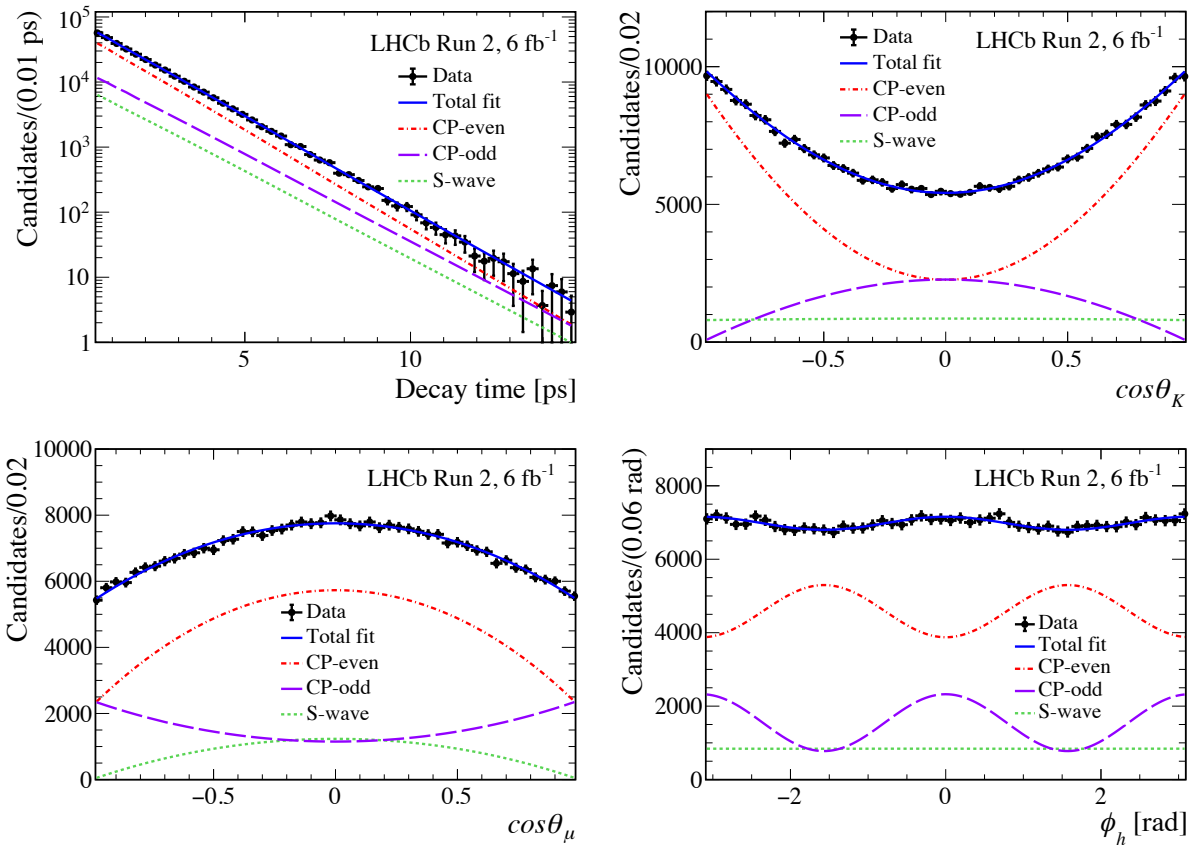

Figure 75.3: Distributions of the proper decay-time and of the three decay angles of background-subtracted $B_s^0 \to J/\psi K^+K^-$ decays reconstructed by LHCb in the vicinity of the ϕ resonance [60]. The kaon pair is predominantly in a P-wave state (from the ϕ decay) which can be CP-even or CP-odd, while a small S-wave state is CP-odd. The curves show the projections of a four-dimensional fit allowing the various components to be disentangled. The different lifetimes of the CP-even and CP-odd components is evident from the decay-time distribution.

this allows the unambiguous determination of the sign of $\Delta\Gamma_s$, which is found to be positive. All these studies use both untagged and tagged B_s^0 candidates and are optimized for the measurement of the phase $\phi_s^{c\bar{c}s}$ that describes CP violation in the interference between B_s^0–$\overline{B}_s^0$ mixing and decay in $b \to c\bar{c}s$ transitions. The published $B_s^0 \to J/\psi K^+K^-$, $J/\psi\phi$ and $\psi(2S)\phi$ analyses [27, 30, 31, 60, 80–86] are combined in a multi-dimensional fit including all measured parameters and their correlations. To account for a tension in the time and angular parameters, scale factors are applied on the combined uncertainty of each parameter where a discrepancy arise. For example, the scale factors on the uncertainties of $\Delta\Gamma_s$, Γ_s and $\phi_s^{c\bar{c}s}$ are 1.84, 2.45 and 1.00, respectively. The averages are then further refined by applying constraints from the published lifetime measurements with flavor-specific [19, 67–69] and pure CP [53, 68, 71–75] final states, to yield [8, 88]

$$\Delta\Gamma_s = +0.083 \pm 0.005 \text{ ps}^{-1} \text{ and } 1/\Gamma_s = 1.520 \pm 0.005 \text{ ps}\,, \quad (75.20)$$

or, equivalently,

$$1/\Gamma_{\rm L} = 1.429 \pm 0.006 \text{ ps} \quad \text{and} \quad 1/\Gamma_{\rm H} = 1.622 \pm 0.008 \text{ ps}\,, \quad (75.21)$$

in good agreement with the Standard Model predictions $\Delta\Gamma_s^{\rm SM} = +0.091 \pm 0.015$ ps^{-1} [7] and $\Delta\Gamma_s^{\rm SM} = +0.076 \pm 0.017$ ps^{-1} [89]. Estimates of $\Delta\Gamma_s/\Gamma_s$ obtained from measurements of the $B_s^0 \to D_s^{(*)+}D_s^{(*)-}$ branching fractions are not included in the average, since they are based on the questionable [90] assumption that these decays account for all CP-even final states.

From Eqs. (75.5), (75.17) and (75.20), one gets

$$\chi_s = 0.499318 \pm 0.000005\,. \quad (75.22)$$

75.5 CP-violation studies

Evidence for CP violation in B_q^0–$\overline{B}_q^0$ mixing has been searched for, both with flavor-specific and inclusive B_q^0 decays, in samples where the initial flavor state is tagged, usually with a lepton from the other b-hadron in the event. In the case of semileptonic (or other flavor-specific) decays, where the final-state tag is also available, the following asymmetry [2]

$$\mathcal{A}_{\rm SL}^q = \frac{N(\overline{B}_q^0(t) \to \ell^+\nu_\ell X) - N(B_q^0(t) \to \ell^-\overline{\nu}_\ell X)}{N(\overline{B}_q^0(t) \to \ell^+\nu_\ell X) + N(B_q^0(t) \to \ell^-\overline{\nu}_\ell X)} \simeq 1 - |q/p|_q^2 \quad (75.23)$$

has been measured either in time-integrated analyses at CLEO [48, 91], BaBar [92], CDF [93], DØ [94–96] and LHCb [97], or in time-dependent analyses at LEP [38, 98], BaBar [49, 99] and Belle [100]. In the inclusive case, also investigated at LEP [98, 101], no final-state tag is used, and the asymmetry [102]

$$\frac{N(\overline{B}_q^0(t) \to \text{all}) - N(B_q^0(t) \to \text{all})}{N(\overline{B}_q^0(t) \to \text{all}) + N(B_q^0(t) \to \text{all})} \simeq \mathcal{A}_{\rm SL}^q \left[\sin^2\left(\frac{\Delta m_q\, t}{2}\right) - \frac{x_q}{2}\sin(\Delta m_q\, t)\right] \quad (75.24)$$

must be measured as a function of the proper time to extract information on CP violation. In addition LHCb has studied the time dependence of the charge asymmetry of $B^0 \to D^{(*)-}\mu^+\nu_\mu X$ decays without tagging the initial state [103], which would be equal to

$$\frac{N(D^{(*)-}\mu^+\nu_\mu X) - N(D^{(*)+}\mu^-\bar{\nu}_\mu X)}{N(D^{(*)-}\mu^+\nu_\mu X) + N(D^{(*)+}\mu^-\bar{\nu}_\mu X)} = \mathcal{A}_{\rm SL}^d \frac{1 - \cos(\Delta m_d\, t)}{2} \quad (75.25)$$

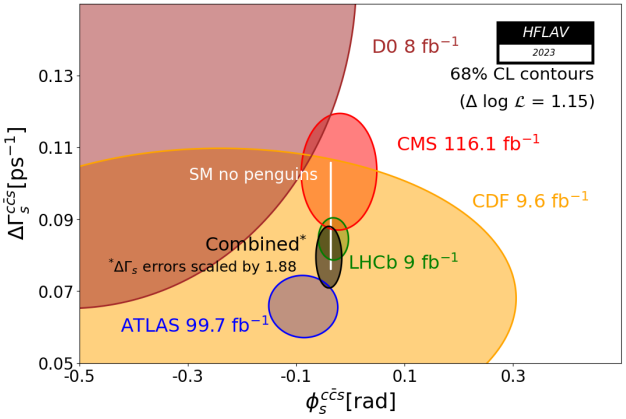

Figure 75.4: 68% CL contours in the $(\phi_s^{c\bar{c}s}, \Delta\Gamma_s)$ plane, showing all measurements from CDF [80], DØ [81], ATLAS [30, 82], CMS [31, 83] and LHCb [27, 60, 75, 84–86, 104, 105] using B_s^0 decays governed by the $b \to c\bar{c}s$ transition. Their average [8] is represented as the black ellipse, where the combined uncertainty on $\Delta\Gamma_s$ has been multiplied by 1.88. The very thin white rectangle represents the Standard Model predictions of $-2\beta_s$ [63, 64] and $\Delta\Gamma_s$ [7].

in absence of detection and production asymmetries.

The DØ collaboration measured a like-sign dimuon charge asymmetry in semileptonic b decays that deviates by $2.8\,\sigma$ from the tiny Standard Model prediction and concluded, from a more refined analysis in bins of muon impact parameters, that the overall discrepancy is at the level of $3.6\,\sigma$ [94]. In all other cases, asymmetries compatible with zero (and the Standard Model [7]) have been found, with a precision limited by the available statistics. Several of the analyses at high energy don't disentangle the B_d^0 and B_s^0 contributions, and either quote a mean asymmetry or a measurement of $\mathcal{A}_{\rm SL}^d$ assuming $\mathcal{A}_{\rm SL}^s = 0$: we no longer include these in the average. An exception is the dimuon DØ analysis [94], which separates the two contributions by exploiting their dependence on the muon impact parameter cut. The resulting measurements of $\mathcal{A}_{\rm SL}^d$ and $\mathcal{A}_{\rm SL}^s$ are then both compatible with the Standard Model. They are also correlated. We therefore perform a two-dimensional average of the measurements of Refs. [48, 49, 91, 92, 94–97, 99, 100, 103] and obtain [8]

$$\mathcal{A}_{\rm SL}^d = -0.0021 \pm 0.0017 \Leftrightarrow |q/p|_d = 1.0010 \pm 0.0008\,, \quad (75.26)$$
$$\mathcal{A}_{\rm SL}^s = -0.0006 \pm 0.0028 \Leftrightarrow |q/p|_s = 1.0003 \pm 0.0014\,, \quad (75.27)$$

with a correlation coefficient of -0.054 between $\mathcal{A}_{\rm SL}^d$ and $\mathcal{A}_{\rm SL}^s$. These results show no evidence of CP violation and are compatible with the very small Standard Model predictions, $\mathcal{A}_{\rm SL}^{d,\rm SM} = -(5.1 \pm 0.5) \times 10^{-4}$ and $\mathcal{A}_{\rm SL}^{s,\rm SM} = +(2.2 \pm 0.2) \times 10^{-5}$ [7], but have insufficient precision yet to constrain the Standard Model.

CP violation induced by B_s^0–$\overline{B}_s^0$ mixing in $b \to c\bar{c}s$ decays is controlled by the small weak phase $\phi_s^{c\bar{c}s}$. Measuring $\phi_s^{c\bar{c}s}$ requires tagging the initial flavour of the decaying B_s^0 meson. In addition to the previously mentioned $B_s^0 \to J/\psi K^+K^-$ (including $B_s^0 \to J/\psi\phi$) and $B_s^0 \to \psi(2S)\phi$ studies, the decay modes $B_s^0 \to J/\psi\pi^+\pi^-$ (including $B_s^0 \to J/\psi f_0(980)$) [75, 105] and $B_s^0 \to D_s^+ D_s^-$ [104] have also been analyzed by LHCb to measure $\phi_s^{c\bar{c}s}$, without the need for an angular analysis. The $J/\psi\pi^+\pi^-$ final state has been shown indeed to be (very close to) a pure CP-odd state [106]. In the $B_s^0 \to J/\psi\phi$ and $B_s^0 \to J/\psi K^+K^-$ analyses, $\phi_s^{c\bar{c}s}$ is obtained together with several other observables, including $\Delta\Gamma_s$, Γ_s, the longitudinal and perpendicular ϕ polarisation amplitudes, the S-wave amplitude, and strong phases. In order to account for all correlations, the full sets of measurements provided by the different analyses are combined in a multidimensional fit [8] of which $\phi_s^{c\bar{c}s}$ is just one of the free parameters. As already mentioned the $B_s^0 \to J/\psi\phi$ analyses of ATLAS, CMS and LHCb show a poor overall compatibility, mostly in the lifetime and angular parameters, corresponding approximately to 3 standard deviations. Therefore, scale factors are applied on the combined uncertainty of each parameter where a discrepancy arises. For the parameters already in agreement, such as $\phi_s^{c\bar{c}s}$, no scale factor is applied. The combined result based on all published analyses [27, 30, 31, 60, 75, 80–86, 104, 105] is

$$\phi_s^{c\bar{c}s} = -0.040 \pm 0.016\,. \quad (75.28)$$

A two-dimensional projection of the overall situation in the $(\phi_s^{c\bar{c}s}, \Delta\Gamma_s)$ plane is shown in Fig. 75.4. The experimental determination of $\phi_s^{c\bar{c}s}$ is still statistically limited. It is consistent with the Standard Model prediction, which is equal to $-2\beta_s = -2\arg(-(V_{ts}V_{tb}^*)/(V_{cs}V_{cb}^*)) = -0.0367 \pm 0.0010$ [63] or $-0.0376\,^{+0.0006}_{-0.0005}$ [64] assuming negligible Penguin pollution.

CP violation induced by B_s^0–$\overline{B}_s^0$ mixing in $b \to s\bar{s}s$ decays is controlled by the weak phase $\phi_s^{s\bar{s}s}$, which is an observable different from $\phi_s^{c\bar{c}s}$. In the Standard Model, such pure gluonic Penguin decays have an amplitude with a CKM phase that cancels that of the mixing amplitude, and hence $\phi_s^{s\bar{s}s}$ is expected to be essentially zero. LHCb has performed a flavour-tagged time-dependent angular analysis of $B_s^0 \to \phi\phi$ decays [28, 107], similar to that of $B_s^0 \to J/\psi\phi$ decays, and measured

$$\phi_s^{s\bar{s}s} = -0.074 \pm 0.069\,, \quad (75.29)$$

in agreement with the Standard Model prediction.

75.6 Summary

B^0–$\overline{B}^0$ mixing has been and still is a field of intense study. The mass differences in the B_d^0–$\overline{B}_d^0$ and B_s^0–$\overline{B}_s^0$ systems are known to relative precisions of 0.38% and 0.03%, respectively. The non-zero decay width difference in the B_s^0–$\overline{B}_s^0$ system is well established, with a relative difference of $\Delta\Gamma_s/\Gamma_s = (12.7 \pm 0.7)\%$, meaning that the heavy state of the B_s^0–$\overline{B}_s^0$ system lives $\sim 14\%$ longer than the light state. In contrast, the relative decay width difference in the B_d^0–$\overline{B}_d^0$ system, $\Delta\Gamma_d/\Gamma_d = (0.1 \pm 1.0)\%$, is still consistent with zero. CP violation in B_d^0–$\overline{B}_d^0$ or B_s^0–$\overline{B}_s^0$ mixing has not been observed yet, with precisions on the semileptonic asymmetries below 0.3%. CP violation induced by B_s^0–$\overline{B}_s^0$ mixing in B_s^0 decays has not yet been observed either, with uncertainties on the $\phi_s^{c\bar{c}s}$ and $\phi_s^{s\bar{s}s}$ phases of 16 mrad and 69 mrad, respectively. All observations so far remain consistent with the Standard Model expectations.

However, the measurements where New Physics might show up are still statistically limited. More results are awaited from the LHC experiments and Belle II, with promising prospects for the investigation of the CP-violating phase $\arg(-M_{12}/\Gamma_{12})$ and improved determination of the $\phi_s^{c\bar{c}s}$ and $\phi_s^{s\bar{s}s}$ phases.

Mixing studies have clearly reached the stage of precision measurements, where much effort is needed, both on the experimental and theoretical sides, in particular to further reduce the hadronic uncertainties of lattice QCD calculations. In the long term, a stringent check of the consistency of the B_d^0 and B_s^0 mixing amplitudes (magnitudes and phases) with all other measured flavor-physics observables will be possible within the Standard Model, leading to very tight limits on (or otherwise a long-awaited surprise about) New Physics.

76. Semileptonic b-Hadron Decays, Determination of V_{cb}, V_{ub}

Revised August 2023 by A.X. El-Khadra (Physics, Illinois U.) and P. Urquijo (School of Phys. U. of Melbourne).

76.1 Introduction

Precision determinations of $|V_{ub}|$ and $|V_{cb}|$ are central to testing the CKM sector of the Standard Model, and complement the measurements of CP asymmetries in B decays. The length of the side of the unitarity triangle opposite the well-measured angle β is proportional to the ratio $|V_{ub}|/|V_{cb}|$; its precise determination is a high priority of the heavy-flavor physics program.

The transitions $b \to c\ell\bar{\nu}_\ell$ and $b \to u\ell\bar{\nu}_\ell$ ($\ell = e, \mu$) each provide two avenues for determining these CKM matrix elements, namely through measurements of inclusive decay rates, $\bar{B} \to X\ell\bar{\nu}_\ell$ with a sum over all possible hadronic states X or of exclusive rates, where the final state hadron is a specific meson ($X = D$, D^*, π, ρ etc.).

Purely leptonic decays, such as $B_c^- \to \tau\bar{\nu}$, $B^- \to \tau\bar{\nu}$, and $B^- \to \mu\bar{\nu}$, provide a third avenue that is theoretically very simple (see the RPP mini-review [1]). However, we do not use this information at present since none of the measurements have reached a competitive level of precision. Hence the results presented here are solely obtained from exclusive and inclusive semileptonic b-hadron decays. This article and the values quoted here update the previous review [2].

The theoretical methods underlying the different determinations of $|V_{qb}|$ are quite mature. The theoretical approach for inclusive determinations uses the fact that the mass m_b of the b quark is large compared to the scale $\Lambda_{\rm QCD}$ that determines low-energy hadronic physics. Thus the basis for precise calculations is a systematic expansion in powers of Λ/m_b, where $\Lambda \sim 500 - 700$ MeV is a hadronic scale of the order of $\Lambda_{\rm QCD}$. Such an expansion can be formulated in the framework of an effective field theory which is described in a separate RPP mini-review [3]. Exclusive determinations rely on non-perturbatively calculated form factors, that encode the low-energy dynamics of the hadronic transition. Here, lattice QCD provides an, in principle, ab-initio method to calculate the non-perturbative QCD contributions to the exclusive decay amplitudes. Thanks to a combination of improved theoretical methods, better algorithms, and large increases in computational power, precise lattice QCD results are now available for the processes that are used in exclusive $|V_{ub}|$ and $|V_{cb}|$ determinations. State-of-the-art lattice QCD calculations are based on gauge-field ensembles that include realistic sea quark effects for degenerate up/down and strange quarks (aka $2+1$-flavor ensembles), and increasingly, also for charm (aka $2+1+1$-flavor ensembles). They employ ensembles generated at three (or more) lattice spacings, different spatial volumes, among other parameter variations to allow for quantification of the underlying systematic errors, and include detailed systematic error analyses. This is described in a separate RPP mini-review [4]. The lattice-QCD results discussed in this review are all state-of-the art with fully quantified uncertainties, and therefore play a central role in exclusive $|V_{qb}|$ determinations. In the case of exclusive $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decays, heavy quark symmetry (HQS) and heavy quark effective theory (HQET) yield constraints on the form factors that can be used to improve exclusive $|V_{cb}|$ determinations, especially when lattice QCD form factor results are incomplete, as was the case until very recently for $\bar{B} \to D^*\ell\bar{\nu}_\ell$. Light-cone sum rules (LCSR) provide another nonperturbative approach to compute form factors. However, while the lattice-QCD results employed in this review have well-quantified uncertainties, LCSR results suffer, in general, from hard-to-quantify systematic errors. The two methods typically provide results in opposite regions of phase space. Lattice-QCD calculations work best at low hadronic recoil or high momentum transfer (q^2) to the leptons, while LCSR calculations provide estimates at high recoil, near $q^2 = 0$. In general, we don't use form factor inputs obtained from LCSR in this review.

The measurements discussed in this review are of branching fractions, ratios of branching fractions, and decay kinematic distributions. The determinations of $|V_{cb}|$ and $|V_{ub}|$ also require a measurement of the total decay widths of the corresponding b hadrons, determined from lifetimes, which is the subject of a separate RPP mini-review [5]. The measurements of inclusive semileptonic decays relevant to this review come primarily from e^+e^- B factories operating at the $\Upsilon(4S)$ resonance, while the measurements of exclusive semileptonic decays come from both the e^+e^- B factories and from the LHCb experiment at CERN.

Semileptonic B-meson decay amplitudes to electrons and muons are well measured and consistent with Standard Model W-boson exchange. As they are expected to be insensitive to the effects of non-Standard-Model physics, they are used to extract $|V_{qb}|$. However, semileptonic decays to tau-lepton final states, such as $\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau$, may be sensitive to effects from beyond the Standard Model particles due to the large mass of the τ lepton. The currently observed tensions between Standard Model theory and experiment for these decays indicate that semitauonic decays must be studied further. For rare decays, tests of lepton-flavor universality violations (LFUV) in ratios involving μ/e final states provide CKM-free tests of the SM. These and other flavor dependent angular analyses are also included in this review.

Many of the numerical results quoted in this review have been provided by the Heavy Flavor Averaging Group (HFLAV) [6].

76.2 Determination of $|V_{cb}|$

Summary: The determination of $|V_{cb}|$ from inclusive decays has a relative uncertainty of about 1.5%; the limitations arise mainly from our ignorance of higher-order perturbative and non-perturbative corrections. Exclusive $\bar{B} \to D^*\ell\bar{\nu}_\ell$ decays provide a determination of $|V_{cb}|$ with a relative precision of about 2%, with comparable contributions from theory and experiment to the total uncertainty; the value determined from $\bar{B} \to D\ell\bar{\nu}_\ell$ decays is consistent and has an uncertainty of 2.5%. The values obtained from the inclusive and exclusive B decay determinations discussed below are:

$$|V_{cb}| = (42.2 \pm 0.5) \times 10^{-3} \quad \text{(inclusive)} \tag{76.1}$$

$$|V_{cb}| = (39.8 \pm 0.6) \times 10^{-3} \quad \text{(exclusive)}. \tag{76.2}$$

An average of these determinations has $p(\chi^2) = 1\%$, so we scale the error by $\sqrt{\chi^2/1} = 3.0$ to find

$$|V_{cb}| = (41.1 \pm 1.2) \times 10^{-3} \quad \text{(average)}. \tag{76.3}$$

Given the only marginal consistency, of approximately 3.0 σ, this average should be treated with caution.

76.2.1 $|V_{cb}|$ *from exclusive decays*

Exclusive determinations of $|V_{cb}|$ make use of semileptonic B decays into the ground state charmed mesons D and D^*. The corresponding hadronic matrix elements can be parameterized in terms of six independent form factors, which depend on the variable $w \equiv v \cdot v'$, where v and v' are the four velocities of the initial and final-state hadrons. In the rest frame of the decay this variable corresponds to the Lorentz factor of the final state $D^{(*)}$ meson. Determinations of $|V_{cb}|$ from experimental measurements of $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decay rates require precise knowledge of these form factors. Fortunately, lattice QCD results for all relevant form factors, including their recoil dependence, are now available [7–12]. Heavy Quark Symmetry (HQS) [13, 14] predicts that in the infinite mass limit the six form factors collapse into a single one, which is normalized at the "zero recoil point" $w = 1$, the point of maximum momentum transfer to the leptons. Heavy Quark Effective Theory (HQET) provides a framework for obtaining the corrections to the HQS prediction in a systematic expansion in powers of $\Lambda_{\rm QCD}/m_c$ which is discussed in a separate RPP mini-review [3].

76.2.2 $\bar{B} \to D^*\ell\bar{\nu}_\ell$

The decay rate for $\bar{B} \to D^*\ell\bar{\nu}_\ell$, assuming massless leptons, is given by

$$\frac{d\Gamma}{dw}(\bar{B} \to D^*\ell\bar{\nu}_\ell) = \frac{G_F^2 m_B^5}{48\pi^3}|V_{cb}|^2|\eta_{\rm EW}|^2(w^2-1)^{1/2}P(w)|\mathcal{F}(w)|^2, \tag{76.4}$$

where $P(w)$ is a phase space factor,

$$P(w) = r^3(1-r)^2(w+1)^2\left(1+\frac{4w}{w+1}\frac{1-2rw+r^2}{(1-r)^2}\right), \quad (76.5)$$

with $r = m_{D^*}/m_B$. The decay amplitude $\mathcal{F}(w)$ can be expressed in terms of the form factors which parametrize the vector and axial vector current matrix elements

$$\frac{\langle D^*(v',\epsilon)|\bar{c}\gamma^\mu b|B(v)\rangle}{\sqrt{m_B m_{D^*}}} = h_V(w)\,\varepsilon^{\mu\nu\rho\sigma}v_{B,\nu}v_{D^*,\rho}\epsilon^*_\sigma\,, \quad (76.6)$$

$$\frac{\langle D^*(v',\epsilon)|\bar{c}\gamma^\mu\gamma^5 b|B(v)\rangle}{\sqrt{m_B m_{D^*}}} = ih_{A_1}(w)\,(1+w)\epsilon^{*\mu} - i\left[h_{A_2}(w)v_B^\mu + h_{A_3}(w)v_{D^*}^\mu\right]\epsilon^*\cdot v_B\,, \quad (76.7)$$

and the ratios

$$R_1(w) = \frac{h_V(w)}{h_{A_1}(w)}\,, \quad R_2(w) = \frac{h_{A_3}(w)+r\,h_{A_2}(w)}{h_{A_1}(w)}\,, \quad (76.8)$$

as

$$P(w)|\mathcal{F}(w)|^2 = |h_{A_1}(w)|^2\times\left\{2\frac{r^2-2rw+1}{(1-r)^2}\left[1+\frac{w-1}{w+1}R_1^2(w)\right] + \left[1+\frac{w-1}{1-r}(1-R_2(w))\right]^2\right\}. \quad (76.9)$$

Note that $\mathcal{F}$ at $w=1$ is unity by HQS in the infinite-mass limit [15–18]. The effect of assuming massless leptons is typically very small, but for the muon case can be non-negligible in fits to data at high hadronic recoil.

The factor $\eta_{\rm EW} = 1.0066\pm0.0050$ accounts for the leading electroweak corrections to the four-fermion operator mediating the semileptonic decay [19], and includes an estimated uncertainty for missing long-distance and structure-dependent QED corrections [20]. While some QED radiative corrections are included in the experimental analysis, the Coulomb correction, which arises when the final-state hadron is charged, is not taken into account.

The determination of $|V_{cb}|$ requires knowledge of the normalization, where one commonly uses a theoretical calculation of the zero recoil input, $\mathcal{F}(1)$. Theoretical knowledge of the shapes of the form factors provides crucial compatibility checks between theory and experiment, and improves the precision of the determinations.

Model-independent shape parametrizations of the form factors make use of analyticity and unitarity constraints and are expressed in terms of the variable

$$z = \frac{\sqrt{w+1}-\sqrt{2N}}{\sqrt{w+1}+\sqrt{2N}}\,, \quad (76.10)$$

originating from a conformal transformation, where $N = (t_+ - t_0)/(t_+ - t_-)$, $t_\pm = (m_B \pm m_{D^*})^2$, and the choice of t_0 determines the kinematic point at which $z=0$. The form factors (generically denoted as F) may then be written as [21–25]

$$F(z) = \frac{1}{P_F(z)\phi_F(z)}\sum_{n=0}^{\infty}a_n z^n \quad (76.11)$$

where the sum is bounded, $\sum|a_n|^2 < 1$. Furthermore, the function $P_F(z)$ takes into account the resonances in the $(\bar{c}b)$ system below the $\bar{D}B$ threshold, and the weighting functions $\phi_F(z)$ are derived from the unitarity constraint on the corresponding form factor. With the conventional choice $N=1$, $z=0$ when $w=1$ and kinematic range of the decay corresponds to $0 \le z \le 0.06$. As a result, only very few terms are needed in the series in z. We refer to Eq. (76.11) as the "BGL" expansion.

The Caprini-Lellouch-Neubert (CLN) parametrization [26] yields a simple form

$$h_{A_1}(w) = h_{A_1}(1)\left[1-8\rho^2 z + (53\rho^2-15)z^2 - (231\rho^2-91)z^3\right] \quad (76.12)$$

with the slope ρ and normalization $h_{A_1}(1)$ as the only parameters, albeit at the cost of introducing model dependence. Furthermore, the ratios $R_1(w)$ and $R_2(w)$ are expanded in $w-1$. However, this simple CLN parametrization does not account for higher-order corrections in the $1/m_{c/b}$ expansion, which are now relevant [25, 27–33]. In addition, the numerical values of the coefficients use outdated knowledge and should include uncertainties. Thus, this report focuses on recent analyses that employ different combinations of HQET expansions through $\mathcal{O}(\alpha_s/m_{b,c}, 1/m_{b,c}^2)$, lattice form factors at non-zero recoil, as well as the model-independent BGL expansion. Typical fits include up to three parameters a_n in Eq. (76.11) for the different form factors.

There now exist three independent lattice QCD calculations by Fermilab/MILC [9], HPQCD [10], and JLQCD [11] of the $\bar{B}\to D^*\ell\bar{\nu}_\ell$ form factors at non-zero recoil. The three groups each employ statistically independent gauge-field ensembles and use different lattice actions for the heavy and light quarks. To obtain results in the continuum and at the physical point, all three analyses first perform chiral-continuum fits and systematic error studies on the corresponding lattice form factor data. The resulting continuum form factors are smooth functions (bands) obtained over recoil ranges which depend on the respective simulation details. In a second step, BGL-expansion fits are used to obtain the form factors over the entire recoil range. We note that the interplay between choices for the ChPT-based continuum extrapolations and BGL coefficients needs further investigation [34]. A comparison of the resulting $|\mathcal{F}(w)|^2$ amplitudes is shown in Fig. 76.1. While the lattice results are reasonably consistent in the low-recoil region, there is some variation in the slopes, as is evident from the spread between the bands at large recoil.

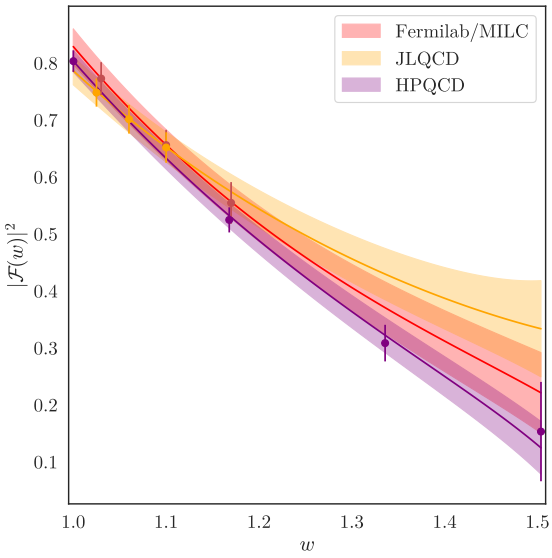

Figure 76.1: Comparison of lattice QCD results for $|\mathcal{F}(w)|^2$ obtained by the Fermilab Lattice and MILC collaborations (red), HPQCD (purple), and JLQCD (yellow). Plot courtesy of A. Vaquero.

Prior lattice calculations obtained results for only the form factor at the zero-recoil point, $\mathcal{F}(1)$, [20,35] with a total uncertainty at the (1-2)% level. A weighted average of the $\mathcal{F}(1)$ results from Refs. [10, 11, 20] yields

$$\mathcal{F}(1) = 0.903 \pm 0.012\,. \quad (76.13)$$

The lattice QCD results in Refs. [9–11] appeared (or were published) after the most recent FLAG review [36], and will therefore be included in the next FLAG review. Non-lattice estimates based on zero-recoil sum rules for the form factor tend to yield lower central values for $\mathcal{F}(1)$ [37–39]. The sum rules indicate that $\mathcal{F}(1) < 0.92$ [37, 38, 40, 41], while an explicit estimate that includes excited state contributions yields $\mathcal{F}(1) \approx 0.86$ [39, 42].

Lattice-QCD form factors at non-zero recoil provide valuable shape constraints, and hence enable more refined $|V_{cb}|$ determinations. However, since they were not available until recently, some $|V_{cb}|$ determinations in the literature use the value for $\mathcal{F}(1)$ from Eq. (76.13) as the only quantitative lattice input. We discuss these first, before turning to results for $|V_{cb}|$ which employ the lattice-QCD form factors at non-zero recoil from Refs. [9–11].

While Light Cone Sum Rules (LCSR) can provide constraints on the form factors at maximum recoil, the underlying systematic errors are not fully quantified. A modern LCSR calculation [43] quotes uncertainties in the $\lesssim 20\%$ range for the $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ form factors at $q^2 = 0$.

Dispersive methods [44] can also be used to provide additional constraints on form factors calculated in lattice QCD. Recent work [45, 46] introduces the dispersive matrix method, which includes a strategy for computing the susceptibilities that are also needed inputs in z-expansion fits. They are calculable in lattice QCD from two-point correlation functions, which must be analyzed with the same care as the form factors themselves. The susceptibilities have also been computed in perturbative QCD in Ref. [47]. The two sets of results in Refs. [46, 47] differ in some cases outside of the quoted error bars, with a significance of up to 2.5σ. A test of the dispersive matrix approach for the $D \to K\ell\nu$ form factors, which can be computed in lattice-QCD over the entire kinematic range, is presented in Ref. [45]. The implementation of the dispersive matrix in Ref. [48] imposes unitarity constraints on the input data via a so-called unitarity filter. The filter has the effect of altering the shapes of the form factor bands while reducing the uncertainties from extrapolating the form factors over the entire kinematic range. Subsequently, the authors of Ref. [48] determine $|V_{cb}|$ from a bin-by-bin analysis of the experimental data, which avoids the common shape constraints in joint z-expansion fits. In follow-up work, this method has also been applied to other semileptonic decay channels [49–51]. A more recent proposal [52] employs Bayesian inference to implement unitarity constraints, which allows for a straightforward combination of inputs from multiple lattice calculations while including experimental data in joint z-expansion fits.

Many experiments [53–65] have measured the differential decay rate as a function of w, employing a variety of methods: using either B^+ or B^0 decays, with or without B-tagging, and with or without explicit reconstruction of the transition pion from $D^* \to D$ decays. In Ref. [6] a subset of the available experimental measurements were input to a four-dimensional fit for $\eta_{\rm EW}\mathcal{F}(1)|V_{cb}|$, $\rho^2_{A_1}$ and the form-factor ratios $R_1 \propto A_2/A_1$ and $R_2 \propto V/A_1$. The fit has a p-value of 0.9%, so we scale the uncertainty by a factor $\sqrt{\chi^2/23}$ to give $\eta_{\rm EW}\mathcal{F}(1)\,|V_{cb}| = (35.00 \pm 0.49) \times 10^{-3}$ (CLN).

The leading sources of uncertainty on $\eta_{\rm EW}\mathcal{F}(1)\,|V_{cb}|$ are due to detection efficiencies and $D^{(*)}$ decay branching fractions. Note that the $\bar{B} \to D^*\ell\bar{\nu}_\ell$ form factor in the fit is parameterized using the CLN form, which has the drawbacks discussed previously.

Using the value from Eq. (76.13) for $\mathcal{F}(1)$ and accounting for the electroweak correction gives

$$|V_{cb}| = (38.5 \pm 0.5 \pm 0.6) \times 10^{-3}\ (\bar{B} \to D^*\ell\bar{\nu}_\ell,\ \text{LQCD, CLN}). \tag{76.14}$$

A safer approach is to use the more general BGL form-factor parameterization [22–25, 29]. The BABAR and Belle experiments have published analyses with BGL based parametrizations at a given order in the expansion [62–64]. A preliminary measurement from Belle II [65] has also been performed with a BGL based parametrization. The main results from these measurements are summarised in Table 76.1 after multiplying through the value of $\mathcal{F}(1)$ quoted in the nominal result of each respective study. These results have not yet been combined by the Heavy Flavor Averaging Group.

The Belle analysis [62] and the Belle II analysis [65] are both based on untagged approaches in the mode $\bar{B}^0 \to D^{*+}\ell\bar{\nu}_\ell$ and measure 1-d projections in bins of the hadronic recoil w, and angular variables $\cos\theta_\ell$, $\cos\theta_V$, and χ. The BABAR analysis [63] and the recent Belle analysis [64] are based on hadronic tagged samples using both charged and neutral B decays. BABAR performs a full 4-d unbinned analysis of neutral and charged B decay modes, while Belle uses unfolded 1-d projections of w, $\cos\theta_\ell$, $\cos\theta_V$, and χ. Only the BGL form factors are directly determined in these tagged analysis, not the normalization, which is taken from the world average $\bar{B} \to D^*\ell\bar{\nu}_\ell$ branching fractions.

The studies in Refs. [62, 64, 65] publish the fully-differential decay rate data and associated covariance matrices. The BGL fit results in the Belle, Belle II and BABAR measurements are all consistent with corresponding results from fits with the CLN parametrization, Eq. (76.14). Each study reports fit results at low order in the three BGL expansion terms when non-zero lattice data is not used as an additional constraint, ranging from zero-order to second-order. Studies of the impact of higher order expansions based on the Belle published decay rate data have been reported in Refs. [30, 31], as well as in the recent Belle and Belle II studies [64, 65], where it is shown that the fit uncertainty on $|V_{cb}|$ increases substantially with respect to the results reported at lower order, while the parameter correlations approach 1. This is due to larger number of degrees of freedom allowed in the higher order expansions, which are not sufficiently constrained without lattice-QCD inputs at nonzero recoil.

In Ref. [9], BGL expansion fits to the FNAL/MILC lattice QCD form factors show that they are insensitive to truncation effects beyond quadratic order. These form factors were subsequently used in Ref. [9] to extract $|V_{cb}|$ from combined BGL fits to the Belle [62] and synthetic BABAR [63] $\bar{B} \to D^*\ell\bar{\nu}_\ell$ data, yielding $|V_{cb}| = (38.74 \pm 0.78) \times 10^{-3}$. The p-values for the combined (experiment+lattice QCD) BGL fits reported in Ref. [9] are small, reflecting tensions between the data sets. For a fit combining only the Belle data with the lattice-QCD form factors, Ref. [9] quotes $|V_{cb}| = 38.60(86) \times 10^{-3}$, while a fit combining the experimental data with only the lattice QCD $\mathcal{F}(1)$ yields $|V_{cb}| = 39.75(92) \times 10^{-3}$. Similarly, Refs. [10, 11] present analyses based on the BGL expansion, combining the respective lattice form factor results with the new Belle data [64]. The HPQCD collaboration [10] reports $|V_{cb}| = 39.31(74) \times 10^{-3}$, while the JLQCD collaboration [11] reports $|V_{cb}| = 39.19(90) \times 10^{-3}$. All these determinations are consistent with the result presented in Eq. (76.15) as well as with other exclusive determinations, where the HPQCD value needs to be shifted due to their inclusion of the Coulomb factor in η_{EW}. As noted in Refs. [9–11, 64, 65], the form factor shapes and $R_2(w)$ ratio predicted from FNAL/MILC [9] and HPQCD [10] are in tension with experimental data yielding small p-values, while those from JLQCD [11] are not. Furthermore, the $R_2(w)$ ratio results from Refs. [9, 10] are also in tension with HQET expectations (see, for example, Refs. [30, 32, 33, 67]). These tensions must be understood better in order to improve the precision of $|V_{cb}|$ extractions. Indeed, ongoing experimental analyses as well as theoretical work may resolve them in the near future.

For this review, we take a naive combination of the results in Table 76.1, assuming minimal correlations between measurements, and correct for the value of $\mathcal{F}(1)\eta_{EW}$. In the future we expect HFLAV to perform a combined global fit analysis. The combination has a p-value of 8%. The nominal result for $|V_{cb}|$ is therefore

$$|V_{cb}| = (39.7 \pm 0.7) \times 10^{-3}\ (\bar{B} \to D^*\ell\bar{\nu}_\ell,\ \text{LQCD, BGL}), \tag{76.15}$$

where the uncertainty contains contributions from experimental, lattice QCD, and $\eta_{\rm EW}$ sources. We note that despite the improvements in the experimental data, theoretical inputs, and $|V_{cb}|$ extraction methods, this new exclusive determination of $|V_{cb}|$, while higher in central value compared to earlier ones, is still in tension with the inclusive determinations discussed in Section 76.2.5 and summarized in Eq. (76.32).

76.2.3 $\bar{B} \to D\ell\bar{\nu}_\ell$

The differential rate for $\bar{B} \to D\ell\bar{\nu}_\ell$ is given by

$$\frac{d\Gamma}{dw}(\bar{B} \to D\ell\bar{\nu}_\ell) = \frac{G_F^2}{48\pi^3}|V_{cb}|^2(m_B + m_D)^2 m_D^3 (w^2-1)^{3/2}(\eta_{\rm EW}\mathcal{G}(w))^2. \tag{76.16}$$

Table 76.1: $\mathcal{F}(1)\eta_{EW}|V_{cb}|$ results from $B \to D^*\ell\nu$ with BGL expansion fits. Note that the tagged analyses combined results from B^- and $\bar{B}^0$ decays, while the untagged analyses study only $\bar{B}^0$ decays. The final column listed the non-zero recoil lattice QCD data used in each study.

Measurement	Tag	$\mathcal{F}(1)\eta_{EW}\lvert V_{cb}\rvert \times 10^3$	Fit inputs
Belle [66]	Untagged	35.22 ± 0.95	FNAL/MILC [20]
Babar [63]	Tagged	34.98 ± 0.65	
Belle [64]	Tagged	37.00 ± 0.56	FNAL/MILC [9], HPQCD [10], JLQCD [11]
Belle II [65]	Untagged	36.94 ± 0.91	FNAL/MILC [9]

The form factor is defined in terms of

$$\frac{\langle D(v')|\bar{c}\gamma^\mu b|B(v)\rangle}{\sqrt{m_B m_D}} = h_+(w)\,(v_B + v_D)^\mu + h_-(w)\,(v_B - v_D)^\mu \tag{76.17}$$

and reads

$$\mathcal{G}(w) = h_+(w) - \frac{m_B - m_D}{m_B + m_D} h_-(w), \tag{76.18}$$

where $h_+(1)$ is normalized to unity due to HQS and $h_-(1)$ vanishes in the infinite-mass limit. Thus

$$\mathcal{G}(1) = 1 + \mathcal{O}\left(\left(\frac{m_B - m_D}{m_B + m_D}\right)^2 \frac{\Lambda_{\rm QCD}}{m_c}\right) \tag{76.19}$$

and the corrections to the HQS prediction are of order $\Lambda_{\rm QCD}/m_c$ in contrast to the case of $\mathcal{F}(1)$. The lattice-QCD result for the normalization, $\mathcal{G}(1)$, obtained in Ref. [7] is

$$\mathcal{G}(1) = 1.054 \pm 0.004 \pm 0.008\,. \tag{76.20}$$

We first turn to $|V_{cb}|$ extractions that rely on only the normalization $\mathcal{G}(1)$ from Eq. (76.20). The most precise measurements of $\bar{B} \to D\ell\bar{\nu}_\ell$ [60, 68, 69] dominate the CLN average [6] value, $\eta_{\rm EW}\mathcal{G}(1)|V_{cb}| = (41.53 \pm 0.98) \times 10^{-3}$. Note that this average corresponds to measurements that are fit to the CLN form factor parameterization; the same concerns expressed above for $\bar{B} \to D^*\ell\bar{\nu}_\ell$ apply here. Using the value from Eq. (76.20) for $\mathcal{G}(1)$ and accounting for the electroweak correction as above gives

$$|V_{cb}| = (39.1 \pm 0.9 \pm 0.4) \times 10^{-3} \quad (\bar{B} \to D\ell\bar{\nu}_\ell,\ \text{LQCD, CLN}), \tag{76.21}$$

where the first uncertainty is from experiment, and the second combines the lattice QCD uncertainty in Eq. (76.20) with the electroweak correction.

For the $\bar{B} \to D\ell\bar{\nu}_\ell$ modes, theoretical input on the shape of the form factor, especially near $w \sim 1$, is especially beneficial to $|V_{cb}|$ determinations, since experimental measurements of the differential decays rate near zero recoil are affected by the more severe phase space suppression, compared to the D^* case. Hence the best $|V_{cb}|$ determinations from exclusive $\bar{B} \to D\ell\bar{\nu}_\ell$ decays employ lattice-QCD form factors obtained over a range of $w \geq 1$ [7,8], where Ref. [70] provides a lattice average of the two results. Using the BCL parametrization (z-expansion from Ref. [71]) for the form factors, they can be combined with binned measurements from Belle [69] and BABAR [68]. Only Ref. [69] published the full measurement covariance matrix, while Ref. [68] provides the statistical uncertainty covariance. Nevertheless, Ref. [69] is more precise and dominates the average [70], giving

$$|V_{cb}| = (40.1 \pm 1.0) \times 10^{-3} \quad (\bar{B} \to D\ell\bar{\nu}_\ell,\ \text{LQCD, BCL}). \tag{76.22}$$

This result is consistent with the value reported in Ref. [47], which is based on the same experimental and lattice inputs.

The $|V_{cb}|$ averages from $\bar{B} \to D^*\ell\bar{\nu}_\ell$ and $\bar{B} \to D\ell\bar{\nu}_\ell$ decays using the BGL (Eq. (76.15)) and BCL (Eq. (76.22)) forms, respectively, are reasonably consistent. The correlations between the lattice uncertainties for $\bar{B} \to D^*\ell\bar{\nu}_\ell$ and $\bar{B} \to D\ell\bar{\nu}_\ell$ are discussed in Ref. [36], and considered to be 100% for the statistical uncertainty component. We assume an experimental uncertainty correlation of order 20% and combine the results of Eq. (76.15) and Eq. (76.22), giving

$$|V_{cb}| = (39.8 \pm 0.6) \times 10^{-3} \quad \text{(exclusive)}. \tag{76.23}$$

76.2.4 $B_s \to D_s^{(*)-}\mu^+\nu_\mu$

Semileptonic decays of B_s mesons are being studied extensively by the LHCb experiment. On the theory side, lattice QCD calculations of the corresponding form factors can proceed using the same methods and gauge-field ensembles as for B-meson decays. In fact, the presence of a strange spectator quark in the B_s-meson decay amplitudes tends to yield smaller statistical and systematic errors in the lattice computation. Nevertheless, to-date there are still fewer lattice-QCD results for B_s-meson form factors available than for the B-meson case, but this situation is expected to change. For the case of the $B_s \to D_s$ transition, two lattice QCD calculations of the form factors over a range of recoil momenta have been performed by the HPQCD collaboration, the first on $2+1$-flavor gauge field ensembles (generated by the MILC collaboration) using NRQCD b-quarks [72]. The second calculation uses the $2+1+1$-flavor gauge-field ensembles (also generated by MILC), employing the HISQ action for all valence quarks [73]. The all-HISQ approach avoids the need to compute renormalization factors separately, at the cost of requiring an extrapolation to the physical b-quark mass at the lattice spacings used in Ref. [73]. For the $B_s \to D_s^*$ transition, Refs. [35,74] provide lattice QCD results for the form factor at zero recoil, where Ref. [74] uses a similar set-up as Ref. [73] and reads

$$\mathcal{F}^{B_s \to D_s^*}(1) = 0.9020(96)_{\rm stat}(90)_{\rm sys}\,. \tag{76.24}$$

A lattice QCD calculation of the $B_s \to D_s^{*-}$ form factors at non-zero recoil, employing $2+1+1$-flavor gauge-field ensembles (generated by MILC) in an all-HISQ approach was presented in Ref. [12] and updated in Ref. [10].

LHCb has extracted $|V_{cb}|$ from semileptonic B_s^0 decays [75]. The measurement uses both $B_s^0 \to D_s^-\mu^+\nu_\mu$ and $B_s^0 \to D_s^{*-}\mu^+\nu_\mu$ decays. The value of $|V_{cb}|$ is determined from the observed yields of B_s^0 decays normalized to those of B^0 decays after correcting for the relative reconstruction and selection efficiencies. The normalization channels are $B^0 \to D^-\mu^+\nu_\mu$ and $B^0 \to D^{*-}\mu^+\nu_\mu$ decays, where the D^- is reconstructed with the same decay mode of the D_s ($D_{(s)}^- \to [K^+K^-]_\phi\pi^-$). The shape of the form factors are extracted using $p_\perp(D_s)$, which is the component of the D_s^- momentum perpendicular to the B_s^0 flight direction. This variable is correlated with q^2 and the helicity angles in the $B_s^0 \to D_s^{*-}\mu^+\nu_\mu$ decay. For the $B_s \to D_s^-\mu^+\nu_\mu$ decay, for example, $|V_{cb}|$ is related to the measured ratio of signal yields, N_{sig}, and the normalization channel yields, N_{ref}, through the relation

$$\frac{N_{sig}}{N_{ref}} = \xi \frac{f_s}{f_d} \frac{\mathcal{B}(D_s^- \to K^+K^-\pi^-)}{\mathcal{B}(D^- \to K^+K^-\pi^-)} \frac{1}{\mathcal{B}(B^0 \to D^-\mu\nu_\mu)} \tau_s \times \int \frac{d\Gamma(B_s \to D_s\mu\nu_\mu)}{dw} dw\,,$$

where τ_s is the B_s lifetime, and ξ is the efficiency ratio between the signal and the normalization. The analysis uses the lattice-QCD form factors obtained for $B_s \to D_s^-$ over the full kinematic range in Ref. [73] and the zero-recoil result for the $B_s \to D_s^{*-}$ form factor from Ref. [74]. Fits to both the CLN parameterization and a 5-parameter version of BGL were performed. The result for $|V_{cb}|$, updated with the most recent determination of f_s/f_d and $\mathcal{B}(D_s^- \to K^-K^+\pi^-)$ from Ref. [76], are $|V_{cb}|_{\rm CLN} = (40.8 \pm 0.6 \pm 0.9 \pm 1.1) \times 10^{-3}$, and $|V_{cb}|_{\rm BGL} = (41.7 \pm 0.8 \pm 0.9 \pm 1.1) \times 10^{-3}$, where the first uncertainty is statistical, the second systematic and the third due to the limited knowledge of the external inputs,

in particular the constant $f_s/f_d \times \mathcal{B}(D_s^- \to K^+K^-\pi^-)$. The determination of $|V_{cb}|$ in Ref. [12], using the lattice form factors obtained therein combined with LHCb data yields a consistent result, $|V_{cb}| = 42.7(1.5)_{\rm latt}(1.7)_{\rm exp}(0.4)_{\rm EM} \times 10^{-3}$. The results obtained are consistent with the exclusive determinations of $|V_{cb}|$ using the B^0 and B^+ decays but are not used in the overall average in this review at this stage. These channels are important in the measurement of the ratio $|V_{ub}|/|V_{cb}|$, which cancels out the B_s normalisation uncertainties, discussed in Section 76.5. LHCb also perform measurements of the $B_s^0 \to D_s^{*-}\mu^+\nu_\mu$ differential decay rate [77]. Fits are performed to extract the form factors in CLN and BGL parametrizations.

76.2.5 $|V_{cb}|$ *from inclusive decays*

Measurements of the total semileptonic branching decay rate, along with moments of the lepton energy and hadronic invariant mass spectra in inclusive semileptonic $b \to c$ transitions, can be used for a precision determination of $|V_{cb}|$. The total semileptonic decay rate can be calculated quite reliably in terms of non-perturbative parameters that can be extracted from the information contained in the moments.

76.2.6 *Inclusive semileptonic rate*

The theoretical foundation for the calculation of the total semileptonic rate is the Operator Product Expansion (OPE) which yields the Heavy Quark Expansion (HQE) [78, 79]. Details can be found in the RPP mini-review on Effective Theories [3].

The OPE result for the total rate can be written schematically (details can be found, *e.g.*, in Ref. [80]) as

$$\begin{aligned}\Gamma =& |V_{cb}|^2 \frac{G_F^2 m_b^5(\mu)}{192\pi^3} |\eta_{\rm EW}|^2 \times \\ & \left[z_0^{(0)}(r) + \frac{\alpha_s(\mu)}{\pi} z_0^{(1)}(r) + \left(\frac{\alpha_s(\mu)}{\pi}\right)^2 z_0^{(2)}(r) + \cdots \right. \\ & + \frac{\mu_\pi^2}{m_b^2}\left(z_2^{(0)}(r) + \frac{\alpha_s(\mu)}{\pi} z_2^{(1)}(r) + \cdots \right) \\ & + \frac{\mu_G^2}{m_b^2}\left(y_2^{(0)}(r) + \frac{\alpha_s(\mu)}{\pi} y_2^{(1)}(r) + \cdots \right) \\ & + \frac{\rho_{\rm D}^3}{m_b^3}\left(z_3^{(0)}(r) + \frac{\alpha_s(\mu)}{\pi} z_3^{(1)}(r) + \cdots \right) \\ & \left. + \frac{\rho_{\rm LS}^3}{m_b^3}\left(y_3^{(0)}(r) + \frac{\alpha_s(\mu)}{\pi} y_3^{(1)}(r) + \cdots \right) + ... \right] \end{aligned} \quad (76.25)$$

where r is the ratio m_c/m_b and the y_i and z_i are perturbatively calculable Wilson coefficients functions that appear at different orders of the heavy mass expansion.

The parameters μ_π^2, μ_G^2, ρ_D^3 and ρ_{LS}^3 constitute the non-perturbative input into the heavy quark expansion; they correspond to certain matrix elements to be discussed below. In the same way the HQE can be set up for the moments of distributions of charged-lepton energy, hadronic invariant mass and hadronic energy, e.g.

$$\langle E_e^n \rangle_{E_e > E_{\rm cut}} = \int_{E_{\rm cut}}^{E_{\rm max}} \frac{d\Gamma}{dE_e} E_e^n dE_e \Big/ \int_{E_{\rm cut}}^{E_{\rm max}} \frac{d\Gamma}{dE_e} dE_e \ . \quad (76.26)$$

The coefficients of the HQE are known up to order $1/m_b^5$ at tree level [81–84]. The leading term $z_0^{(i)}$ is the parton model, and is known completely through order α_s^2 [85–87] and now also at α_s^3 [88]. The terms of order $\alpha_s^{n+1}\beta_0^n$ (where β_0 is the first coefficient of the QCD β function, $\beta_0 = (33 - 2n_f)/3$) have been included following the BLM procedure [80, 89–92]. Corrections of order $\alpha_s\mu_\pi^2/m_b^2$ have been computed in Ref. [93] and Ref. [94], while the $\alpha_s\mu_G^2/m_b^2$ terms have been calculated in Ref. [95] and Ref. [96], and the $\alpha_s\rho_D^3/m_b^3$ corrections in Refs. [97, 98].

Starting at order $1/m_b^3$ contributions with an infrared sensitivity to the charm mass, m_c, appear [81, 83, 99, 100]. At order $1/m_b^3$ this "intrinsic charm" contribution manifests as a $\log(m_c)$ in the coefficient of the Darwin term ρ_D^3. At higher orders, terms such as $1/m_b^3 \times 1/m_c^2$ and $\alpha_s(m_c)1/m_b^3 \times 1/m_c$ appear; numerically these terms may be comparable in size to the contributions of order $1/m_b^4$.

The HQE parameters are given in terms of forward matrix elements of local operators; the parameters entering the expansion for orders up to $1/m_b^3$ are ($D_\perp^\mu = (g_{\mu\nu} - v_\mu v_\nu)D^\nu$, where $v = p_B/M_B$ is the four-velocity of the B meson)

$$\begin{aligned} \overline{\Lambda} &= M_B - m_b \,, \\ \mu_\pi^2 &= -\langle B|\bar{b}(iD_\perp)^2 b|B\rangle \,, \\ \mu_G^2 &= \langle B|\bar{b}(iD_\perp^\mu)(iD_\perp^\nu)\sigma_{\mu\nu} b|B\rangle \,, \\ \rho_{\rm D}^3 &= \langle B|\bar{b}(iD_{\perp\mu})(ivD)(iD_\perp^\mu) b|B\rangle \,, \\ \rho_{\rm LS}^3 &= \langle B|\bar{b}(iD_\perp^\mu)(ivD)(iD_\perp^\nu)\sigma_{\mu\nu} b|B\rangle. \end{aligned} \quad (76.27)$$

These parameters still depend on the heavy quark mass. Sometimes the infinite mass limits of these parameters $\overline{\Lambda} \to \overline{\Lambda}_{\rm HQET}$, $\mu_\pi^2 \to -\lambda_1$, $\mu_G^2 \to 3\lambda_2$, $\rho_D^3 \to \rho_1$ and $\rho_{LS}^3 \to 3\rho_2$, are used instead. Beyond $1/m^3$ the number of independent HQE parameters starts to proliferate [84, 101]. In general, there are 13 parameters (at tree level) up to order $1/m^4$ and 31 (at tree level) up to order $1/m^5$, not including $\overline{\Lambda}$. A framework to compute observables at higher order in $1/m$ [84, 102] has been used to estimate the HQE parameters of the orders $1/m_b^4$ and $1/m_b^5$. Their their impact on the $|V_{cb}|$ determination has been studied in Ref. [103]. However, as pointed out in Ref. [104] one may reduce the number of independent parameters in the HQE by exploiting reparametrization invariance, which is a symmetry of the HQE stemming from Lorentz invariance of QCD. For a subset of observables this allows us to reduce the number of parameters to three up to order $1/m^3$ (ρ_{LS}^3 can be absorbed into μ_G^2 by a re-definition) and to 8 up to order $1/m^4$ [105].

The perturbative QCD expansion for the decay rate does not converge, in general. In addition, the expansion coefficients in the rates and spectra depend strongly on the scheme used for m_b (or equivalently on $\overline{\Lambda}$). It is well known (see eg. [106]) that using the pole mass definition for heavy quark masses leads to particularly badly behaved expansions. This motivates the use of "short-distance" mass definitions, such as the kinetic scheme [37] or the $1S$ scheme [107–109]. Both schemes are well suited for the HQE, since they allow the choice of the renormalization scale $\mu \le m_b$. Furthermore, in both schemes, the masses can be extracted from other observables with sufficient precision, enabling a precise determination of $|V_{cb}|$, despite of the strong quark-mass dependence of the total rate.

The $1S$ scheme eliminates the b quark pole mass by relating it to the perturbative expression for the mass of the $1S$ state of the Υ system. The b quark mass in the $1S$ scheme is half of the perturbatively calculated mass of the $1S$ state of the Υ system. The best determination of the b quark mass in the $1S$ scheme is obtained from sum rules for $e^+e^- \to b\bar{b}$ [110]. A second alternative is the so-called "kinetic mass" $m_b^{\rm kin}(\mu)$, which enters the non-relativistic expression for the kinetic energy of a heavy quark, and is defined using heavy-quark sum rules [37]. The relation between $m_b^{\rm kin}$ and $m_b^{\overline{MS}}$ is known through three-loop order [111].

Finally, we note that the theoretical description of inclusive decays employed here, is based on the assumption of quark-hadron duality. While there is no evidence of violations of quark-hadron duality, the theoretical uncertainties due to such violations are not well quantified [3].

76.2.7 *Determination of HQE Parameters and* $|V_{cb}|$

Several experiments have measured moments in $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays [112–120] as a function of the minimum lepton momentum. Recently, moments measurements have been performed as a function of lepton invariant mass squared, q^2 [121, 122]. The measurements of the moments of the electron energy spectrum ($0^{\rm th}$-$3^{\rm rd}$) and of the squared hadronic mass spectrum ($0^{\rm th}$-$2^{\rm nd}$) have statistical uncertainties that are roughly equal to their systematic uncertainties. The $3^{\rm rd}$ order hadronic mass spectrum moments have also been measured by some experiments, with relatively large statistical uncertainty. The sets of moments mea-

sured within each experiment have strong correlations; their use in a global fit requires fully specified statistical and systematic covariance matrices. Measurements of photon energy moments (0^{th}-2^{nd}) in $B \to X_s\gamma$ decays [123–127] as a function of the minimum accepted photon energy are also used in some fits; the dominant uncertainties on these measurements are statistical.

Global fits [120, 124, 128–134] to the moments of the electron energy spectrum and the squared hadronic mass spectrum have been performed in the $1S$ and kinetic schemes. The semileptonic moments alone determine a linear combination of m_b and m_c very accurately but leave the orthogonal combination poorly determined (See e.g. [135]); additional input is required to allow a precise determination of m_b. This additional information can come from the radiative $B \to X_s\gamma$ moments (with the caveat that the OPE for $b \to s\gamma$ breaks down beyond leading order in $\Lambda_{\rm QCD}/m_b$), which provide complementary information on m_b and μ_π^2, or from precise determinations of the charm and beauty quark masses [36, 70, 136]. The values obtained in the kinetic scheme fits [6, 132, 133] with these two constraints are consistent. Based on the charm and beauty quark mass constraints [36, 134] $m_c^{\overline{\rm MS}}(3\,{\rm GeV}) = 0.988 \pm 0.007\,{\rm GeV}$, and $m_b^{\overline{\rm MS}} = 4.198 \pm 0.012){\rm GeV}$ a fit in the kinetic scheme [134] obtains

$$|V_{cb}| = (42.16 \pm 0.51) \times 10^{-3} \tag{76.28}$$

where the error include experimental and theoretical uncertainties. This analysis [134] includes calculations of the third-order corrections to the semi-leptonic $b \to c\ell\nu$ decay width [88] and mass relations [111, 137] Theoretical uncertainties from higher orders in $1/m$ as well as in α_s are estimated and included in performing the fits. Similar values for the parameters are obtained with a variety of assumptions about the theoretical uncertainties and their correlations. The χ^2/dof is well below unity, which could suggest that the theoretical uncertainties may be overestimated. However, while one could obtain a satisfactory fit with smaller uncertainties, this would result in unrealistically small uncertainties on the extracted HQE parameters, which are used as input to other calculations (e.g. the determination of $|V_{ub}|$).

A fit to the measured moments in the $1S$ scheme [6, 124, 131] gives

$$|V_{cb}| = (41.98 \pm 0.45) \times 10^{-3}, \tag{76.29}$$

$$m_b^{1S} = (4.691 \pm 0.037)\,{\rm GeV}. \tag{76.30}$$

This fit uses moments measurements from semileptonic and radiative decays and constrains the chromomagnetic operator using the B^*-B and D^*-D mass differences, but does not include the constraint on m_c nor all known higher order corrections.

Measurements of higher order moments and moments of additional variables, such as q^2, can further improve the sensitivity of the fits to higher-order terms in the HQE [105]. The q^2 moments depend on a reduced set of operators, thereby possibly making it easier to extract higher-order terms from data. A fit to the q^2 moments measured by the Belle [121] and Belle II [122] experiments combined with the world average inclusive branching fractions, finds [138]:

$$|V_{cb}| = (41.69 \pm 0.63) \times 10^{-3}\ , \tag{76.31}$$

which is compatible with the fit to the other moments. Note there is a strong correlation with the other determinations due to the use of common inputs for the branching fractions.

These fits give consistent results for $|V_{cb}|$ and, after translation to a common renormalization scheme, for m_b. We take the fit in the kinetic scheme [134], which includes higher-order perturbative corrections, as the inclusive determination of $|V_{cb}|$:

$$|V_{cb}| = (42.2 \pm 0.5) \times 10^{-3}\ \text{(inclusive)}. \tag{76.32}$$

76.3 Determination of $|V_{ub}|$

Summary: Currently the best determinations of $|V_{ub}|$ are from $\bar{B} \to \pi\ell\bar{\nu}_\ell$ decays, where combined fits to theory and experimental data as a function of q^2 provide a precision of about 4%; the uncertainties from experiment and theory are comparable in size. Determinations based on inclusive semileptonic B decays are based on different observables and use different strategies to suppress the $b \to c$ background. Most of the determinations are consistent and provide a precision of about 7%, with comparable contributions to the uncertainty from experiment and theory.

The values obtained from inclusive and exclusive B decay determinations are

$$|V_{ub}| = (4.13 \pm 0.12\ ^{+\ 0.13}_{-\ 0.14} \pm 0.18) \times 10^{-3} \quad \text{(inclusive)}, \tag{76.33}$$

$$|V_{ub}| = (3.70 \pm 0.10 \pm 0.12) \times 10^{-3} \quad \text{(exclusive)}, \tag{76.34}$$

where the last uncertainty on the inclusive result was added by the authors of this review and is discussed below. The exclusive and inclusive determinations are independent, and the dominant uncertainties are on multiplicative factors. The results from the two determinations are compatible to within two standard deviations.

This can be compared to the values derived from $|V_{ub}|/|V_{cb}|$ ratio measurements, described in the next section. Taking the value for this ratio from Eq. (76.54), and $|V_{cb}|$ from Eq. (76.3) we obtain.

$$|V_{ub}| = (3.43 \pm 0.32) \times 10^{-3} \qquad (\mathrm{B_s},\ \Lambda_\mathrm{b}), \tag{76.35}$$

We choose to combine only the direct determinations of $|V_{ub}|$, based on the inclusive and exclusive B measurements. In the combination they are weighted by their relative errors, where the uncertainties are treated as normally distributed. The resulting average has $p(\chi^2) = 15\%$, so we scale the error by $\sqrt{\chi^2/1} = 1.4$ to find

$$|V_{ub}| = (3.82 \pm 0.20) \times 10^{-3} \quad \text{(average)}. \tag{76.36}$$

In a future update we may consider the constraints in the $|V_{ub}|$-$|V_{cb}|$ plane from the direct determinations together with the LHCb $|V_{ub}/V_{cb}|$ results, although the agreement among all inputs is somewhat marginal.

76.3.1 $|V_{ub}|$ *from inclusive decays*

The theoretical description of inclusive $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays is based on the Heavy Quark Expansion and leads to a predicted total decay rate with uncertainties below 5% [108, 139]. However, the total decay rate is hard to measure due to the large background from CKM-favored $\bar{B} \to X_c\ell\bar{\nu}_\ell$ transitions, and hence the theoretical methods differ from the $\bar{B} \to X_c\ell\bar{\nu}_\ell$ case. For a calculation of the partial decay rate in regions of phase space where $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays are suppressed one cannot use the HQE as for $b \to c$, rather one needs to introduce non-perturbative distribution functions, the "shape functions" (SF) [140, 141]. Their exact form is not known, but its moments can be related to the HQE parameters known e.g from the $b \to c$ case.

The shape functions become important when the light-cone momentum component $P_+ \equiv E_X - |P_X|$ is not large compared to Λ_{QCD}, as is the case near the endpoint of the $\bar{B} \to X_u\ell\bar{\nu}_\ell$ lepton spectrum. Partial rates for $\bar{B} \to X_u\ell\bar{\nu}_\ell$ are predicted and measured in a variety of kinematic regions that differ in their sensitivity to shape-function effects.

At leading order in $1/m_b$ only a single shape function (SF) appears, which is universal for all heavy-to-light transitions [140, 141] and can be extracted in $\bar{B} \to X_s\gamma$ decays. At subleading order in $1/m_b$, several shape functions appear [142], along with small "resolved photon contributions" specific for $\bar{B} \to X_s\gamma$ [143–145], and thus the prescriptions that relate directly the partial rates for $\bar{B} \to X_s\gamma$ and $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays [146–154] are limited to leading order in $1/m_b$.

Existing approaches use parametrizations of the leading SF that respect constraints on the normalization and on the first and second moments, which are given in terms of the HQE parameters $\overline{\Lambda} = M_B - m_b$ and μ_π^2, respectively. The relations between SF moments and the HQE parameters are known to second order in α_s [155]; as a result, measurements of HQE parameters from global fits to $\bar{B} \to X_c\ell\bar{\nu}_\ell$ and $\bar{B} \to X_s\gamma$ moments can be used to constrain the SF moments, as well as to provide accurate values of m_b and other parameters for use in determining $|V_{ub}|$. Flexible parametrizations of the SF using orthogonal basis functions [156] or artificial neural networks [157] allow global fits to inclusive B

meson decay data [145] that incorporate the known short-distance contributions and renormalization properties of the SF.

HFLAV performs fits on the basis of several approaches, with varying degrees of model dependence. We will consider here the approaches documented in Ref. [158] (BLNP), Ref. [159] (GGOU) and Ref. [160] (DGE).

The triple differential rate in the variables

$$P_\ell = M_B - 2E_\ell, \quad P_- = E_X + |\vec{P}_X|, \quad P_+ = E_X - |\vec{P}_X| \quad (76.37)$$

is

$$\frac{d^3\Gamma}{dP_+\, dP_-\, dP_\ell} = \frac{G_F^2 |V_{ub}|^2}{16\pi^2}(M_B - P_+) \quad (76.38)$$
$$\Big\{(P_- - P_\ell)(M_B - P_- + P_\ell - P_+)\mathcal{F}_1$$
$$+ (M_B - P_-)(P_- - P_+)\mathcal{F}_2 + (P_- - P_\ell)(P_\ell - P_+)\mathcal{F}_3\Big\}.$$

The "structure functions", $\mathcal{F}_i$, can be calculated using factorization theorems that have been proven to subleading order in the $1/m_b$ expansion [161].

The BLNP [158] calculation uses these factorization theorems to write the $\mathcal{F}_i$ terms as functions of perturbatively calculable hard coefficients and jet functions, which are convolved with the (soft) light-cone distribution functions.The calculation of $\mathcal{O}(\alpha_s^2)$ contributions [162,163] is not yet complete and is not included in the $|V_{ub}|$ determination given below.

The leading order term in the $1/m_b$ expansion of the $\mathcal{F}_i$ terms contains a single non-perturbative function and is calculated to subleading order in α_s, while at subleading order in the $1/m_b$ expansion there are several independent non-perturbative functions that have been calculated only at tree level in the α_s expansion.

A distinct approach (GGOU) [159] uses a hard, Wilsonian cutoff that matches the definition of the kinetic mass. The non-perturbative input is similar to what is used in BLNP, but the shape functions are defined differently. In particular, they are defined at finite m_b and depend on the light-cone component k_+ of the b quark momentum and on the momentum transfer q^2 to the leptons. These functions include subleading effects to all orders; as a result they are non-universal, with one shape function corresponding to each structure function in Eq. (76.38). Their k_+ moments can be computed in the OPE.

Going to subleading order in α_s requires the definition of a renormalization scheme for the HQE parameters and for the SF. The relation between the moments of the SF and the forward matrix elements of local operators appearing the HQE is plagued by ultraviolet problems and requires additional renormalization. A scheme for improving this behavior was suggested in Refs. [158,164], which introduce a definition of the quark mass (the so-called shape-function scheme) based on the first moment of the measured $\bar{B} \to X_s\gamma$ photon energy spectrum. Likewise, the HQE parameters can be defined from measured moments of spectra, corresponding to moments of the SF.

There are various ideas to model the SF, but this requires additional assumptions. One approach (DGE) is the so-called "dressed gluon exponentiation" [160], where the perturbative result is continued into the infrared regime using the renormalon structure obtained in the large β_0 limit, where β_0 has been defined following Eq. (76.25). Other approaches make even stronger assumptions, such as in Ref. [165], which assumes an analytic behavior for the strong coupling in the infrared to perform an extrapolation of perturbation theory.

In order to reduce sensitivity to SF uncertainties, measurements that use a combination of cuts on the leptonic momentum transfer q^2 and the hadronic invariant mass m_X, as suggested in Ref. [166, 167], have been made. In general, experimental measurements of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ into charm-dominated regions (in order to reduce SF uncertainties) are sensitive to the modeling of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ and $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays. The measurements quoted below have used a variety of functional forms to parametrize the leading SF; a specific error budget for one determination is quoted in the next section. In no case is the parametrization uncertainty estimated to be more than a 2% on $|V_{ub}|$.

Weak Annihilation [159, 168, 169] (WA) can in principle contribute significantly in the high-q^2 region of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays. Estimates based on semileptonic D_s decays [100, 166, 167, 169] lead to a $\sim 2\%$ uncertainty on the total $\bar{B} \to X_u\ell\bar{\nu}_\ell$ rate from the $\Upsilon(4S)$. The q^2 spectrum of the WA contribution is not well known, but from the OPE it is expected to contribute predominantly at high q^2. Other theoretical investigations [100, 170, 171], a direct search [172], and $\mathcal{B}(B^0 \to X_u\ell\bar{\nu})/\mathcal{B}(B^+ \to X_u\ell\bar{\nu})$ ratio measurements [173–176] indicate that WA is a small effect, but may become a significant source of uncertainty for $|V_{ub}|$ measurements that accept only a small fraction of the full $\bar{B} \to X_u\ell\bar{\nu}_\ell$ phase space.

76.3.2 *Measurements*

We summarize the measurements used in the determination of $|V_{ub}|$ below. Given the improved precision and more rigorous theoretical interpretation of more recent measurements, determinations [177–180] done with LEP data are not considered in this review.

Inclusive electron momentum measurements [181, 182] reconstruct a single charged electron to determine a partial decay rate for $\bar{B} \to X_u\ell\bar{\nu}_\ell$ near the kinematic endpoint. This results in a selection efficiency of order 50% and only modest sensitivity to the modeling of detector response. The inclusive electron momentum spectrum from $B\bar{B}$ events, after subtraction of the $e^+e^- \to q\bar{q}$ continuum background, is fitted to a model $\bar{B} \to X_u\ell\bar{\nu}_\ell$ spectrum and several components ($D\ell\bar{\nu}_\ell$, $D^*\ell\bar{\nu}_\ell$, ...) of the $\bar{B} \to X_c\ell\bar{\nu}_\ell$ background; the dominant uncertainties are related to this subtraction and modelling. The decay rate can be cleanly extracted for $E_e > 2.3\,\text{GeV}$, but this is deep in the SF region, where theoretical uncertainties are large. More recent measurements have increased the accessed phase phase. The resulting $|V_{ub}|$ values for various E_e cuts are given in Table 76.2.

The most recent BABAR measurement [183] is based on the inclusive electron spectrum and determines the partial branching fraction and $|V_{ub}|$ for $E_e > 0.8\,\text{GeV}$. The analysis shows that the partial branching fraction measurements can have signal model dependence when the kinematic acceptance includes regions dominated by $\bar{B} \to X_c\ell\bar{\nu}_\ell$ background. The model dependence enters primarily through the partial branching fractions, and arises because the signal yield fit has sensitivity to $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays only in regions with good signal to noise.

An untagged "neutrino reconstruction" measurement [184] from BABAR uses a combination [185] of a high-energy electron with a measurement of the missing momentum vector. This allows S/B~ 0.7 for $E_e > 2.0\,\text{GeV}$ and a $\approx 5\%$ selection efficiency, but at the cost of a smaller accepted phase space for $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays and uncertainties associated with the determination of the missing momentum.

The large samples accumulated at the B factories allow studies in which one B meson is fully reconstructed and the recoiling B decays semileptonically [186–189]. The experiments can fully reconstruct a "tag" B candidate in about 0.5% (0.3%) of B^+B^- ($B^0\bar{B}^0$) events. An electron or muon with center-of-mass momentum above 1.0 GeV is required amongst the charged tracks not assigned to the tag B and the remaining particles are assigned to the X_u system. The full set of kinematic properties (E_ℓ, m_X, q^2, *etc.*) are available for studying the semileptonically decaying B, making possible selections that accept up to 90% of the full $\bar{B} \to X_u\ell\bar{\nu}_\ell$ rate; however, the sensitivity to $\bar{B} \to X_u\ell\bar{\nu}_\ell$ decays is still driven by the regions where $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays are suppressed. Despite requirements (e.g. on the square of the missing mass) aimed at rejecting events with additional missing particles, undetected or mis-measured particles from $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decay (e.g., K_L^0 and additional neutrinos) remain an important source of uncertainty.

A recent recoil method measurement of partial branching fractions in three phase-space regions, covering about 31% to 86% of the accessible phase space, was performed by Belle [173], where machine learning techniques were used to reduce background levels. The measurement contains substantial decay model updates and supersedes previous measurements from Belle [187,188]. The measurement of the partial branching fraction obtained in the $E_\ell^B > 1\text{GeV}$ region, the most precise one, is used to obtain

$|V_{ub}|$ [173]. Belle also reports measurements of the background subtracted, and unfolded differential decay spectra in bins of m_X, m_X and q^2, P_+ and E_ℓ [190] for use in global fit analyses.

Earlier measurements by BABAR [186] were also performed with cuts on m_X, m_X and q^2, P_+ and E_ℓ using the recoil method. In each case the experimental systematic uncertainties have significant contributions from the modeling of $\bar{B} \to X_u \ell \bar{\nu}_\ell$ and $\bar{B} \to X_c \ell \bar{\nu}_\ell$ decays and from the detector response to charged particles, photons and neutral hadrons.

To reduce modelling uncertainties associated to $\bar{B} \to X_c \ell \bar{\nu}_\ell$ decays a recent Belle tagged measurement [176] uses a novel data driven approach to correct the kinematics and normalisation of this background component, while using less restrictive event selection with higher efficiency than the other recent Belle result. In the analysis the ratio $|V_{ub}|/|V_{cb}|$ is directly extracted from inclusive decays for the first time. While a value for $|V_{ub}|$ is provided here, it is not yet included in the combination.

The corresponding $|V_{ub}|$ values are given in Table 76.2.

76.3.3 $|V_{ub}|$ *from inclusive partial rates*

The measured partial rates and theoretical calculations from BLNP, GGOU and DGE described previously are used to determine $|V_{ub}|$ from all measured partial $\bar{B} \to X_u \ell \bar{\nu}_\ell$ rates [6]; selected values are given in Table 76.2. The correlations amongst the multiple BABAR recoil-based measurements [186] are fully accounted for in the average. The statistical correlations amongst the other measurements used in the average are small (due to small overlaps among signal events and large differences in S/B ratios) and have been ignored. Correlated systematic and theoretical errors are taken into account, both within an experiment and between experiments. As an illustration of the relative sizes of the uncertainties entering $|V_{ub}|$ we give the error breakdown for the GGOU average: statistical—1.3%; experimental—1.6%; $\bar{B} \to X_c \ell \bar{\nu}_\ell$ modeling—0.9%; $\bar{B} \to X_u \ell \bar{\nu}_\ell$ modeling—1.7%; HQE parameters (m_b) —1.8%; higher-order corrections—1.5%; q^2 modeling—1.3%; Weak Annihilation—$^{+0.0}_{-1.1}$%; SF parametrization—0.1%.

The averages quoted here are based on the following m_b values: $m_b^{SF} = 4.582 \pm 0.023 \pm 0.018$ GeV for BLNP, $m_b^{\rm kin} = 4.554 \pm 0.018$ GeV for GGOU, and $m_b^{\overline{MS}} = 4.188 \pm 0.043$ GeV for DGE. The $m_b^{\rm kin}$ value is determined in a global fit to moments in the kinetic scheme [6]; this value is translated into m_b^{SF} and $m_b^{\overline{MS}}$ at fixed order in α_s. The second uncertainty quoted on m_b arises from the scheme translation.

Hadronization uncertainties also impact the $|V_{ub}|$ determination. The theoretical expressions are valid at the parton level and do not incorporate any resonant structure (*e.g.* $\bar{B} \to \pi \ell \bar{\nu}_\ell$); this must be added to the simulated $\bar{B} \to X_u \ell \bar{\nu}_\ell$ event samples, since the detailed final state multiplicity and structure impacts the estimates of experimental acceptance and efficiency. The experiments have adopted procedures to input resonant structure while preserving the appropriate behavior in the kinematic variables (q^2, E_ℓ, m_X) averaged over the sample, but these prescriptions are *ad hoc* and ultimately require *in situ* calibration. The resulting uncertainties have been estimated to be $\sim$ 1-2% on $|V_{ub}|$. A recent inclusive $|V_{ub}|$ Belle measurement is the first to perform a fit to final state pion multiplicity for *in situ* calibration of the hadronization models used. The measurement simultaneously extracts inclusive and exclusive $|V_{ub}|$, with compatible results [191].

All calculations yield compatible $|V_{ub}|$ values and similar error estimates. The arithmetic mean of the values and errors of the HFLAV combinations listed in Table 76.2 is $|V_{ub}| = (4.13 \pm 0.12_{\rm exp}\ ^{+0.13}_{-0.14\ \rm theo}) \times 10^{-3}$, although there is a spread of approximately 10% in the evaluations with the three theoretical models. For reasons discussed below, we assign an additional uncertainty due to model dependence that is not reflected in the HFLAV averages. As highlighted in the BABAR analysis [173,183], model dependence entering measurement procedures can be sizeable, and is not consistently treated across analyses. Many of the analyses shown in Table 76.2 were based on partial branching fraction measurements determined in a single model (i.e. the one used by that analysis when simulating $\bar{B} \to X_u \ell \bar{\nu}_\ell$ decays), although in some cases simulated events were weighted to match the expected spectra in other models and the differences introduced as systematic uncertainties, e.g. Ref. [188]. The $|V_{ub}|$ value quoted by HFLAV for each model are, typically, derived from this unique partial branching fraction combined with another model-specific partial rate calculation. The model dependence in the partial branching fraction is sensitive to how the model predictions compare in the restricted region with good signal-to-noise, not by how they compare when integrated over the full kinematic range used in the fit. Ideally this effect needs to be accounted for by the experiments; the published information is insufficient to determine it. To account for the range in results using the different theoretical models, we take half of the spread of the averages as an additional systematic uncertainty, denoted Δmodel. With this addition, the inclusive $|V_{ub}|$ average is

$$|V_{ub}| = (4.13 \pm 0.12_{\rm exp}\ ^{+0.13}_{-0.14\ \rm theo} \pm 0.18_{\Delta \rm model}) \times 10^{-3} \quad \text{(inclusive)}. \tag{76.39}$$

76.3.4 $|V_{ub}|$ *from exclusive decays*

Exclusive charmless semileptonic decays offer a complementary means of determining $|V_{ub}|$. For the experiments, the specification of the final state provides better background rejection, but the branching fraction to a specific final state is typically only a few percent of that for inclusive decays. For theory, the calculation of the form factors for decays of B-mesons into exclusive final states is challenging, but brings in a different set of uncertainties from those encountered in inclusive decays. In this review we focus on $\bar{B} \to \pi \ell \bar{\nu}_\ell$, as it is the most promising decay mode for both experiment and theory. However, we also discuss $\bar{B}_s \to K \ell \bar{\nu}_\ell$ decays, for which there are recent interesting results. Measurements of other exclusive $\bar{B} \to X_u \ell \bar{\nu}_\ell$ decays can be found in Refs. [192–205].

76.3.5 $\bar{B} \to \pi \ell \bar{\nu}_\ell$ *form factor calculations*

The relevant form factors for the decay $\bar{B} \to \pi \ell \bar{\nu}_\ell$ are usually defined as

$$\langle \pi(p_\pi) | V^\mu | B(p_B) \rangle = f_+(q^2) \left[p_B^\mu + p_\pi^\mu - \frac{m_B^2 - m_\pi^2}{q^2} q^\mu \right] + f_0(q^2) \frac{m_B^2 - m_\pi^2}{q^2} q^\mu \tag{76.40}$$

in terms of which the rate becomes (in the limit $m_\ell \to 0$)

$$\frac{d\Gamma}{dq^2} = \frac{G_F^2 |V_{ub}|^2}{24\pi^3} |p_\pi|^3 |f_+(q^2)|^2, \tag{76.41}$$

where p_π is the pion momentum in the B meson rest frame.

Lattice-QCD calculations of the form factors for the $B \to \pi \ell \bar{\nu}$ and $B_s \to K \ell \bar{\nu}$ transitions are available from the Fermilab/MILC [206,207], HPQCD [208], RBC/UKQCD [209,210], and JLQCD [211] collaborations. The lattice form factors are obtained in the large q^2 region, $q^2_{\rm max} > q^2 \gtrsim 15\,{\rm GeV}^2$ and the calculations differ in actions employed for the b quark. While HPQCD [208] is using lattice-nonrelativistic QCD, the results from Fermilab/MILC [206, 207]and RBC/UKQCD [209] are obtained with relativistic b quark actions based on the Fermilab approach [212], albeit using independently generated gauge-field configurations. The JLQCD collaboration is using all-domain-wall-fermion set-up, The results agree within the quoted errors. For the $B \to \pi$ form factor $f_+(q^2 = 20\,{\rm GeV}^2)$, Ref. [206] quotes uncertainty of 3.4%, where the leading contribution is due to the chiral-continuum extrapolation fit, which includes statistical and heavy-quark discretization errors.

The extrapolation to small values of q^2 can be performed using guidance from analyticity and unitarity together with a conformal mapping of the kinematical variables onto the complex unit disc, which yields series in the variable

$$z = \frac{\sqrt{t_+ - q^2} - \sqrt{t_+ - t_0}}{\sqrt{t_+ - q^2} + \sqrt{t_+ - t_0}}\,, \tag{76.42}$$

where $t_\pm = (M_B \pm m_\pi)^2$ and the choice of t_0 determines the range of z that corresponds to the kinematic range of the decay. Setting $t_0 = t_-$ results in $z = 0$ when $q^2 = q^2_{\rm max}$. The choice $t_0 = (m_B + m_\pi)/(\sqrt{m_B} - \sqrt{m_\pi})^2$ centers the kinematic range around $z = 0$, so that $|z| < 0.3$.

Table 76.2: $|V_{ub}|$ (in units of 10^{-5}) from inclusive $\bar{B} \to X_u \ell \bar{\nu}_\ell$ measurements. The first uncertainty on $|V_{ub}|$ is experimental, while the second includes both theoretical and HQE parameter uncertainties. The values are generally listed in order of increasing kinematic acceptance, f_u (0.19 to 0.90), except for the BABAR E_e >0.8 GeV measurement; those below the horizontal bar are based on recoil methods. The Belle 2023 measurement is not yet included in the combination.

Ref.	cut (GeV)	BLNP	GGOU	DGE
CLEO [181]	$E_e > 2.1$	$422 \pm 49 \,^{+\,29}_{-\,34}$	$423 \pm 49 \,^{+\,22}_{-\,31}$	$386 \pm 45 \,^{+\,25}_{-\,27}$

We note that the $\bar{B}_s \to K \ell \bar{\nu}_\ell$ decay is an example were the implementation of unitarity bounds is complicated by the fact that the location of the cut in the q^2 plane is different from the $B_s K$ threshold, because the cut starts at $B\pi$ production threshold. Modifications of the unitarity constraints in this and similar examples are discussed in Refs. [210, 213–216].

The "BCL" parameterization of Ref. [71] is commonly used for these decays, as it is consistent with the asymptotic scaling ($q^2 \to \infty$) as well as near threshold, $q^2 = t_+$. As pointed out in Ref. [217] the unitarity sum of the z-expansion coefficients for f_+ is expected to be of order $(\Lambda/m)^3$, hence yielding a rapidly converging series. We note that relatively small differences in different lattice QCD form factor results can be amplified by a long extrapolation to the low-q^2 region. However, such extrapolations are not needed, when lattice form factors are combined with experimental measurements of the differential decay rate. The joint fits provide constraints on the shape of the form factor over the entire kinematic range, in addition to enabling precise determinations of $|V_{ub}|$ [218].

LCSR calculations provide estimates for the product $f_B f_+(q^2)$, valid in the region $0 < q^2 \lesssim 12$ GeV. The determination of $f_+(q^2)$ itself requires knowledge of the decay constant f_B, which is usually obtained by replacing f_B by its two-point QCD (SVZ) sum rule [219] in terms of perturbative and condensate contributions. The advantage of this procedure is the approximate cancellation of various theoretical uncertainties in the ratio $(f_B f_+)/(f_B)$. The LCSR for $f_B f_+$ is based on the light-cone OPE of the relevant vacuum-to-pion correlation function, calculated in full QCD at finite b-quark mass. The resulting expressions comprise a triple expansion: in the twist, t, of the operators near the light-cone, in α_s, and in the deviation of the pion distribution amplitudes from their asymptotic form, which is fixed from conformal symmetry. The state-of-the-art calculations include the leading twists two, three and four with full one-loop α_s corrections [220,221] and partial two-loop corrections [222]. Higher-twist contributions have been investigated in Ref. [223] and two-particle higher twist contributions are studied in Ref. [43]. Nevertheless, estimates based on LCSR generally suffer from difficult to quantify systematic uncertainties.

A detailed statistical analysis including the various correlations has been performed in Ref. [224], also including unitarity bounds on the form factor. The results obtained are numerically compatible with the lattice QCD calculations of the form factor. A more recent analysis [225] employs a modified BCL expansion to extrapolate the LCSR form factors obtained at low q^2 to the high q^2 region, where good agreement with lattice QCD form factor predictions is found. The LCSR form factors can be combined with experimental data in joint z-expansion fits to determine $|V_{ub}|$.

76.3.6 $\bar{B} \to \pi \ell \bar{\nu}_\ell$ measurements

The $\bar{B} \to \pi \ell \bar{\nu}_\ell$ measurements fall into two broad classes: untagged, in which case the reconstruction of the missing momentum of the event serves as an estimator for the unseen neutrino, and tagged, in which the second B meson in the event is fully reconstructed in either a hadronic or semileptonic decay mode. The tagged measurements have better q^2 resolution, high and uniform acceptance and S/B as high as 10, but lower statistical power. The untagged measurements have higher background (S/B < 1) and make slightly more restrictive kinematic cuts, but still provide statistical power precision on the q^2 dependence of the form factor.

CLEO has analyzed $\bar{B} \to \pi \ell \bar{\nu}_\ell$ and $\bar{B} \to \rho \ell \bar{\nu}_\ell$ using an untagged analysis [199–201]. Similar analyses have been done at BABAR [202–205] and Belle [226]. The leading systematic uncertainties in the untagged $\bar{B} \to \pi \ell \bar{\nu}_\ell$ analyses are associated with modeling the missing momentum reconstruction, with background from $\bar{B} \to X_u \ell \bar{\nu}_\ell$ decays and $e^+e^- \to q\bar{q}$ continuum events, and with varying the form factor used to model $\bar{B} \to \rho \ell \bar{\nu}_\ell$ decays.

Analyses [194,227] based on reconstructing a B in the $\bar{D}^{(*)} \ell^+ \nu_\ell$ decay mode and looking for a $\bar{B} \to \pi \ell \bar{\nu}_\ell$ or $\bar{B} \to \rho \ell \bar{\nu}_\ell$ decay amongst the remaining particles in the event make use of the fact that the B and $\bar{B}$ are back-to-back in the $\Upsilon(4S)$ frame to construct a discriminant variable that provides a signal-to-noise ratio above unity for all q^2 bins. A related technique was discussed in Ref. [228]. BABAR [227] and Belle [192] have used their samples of B mesons reconstructed in hadronic decay modes to measure exclusive charmless semileptonic decays, resulting in very clean but smaller samples. The dominant systematic uncertainties in the tagged analyses arise from tag calibration.

$|V_{ub}|$ can be obtained from the average $\bar{B} \to \pi \ell \bar{\nu}_\ell$ branching fraction and the measured q^2 spectrum. Fits to the q^2 spectrum using a theoretically motivated parametrization (e.g. "BCL" from Ref. [71]) remove most of the model dependence from theoretical uncertainties in the shape of the spectrum. The most sensitive method for determining $|V_{ub}|$ from $\bar{B} \to \pi \ell \bar{\nu}_\ell$ decays employs a simultaneous fit [6,206,217,218,229,230] to measured experimental partial rates and lattice points versus q^2 (or z) to determine $|V_{ub}|$ and the first few coefficients of the expansion of the form factor in z. We quote the result from Ref. [6], which uses as experimental input an average of the measurements in Refs. [192, 202, 205, 226] and an average [231] of the LQCD input from Refs. [206] and [209]. The p-value of the q^2 measurement average is 6%. The average for the total $B^0 \to \pi^- \ell^+ \nu_\ell$ branching fraction is obtained by summing up the partial branching fractions:

$$\mathcal{B}(B^0 \to \pi^- \ell^+ \nu_\ell) = (1.50 \pm 0.02_{\rm stat} \pm 0.06_{\rm syst}) \times 10^{-4} \quad (76.43)$$

The corresponding value of $|V_{ub}|$ with this approach is found to

be

$$|V_{ub}| = (3.70 \pm 0.10 \pm 0.12\,) \times 10^{-3} \quad \text{(exclusive)}, \tag{76.44}$$

where the first uncertainty is experimental and the second is from theory. A consistent result for $|V_{ub}|$ was reported in Ref. [36], which uses the same experimental and lattice-QCD inputs. Adding additional constraints using input from LCSR [222] gives [6] $|V_{ub}| = (3.67 \pm 0.09 \pm 0.12\,) \times 10^{-3}$ (exclusive, LQCD+LCSR). Other recent LCSR estimates [225, 232] have been used to obtain consistent results for $|V_{ub}|$, albeit with slightly higher central values. Ref. [232] also presents results for $|V_{ub}|$ from joint fits that exclude some of the experimental data in order to bring the exclusive values into agreement with the inclusive ones.

76.3.7 $\bar{B}_s \to K\ell\bar{\nu}_\ell$

The LHCb experiment have conducted the first observation of the decay $B_s^0 \to K^-\mu^+\nu_\mu$ and the measurements of its branching fraction normalised to the $B_s^0 \to D_s^-\mu^+\nu_\mu$ decays [233]. The measurement has been performed in two bins of q^2, derived using the B_s^0 flight direction and the known B_s^0 mass. The analysis uses a BDT classifier to suppress semileptonic b-hadron background. The results of the partial branching fractions have been translated into measurements of $|V_{ub}|/|V_{cb}|$ using form factor calculations from LCSR for $q^2 < 7$ GeV^2 [234], and a recent LQCD calculation for $q^2 > 7$ GeV^2 [207]. The results are

$$|V_{ub}|/|V_{cb}| = 0.0607 \pm 0.0021 \pm 0.0030,\ q^2 < 7\ \text{GeV}^2 \tag{76.45}$$
$$|V_{ub}|/|V_{cb}| = 0.0946 \pm 0.0041 \pm 0.0068,\ q^2 > 7\ \text{GeV}^2 \tag{76.46}$$

where the first uncertainties include also experimental and external input sources, and the latter are due to the form factor calculations. The sizeable discrepancy between the values of $|V_{ub}|/|V_{cb}|$ for the low and high q^2, requires further theoretical and experimental investigation. On the theory side, FLAG [36] perform a joint z-fit to the lattice QCD results in Refs. [207–209], with error inflation to account for the tensions between lattice results for f_0. They then use the form factors for $\bar{B}_s \to K\ell\bar{\nu}_\ell$ and $\bar{B}_s \to D_s^*\ell\bar{\nu}_\ell$ to determine the ratio $|V_{ub}|/|V_{cb}|$ in combination with the LHCb measurements in the high- and low-q^2 regions, finding good agreement between the two:

$$|V_{ub}|/|V_{cb}| = 0.0819 \pm 0.0029 \pm 0.0072,\ q^2 < 7\ \text{GeV}^2 \tag{76.47}$$
$$|V_{ub}|/|V_{cb}| = 0.0860 \pm 0.0038 \pm 0.0037,\ q^2 > 7\ \text{GeV}^2 \tag{76.48}$$

While the experimental measurement has higher purity in the low q^2 region, the lattice QCD form factors are constrained more reliably in high-q^2 region. RBC/UKQCD recently presented in Ref. [210] an update of their previous calculation. They studied the effect of different strategies for obtaining the form factors $f_{+,0}$ in the continuum limit, finding sizeable differences for f_0, but not f_+. This issue needs to be studied further. In particular, such differences were not seen in a similar study, albeit for D-meson decay form factors [235]. However, the resulting effect on $|V_{ub}|/|V_{cb}|$ is relatively small, as the f_0 form factor enters the determination only via the kinematic constraint at $q^2 = 0$. A very recent analysis in Ref. [236] combines the lattice QCD form factors from Refs. [208, 210] with the LHCb data in $|V_{ub}|/|V_{cb}|$ determinations that are compatible with Eq. (76.48). When they combine their updated LCSR results with the low-q^2 LHCb data, they find $|V_{ub}|/|V_{cb}| = 0.057 \pm 0.005$, compatible with Eq. (76.45), and hence also in tension with Eq. (76.48). Experimental measurements of the differential rates in smaller bins would provide valuable shape constraints and additional compatibility tests, improving the reliability of the $|V_{ub}|/|V_{cb}|$ determinations by reducing the need for extrapolations of form factors.

76.4 Semileptonic b-baryon decays

Summary: A significant sample of Λ_b^0 baryons is available at the LHCb experiment, and methods have been developed to study their semileptonic decays. Both $\Lambda_b^0 \to p\mu\bar{\nu}$ and $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ decays have been measured at LHCb, and the ratio of branching fractions to these two decay modes is used to determine the ratio $|V_{ub}/V_{cb}|$.

76.4.1 $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ and $\Lambda_b^0 \to p\mu\bar{\nu}$

The $\Lambda_b^0 \to \Lambda_c^+$ and $\Lambda_b^0 \to p$ semileptonic transitions are described in terms of six form factors each. The three form factors corresponding to the vector current can be defined as [237]

$$\begin{aligned}\langle F(p',s')|\bar{q}\,\gamma_\mu\,b|\Lambda_b^0(p,s)\rangle = \bar{u}_F(p',s')\Bigg\{ & f_0(q^2)\,(M_{\Lambda_b^0} - m_F)\,\frac{q_\mu}{q^2} \\ & + f_+(q^2)\,\frac{M_{\Lambda_b^0} + m_F}{s_+}\left(p_\mu + p'_\mu - \frac{q_\mu}{q^2}\,(M_{\Lambda_b^0}^2 - m_F^2)\right) \\ & + f_\perp(q^2)\left(\gamma_\mu - \frac{2m_F}{s_+}\,p_\mu - \frac{2M_{\Lambda_b^0}}{s_+}\,p'_\mu\right)\Bigg\}\,u_{\Lambda_b^0}(p,s)\,,\end{aligned} \tag{76.49}$$

where $F = p$ or Λ_c^+ and where we define $s_\pm = (M_{\Lambda_b^0} \pm m_F)^2 - q^2$. At vanishing momentum transfer, $q^2 \to 0$, the kinematic constraint $f_0(0) = f_+(0)$ holds. The form factors are defined in such a way that they correspond to time-like (scalar), longitudinal and transverse polarization with respect to the momentum-transfer q^μ for f_0, f_+ and $f_\perp$, respectively. Likewise, the expression for the axial-vector current is

$$\begin{aligned}\langle F(p',s')|\bar{q}\,\gamma_\mu\gamma_5\,b|\Lambda_b^0(p,s)\rangle = & \\ & - \bar{u}_F(p',s')\gamma_5\Bigg\{ g_0(q^2)\,(M_{\Lambda_b^0} + m_F)\,\frac{q_\mu}{q^2} \\ & + g_+(q^2)\,\frac{M_{\Lambda_b^0} - m_F}{s_-}\left(p_\mu + p'_\mu - \frac{q_\mu}{q^2}\,(M_{\Lambda_b^0}^2 - m_F^2)\right) \\ & + g_\perp(q^2)\left(\gamma_\mu + \frac{2m_F}{s_-}\,p_\mu - \frac{2M_{\Lambda_b^0}}{s_-}\,p'_\mu\right)\Bigg\}\,u_{\Lambda_b^0}(p,s)\,,\end{aligned} \tag{76.50}$$

with the kinematic constraint $g_0(0) = g_+(0)$ at $q^2 \to 0$.

In the heavy-quark limit, where both the b and c quarks are treated as heavy, all the form factors reduce to the Isgur Wise function ξ_B for baryons [237]:

$$f_0 = f_+ = f_\perp = g_0 = g_+ = g_\perp = \xi_B \tag{76.51}$$

With a light baryon in the final state, the form factors are related through the heavy quark symmetries of the Λ_b^0, reducing the the number of independent form factors to two. It should be noted that the differential $\Lambda_b^0 \to (p/\Lambda_c^+)\mu\bar{\nu}$ decay rates peak at high q^2, so that the kinematic regions where both lattice QCD calculations and experimental measurements are precise are well matched.

The form factors for Λ_b^0 decays have been studied with lattice QCD [238]. Based on these results the differential rates for both $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ as well as for $\Lambda_b^0 \to p\mu\bar{\nu}$ can be predicted in the full phase space. In particular, for the experimentally interesting region they find the ratio of decay rates to be [238]

$$\frac{\mathcal{B}(\Lambda_b^0 \to p\mu\bar{\nu})_{q^2>15\,\text{GeV}^2}}{\mathcal{B}(\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu})_{q^2>7\,\text{GeV}^2}} = (1.471 \pm 0.095 \pm 0.109)\left|\frac{V_{ub}}{V_{cb}}\right|^2 \tag{76.52}$$

where the first uncertainty is statistical and the second, systematic.

76.4.2 *Measurements at LHCb*

The LHCb experiment has measured the branching fractions of the semileptonic decays $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ and $\Lambda_b^0 \to p\mu\bar{\nu}$, from which they determine $|V_{ub}|/|V_{cb}|$. This is the first such determination at a hadron collider, the first to use a b baryon decay, and the first observation of $\Lambda_b^0 \to p\mu\bar{\nu}$. Excellent vertex resolution allows the $p\mu$ and production vertices to be separated, which permits the calculation of the transverse momentum $p_\perp$ of the $p\mu$ pair relative to the Λ_b^0 flight direction. The corrected mass, $m_{\text{corr}} = \sqrt{p_\perp^2 + m_{p\mu}^2} + p_\perp$, peaks at the Λ_b^0 mass for signal decays and provides good discrimination against background combinations. The topologically similar decay $\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu}$ is also measured, which eliminates the need to know the production cross-section or absolute efficiencies. Using vertex and Λ_b^0 mass constraints,

q^2 can be determined up to a two-fold ambiguity. The LHCb analysis requires both solutions to be in the high q^2 region to minimise contamination from the low q^2 region. Their result [239], rescaled [6] to take into account the recent branching fraction measurement [240] $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+) = (6.28 \pm 0.32)\%$, is

$$\frac{\mathcal{B}(\Lambda_b^0 \to p\mu\bar{\nu})_{q^2>15\mathrm{GeV}^2}}{\mathcal{B}(\Lambda_b^0 \to \Lambda_c^+\mu\bar{\nu})_{q^2>7\mathrm{GeV}^2}} = (0.92 \pm 0.04 \pm 0.07) \times 10^{-2} \quad . \tag{76.53}$$

The largest systematic uncertainty is from the measured $\mathcal{B}(\Lambda_c^+ \to pK^-\pi^+)$; uncertainties due to trigger, tracking and the Λ_c^+ selection efficiency are each about 3%.

A LHCb analysis [241] measures the normalized q^2 spectrum and finds good agreement with the shape calculated with lattice QCD [238].

The decay rate for $\Lambda_b^0 \to p\mu\bar{\nu}$ peaks at high q^2 where the calculation of the associated form factors using lattice QCD is under good control. Using the measured ratio from Eq. (76.53) along with the calculated ratio from Ref. [238] (see Eq. (76.52)) results in [6]

$$|V_{ub}|/|V_{cb}| = 0.079 \pm 0.004 \pm 0.004(\Lambda_b). \tag{76.54}$$

where the first uncertainty is experimental and the second is from the LQCD calculation.

76.5 The ratio $|V_{ub}|/|V_{cb}|$

The ratio of matrix elements, $|V_{ub}|/|V_{cb}|$, is often required when testing the compatibility of a set of measurements with theoretical predictions. It can be determined from the ratio of branching fractions and has been directly measured by the LHCb (quoted in the previous sections) and Belle experiments. It can also be calculated based on the $|V_{ub}|$ and $|V_{cb}|$ values quoted earlier in this review.

The average of the LHCb results extracted at high q^2 from B_s and Λ_b decays, taken to be uncorrelated, is

$$|V_{ub}|/|V_{cb}| = 0.083 \pm 0.004 \quad (\Lambda_b,\ B_s). \tag{76.55}$$

The first direct extraction of this ratio from inclusive B decays was recently performed by Belle [176]. Belle measures the ratio of $\bar{B} \to X_u\ell\bar{\nu}_\ell$ and $\bar{B} \to X_c\ell\bar{\nu}_\ell$ branching fractions with a lepton energy threshold of 1.0 GeV. The partial decay widths, omitting the CKM factors, are taken from BLNP and GGOU for $|V_{ub}|$ and the kinetic scheme for $|V_{cb}|$ to extract the ratio of CKM factors. The results are found to be

$$|V_{ub}|/|V_{cb}| = 0.097 \pm 0.008 \quad (\mathrm{BLNP}), \tag{76.56}$$
$$|V_{ub}|/|V_{cb}| = 0.100 \pm 0.006 \quad (\mathrm{GGOU}). \tag{76.57}$$

These values are in excellent agreement with $|V_{ub}|/|V_{cb}|$ from independent inclusive determinations, given below, but involve non-zero correlations in both the theoretical and experimental uncertainties. We will therefore leave it out of the combination for this edition.

Given the similarities in the theoretical frameworks used for charmed and charmless decays, we choose to also quote separate ratios of $|V_{ub}|/|V_{cb}|$ for inclusive and exclusive B decays, as discussed earlier:

$$|V_{ub}|/|V_{cb}| = 0.098 \pm 0.006 \quad (\mathrm{inclusive}), \tag{76.58}$$
$$|V_{ub}|/|V_{cb}| = 0.093 \pm 0.004 \quad (\mathrm{exclusive}). \tag{76.59}$$

The respective determinations of $|V_{ub}|$ and $|V_{cb}|$ are taken to be uncorrelated in the ratio, although there could be some small cancellations of the uncertainties in both the experimental and the theoretical input. We average the B decay values, along with the B_s and baryonic result in Eq. (76.55), weighting by relative errors to find

$$|V_{ub}|/|V_{cb}| = 0.089 \pm 0.005 \quad (\mathrm{average}). \tag{76.60}$$

where the uncertainty has been scaled by a factor $\sqrt{\chi^2/2} = 1.6$.

76.6 Lepton flavour universality violation

76.6.1 *Semitauonic decays*

Summary: Semileptonic decays to third-generation leptons provide sensitivity to non-Standard Model amplitudes, such as from a charged Higgs boson [242–245] and from leptoquarks [246–252]. The ratios of branching fractions of semileptonic decays involving tau leptons to those involving $\ell = e/\mu$, $R(D^{(*)}) \equiv \mathcal{B}(\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau)/\mathcal{B}(\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell)$, are predicted with good precision and consistency in the Standard Model [7–11, 27, 28, 30, 47, 48], using a variety of different strategies. Because this ratio is independent of $|V_{cb}|$, it can, in principle, be computed entirely from within the Standard Model, without using experimental decay rate data. For example, in Refs. [7, 9] the lattice-QCD only ratios are obtained as:

$$R(D)^{\mathrm{LQCD,FNAL-MILC}} = 0.284 \pm 0.014 \ ,$$
$$R(D^*)^{\mathrm{LQCD,FNAL-MILC}} = 0.265 \pm 0.013 \ . \tag{76.61}$$

Without constraints from experimental data at large recoil, such SM-theory only evaluations tend to be less precise than those obtained from joint fits that employ experimental data as well as Standard-Model theory inputs (lattice-QCD form factors, HQET constraints, etc.). Other recent lattice-QCD only results are found in Refs. [10, 11]. Here we use an average of Refs. [27, 28, 47, 48, 253] for $R(D)$ and Refs. [27, 28, 30, 63, 253] for $R(D^*)$.

$$R(D)^{\mathrm{SM+Exp}} = 0.298 \pm 0.004 \ ,$$
$$R(D^*)^{\mathrm{LQCD+Exp}} = 0.254 \pm 0.005 \ . \tag{76.62}$$

These use various combinations of experimental data, lattice-QCD form factor inputs, HQET constraints, and LCSR estimates and are consistent with the values quoted above.

Measurements [254–261], of these ratios yield higher values; averaging B-tagged measurements of $R(D)$ and $R(D^*)$ at the $\Upsilon(4S)$ and at LHCb yields [6]

$$R(D)^{\mathrm{meas}} = 0.357 \pm 0.029 \ ,$$
$$R(D^*)^{\mathrm{meas}} = 0.284 \pm 0.012 \ , \tag{76.63}$$

with a linear correlation of -0.37. These values exceed the Standard Model predictions of Eq. (76.62) by 2.0σ and 2.2σ, respectively. A variety of new physics models have been proposed to explain this excess, see eg. Refs. [242–249] as well as reviews in Refs. [262–264].

76.6.2 *Sensitivity of $\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau$ to additional amplitudes*

In addition to the helicity amplitudes present for decays to $e\bar{\nu}_e$ and $\mu\bar{\nu}_\mu$, decays proceeding through $\tau\bar{\nu}_\tau$ include a scalar amplitude H_s. The differential decay rate is given by [266]

$$\frac{d\Gamma}{dq^2} = \frac{G_F^2\,|V_{cb}|^2\,|\mathbf{p}^*_{D^{(*)}}|q^2}{96\pi^3 m_B^2}\left(1-\frac{m_\tau^2}{q^2}\right)^2 \left[(|H_+|^2+|H_-|^2+|H_0|^2)\left(1+\frac{m_\tau^2}{2q^2}\right)+\frac{3m_\tau^2}{2q^2}|H_s|^2\right], \tag{76.64}$$

where $|\mathbf{p}^*_{D^{(*)}}|$ is the 3-momentum of the $D^{(*)}$ in the $\bar{B}$ rest frame and the helicity amplitudes H depend on the four-momentum transfer q^2. All four helicity amplitudes contribute to $\bar{B} \to D^*\tau\bar{\nu}_\tau$, while only H_0 and H_s contribute to $\bar{B} \to D\tau\bar{\nu}_\tau$; as a result, new physics contributions can produce larger effects in the latter mode. Semi-leptonic B decays into a τ lepton provide a stringent test of the two-Higgs doublet model of type II (2HDMII), i.e. where the two Higgs doublets couple separately to up- and down-type quarks. The distinct feature of the 2HDMII is that the contributions of the charged scalars scale as $m_\tau^2/m_{H^+}^2$, since the couplings to the charged Higgs particles are proportional to the mass of the lepton. As a consequence, one may expect visible effects in decays into a τ, but only small effects for decays into e and μ. The present data disfavors the 2HDMII, see below.

Table 76.3: Measurements of $R(D)$ and $R(D^*)$, their correlations, ρ, and the combined averages [6].

		$R(D) \times 10^2$	$R(D^*) \times 10^2$	ρ
BABAR [254, 255]	B^0, B^+	$44.0 \pm 5.8 \pm 4.2$	$33.2 \pm 2.4 \pm 1.8$	-0.27
Belle [256]	B^0, B^+	$37.5 \pm 6.4 \pm 2.6$	$29.3 \pm 3.8 \pm 1.5$	-0.49
Belle [257, 265]	B^0, B^+		$27.0 \pm 3.5 \,^{+\,2.8}_{-\,2.5}$	
Belle [258]	B^0, B^+	$30.7 \pm 3.7 \pm 1.6$	$28.3 \pm 1.8 \pm 1.4$	-0.51
LHCb [261]	B^+ ($R(D)$), B^0	$44.1 \pm 6.0 \pm 6.6$	$28.1 \pm 1.8 \pm 2.4$	-0.43
LHCb [260]	B^0		$25.7 \pm 1.2 \pm 1.8$	
Belle II [259]	B^0, B^+		$26.2^{+4.1+3.5}_{-3.9-3.2}$	
Average	B^0, B^+	35.7 ± 2.9	28.4 ± 1.2	-0.40

76.6.3 *Measurement of $R(D^{(*)})$*

$\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau$ decays have been studied at the $\Upsilon(4S)$ resonance and in pp collisions. At the $\Upsilon(4S)$, the majority of experimental measurements are based on signatures that consist of a D or D^* meson, an electron or muon (denoted here by ℓ) from the decay $\tau \to \ell\nu_\tau\bar{\nu}_\ell$, a fully-reconstructed decay of the second B meson in the event, and multiple missing neutrinos. One analysis reconstructs the τ in a hadronic mode. The analyses that use hadronic B tags separate signal decays from $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decays using the lepton momentum and the measured missing mass squared; decays with only a single missing neutrino peak sharply at zero in this variable, while the signal is spread out to positive values. When a semileptonic B tag is used, the discrimination between signal and $\bar{B} \to D^{(*)}\ell\bar{\nu}_\ell$ decays comes from the calorimeter energy that is not associated with any particle used in the reconstruction of the B meson candidates, the measured missing mass squared and the cosine of the angle between the $D^*\ell$ system and its parent B meson, which is calculated under the assumption that only one particle (a neutrino) is missing. In both these approaches, background from $\bar{B} \to D^{**}\ell\bar{\nu}_\ell$ decays with one or more unreconstructed particles is challenging to separate from signal, as is background from $\bar{B} \to D^{(*)}H_{\bar{c}}X$ (where $H_{\bar{c}}$ is a hadron containing a $\bar{c}$ quark) decays. The leading sources of systematic uncertainty are due to the limited size of simulation samples used in constructing the PDFs, the composition of the D^{**} states, efficiency corrections, and cross-feed (swapping soft particles between the signal and tag B).

The most precise measurement from Belle [258] uses semileptonic B tags and leptonic τ decays to simultaneously measure $R(D^*)$ and $R(D)$. The measurement combines results from charged and neutral B decays for both $R(D^*)$ and $R(D)$, and is compatible with the Standard Model expectation to approximately 1σ. The first result from Belle II [259] uses a hadronic tag to measure $R(D^*)$ in $\bar{B} \to D^*\tau^-\bar{\nu}_\tau$ decays with a 189 fb^{-1} dataset. The statistical power of the Belle II dataset has been found to outperform that of Belle in this channel.

In addition to the ratio measurements, the Belle experiment has performed polarization measurements of the τ [257] and D^* [267] respectively. The τ polarization measurement uses hadronic B tags and τ^- decays to $\pi^-\nu_\tau$ or $\rho^-\nu_\tau$. The main discriminant variables are the measured missing mass squared and the unassociated calorimeter energy. This measurement provides the first determination of the τ polarization in the $\bar{B} \to D^*\tau\bar{\nu}_\tau$ decay, $\mathcal{P}_\tau(D^*) = -0.38 \pm 0.51\,^{+0.21}_{-0.16}$, compatible with the Standard Model expectation [30], $\mathcal{P}_\tau(D^*) = -0.476^{+0.037}_{-0.034}$.

The main uncertainties on the $R(D^*)$ measurement come from the composition of the hadronic B background and from modeling of semileptonic B decays and mis-reconstructed D^* mesons. The D^* polarization measurement uses an inclusive tag approach based on Refs. [268, 269], and reconstructs the τ decays in $\ell\nu_\tau\bar{\nu}_\ell$ and $\pi^+\bar{\nu}_\tau$ channels. The main discriminant variables are $X_{\rm miss}$, a quantity that approximates missing mass but does not depend on tag B reconstruction, the visible energy of the event, and the beam-energy constrained mass, $M_{\rm bc}$, of the inclusively reconstructed tag side B. This measurement provides the first determination of the D^* longitudinal polarization fraction in the $\bar{B} \to D^*\tau\bar{\nu}_\tau$ decay, $\mathcal{F}_L(D^*) = -0.38 \pm 0.60\,^{+0.08}_{-0.04}$, compatible with the Standard Model expectation [270] within 1.7σ.

The LHCb experiment has performed a simultaneous analysis of $R(D^*)$ and $R(D)$ where $\tau \to \mu\nu_\tau\bar{\nu}_\mu$. The reconstructed decay modes are $\bar{B}^0 \to D^{*+}\tau^-\bar{\nu}_\tau$ with $D^{*+} \to D^0\pi^+$, $B^- \to D^{*0}\tau^-\bar{\nu}_\tau$ with $D^{*0} \to D^0\pi^0$ and $D^{*0} \to D^0\pi^0$, and $B^- \to D^0\tau^-\bar{\nu}_\tau$. Their analysis [261] takes advantage of the measurable flight lengths of b and c hadrons and τ leptons. A multivariate discriminant is used to select decays where no additional charged particles are consistent with coming from the signal decay vertices. The separation between the primary and B decay vertices is used to calculate the momentum of the B decay products transverse to the B flight direction. The longitudinal component of the B momentum can be estimated based on the visible decay products; this allows a determination of the B rest frame, with modest resolution, and enables the calculation of similar discrimination variables to those available at the e^+e^- B factories. The (rest frame) muon energy, missing mass-squared and q^2 are used in a 3-d fit.

A complementary LHCb result [260] on $R(D^*)$ uses three-prong τ decays that take advantage of their excellent vertex resolution to isolate the τ decay from hadronic background. A 3-d fit is performed to determine the signal yield, based on the τ-ν_τ pair q^2, the τ lifetime, as well as a boosted decision tree classifier based on isolation, invariant mass and flight distance information. The leading sources of systematic uncertainty are due to the size of the simulation sample used in constructing the fit templates, uncertainties in modelling the background from hadronic $\bar{B} \to D^{(*)}H_{\bar{c}}X$ decays, as well as reconstruction and trigger effects. The result is normalized to $B^0 \to D^{*-}\pi^+\pi^-\pi^+$ and found to be 1σ from the Standard Model expectation (using the expectation value quoted here). An analogous measurement of $B_c \to J/\psi\tau\bar{\nu}_\tau$ was performed by the LHCb measurement [271], in leptonic τ decays. The result, $R(J/\psi) = 0.71 \pm 0.17 \pm 0.18$, while relatively high is compatible to within 2σ of a recent Standard Model evaluation [272] based on a latttice-QCD calculation [273] of the form factors. Systematic uncertainties are dominated by form factors, as B_c decays are relatively unexplored.

Measurements from BABAR [254, 255], Belle [256–258], Belle II [259] and LHCb [260, 261] result in values for $R(D)$ and $R(D^*)$ that exceed Standard Model predictions. Table 76.3 lists these values and their average. The simultaneous measurements of $R(D)$ and $R(D^*)$ have linear correlation coefficients of -0.27 (BABAR [254, 255]), -0.49 (Belle hadronic tag [256]), -0.51 (Belle semileptonic tag [258]), and 0.43 (LHCb $\tau^- \to \mu^-\nu_\tau\bar{\nu}_\mu$); the $R(D)$ and $R(D^*)$ averages have a correlation of -0.40. Two early untagged Belle measurements [268, 269] are subject to larger systematic uncertainties, with a breakdown of the respective contributions that is inconsistent with the more recent determinations, hence they cannot be reliably combined in the average. All three experiments assume the Standard Model kinematic distributions for $\bar{B} \to D^{(*)}\tau\bar{\nu}_\tau$ in their determinations of the branching fraction ratios.

The measurement combination in the $R(D) - R(D^*)$ plane is shown in Fig. 76.2, compared with the predictions in Eq. (76.61) (LQCD) and Eq. (76.62) (Experiment+LQCD+HQET). The measurement combination is based on Ref. [6] and online updates with the inclusion of recent results from LHCb and Belle II. The tension between the Standard Model prediction in Eq. (76.62) and the measurements is at the level of 2.0σ ($R(D)$) and 2.2σ ($R(D^*)$); if one considers these deviations together the significance is 3.3σ. This motivates speculation on possible new physics contributions.

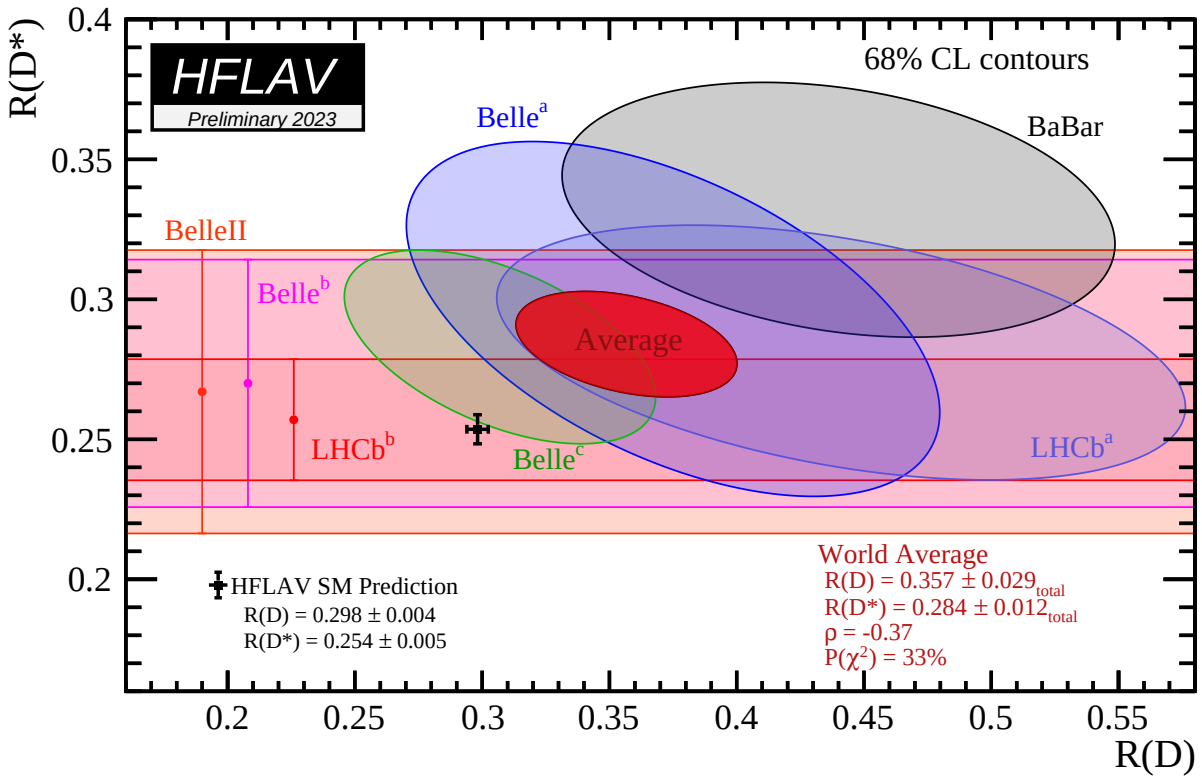

Figure 76.2: Measurements of $R(D)$ and $R(D^*)$ and their two-dimensional average compared with the average predictions for $R(D)$ and $R(D^*)$ given in Eq. 76.62. Contours correspond to 68% CL. The experiment-lattice QCD-HQET predictions and the experimental average deviate from each other by 3.3σ.

The measurements reported in Refs. [259, 260, 265] are all in reasonable agreement with the Standard-Model predictions. There is some tension in the combination coming from the BABAR measurement and the most recent LHCb measurement [261]. The BABAR measurement is the only one to claim a deviation from the Standard Model of more than 3σ, although the $p-$value of the full combination is an acceptable 33%.

The current discussion of $R(D)$ and $R(D^*)$ may be embedded in the theoretical analysis of the other anomalies that have been observed in semileptonic FCNC ($b \to s\ell\ell$) transitions. More sophisticated approaches fit the data to a general effective Hamiltonian. Matching this effective Hamiltonian to simplified models, the current situation of the anomalies seems to be compatible with scenarios with an additional Z' or a leptoquark scenario, see eg. [246–252].

76.6.4 *Measurements of* $R(X)$

We note that in addition to exclusive modes, inclusive modes also offer an opportunity to test the presence of non-Standard Model contributions, although typically with lower precision. The first measurement of $R(X)$ from a B-factory was recently performed by Belle II [274], $R(X) = 0.228 \pm 0.039$, and found to be compatible with an average of Standard Model predictions $R(X) = 0.223 \pm 0.005$ [275–277]. Prior measurements of the branching fractions of $b \to X\tau\nu$ were performed by LEP experiments and also found to be compatible with Standard Model predictions.

76.6.5 *Ratios of semileptonic decay rates with* e *to* μ *final states*

Several tests of lepton flavor universality in semileptonic B decays have recently been undertaken at Belle and Belle II. This includes ratios of rates to electron and muon modes (i.e. $R(e/\mu)$) performed as part of CKM matrix element extraction analyses (Table 76.4), as well as dedicated flavour dependent angular analyses [278]. Refs. [62, 64, 65] provide measurements of LFUV in $\bar{B} \to D^*\ell\bar{\nu}$ decays at Belle (untagged, and hadron tagged) and Belle II (hadron tagged). The corresponding theoretical prediction is $\mathcal{B}(B \to D^*e\nu)/\mathcal{B}(B \to D^*\mu\nu) = 1.0041 \pm 0.0001$ [33]. Refs. [176, 279] provide measurements of LFUV in $B \to X_c\ell\bar{\nu}$ in hadron tagged events at Belle and Belle II, where the theoretical expectation is $\mathcal{B}(B \to X_c e\nu)/\mathcal{B}(B \to X_c\mu\nu) = 1.006 \pm 0.001$ [276]. Finally, Ref. [173] provides a result for LFUV in $B \to X_u\ell\nu$ decays where the ratio is expected to be close to 1, as in the $B \to X_c\ell\nu$ case. With the exception of the charmless decay measurement, the experimental uncertainties are dominated by lepton identification uncertainties that do not cancel in the ratios. All results are found to be highly compatible with SM expectations.

Table 76.4: Measurements of $R(e/\mu) = \mathcal{B}(B \to Xe\nu)/\mathcal{B}(B \to X\mu\nu)$ where the specific decay process is listed.

Ref.	Decay	$R(e/\mu) \times 100$
Belle [64]	$\bar{B} \to D^*\ell\bar{\nu}$	$99.2 \pm 2.3 \pm 2.3$
Belle [62]	$B^0 \to D^{*+}\ell\nu$	$101 \pm 1 \pm 3$
Belle II [65]	$B^0 \to D^{*+}\ell\nu$	$99.8 \pm 0.9 \pm 2.0$
Belle II [279]	$B \to X_c\ell\nu$	$100.7 \pm 0.9 \pm 1.9$
Belle [176]	$B \to X_c\ell\nu$	$100.3 \pm 0.5 \pm 2.4$
Belle [173]	$B \to X_u\ell\nu$	$97 \pm 9 \pm 4$

76.7 Conclusion

The study of semileptonic B meson decays continues to be an active area for both theory and experiment. The application of HQE calculations to inclusive decays is well established, and fits to moments of $\bar{B} \to X_c\ell\bar{\nu}_\ell$ decays provide precise values for $|V_{cb}|$ and, in conjunction with input on m_c or from $B \to X_s\gamma$ decays, provide precise and consistent values for m_b. Recent developments

will make use of more types of moments and better theoretical inputs to constrain higher order effects. Further into the future, new nonperturbative methods to compute inclusive decay rates, for example, in lattice QCD [280–282], may provide interesting new insights.

The determination of $|V_{ub}|$ from inclusive $\bar{B} \to X_u \ell \bar{\nu}_\ell$ decays is based on multiple calculational approaches and independent measurements over a variety of kinematic regions, all of which provide consistent results. Further progress in this area is possible, but will require better theoretical control over higher-order terms, improved experimental knowledge of the $\bar{B} \to X_c \ell \bar{\nu}_\ell$ background and improvements to the modeling of the $\bar{B} \to X_u \ell \bar{\nu}_\ell$ signal distributions.

In both $b \to u$ and $b \to c$ exclusive channels there has been significant recent progress in lattice-QCD calculations, resulting in improved precision on both $|V_{ub}|$ and $|V_{cb}|$. These calculations now provide information on the form factors well away from the high q^2 region, allowing better use of experimental data. For $|V_{cb}|$ recent measurements have provided binned data enabling model-independent fits.

The values from the inclusive and exclusive determinations of $|V_{cb}|$ and $|V_{ub}|$ are only marginally consistent. This is a long-standing puzzle that the recent improvements have, unfortunately, not yet resolved.

Both $|V_{cb}|$ and $|V_{ub}|$ are indispensable inputs into unitarity triangle fits. In particular, knowing $|V_{ub}|$ with good precision allows a test of CKM unitarity in a most direct way, by comparing the length of the $|V_{ub}|$ side of the unitarity triangle with the measurement of $\sin(2\beta)$. This comparison of a "tree" process ($b \to u$) with a "loop-induced" process ($B^0 - \bar{B}^0$ mixing) provides sensitivity to possible contributions from new physics.

The observation of semileptonic decays into τ leptons has opened a new window to the physics of the third generation. The measurements indicate a tension between the data and Standard-Model predictions, which could be a hint for new physics, manifesting itself as a violation of lepton universality beyond the Standard-Model couplings to the Higgs. It should be noted that none of the most recent measurements alone claim discovery of a deviation from the Standard Model. Combining the data of the semitauonic decays with the anomalies observed in the FCNC $b \to s\ell\ell$ transitions allows an interpretation in terms of additional Z' or in terms of additional leptoquarks, but the current data does not allow us to draw a definite conclusion.

Acknowledgements

We thank J. Flynn, E. Kou, C. Schwanda, and K. Vos for useful discussions and comments on this review, and A. Vaquero for creating Fig. 76.1. Previous assistance from D. Ferlewicz, P. Gambino, S. Hashimoto, Z. Ligeti, and M. Rotondo is also acknowledged.

77. Determination of CKM angles from B hadrons

Revised February 2024 by T. Gershon (Warwick U.), M. Kenzie (Cambridge U.) and K. Trabelsi (U. Paris-Saclay, IJCLab).

77.1 Introduction

The Cabibbo–Kobayashi–Maskawa (CKM) description of quark mixing [1,2] leads to a number of triangle relations between pairs of CKM matrix elements. One of these,

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0 \,, \tag{77.1}$$

is of particular interest since (i) all its terms are of comparable magnitude, and (ii) its properties can be measured through studies of oscillations and decays of B mesons. As the area of this unitary triangle is a measure of the amount of CP violation in the Standard Model [3], it is of particular interest to determine the values of its angles and to test the consistency of the CKM paradigm with the experimental measurements. The angles are defined as

$$\begin{aligned} \alpha &= \arg\left[-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right] \,, \qquad \beta = \arg\left[-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right] \,, \\ \gamma &= \arg\left[-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right] \,, \end{aligned} \tag{77.2}$$

with an alternative notation $(\phi_2, \phi_1, \phi_3) \equiv (\alpha, \beta, \gamma)$ also widely used in the literature.

In this mini-review, the most precise methods to determine the CKM angles are described, with a particular focus on nontrivial aspects of the combination of results. More detailed discussions of these points can be found in Ref. [4]. A similar mini-review on the side of the unitarity triangle adjacent to the angle γ can be found in Ref. [5]. A detailed overview of the CKM quark-mixing matrix is given in Ref. [6] while CP violation in the quark sector is discussed in Ref. [7].

77.2 β

The relative weak (*i.e.* CP-violating) phase between the amplitude for any CKM-favoured B^0 meson decay to a CP eigenstate and that for the decay following B^0–$\overline{B}^0$ oscillation is twice the angle β. The decay-time-dependent CP asymmetry can be expressed as

$$\mathcal{A}_{f_{CP}}(t) \equiv \frac{d\Gamma/dt\left[\overline{B}^0_{\rm phys}(t) \to f_{CP}\right] - d\Gamma/dt\left[B^0_{\rm phys}(t) \to f_{CP}\right]}{d\Gamma/dt\left[\overline{B}^0_{\rm phys}(t) \to f_{CP}\right] + d\Gamma/dt\left[B^0_{\rm phys}(t) \to f_{CP}\right]} \,, \tag{77.3a}$$

$$= S_f \sin(\Delta m t) - C_f \cos(\Delta m t) \,, \tag{77.3b}$$

where the notation $B^0_{\rm phys}(t)$ ($\overline{B}^0_{\rm phys}(t)$) denotes a neutral B meson that decays at time t into the final state f_{CP}, and is known ("tagged") at time $t = 0$ to have flavour content corresponding to B^0 ($\overline{B}^0$). In Eq. (77.3b), Δm denotes the mass difference between the two physical eigenstates of the B^0–$\overline{B}^0$ system, while the corresponding decay-width difference is assumed to be negligible [8]; moreover CPT symmetry and the absence of CP violation in B^0–$\overline{B}^0$ mixing is assumed throughout this mini-review.

In the general case, one can write

$$S_f \equiv \frac{2\mathcal{I}m(\lambda_f)}{1+\left|\lambda_f\right|^2} \qquad \text{and} \qquad C_f \equiv \frac{1-\left|\lambda_f\right|^2}{1+\left|\lambda_f\right|^2} \,, \tag{77.4}$$

where the parameter $\lambda_f = \frac{q}{p}\frac{\overline{A}_f}{A_f}$ is defined in terms of p and q, which define the flavour content of the mass eigenstates of the B^0–$\overline{B}^0$ system [8], and the amplitudes $\overline{A}_f$ (A_f) for a $\overline{B}^0$ (B^0) decay to the final state f_{CP}. In the limit that the decay amplitude is dominated by a CKM-favoured transition, as is the case for $B^0 \to J/\psi K^0_{\rm S}$ decays, one obtains simple relations: $S_f = -\eta_{CP}\sin(2\beta)$ and $C_f = 0$, where η_{CP} is the CP eigenvalue of the final state [9,10]. This method has been pursued intensively by experiments. The current world averages, combining results for several charmonium-kaon final states but dominated by results on $B^0 \to J/\psi K^0_{\rm S}$ (CP odd) and $B^0 \to J/\psi K^0_{\rm L}$ (CP even), are [4]

$$-\eta_{CP}S_f = 0.709 \pm 0.011 \,, \qquad C_f = +0.004 \pm 0.010 \,. \tag{77.5}$$

Despite the large number of signal events in the data, the dominant uncertainties are still statistical. One important source of potential systematic correlation between results from different experiments is that due to "tag-side interference" [11],2 which is common to measurements exploiting production through the $e^+e^- \to \Upsilon(4S) \to B^0\overline{B}^0$ process, including the latest results from BaBar [12] and Belle [13]. It does not, however, affect the results from LHCb [14] that now have better statistical sensitivity. Another common source of systematic uncertainty is due to knowledge of the value of Δm, but since this quantity has been measured precisely [8] the effect remains small.

The interpretation of the value of $-\eta_{CP}S_f$ from Eq. (77.5) as $\sin(2\beta)$ assumes negligible contributions from subleading amplitudes with a different weak phase to that of the tree diagram (*i.e.* to that of the CKM matrix elements $V_{cb}V_{cs}^*$). This potential additional contribution is often referred to as "penguin pollution". All existing data, including the value of C_f in Eq. (77.5), as well as several explicit calculations [15–18], are consistent with penguin pollution in B^0 meson decays to charmonium-kaon decays being negligible at the current level of precision. Therefore, the value of $-\eta_{CP}S_f$ is generally converted to $\sin(2\beta)$ without any correction or additional uncertainty being assigned due to this assumption. This gives [4]

$$\beta = \left(22.6\,^{+0.5}_{-0.4}\right)^\circ \,, \tag{77.6}$$

where only the solution consistent with the Standard Model is reported (methods to resolve the trigonometric ambiguity in the result are discussed below). It is also possible to use data-driven methods, typically based on flavour symmetries plus some additional assumptions, to constrain the effects of penguin pollution [19–21]. In this case it is necessary to consider each charmonium-kaon final state separately, since the penguin pollution to each may differ. The most common approach [19], which relies on experimental information on $B^0 \to J/\psi\pi^0$ decays, currently gives an additional uncertainty on $\sin(2\beta)$ from $B^0 \to J/\psi K^0_{\rm S}$ of around 0.01.

It is possible to avoid the issue of penguin pollution in the measurement of β by using B^0 meson decays to a charm- and light-meson final state, such as $D_{CP}\pi^0$ (where D_{CP} represents a D^0 meson decaying into a CP eigenstate), instead of the charmonium-kaon final states. These decays do have a CKM-suppressed contribution ($V_{ub}V_{cd}^*$ instead of $V_{cb}V_{ud}^*$), which can in principle bias the determination of $\sin(2\beta)$ from S_f, but this can be calculated and is known to be negligible at current precision. The requirement that the neutral D meson decays to a final state that is common to both D^0 and $\overline{D}^0$, such as the CP-even eigenstate K^+K^-, reduces the sample size that is available for analysis. Consequently, the world average [4], $\sin(2\beta) = 0.71 \pm 0.09$, with these channels is not as precise as that from the charmonium-kaon states.

Converting experimental results on $\sin(2\beta)$ into constraints on β leads to a trigonometric ambiguity in the range $[0°, 180°]$. This can be resolved with experimental measurements of $\cos(2\beta)$, which can be obtained from decay-time-dependent analyses of B^0 meson decays to multibody (non-CP-eigenstate) final states. Among the charmonium-kaon decays, study of $B^0 \to J/\psi K^*(892)^0$ with $K^*(892)^0 \to K^0_{\rm S}\pi^0$ is the most promising approach, but due to the limited sample size that has been analysed to date the precision is not sufficient to resolve the ambiguity conclusively. The charm- and light-meson channels such as $B^0 \to D\pi^0$ with $D \to K^0_{\rm S}\pi^+\pi^-$ have been shown to provide good statistical power for this purpose, with a joint analysis of BaBar and Belle data giving $\cos(2\beta) = 0.91 \pm 0.25$ [22,23], sufficient to rule out the alternative solution for β.

77.3 α

In the limit that only tree amplitudes contribute to B^0 meson decays to light mesons, such as $B^0 \to \pi^+\pi^-$, then the observables of the decay-time-dependent CP asymmetry of Eq. (77.3) would allow a straight-forward determination of 2α: $S_f = +\eta_{CP}\sin(2\alpha)$

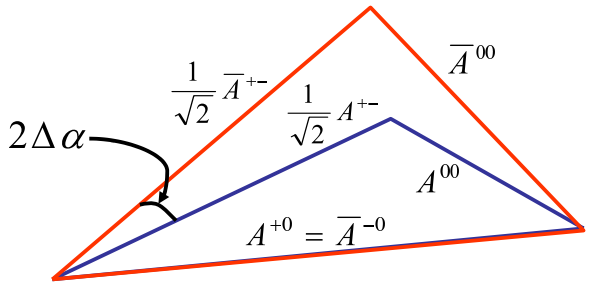

Figure 77.1: Isospin triangles for $B \to \pi\pi$ decays, reproduced from Ref. [24]. Here, the relative phase between A^{+0} and $\overline{A}^{-0}$ has been rotated away to simplify the picture. The total relative phase probed by $S_{\pi^+\pi^-}$ is $\arg\left(\frac{q}{p}\frac{\overline{A}^{+-}}{A^{+-}}\right) = 2\alpha - 2\Delta\alpha$, including contributions from B^0–$\overline{B}^0$ mixing, the tree-level amplitudes and the correction $\Delta\alpha$, and exploiting the unitarity requirement $\alpha + \beta + \gamma = 180°$.

and $C_f = 0$. In general, however, the determination of α is complicated by the presence of contributions from $b \to d(u\bar{u})$ neutral-current penguin transitions, which have a similar level of CKM-suppression as the $b \to u(\bar{u}d)$ charged-current tree amplitudes but have a different weak phase. Consequently, one obtains instead for $B^0 \to \pi^+\pi^-$

$$S_{\pi^+\pi^-} = \sqrt{1 - C^2_{\pi^+\pi^-}}\,\sin(2\alpha - 2\Delta\alpha), \qquad (77.7)$$

where $\Delta\alpha$ is the *a priori* unknown penguin contribution.

This contribution from the penguin amplitude can be accounted for in an analysis relating the amplitudes for isospin partner decays, *e.g.* A^{+-} for $B^0 \to \pi^+\pi^-$, A^{+0} for $B^+ \to \pi^+\pi^0$, A^{00} for $B^0 \to \pi^0\pi^0$ decays and $\left(\overline{A}^{+-}, \overline{A}^{-0}, \overline{A}^{00}\right)$ for their charge conjugates. The isospin analysis relies on the fact that there is no penguin contribution to A^{+0} and $\overline{A}^{-0}$, because $\pi^\pm\pi^0$ is a pure isospin-2 state, and the ($\Delta I = \frac{1}{2}$) QCD-penguin amplitudes only contribute to the isospin-0 final state. One therefore obtains the following isospin triangle relations [25]

$$A^{+0} = \frac{1}{\sqrt{2}}A^{+-} + A^{00} \quad \text{and} \quad \overline{A}^{-0} = \frac{1}{\sqrt{2}}\overline{A}^{+-} + \overline{A}^{00}\,, \quad (77.8)$$

from which it is possible to determine $\Delta\alpha$, as shown in Fig. 77.1.

Since the determination of $\Delta\alpha$ and thus also α requires construction of amplitude-level relations, it is not appropriate to simply average results of α from different experiments. Instead, measurements of each of the observable quantities needed to determine α are input into a combination. For the $B \to \pi\pi$ system, the inputs are the branching fractions of $B^0 \to \pi^+\pi^-$, $B^+ \to \pi^+\pi^0$ and $B^0 \to \pi^0\pi^0$ decays, the lifetimes of the B^+ and B^0 mesons (which relate the branching fractions to amplitude-level quantities), and the $S_{\pi^+\pi^-}$, $C_{\pi^+\pi^-}$ and $C_{\pi^0\pi^0}$ observables. Potential sources of correlation must be taken into account, but these are predominantly systematic in origin and thus have a small effect on the combination, since the measurements are statistically limited. An exception is that the LHCb measurements of $(S_{\pi^+\pi^-}, C_{\pi^+\pi^-})$ [26,27] have a significant statistical correlation due to the fact that the time variable of Eq. (77.3) is the difference between production and decay, and hence is in the range $[0, \infty]$. This correlation is largely absent for measurements from BaBar [28] and Belle [29], where the difference between the signal and tagging B meson decay times is measured, and hence $t \in [-\infty, \infty]$. The combination itself can be performed with different statistical approaches; the procedure described in detail in Ref. [30], based on a frequentist treatment, is used here. The knowledge of $C_{\pi^0\pi^0}$ [28,31] is currently the limiting factor in the precision on α from the $B \to \pi\pi$ system, and is likely to remain so for some time due to the difficulty to reconstruct this final state.

In general, the isospin triangle construction gives a four-fold ambiguity on $2\Delta\alpha$ (each triangle can face either up or down), leading to an eight-fold ambiguity on α in the range $[0°, 180°]$. This is reduced if either or both of the triangles are flat, or if the two triangles have sides of identical length. The ambiguities can also be reduced if measurement of the $S_{\pi^0\pi^0}$ (or equivalent) observable is available, since this can be combined with the corresponding $\Delta\alpha$ parameter from the right-hand corner of the triangle in Fig. 77.1 to provide an additional constraint. None of these possibilities are realised in the $B \to \pi\pi$ system; in particular a decay-time-dependent analysis of $B^0 \to \pi^0\pi^0$ is extremely challenging experimentally due to the absence of any charged particle originating from the B decay position. Nonetheless, solutions consistent with $\alpha = 0$ can be rejected on physical grounds [24].

The isospin analysis can also be performed with the $B \to \rho\rho$ system, which contains two vector particles in the final state and so does not have a fixed CP eigenvalue. In principle the analysis can be performed separately for each $\rho\rho$ polarization state, but in practise it is found that the longitudinal polarization fraction, f_L, is close to unity, and hence the final state is approximately CP-even. Compared to $B^0 \to \pi\pi$, the $\rho\rho$ modes benefit experimentally from a higher branching fraction and smaller penguin contributions, so that the isospin triangles are flatter, reducing the ambiguities. (The value of $\Delta\alpha$ in the $B \to \rho\rho$ system, obtained from the isospin analysis, has a single solution in $[0, \pi]$ at $(3 \pm 5)°$, while for $B \to \pi\pi$ there are two solutions at 13° and 27° with $\Delta\alpha \in [7, 33]°$ at 68.3% confidence level (CL). The isospin analysis with either final state has an ambiguity under $\Delta\alpha \Leftrightarrow -\Delta\alpha$.) For the BaBar [32] and Belle [33] experiments, the high branching fraction and smaller penguin contribution compensate for the increased difficulty to reconstruct the $\rho\rho$ final state relative to $\pi\pi$. Moreover, in contrast to $S_{\pi^0\pi^0}$, measurement of $S_{\rho^0\rho^0}$ is possible due to the four charged pion final state, following $\rho^0 \to \pi^+\pi^-$ decay, as has been demonstrated by BaBar [34].

In the $B \to \rho\pi$ system there are more amplitudes to consider, so that the isospin relation corresponds to a pentagon rather than a triangle and Eq. (77.8) is modified to become

$$\begin{aligned}\sqrt{2}(A^{+0} + A^{0+}) &= A^{+-} + A^{-+} + 2A^{00} \quad \text{and} \\ \sqrt{2}(\overline{A}^{-0} + \overline{A}^{0-}) &= \overline{A}^{+-} + \overline{A}^{-+} + 2\overline{A}^{00}\,.\end{aligned} \qquad (77.9)$$

As in Eq. (77.8), the left-hand sides of these expressions correspond to a pure isospin-2 final state, and therefore the ratio of the right-hand sides gives a pure phase term that, accounting for the B^0–$\overline{B}^0$ mixing phase that also contributes to the measured quantities, is 2α. The relative amplitudes for B^0 and $\overline{B}^0$ decays to $\rho^+\pi^-$, $\rho^-\pi^+$ and $\rho^0\pi^0$ can all be determined from a decay-time-dependent analysis of the $\pi^+\pi^-\pi^0$ Dalitz plot, so that study of this channel alone allows determination of α [35]. This analysis in principle leads to a single solution for α in $[0°, 180°]$, but the precision of current measurements [36–38] is limited.

The isospin analysis used to determine α is believed to be valid to high precision, and theoretical uncertainties in the procedure are usually neglected. Nonetheless, it should be noted that the analysis assumes the absence of electroweak penguin amplitudes, which can contribute to $\Delta I = \frac{3}{2}$ transitions with a different weak phase to that of the tree amplitudes [39, 40]. Moreover, isospin-breaking effects such as $\left(\pi^0, \eta, \eta'\right)$ mixing would impact on the relations of Eq. (77.8). A further complication in the $B \to \rho\rho$ system is the effect of the non-zero ρ meson width [41]. Estimates of the size of these effects on the determined value of α are typically at the 1° level or less [30]. By contrast, methods to determine α using SU(3) or other flavour symmetries are generally considered to have larger theoretical uncertainties and are not included here.

The world average obtained for the angle α from isospin analysis of $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ decays is [4]

$$\alpha = (84.1\,^{+4.5}_{-3.8})°\,, \qquad (77.10)$$

where the quoted uncertainty is at the 68.3% CL and does not include effects due to isospin-breaking. This world average, together with results split by decay mode, is shown in Fig. 77.2. The combination has a total of 57 experimental inputs from which 24 parameters are determined, and an overall χ^2 of 22.4, which corresponds to a p-value of 91%. Thus, there is excellent overall consistency between the inputs, despite the tension apparent in

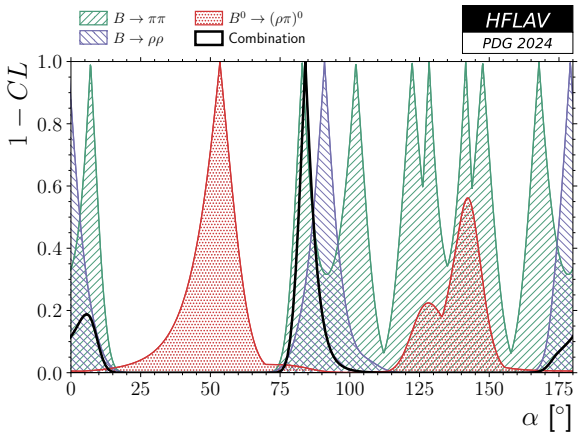

Figure 77.2: World average of α, as well as contributions from individual modes, in terms of 1−CL.

Fig. 77.2 between the results from $B^0 \to (\rho\pi)^0$ and the others. The combination gives a single best-fit for α in $[0°, 180°]$, but an ambiguous solution exists at $\alpha \Leftrightarrow \alpha{+}180°$. A secondary minimum close to zero is disfavoured [30].

77.4 γ

The angle γ is the weak phase between Cabibbo-favoured $b \to c$ and suppressed $b \to u$ quark transitions and can be determined by exploiting interference between them. Explicitly, the ratio of suppressed to favoured amplitudes is parameterized by

$$r_B e^{i(\delta_B \pm \gamma)} = \frac{A_{\rm sup}}{A_{\rm fav}} \,, \tag{77.11}$$

where r_B is the ratio of amplitude magnitudes, δ_B the strong phase difference and the + or − sign depends on whether the transition involves a $\bar{b}$ or b quark, respectively. Measurement of γ in this way has negligible theoretical uncertainty in the Standard Model [42], and therefore this approach provides a benchmark against which determinations from other methods, typically involving loop diagrams, can be compared.

Interference between these amplitudes is realised in $B^+ \to DK^+$ decays, where D represents an admixture of D^0 and $\overline{D}^0$ mesons. The simplest case is that of D decays to *CP*-eigenstates (GLW method [43, 44]), either *CP*-even such as K^+K^- (*CP*+) or *CP*-odd such as $K^0_S\pi^0$ (*CP*−). The normalized decay rate and *CP* asymmetry are given by

$$\begin{aligned} R_{CP\pm} &= \frac{\Gamma(B^- \to D_{CP\pm}K^-) + \Gamma(B^+ \to D_{CP\pm}K^+)}{\Gamma(B^- \to D^0K^-) + \Gamma(B^+ \to \overline{D}^0K^+)} \\ &= 1 + r_B^2 \pm 2r_B\cos(\delta_B)\cos(\gamma) \,, \qquad (77.12a) \\ A_{CP\pm} &= \frac{\Gamma(B^- \to D_{CP\pm}K^-) - \Gamma(B^+ \to D_{CP\pm}K^+)}{\Gamma(B^- \to D_{CP\pm}K^-) + \Gamma(B^+ \to D_{CP\pm}K^+)} \\ &= \frac{\pm 2r_B\sin(\delta_B)\sin(\gamma)}{1 + r_B^2 \pm 2r_B\cos(\delta_B)\cos(\gamma)} \,. \qquad (77.12b) \end{aligned}$$

These relations assume the absence of direct *CP* violation in the charm system; experimentally allowed deviations from this assumption are too small to cause a significant bias on γ [7, 45]. It is convenient to determine the $R_{CP\pm}$ quantities through a double ratio, normalizing to $B^+ \to D\pi^+$ decays involving the same final states, since this cancels potential sources of systematic uncertainty due to the branching fractions of the D decays that are used; small possible effects of *CP* violation in $B^+ \to D\pi^+$ decays are a source of systematic uncertainty in this procedure. The GLW method can be extended to include final states that are almost *CP*-eigenstates [46], as is the case in $D \to \pi^+\pi^-\pi^0$ and $D \to K^+K^-\pi^0$ decays, via inclusion of a factor encoding the fraction of *CP*-even (or *CP*-odd) content, $F_\pm$, which dilutes the sensitivity to γ by reducing the size of the interference terms (the terms linear with r_B) in Eq. (77.12).

For other D decays, the ratio of amplitudes for the D^0 and $\overline{D}^0$ decays to the final state of interest has to be accounted for in the formalism. The ADS method [47, 48] uses D decays to final states such as $K^\mp\pi^\pm$, which involve interference between Cabibbo-favoured (CF) and doubly-Cabibbo-suppressed (DCS) transitions. The observables in this case are

$$\begin{aligned} A_{\rm ADS} &= \frac{\Gamma(B^- \to [K^+\pi^-]_D K^-) - \Gamma(B^+ \to [K^-\pi^+]_D K^+)}{\Gamma(B^- \to [K^+\pi^-]_D K^-) + \Gamma(B^+ \to [K^-\pi^+]_D K^+)} \\ &= \frac{2r_B r_D \sin(\delta_B + \delta_D)\sin(\gamma)}{r_B^2 + r_D^2 + 2r_B r_D \cos(\delta_B + \delta_D)\cos(\gamma)} \,, \qquad (77.13a) \\ R_{\rm ADS} &= \frac{\Gamma(B^- \to [K^+\pi^-]_D K^-) + \Gamma(B^+ \to [K^-\pi^+]_D K^+)}{\Gamma(B^- \to [K^-\pi^+]_D K^-) + \Gamma(B^+ \to [K^+\pi^-]_D K^+)} \\ &= r_B^2 + r_D^2 + 2r_B r_D \cos(\delta_B + \delta_D)\cos(\gamma) \,, \qquad (77.13b) \end{aligned}$$

where r_D and δ_D are the amplitude magnitude ratio and strong phase difference between the CF and DCS D decay. An alternative pair of observables, (R_-, R_+), is also sometimes used, where R_- (R_+) is the ratio of decay rates between the suppressed and favoured transitions for B^- (B^+) decays. The R_- and R_+ observables are statistically independent, while $A_{\rm ADS}$ and $R_{\rm ADS}$ are not (in particular, the uncertainty on $A_{\rm ADS}$ depends on the central value of $R_{\rm ADS}$). However, the pair (R_-, R_+) has more correlated sources of systematic uncertainty compared to $(A_{\rm ADS}, R_{\rm ADS})$. The observables of Eq. (77.13) are therefore usually preferred once a significant signal is established. The ADS method can also be extended to include decays to multibody final states, such as $D \to K^\pm\pi^\mp\pi^0$ and $D \to K^\pm\pi^\mp\pi^+\pi^-$, by addition of a coherence factor [49] which appears in the interference terms of Eq. (77.13) and accounts for dilution of the sensitivity due to variation of the decay amplitude across the phase space of the final state. A similar method can be used for singly Cabibbo-suppressed D decays to non-*CP* eigenstates such as K^*K [50].

For D decays to multibody self-conjugate final states (BPGGSZ method [51,52]), such as $D \to K^0_S\pi^+\pi^-$, one can write the partial decay rate as a function of the position in the phase space in terms of the "Cartesian parameters" $x_\pm + iy_\pm = r_B e^{i(\delta_B \pm \gamma)}$:

$$\begin{aligned} d\Gamma(B^\pm \to [K^0_S\pi^+\pi^-]_D K^\pm) &= A^2_{(\mp,\pm)} + r_B^2 A^2_{(\pm,\mp)} \\ &+ 2A_{(\pm,\mp)}A_{(\mp,\pm)}[x_\pm c_{D(\pm,\mp)} + y_\pm s_{D(\pm,\mp)}], \end{aligned} \tag{77.14}$$

where the notation $(+,-)$ is shorthand for the dependence on the Dalitz-plot position — the squared invariant masses of $K^0_S\pi^+$ and $K^0_S\pi^-$ combinations, respectively. The quantities $A_{(+,-)}$ and $A_{(-,+)}$ represent the magnitudes of the D^0 and $\overline{D}^0$ decay amplitudes at the position $(+,-)$ and are interchangable with their *CP* conjugate amplitudes because *CP* conservation is assumed in the D decay (*i.e.* $A_{(-,+)} = \overline{A}_{(+,-)}$). The quantities $c_{D(\pm,\mp)}$ and $s_{D(\pm,\mp)}$ are the cosine and sine of the strong phase difference, $\delta_{D(+,-)} = \arg(\overline{A}_{(+,-)}) - \arg(A_{(+,-)})$, between the $\overline{D}^0$ and D^0 amplitudes. These quantities can be determined from an amplitude model, although this leads to a hard-to-quantify systematic uncertainty associated to the composition of the model. An alternative, "model-independent", approach involves dividing the phase space into appropriate bins. In this case, the analysis benefits from external input on the values of c_D and s_D integrated over each bin. Measurements of these external parameters have been performed for the $D \to K^0_S\pi^+\pi^-$ decay by the CLEO-c and BESIII collaborations [53–56]. The use of common input values for these parameters in model-independent determinations of γ with the BPGGSZ method by different experiments is a source of correlation between experiments that is currently negligible but will become more significant as the available B meson data samples increase in size.

The discussion above refers to $B^+ \to DK^+$ decays, but analogous measurements can be made also for additional channels such as $B^+ \to D^*K^+$ (with $D^* \to D\pi^0$, $D\gamma$) and $B^+ \to DK^{*+}$ (with $K^{*+} \to K^0_S\pi^+$, $K^+\pi^0$). In the limit that these can be treated purely as two-body decays, the expressions for $B^+ \to DK^+$ are modified only by ensuring the r_B and δ_B parameters are specific to each B decay. Moreover, for $B^+ \to D^*K^+$ decays an effective

shift of the strong phase by π between $D^* \to D\pi^0$ and $D\gamma$ decays [57] has to be taken into account. In case the finite width of the decaying resonance is non-negligible, as is the case for the $K^*(892)$ state, additional amplitudes can contribute leading to a dilution of the sensitivity, which can be accounted for in the formalism through the introduction of a relevant coherence factor. For the $B^0 \to DK^{*0}$ decay, full amplitude analysis of the $B^0 \to DK^+\pi^-$ Dalitz plot provides additional sensitivity compared to the quasi-two-body approach [58, 59].

It is also possible to measure γ using decay-time-dependent analysis of the B_s^0 meson [60]. The weak phase arising in the interference between direct decay of $B_s^0 \to D_s^\mp K^\pm$ and decay via mixing is $(\gamma - 2\beta_s)$, where β_s is the angle associated with $B_s^0 \to J/\psi\phi$ decays in a similar way to the relation between β and $B^0 \to J/\psi K_S^0$ decays described in Sec. 77.2. Sufficient information can be obtained from the tagged, decay-time-dependent rates of $B_s^0 \to D_s^\mp K^\pm$ decays that this weak phase can be determined, up to an ambiguity, together with the strong phase difference between, and the ratio of the magnitudes of, the suppressed and favoured amplitudes. Since β_s is known to good precision [8], measurements of the decay-time-dependent *CP*-asymmetry observables in $B_s^0 \to D_s^\mp K^\pm$ decays can be used to infer constraints on γ. Alternatively, if effects of penguin pollution in $B_s^0 \to J/\psi\phi$ decays [17, 18] are a concern, as they will become in the future, results from the $B_s^0 \to D_s^\mp K^\pm$ mode can be combined with an independent precise measurement of γ to provide a penguin-free determination of β_s.

The average for γ requires a non-trivial combination due the complicated relations between the observables and the physics parameters of interest, such as in Eqs. (77.12), (77.13) and (77.14). Moreover, hadronic parameters such as r_B and δ_B defined in Eq. (77.11) are common to all different D decay modes (but differ for each B decay mode). Thus, it is not correct to simply average results for γ obtained by different experiments or in different channels. Instead, measurements of rate asymmetries, rate ratios and the Cartesian parameters are taken as inputs to the combination, from which results are obtained not only for γ but also for the hadronic parameters. Independent measurements of auxiliary parameters such as r_D and δ_D are also treated as inputs to the combination. In some cases the B decay data can help to reduce uncertainties on these auxiliary parameters and therefore a simultaneous fit of charm and beauty data can provide stronger constraints [61]; this approach however is not currently used for the world average.

The precision to which γ can be measured with a particular B decay is approximately inversely proportional to the value of r_B. Thus, results from channels with smaller yields but larger values of r_B, such as $B^0 \to DK^{*0}$ and $B_s^0 \to D_s^\mp K^\pm$ ($r_B \approx 0.3$–0.4), can have a significant impact on the world average and are included in the combination. By contrast the $B^+ \to D\pi^+$ mode, for which large samples are available but $r_B \approx 0.005$, has little impact and is also more sensitive to potential systematic biases; hence it is not included. The sensitivity of the world average at present is dominated by results from $B^+ \to DK^+$, where $r_B \approx 0.1$, in particular results with the GLW [62], ADS [62] and BPGGSZ [63] methods.

The world average obtained for the angle γ, obtained by combining results from $B^+ \to DK^+$, D^*K^+, DK^{*+}, $DK^+\pi^+\pi^-$, $B^0 \to DK^+\pi^-$, $B_s^0 \to D_s^\mp K^\pm$ and $B_s^0 \to D_s^\mp K^\pm\pi^+\pi^-$ decays, is [4]

$$\gamma = (65.7 \pm 3.0)^\circ \ , \qquad (77.15)$$

where the quoted uncertainty is at the 68.3% CL.

Effects related to charm and kaon mixing and *CP* violation are generally negligible at the current level of precision, in particular for modes with $r_B \gtrsim 0.1$. An exception is that a dependence of the selection efficiency on the charm decay time can induce a dependence of the observables on charm mixing parameters [64]. Such effects can be important at hadron collider experiments such as LHCb, but can be and are corrected for. Interactions of neutral kaons with detector material can also cause a bias in determination of γ from modes with low values of r_B [65], such as the BPGGSZ method applied to $B^+ \to D\pi^+$, but are negligible in modes with larger r_B values. A further subtlety is that the identification of the weak phase between suppressed and favoured amplitudes in $B \to DK$ decays with γ, as defined in Eq. (77.2), assumes that the 2×2 submatrix of the CKM matrix is real, *i.e.* that $\arg\left[V_{ud}V_{us}^*/\left(V_{cd}V_{cs}^*\right)\right] = 0$. This is true to an excellent approximation in the Standard Model, and is known experimentally from independent studies of the charm system [45] to contribute negligible bias to current measurements. Nonetheless, in future it will be possible to test directly this assumption by comparing the value of γ obtained from the $B \to DK$ and $B \to D\pi$ systems.

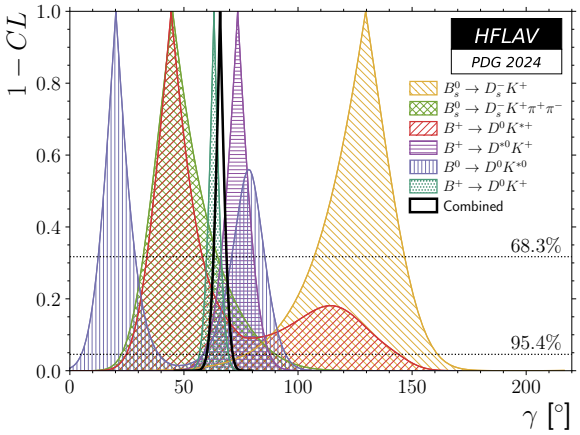

Figure 77.3: World average of $\gamma \equiv \phi_3$, as well as contributions from individual modes, in terms of 1−CL.

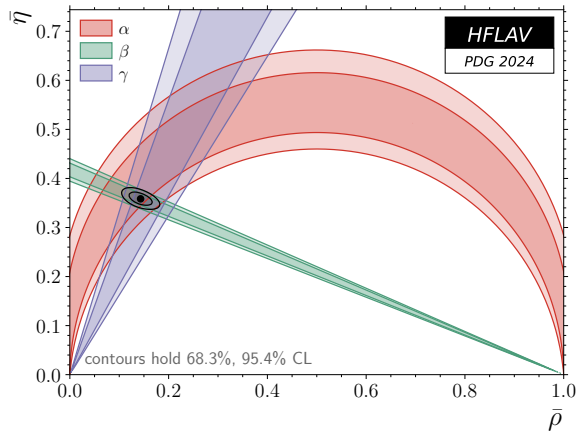

Figure 77.4: Constraints from the measurements of the angles of the CKM unitarity triangle in the $(\overline{\rho}, \overline{\eta})$ plane.

Effects from correlated uncertainties between amplitude models and strong phase differences in charm decays are negligible and are not explicitly accounted for in the combination, nor are effects related to charm and kaon mixing and *CP* violation. This world average, together with results split by decay mode, is shown in Fig. 77.3. The combination has a total of 173 experimental inputs from which 36 parameters are determined, an an overall χ^2 of 159.5, which corresponds to a p-value of 9% indicating reasonable agreement between the inputs. The combination gives a single solution for γ in $[0°, 180°]$, but an ambiguous solution exists at $\gamma \Leftrightarrow \gamma + 180°$.

77.5 Summary

Experimental progress has resulted in all three angles of the CKM unitarity triangle being measured with good accuracy, with β known to subdegree precision and both α and γ known to better than 5°. The constraints from these three measurements in the $(\overline{\rho}, \overline{\eta})$ plane are shown in Fig. 77.4; further discussion and comparison with constraints from independent measurements can be found in Ref. [6]. The determinations of all three angles remain statistically limited, but it will be a challenge for experiments to

ensure that this remains the case as the precision improves. Consequently, the correct treatment of sources of correlation between the measurements that go into the world average combinations is becoming increasingly important.

78. Spectroscopy of Mesons Containing Two Heavy Quarks

Revised March 2024 by J. J. Hernández-Rey (IFIC, Valencia), C. Lourenço (CERN), R.E. Mitchell (Indiana U.), S. Navas (Granada U.) and C. Patrignani (Bologna U.).

A golden age for heavy quarkonium physics dawned at the turn of this century, initiated by the confluence of exciting advances in quantum chromodynamics (QCD) and an explosion of related experimental activity. The subsequent broad spectrum of breakthroughs, surprises, and continuing puzzles had not been anticipated. Indeed, CLEO-c, BESIII, and the B-factories, later joined by ATLAS, CMS and LHCb, have made a series of groundbreaking observations. For an extensive presentation of the status of heavy quarkonium physics, the reader is referred to several reviews [1–9]. This note focuses on experimental developments in heavy quarkonium spectroscopy with very few theoretical comments. Possible theoretical interpretations of the states not predicted by the quark model are presented in the review "Heavy non-$q\bar{q}$ mesons". Note that in this review we follow the new naming scheme for hadrons (see the review "Naming scheme for hadrons" in the current edition of the RPP).

This review covers states discovered since 2003, the year that marked the unexpected discovery of the $X(3872)$ [10]. The $X(3872)$, now called $\chi_{c1}(3872)$, was the first of the mesons containing two heavy quarks that could not be easily accommodated by the $q\bar{q}$ quark model. Its discovery was a watershed event in meson spectroscopy. In earlier versions of this write-up the particles were sorted according to an assumed *conventional* or *unconventional* nature with respect to the quark model. However, since this classification is not always unambiguous, we here follow Ref. [11] and sort the states into three groups, namely states below (*cf.* Table 78.1), above (*cf.* Table 78.2), and near (*cf.* Table 78.3) the lowest open-flavor thresholds. Due to the presence of many open-flavor thresholds, we note that the division of states between "above" and "near" open-flavor thresholds is not absolute.

78.1 States Below Open-Flavor Threshold

Table 78.1 lists properties of recently observed heavy quarkonium states located below the lowest open-flavor thresholds. Those are expected to be (at least prominently) conventional quarkonia. The majority of charmonium ($c\bar{c}$) and bottomonium ($b\bar{b}$) states were established prior to 2003.

78.1.1 *Charmonium*

The $h_c(1P)$ is the 1^1P_1 charmonium state, the singlet partner of the long-known χ_{cJ} triplet 1^3P_J. After being firmly established in 2005 through the process $\psi(2S) \to \pi^0 h_c(1P)$ [12], it has since been studied extensively by BESIII using large samples of $\psi(2S)$ decays. Exclusive hadronic decays of the $h_c(1P)$, strongly suppressed relative to the dominant radiative transition $h_c(1P) \to \gamma\eta_c(1S)$, were first observed in 2019 [13] and additional decays were found in 2020 [14] and 2022 [15].

Belle reported an observation of the $\psi_2(1D)$ decaying to $\gamma\chi_{c1}(1P)$ with J^{PC} presumed to be 2^{--} [16]. This state is listed in Table 78.1 as $\psi_2(3823)$. Its existence was confirmed with high significance by BESIII [17, 18]. While the negative C-parity is indeed established by its observed decay channel, the assignment of $J = 2$ was made by matching to the closest quark model state (1^3D_2) and requires experimental confirmation.

The 1^1D_2 state, or the $\eta_{c2}(1D)$, with a mass expected near 3820 MeV, has not yet been observed. Recently Belle performed a search in $B \to \eta_{c2}(1D)K(\pi)$ decays in the mass range 3795–3845 MeV and found no signal [19]. Thus, the $\eta_{c2}(1D)$ remains the only unobserved conventional charmonium state that does not have open-charm decays.

78.1.2 *Bottomonium*

The ground state of bottomonium, $\eta_b(1S)$, is well established. After the initial reports from BaBar in radiative decays of the $\Upsilon(3S)$ (observation) [20] and $\Upsilon(2S)$ (evidence) [21], Belle confirmed the existence of the $\eta_b(1S)$ with more than 5σ significance in radiative decays of the newly discovered $h_b(1P)$ [22, 23] and $h_b(2P)$ [22] (see next paragraph), as well as in $\Upsilon(2S)$ radiative decays [24]. Belle has also reported strong evidence for the $\eta_b(2S)$ [22], but it still needs confirmation at the 5σ level. Note that there are hints of tension in the $\eta_b(1S)$ mass as measured in radiative M1 and E1 transitions. In the M1 transition $\Upsilon(2S) \to \gamma\eta_b(1S)$ Belle measures a mass of $9394.8^{+2.7+4.5}_{-3.1-2.7}$ MeV [24], while in the E1 transitions $h_b(1P, 2P) \to \gamma\eta_b(1S)$ Belle measures $9402.4 \pm 1.5 \pm 1.8$ MeV [22]. This tension may point to an incomplete understanding of the $\eta_b(1S)$ lineshape in different production mechanisms.

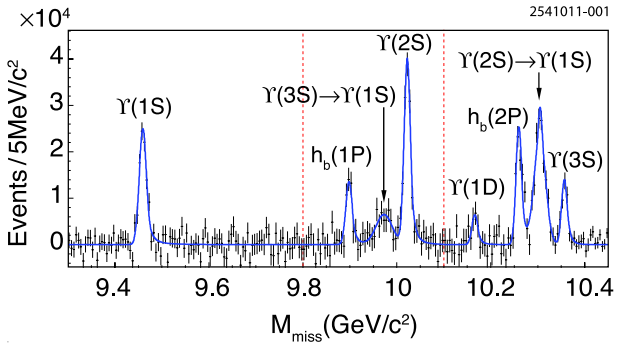

Figure 78.1: From Belle [25], the mass recoiling against $\pi^+\pi^-$ pairs, $M_{\rm miss}$, in e^+e^- collision data taken near the peak of the $\Upsilon(10860)$. The smooth combinatorial and $K^0_S \to \pi^+\pi^-$ background contributions have been subtracted. The fit to the various labeled signal contributions is overlaid (*curve*). The fit is performed separately in three regions with boundaries indicated by the vertical dashed lines.

The $h_b(1P)$, the bottomonium counterpart of the $h_c(1P)$, and the next excited state, the $h_b(2P)$, were simultaneously discovered by Belle using dipion transitions from the $\Upsilon(10860)$ [25] (Fig. 78.1). The same analysis also showed the $\Upsilon_J(1D)$, the lowest-lying D-wave triplet of the $b\bar{b}$ system, but did not resolve the $J = 1, 2, 3$ components. The search for the $h_b(1P)$ was directly inspired by a CLEO result [26], which found a surprisingly copious production of $e^+e^- \to \pi^+\pi^- h_c(1P)$ as well as an indication that $\psi(4230) \to \pi^+\pi^- h_c(1P)$ occurs at a comparable rate with the signature mode $\psi(4230) \to \pi^+\pi^- J/\psi(1S)$. The presence of $\Upsilon(nS)$ peaks in Fig. 78.1 at rates two orders of magnitude larger than expected, along with separate studies with exclusive decays $\Upsilon(nS) \to \mu^+\mu^-$, allow precise calibration of the $\pi^+\pi^-$ recoil mass spectrum and very accurate measurements of the $h_b(1P)$ and $h_b(2P)$ masses. Both corresponding hyperfine splittings are consistent with zero within an uncertainty of about 1.5 MeV (lowered to 1.1 MeV for the $h_b(1P)$ in Ref. [27]). Belle later observed the transition $\Upsilon(4S) \to h_b(1P)\eta$ [23] and the corresponding 1P hyperfine splitting was also found to be compatible with zero at a similar precision level.

Just before Christmas 2011, ATLAS offered the world a beautiful gift, in the form of the discovery of the $\chi_b(3P)$ quarkonium state [28], observed by combining dimuons from $\Upsilon(1S)$ or $\Upsilon(2S)$ decays with photons emitted in the radiative $\chi_b(3P)$ decays (Fig. 78.2, bottom left panel). The new resonance, with a mass of $10\,530 \pm 5(\text{stat}) \pm 9(\text{syst})$ MeV, was soon confirmed by D0 [29]. Also LHCb observed the $\chi_b(3P)$ peak, using the full Run 1 event sample, corresponding to an integrated luminosity of 3 fb^{-1} [30] (Fig. 78.2, middle left panel). Finally, CMS used 80 fb^{-1} of 13 TeV pp collisions, collected in 2016 and 2017, to show two well-resolved $\chi_{b1}(3P)$ and $\chi_{b2}(3P)$ peaks [31], separated by a mass difference of $10.60 \pm 0.64(\text{stat}) \pm 0.17(\text{syst})$ MeV (Fig. 78.2, top left panel). The remarkable precision of the individual mass measurements, with relative uncertainties as small as 50 ppm, shows that the LHC experiments can provide important results in the field of hadron spectroscopy, especially in the case of heavy particles, which require very high collision energies and large event samples.

78.1.3 B_c *System*

The $B_c^\pm$ family is quite special because these (charged) quarkonium states consist of two heavy quarks of different flavor. Among

Table 78.1: New states below the open-flavor thresholds in the $c\bar{c}$, $b\bar{c}$, and $b\bar{b}$ regions, ordered by mass. Masses m and widths Γ represent the PDG23 weighted averages with statistical and systematic uncertainties added in quadrature. In the Production column, the state is always denoted by X. Ellipses (...) indicate inclusively selected event topologies, *i.e.*, additional particles not directly detected by experiment. A question mark (?) indicates an unmeasured value. The Discovery Year column gives the date of the first measurement cited. The Summary Table column indicates whether or not the state appears in the summary tables, usually requiring at least two independent experiments with significance of $>5\sigma$. Refer to the particle listings for references and further information.

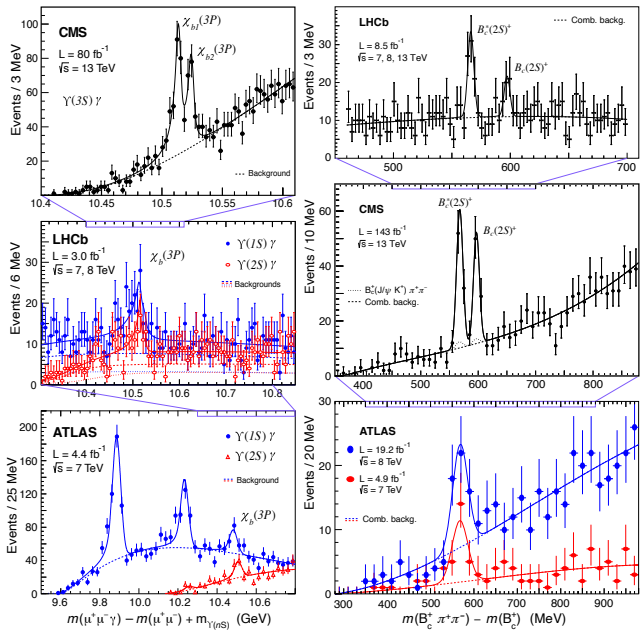

Figure 78.2: (Left Column) Invariant mass distributions measured by the ATLAS [28] (bottom), LHCb [30] (middle) and CMS [31] (top) experiments in their searches for the $\chi_b(3P)$ states through their radiative decays to one of the S-wave bottomonia. (Right Column) Invariant mass distributions measured by the ATLAS [32] (bottom), CMS [33] (middle) and LHCb [34] (top) experiments in their searches for $B_c^\pm$ excited states decaying to the $B_c^\pm$ ground state with the emission of two charged pions.

other interesting properties, this means that they cannot annihilate into gluons, the excited states only decaying to the pseudoscalar ground state, $B_c^\pm$, via electromagnetic and pionic transitions.

On the basis of an event sample collected in the Run 1 of the LHC, corresponding to an integrated luminosity of 24 fb^{-1}, adding the 7 and 8 TeV data, the ATLAS Collaboration observed a resonance in the $B_c^+\pi^+\pi^-$ invariant mass spectrum [32] (Fig. 78.2, bottom right panel). This peak, observed with a significance of 5.2 standard deviations and a mass of $6842 \pm 4(\text{stat}) \pm 5(\text{syst})$ MeV, was immediately recognized as the $B_c(2S)^\pm$ state, the first radial excitation in the $B_c^\pm$ family. Profiting from the much larger Run 2 event sample, collected in the 2015, 2016, 2017 and 2018 running periods and corresponding to 143 fb^{-1} of 13 TeV pp collisions, as well as from a measurement resolution of around 6 MeV, the CMS Collaboration could observe *two* well-resolved peaks, separated by $29.1 \pm 1.5(\text{stat}) \pm 0.7(\text{syst})$ MeV [33] (Fig. 78.2, middle right panel). The existence of two peaks, rather than a single one, is established with a significance of 6.5 standard deviations. The "right peak" has a mass of $6871.0 \pm 1.2(\text{stat}) \pm 0.8(\text{syst}) \pm 0.8(B_c^+)$ MeV, where the last term is the uncertainty in the B_c^+ mass, and is identified as the $B_c(2S)^\pm$ state, which decays directly to the $B_c^\pm$, emitting two (easy to detect) pions. The CMS observation, reported a couple of months after the end of the LHC Run 2, was soon followed by the corresponding LHCb result [34] (Fig. 78.2, top right panel), which confirmed the existence of the two states and reported a second measurement of the $B_c(2S)^\pm$ mass, $6872.1 \pm 1.3(\text{stat}) \pm 0.1(\text{syst}) \pm 0.8(B_c^+)$ MeV.

The "left peak" is interpreted as being the $B_c^*(2S)^\pm$ signal. It is observed at a mass lower than the real value because the experiments are unable to detect the low-energy photon emitted in the decay chain, $B_c^*(2S)^\pm \to B_c^{*\pm}\pi^+\pi^-$ followed by $B_c^{*\pm} \to B_c^\pm\gamma$ (Fig. 78.3). Its energy, expected to be in the range 40–80 MeV, leads to a very small probability that the photon converts into an e^+e^- pair and the two electrons are reconstructed. The relative ordering of the two peaks is based on a generally-agreed assumption: the $M(B_c^{*\pm}) - M(B_c^\pm)$ mass difference is larger than the $M(B_c^*(2S)^\pm) - M(B_c(2S)^\pm)$ differ-

ence. Naturally, these observations provide evidence for the existence of the $B_c^*(1S)^\pm$ state. They also provide measurements of two interesting mass differences, between the masses of the pseudoscalar mesons, $M(B_c(2S)^\pm) - M(B_c(1S)^\pm) = 596.1$ MeV, and of the vector mesons, $M(B_c^*(2S)^\pm) - M(B_c^*(1S)^\pm) = 567.0$ MeV (Fig. 78.3).

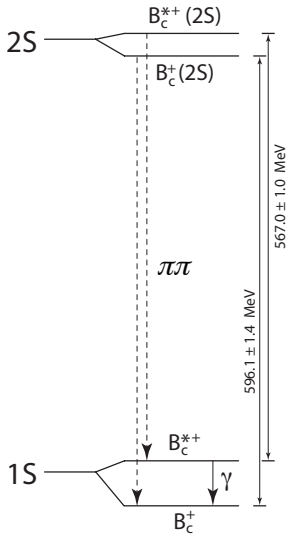

Figure 78.3: Diagram showing the decays mentioned in the text.

78.2 States Above Open-Flavor Threshold

Many states have been discovered both above and near the lowest open-flavor thresholds. They are displayed in Tables 78.2 and 78.3, respectively. With the exception of the $\psi_3(3842)$ and the tensor state located at 3930 MeV (now called $\chi_{c2}(3930)$), which have properties consistent with those expected for the $\psi_3(1^3D_3)$ and $\chi_{c2}(2^3P_2)$, respectively, none of these states can easily be assigned a place in the quark model spectrum of the charmonium or bottomonium families. The theoretical interpretation of these states remains under discussion.

78.2.1 *Charmonium*

Using proton-proton collisions, LHCb observed a narrow state, the $\psi_3(3842)$ resonance, in the decay modes $\psi_3(3842) \to D^0\bar{D}^0$ and D^+D^- [35]. The mass and width of this state are measured to be $3842.71 \pm 0.16 \pm 0.12$ MeV and $2.79 \pm 0.51 \pm 0.35$ MeV, respectively. The observed mass and narrow width are consistent with expectations for the spin-3 $\psi_3(1^3D_3)$ charmonium. Accordingly, the state is given the name $\psi_3(3842)$ in the listings, with the remark that the quantum numbers are fixed from the quark model and need to be confirmed.

The $\chi_{c2}(3930)$, which is a natural candidate for the $\chi_{c2}(2^3P_2)$ quark model state, was originally seen by Belle [36] and later confirmed by BaBar [37] in the $\gamma\gamma$ process $e^+e^- \to e^+e^-D\bar{D}$. This interpretation was strengthened by the more recent LHCb observation of the $\chi_{c2}(3930)$ alongside the $\psi_3(3842)$ in proton-proton collisions [35].

Unlike the $\chi_{c2}(2^3P_2)$, the identification of the $\chi_{c0}(2^3P_0)$ quark model state remains controversial. The original candidate was the $\chi_{c0}(3915)$, discovered by Belle in the $\gamma\gamma$ process $e^+e^- \to e^+e^-\omega J/\psi(1S)$ [38]. In a subsequent measurement by BaBar, its quantum numbers were determined to be $J^{PC} = 0^{++}$ [39]. However, its identification as the $\chi_{c0}(2^3P_0)$ quark model state was soon challenged [40, 41]. In addition, it was pointed out in Ref. [42] that if the assumption of helicity-2 dominance is abandoned and, instead, one allows for a sizeable helicity-0 component, a $J^{PC} = 2^{++}$ assignment is possible. This could imply that it is the same as the $\chi_{c2}(3930)$, but to explain the large helicity-0 component a sizable portion of non-$q\bar{q}$ is necessary [42]. A more recent LHCb amplitude analysis of the process $B^+ \to D^+D^-K^+$ finds distinct 0^{++} and 2^{++} components decaying to D^+D^- [43], which are currently identified in the listings as the $\chi_{c0}(3915)$ and $\chi_{c2}(3930)$, respectively.

An alternative candidate for the $\chi_{c0}(2^3P_0)$ (here referred to as the $\chi_{c0}(3860)$) was reported in Ref. [44] with properties more consistent with expectation: its mass is close to the potential model expectations, it decays to $D\bar{D}$, and the preferred quantum numbers are $J^{PC} = 0^{++}$ (this hypothesis is favored over the 2^{++} one with a 2.5σ significance).

In the excited vector charmonium spectrum, the $\psi(4040)$, $\psi(4160)$, and $\psi(4415)$ are prominent in the inclusive e^+e^- hadronic cross section and are naturally identified as the 3^3S_1, 2^3D_1, and 4^3S_1 $c\bar{c}$ quark model states, respectively. In addition to these long-established states, however, another set of peaks has been found in exclusive e^+e^- cross sections. Unlike conventional vector charmonia, they do not appear in the inclusive hadronic cross section and they apparently do not decay to $D\bar{D}$. The PDG summary table currently lists the $\psi(4230)$, $\psi(4360)$, and $\psi(4660)$ within this category. The first of these to be discovered was originally known as the $Y(4260)$ (now the $\psi(4230)$), seen by BaBar [45] and Belle [46, 47] in $e^+e^- \to \pi^+\pi^- J/\psi(1S)$ using initial state radiation. In a more recent high-statistics scan of $e^+e^- \to \pi^+\pi^- J/\psi(1S)$, BESIII demonstrated that the lineshape in this mass range is highly non-trivial [48]. The latter observation was interpreted by the authors as the presence of two states. However, this lineshape is also consistent with other possible interpretations, such as one assuming a molecular structure for the $\psi(4230)$ [49]. The data of Ref. [48] also called for a significant downward shift of the mass of what was originally called the $Y(4260)$, making it consistent with peaks in other exclusive cross sections, such as $h_c(1P)\pi\pi$ [50]. We thus merged the original $Y(4260)$ (or, more formally, the $\psi(4260)$) with the $\psi(4230)$ in the listings.

BESIII observed the $\chi_{c1}(3872)$, also known as $X(3872)$, in $e^+e^- \to \gamma\chi_{c1}(3872)$ in the $\psi(4230)$ mass range [51], which could allow for additional insight into the structure of both states (see the review on heavy non-$q\bar{q}$ mesons). BESIII also performed a recent study of the process $e^+e^- \to \pi^+\pi^-\psi(2S)$ and found evidence for a lower mass state, possibly the $\psi(4230)$, in addition to the more dominant $\psi(4360)$ [52].

Another interesting question is whether a heavier $\pi^+\pi^-\psi(2S)$ state, the $\psi(4660)$, discovered by Belle [53, 54] and confirmed by BaBar [55], is identical to the $\Lambda_c^+\bar{\Lambda}_c^-$ resonance observed by Belle with a nearby mass and width [56]. Most probably it is, the $\Lambda_c^+\bar{\Lambda}_c^-$ being one more decay mode of the $\psi(4660)$ (see the review on heavy non-$q\bar{q}$ mesons for more details). Note that this is the interpretation adopted in the particle listings. In addition, Belle reported the first observation of a vector charmonium-like state decaying to $D_s^+D_{s1}(2536)$ with a significance of 5.9σ [57]. Its measured mass and width are $4625.9^{+6.2}_{-6.0} \pm 0.4$ MeV and $49.8^{+13.9}_{-11.5} \pm 4.0$ MeV, respectively, consistent with those of the $\psi(4660)$. Therefore, $D_s^+D_{s1}(2536)$ appears as an additional decay mode of the $\psi(4660)$ in the listings.

A series of isovector states[1] containing $c\bar{c}$ have been found in B decays to $K\pi(c\bar{c})$, where the isovector state decays to $\pi(c\bar{c})$ and $(c\bar{c})$ stands for $J/\psi(1S)$, $\psi(2S)$, or $\chi_{c1}(1P)$. They are manifestly non-$q\bar{q}$. The $T_{c\bar{c}1}(4430)$ (originally called the $Z_c(4430)$), decaying to $\pi\psi(2S)$, is the most well established. Based on a full amplitude analysis of $B^0 \to K^+\pi^-\psi(2S)$ decays, Belle determined the spin-parity of the $T_{c\bar{c}1}(4430)$ to be $J^P = 1^+$ [58]. From their study of $B^0 \to K^+\pi^- J/\psi(1S)$ decays, Belle also found evidence for the decay mode $T_{c\bar{c}1}(4430) \to \pi J/\psi(1S)$ [59], which has an order of magnitude lower branching fraction than the discovery mode $T_{c\bar{c}1}(4430) \to \pi\psi(2S)$. In the same analysis, Belle reported evidence for one more charged state, dubbed $T_{c\bar{c}1}(4200)$, decaying to $\pi J/\psi(1S)$. The observation of the $T_{c\bar{c}1}(4430)$ in $\pi\psi(2S)$, as well as its quantum number assignments, were confirmed by LHCb [60] with a much larger data sample, leading to improved mass and width values, consistent with earlier measurements; the experiment even reports a resonant behavior of the $T_{c\bar{c}1}(4430)$ amplitude. The $T_{c\bar{c}1}(4430)$ was not confirmed (or excluded) by BaBar [61].

Table 78.2: As in Table 78.1, but for states above the first open-flavor thresholds in the $c\bar{c}$ and $b\bar{b}$ regions, ordered by mass.

*Quantum numbers fixed from the quark model and need confirmation.

Belle also reported an observation of two charged states decaying to $\pi\chi_{c1}(1P)$ in an analysis of $B^0 \to K^+\pi^-\chi_{c1}(1P)$ decays [62]. These were originally called $Z_1(4050)^\pm$ and $Z_2(4250)^\pm$, but are referred to in Table 78.2 as $T_{c\bar{c}}(4050)$ and $T_{c\bar{c}}(4250)$. These states were not confirmed by BaBar [63]. Belle observes signals with 5.0σ significance for both the $T_{c\bar{c}}(4050)$ and $T_{c\bar{c}}(4250)$, whereas BaBar reports 1.1σ and 2.0σ effects, respectively, setting upper limits that are not inconsistent with Belle's measured rates. The situation remains unresolved.

The decay $B^+ \to K^+\phi J/\psi(1S)$ appears to be especially rich in resonant substructure. The $Y(4140)$ (now the $\chi_{c1}(4140)$), decaying to $\phi J/\psi(1S)$, was first observed in 2008 by CDF [64, 65], and confirmed by D0 and CMS [66, 67]. However, a second structure, the $Y(4274)$ (now the $\chi_{c1}(4274)$), could not be established

[1] These isovector states were originally called Z_c. They are now referred to as $T_{c\bar{c}}$. See the naming scheme review.

unambiguously. Neither of the two states was seen in B decays at Belle [68], LHCb [69] and BaBar [70], or in $\gamma\gamma$ collisions at Belle [71]. The real breakthrough happened when LHCb performed a full amplitude analysis of $B^+ \to K^+\phi J/\psi(1S)$ with $J/\psi(1S) \to \mu^+\mu^-$, $\phi \to K^+K^-$ decays and showed that the data cannot be described in a model that contains only excited kaon states decaying into $K^+\phi$ [72, 73]. They observe two 1^{++} states with masses close to those originally reported by CDF (the $\chi_{c1}(4140)$ and $\chi_{c1}(4274)$), but the width of the one at 4140 MeV is much larger. In addition, they find two significant 0^{++} structures at 4500 and 4700 MeV (the $\chi_{c0}(4500)$ and $\chi_{c0}(4700)$). The LHCb analysis was extended even further in Ref. [74] with a factor of six increase in statistics: the $\chi_{c1}(4140)$, $\chi_{c1}(4274)$, $\chi_{c0}(4500)$, and $\chi_{c0}(4700)$ were confirmed, and two new states, the $X(4630)$ and $\chi_{c1}(4685)$ were reported, also decaying to $\phi J/\psi(1S)$.

78.2.2 *Resonances in the $J/\psi(1S)$-pair mass spectrum*

Based on proton-proton event samples collected at $\sqrt{s}$ = 7, 8 and 13 TeV, corresponding to an integrated luminosity of 9 fb^{-1}, the LHCb Collaboration reported the observation of a narrow structure in the invariant mass distribution of $J/\psi(1S)$ pairs [75]. The new resonance, denoted as $T_{cc\bar{c}\bar{c}}(6900)$ (also $X(6900)$), is clearly seen at a mass of 6.9 GeV in the bottom panel of Fig. 78.4, as indicated by the red curve. The ATLAS Collaboration has also

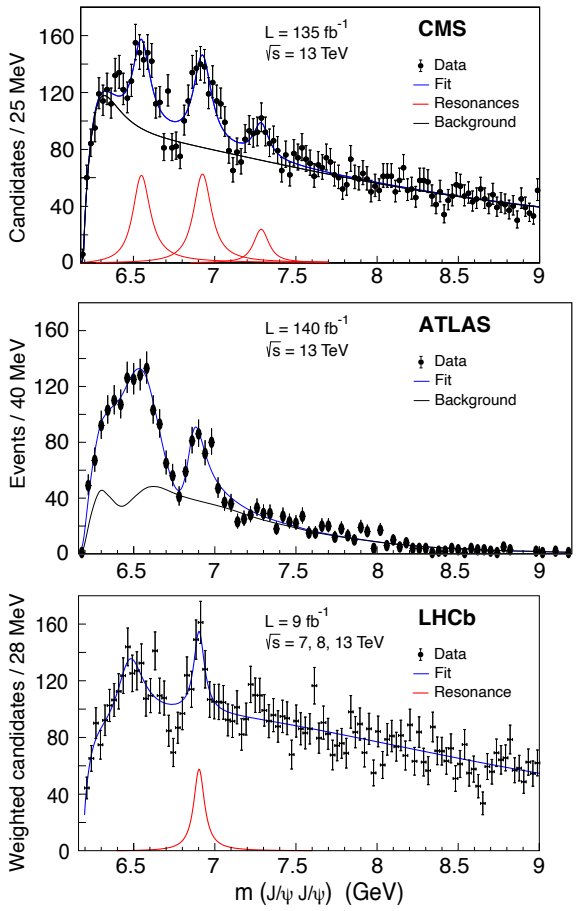

Figure 78.4: $J/\psi(1S)$-pair invariant mass distributions measured by the LHCb [75] (bottom), ATLAS [76] (middle), and CMS [77] (top) experiments.

observed the $T_{cc\bar{c}\bar{c}}(6900)$ resonance in the di-$J/\psi(1S)$ mass spectrum, using 140 fb^{-1} of pp collisions at $\sqrt{s}$ = 13 TeV [76], as can be seen in the middle panel of Fig. 78.4. More recently, also the CMS Collaboration reported the observation of the $T_{cc\bar{c}\bar{c}}(6900)$ in the $J/\psi(1S)$-pair mass distribution, using 135 fb^{-1} of 13 TeV pp collisions [77]. Thanks to its good mass resolution and relatively large event yields, CMS determined the mass and width of the $T_{cc\bar{c}\bar{c}}(6900)$ with the best precision among the three measurements. Furthermore, another resonance is seen with a significance exceeding 5 standard deviations, at a mass of 6.55 GeV, as shown in the top panel of Fig. 78.4. The measured values of the masses and widths of the new states depend on whether the model used to fit the distributions includes interference effects between the resonances and the underlying continuum (and also among the resonances). The larger event samples presently being collected by the LHC experiments will surely lead to significantly improved measurements, as well as to complementary results (including determinations of spin-parity quantum numbers), so that one can expect near-future progress in our understanding of the nature of these "narrow structures".

78.2.3 *Bottomonium*

Belle reported a new measurement of the $e^+e^- \to \Upsilon(nS)\pi^+\pi^-$ ($n = 1, 2, 3$) cross sections at energies from 10.52 to 11.02 GeV [78]. They observed, with a 5.2σ significance, a new structure in the energy dependence of the cross sections. If described by a Breit–Wigner function, its mass and width are $10752.7 \pm 5.9^{+0.7}_{-1.1}$ MeV and $35.5^{+17.6+3.9}_{-11.3-3.3}$ MeV, respectively. The new structure could have a resonant origin and correspond to the not yet observed $\Upsilon(3D)$ state, provided $S-D$ mixing is enhanced, or an exotic state, e.g., a compact tetraquark or hadrobottomonium. It could also be a non-resonant effect due to rescattering. The $\Upsilon(10750)$ was confirmed in a global K-matrix fit to exclusive and inclusive $e^+e^- \to b\bar{b}$ cross sections in Ref. [79].

We no longer mention a hypothetical $Y_b(10888)$ state since a new analysis of the $\Upsilon(10860)$ energy range does not show evidence for an additional state with a mass different from that of the $\Upsilon(10860)$ [80]. After the mass of the $\eta_b(1S)$ was shifted upwards by about 10 MeV based on the Belle measurements [22,23], all of the bottomonium states mentioned above fit into their respective spectroscopies, roughly where expected. An independent experimental confirmation of the shifted masses came from the Belle observation of $\Upsilon(4S) \to \eta h_b(1P)$ decays [23]. This process turns out to be the strongest observed transition of the $\Upsilon(4S)$ to lower bottomonium states.

78.3 States Near Open-Flavor Threshold

A number of states, listed in Table 78.3, appear near open-flavor thresholds, which is likely an important factor in their theoretical interpretation [81].

78.3.1 *Charmonium*

The $\chi_{c1}(3872)$, also known as $X(3872)$, is widely studied and seen in many transitions — see Table 78.3. Yet its interpretation remains unsettled (see the heavy non-$q\bar{q}$ review). Its unique experimental features include: it has $J^{PC} = 1^{++}$ [82, 83], yet it is too light to be the $\chi_{c1}(2^3P_1)$ quark model state; its mass is within 200 keV of the $D^0\bar{D}^{0*}$ threshold; it shows substantial isospin-breaking in its decays to $\rho J/\psi(1S)$ and $\pi^0\chi_{c1}(1P)$; and it is extremely narrow. Using a large sample of inclusively produced $\chi_{c1}(3872)$ decaying to $\pi^+\pi^- J/\psi(1S)$, LHCb recently determined the decay width of the $\chi_{c1}(3872)$ under two different assumptions [84]. Assuming a Flatté-inspired line shape and exploiting the strong coupling of the $\chi_{c1}(3872)$ to $D^0\bar{D}^{*0}$, LHCb performed the first exploration of the pole structure of the $\chi_{c1}(3872)$, finding a FWHM width of $0.22^{+0.06+0.25}_{-0.08-0.17}$ MeV. On the other hand, assuming a Breit–Wigner line shape, its width was found to be $1.39 \pm 0.24 \pm 0.10$ MeV. While the former analysis has a more firm theoretical foundation, the LHCb detector resolution did not allow for a distinction between the different line shapes.

In addition to the $T_{c\bar{c}}$ (also known as Z_c) states found in B decays, discussed above, several isovector states with masses near $D\bar{D}^*$ and $D^*\bar{D}^*$ thresholds appear to be unique to e^+e^- annihilation. In 2013, a state named $T_{c\bar{c}1}(3900)$ (originally $Z_c(3900)$) was unearthed in the charmonium region at BESIII [86] and Belle [47] in the process $e^+e^- \to \pi^\mp T_{c\bar{c}1}(3900)^\pm$ with $T_{c\bar{c}1}(3900)^\pm \to \pi^\pm J/\psi(1S)$. The corresponding spectrum from BESIII is shown in Fig. 78.5. An analysis of CLEO data [87] confirmed this finding and also provided evidence for a neutral partner. A nearby signal was also seen in the $D\bar{D}^*$ channel [88] whose quantum numbers were fixed to 1^{+-}. BESIII reported its neutral partner in both $J/\psi(1S)\pi^0$ [89] and $D\bar{D}^*$ [90] decay modes. The masses extracted

Table 78.3: As in Table 78.1, but for states near the first open-flavor thresholds in the $c\bar{c}$ and $b\bar{b}$ regions, ordered by mass. Updated from Ref. [85] with kind permission, copyright (2011), Springer, and from Ref. [11] with kind permission from the authors.

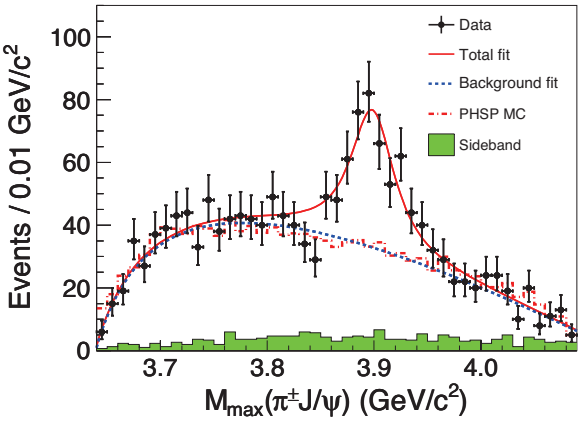

Figure 78.5: The $\pi^\pm J/\psi(1S)$ invariant mass distribution from BESIII [86] e^+e^- collision data taken at a center-of-mass energy near 4260 MeV.

from these experiments in different decay modes agree within 2σ. However, since the extraction of the mass and width parameters did not allow for an interference with the background and Breit–Wigner line shapes are used, which is not justified near thresholds, there might be some additional systematic uncertainty in the mass values. Therefore, in the RPP listings as well as in Table 78.3 both structures appear under the name $T_{c\bar{c}1}(3900)$. BESIII also reported the observation of another charged state, the $T_{c\bar{c}}(4020)^\pm$ (originally called $Z_c(4020)^\pm$), in two decay modes: $h_c(1P)\pi^\pm$ [91] and $(D^*\bar{D}^*)^\pm$ [92]. The neutral partners have also been observed by BESIII in the $h_c(1P)\pi^0$ [93] and $(D^*\bar{D}^*)^0$ [94] final states. The $T_{c\bar{c}}$ states show some remarkable similarities to the $T_{b\bar{b}}$ states (discussed below), e.g. they decay dominantly to $D^{(*)}\bar{D}^*$ channels. However, current analyses suggest that the mass of the $T_{c\bar{c}1}(3900)$ might be somewhat above the $D\bar{D}^*$ threshold. If confirmed, this feature would challenge a possible $D\bar{D}^*$–molecular interpretation with S-wave interactions only — prominent D-waves can shift molecular poles above threshold (see the discussion in Sec. 78.3.3).

Finally, 3.5σ evidence for one more charged charmonium-like state at 4055 MeV decaying into $\psi(2S)\pi^\pm$ was reported by Belle in their analysis of the process $e^+e^-\to\psi(2S)\pi^+\pi^-$ [54]. The same process was studied by BESIII, where there appears to be complications in the Dalitz plot requiring further investigation [52].

An isospin-1/2 state with open strangeness, the $T_{c\bar{c}\bar{s}1}(4000)$, has been reported near D_sD^* threshold by both BESIII [95,96] and LHCb [74]. BESIII observes the charged $T_{c\bar{c}\bar{s}1}(4000)$ in the process $e^+e^-\to K^+(D_s^-D^{*0}+D_s^{*-}D^0)$ [95] and the neutral $T_{c\bar{c}\bar{s}1}(4000)$ in the process $e^+e^-\to K_S(D_s^-D^{*+}+D_s^{*-}D^+)$ [96]. LHCb observes the charged version in $B^+\to\phi(K^+J/\psi(1S))$ [74], although with a much larger decay width. The same LHCb analysis also finds a higher mass $T_{c\bar{c}\bar{s}}$ candidate, the $T_{c\bar{c}\bar{s}1}(4220)$. A search by BESIII for a heavier partner $T'_{c\bar{c}\bar{s}}$ near $D_s^*D^*$ threshold was negative [97].

78.3.2 *Double Charm*

The most striking recent result, however, is due to the observation by LHCb [98,99] of a doubly charmed state, the $T_{cc}(3875)^+$, in the inclusive cross section of $D^{*+}D^0\to D^0D^0\pi^+$ (see Fig. 78.6). The statistical significance is overwhelming, the minimal quark content is $cc\bar{u}\bar{d}$, and the width is approximately what would be expected for an isoscalar ground state having $J^P=1^+$. The integrated luminosity used in this study was 9 fb^{-1}. The larger integrated luminosity of the event sample to be collected by the end of the LHC Run 3, together with improved analysis techniques, might bring the T_{bc} states within reach.

78.3.3 *Bottomonium*

New results on the η_b, h_b, and $T_{b\bar{b}}$ mostly come from Belle [22,23,25,27,80,100–106], all from analyses of 121.4 fb^{-1} of e^+e^- collision data collected near the peak of the $\Upsilon(10860)$ resonance, as well as from an additional 25 fb^{-1} of data collected during the scans of the c.m. energy range 10.63–11.05 GeV. The η_b, h_b, and $T_{b\bar{b}}$ appear in the decay chains $\Upsilon(10860)\to\pi^-T^+_{b\bar{b}}$, $T^+_{b\bar{b}}\to\pi^+(b\bar{b})$, and, when the $b\bar{b}$ forms an $h_b(1P)$, frequently decaying as $h_b(1P)\to\gamma\eta_b$.

Belle soon noticed that, for events in the peaks of Fig. 78.1 corresponding to the processes $e^+e^-\to\pi^+\pi^-\Upsilon(1S,2S,3S)$ and $\pi^+\pi^-h_b(1P,2P)$, there seemed to be two intermediate charged

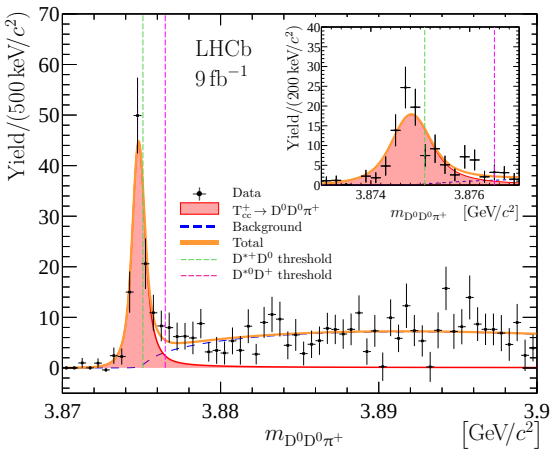

Figure 78.6: The $D^0D^0\pi^+$ invariant mass distribution from LHCb [98, 99]

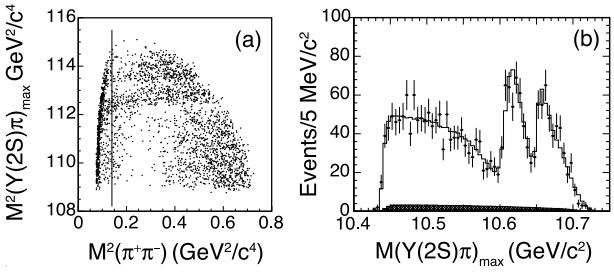

Figure 78.7: From Belle [100] e^+e^- collision data taken near the peak of the $\Upsilon(10860)$ for events with a $\pi^+\pi^-$-missing mass consistent with an $\Upsilon(2S) \to \mu^+\mu^-$, (a) the maximum of the two possible single $\pi^\pm$-missing-mass-squared combinations vs. the $\pi^+\pi^-$-mass-squared; and (b) projection of the maximum of the two possible single $\pi^\pm$-missing-mass combinations overlaid with a fit (*curve*). Events to the left of the vertical line in (a) are excluded from the amplitude analysis. The hatched histogram in (b) corresponds to the combinatorial background. The two horizontal stripes in (a) and two peaks in (b) correspond to the two $T_{b\bar{b}}$ states.

states in the $\pi^\pm\Upsilon$ and $\pi^\pm h_b$ channels, called the $T_{b\bar{b}}(10610)$ and the $T_{b\bar{b}}(10650)$. For example, Fig. 78.7 shows a Dalitz plot for events restricted to the $\Upsilon(2S)$ region of $\pi^+\pi^-$ recoil mass, with $\Upsilon(2S) \to \mu^+\mu^-$ [100]. The two bands observed in the maximum of the two $M[\pi^\pm\Upsilon(2S)]^2$ values also appear in the $\Upsilon(1S)$, $\Upsilon(3S)$, $h_b(1P)$, and $h_b(2P)$ samples. Belle fits all subsamples to resonant plus non-resonant amplitudes, allowing for interference (notably, between $\pi^- T_{b\bar{b}}^+$ and $\pi^+ T_{b\bar{b}}^-$), and finds consistent pairs of $T_{b\bar{b}}$ masses for all bottomonium transitions, and comparable strengths of the two states. A recent angular analysis assigned $J^P = 1^+$ for both $T_{b\bar{b}}$ states [101], which must also have negative G-parity. Transitions through $T_{b\bar{b}}$ to the $h_b(nP)$ saturate the observed $\pi^+\pi^- h_b(nP)$ cross sections. While the two masses of the $T_{b\bar{b}}$ states as extracted from Breit–Wigner fits for the various channels are just a few MeV above the $B^*\bar{B}$ and $B^*\bar{B}^*$ thresholds, more refined analyses using only S-waves find pole locations right below the corresponding thresholds either on the physical [107] or the unphysical [108] sheet. Once D-waves are included, the pole of the $T_{b\bar{b}}(10650)$ moves above the $B^*\bar{B}^*$ threshold [109]. Regardless of their proximity to the corresponding thresholds, both states predominantly decay into these open-flavor channels [103, 110] with branching fractions that exceed 80% and 70%, respectively, at 90% CL. This feature provides strong evidence for their molecular nature.

78.4 Concluding Remarks

The discovery of the $\chi_{c1}(3872)$ (also known as the $X(3872)$) in 2003 ushered in an era of tremendous progress in experimental heavy quark meson spectroscopy, even though many issues remain unsettled. As shown in Tables 78.1 to 78.3, more than 40 new states have been reported during this period, many of which were unanticipated. While the states below open-flavor thresholds (Table 78.1) appear to be well-explained by the conventional $q\bar{q}$ quark model, a thorough understanding of the suite of states above (Table 78.2) and near (Table 78.3) open-flavor thresholds remains elusive. After nearly two decades, experimental progress remains rapid with the continuation of BESIII, the commencement of the Belle II program, and the imminent accumulation of additional data at the LHC.

79. Heavy Non-$q\bar{q}$ Mesons

Revised March 2024 by T. Gutsche (Tübingen U.), C. Hanhart (FZ Jülich) and R.E. Mitchell (Indiana U.).

The constituent quark model describes the observed meson spectrum as bound $q\bar{q}$ states grouped into SU(N) flavor multiplets (see the 'Quark Model' in this issue of the *Review of Particle Physics*). However, the self coupling of gluons in QCD suggests that additional mesons made of bound gluons (glueballs), or $q\bar{q}$-pairs with an excited gluon (hybrids), may exist. Furthermore, multiquark color singlet states such as $qq\bar{q}\bar{q}$ (tetraquarks as compact diquark-antidiquark systems and 'molecular' bound states of two mesons) or $qqq\bar{q}\bar{q}\bar{q}$ (six-quark, 'baryonium' or quasinuclear baryon-antibaryon bound states) have also been predicted. The focus of this review is on the current understanding of exotic states that apparently do not fit into the constituent quark model and contain at least one heavy quark (charm or bottom — the lifetime of the top quark is too short to allow it to hadronise). Light non-$q\bar{q}$ candidates (made of u, d and s quarks) are discussed in 'Scalar Mesons below 1 GeV' and 'Spectroscopy of Light Meson Resonances' in this *Review*.

There are candidates for exotic states with both quantum numbers not allowed and quantum number allowed for $\bar{q}q$ states. For the latter class it is up to now unclear to what extend a mixing of conventional and unconventional states occurs. While Refs. [1–4] report a significant mixing, Refs. [5, 6] describe a scenario where the mixing especially between molecular structures and $\bar{q}q$ states is suppressed.

The review is split into 3 parts, discussing separately heavy–light systems, heavy–heavy systems, as well as systems with more than two heavy quarks. For a more detailed discussion of the experimental and/or theoretical status on exotic meson candidates in the doubly heavy meson sector we refer to Refs. [7–13]. Reviews with main focus on tetraquarks and molecular states are presented in Ref. [14] and in Ref. [15], respectively.

The naming scheme for hadrons has been updated by the Particle Data Group in 2023, and now covers the heavy "exotic" tetraquark ($qq\bar{q}\bar{q}$) and pentaquark ($qqqq\bar{q}$) candidates recently discovered. We use the new naming scheme in the following. See "Naming Scheme for Hadrons" in this *Review* for details and a table mapping old and new particle names.

79.1 Heavy-light systems

79.1.1 *Positive parity open charm ground states*

Two very narrow states, $D_{s0}^*(2317)^\pm$ and $D_{s1}(2460)^\pm$, were observed at B factories [16, 17]. They lie far below the predicted masses for the two expected broad P-wave $c\bar{s}$ mesons. However, strong cusp effects, due to the nearby DK (DK^*) thresholds, could shift their masses downwards and quench the observed widths, still allowing for a conventional explanation of these states [18]. Such an effect was also claimed for the $a_0(980)$ and $f_0(980)$ mesons, which lie just below the $K\overline{K}$ threshold. In contrast to this picture, many authors favour exotic explanations for these lightest positive parity charmed states, such as four-quark states [19–22] or DK (DK^*) molecules [23–28]. Both states are isoscalars and thus strong isospin-violating decays are possible only to the isovector channels $D_s^{(*)\pm}\pi^0$, leading to very small widths. For compact structures the hadronic decay is driven by $\eta - \pi^0$ mixing and one finds widths below 10 keV [18, 29]. In contrast to this a hadronic width typically larger than 100 keV would be the unequivocal signature for a prominent molecular nature of $D_{s0}^*(2317)^\pm$ [25, 27, 28, 30, 31], since then meson loops generating enhanced isospin violation due to the energy difference between the $D^{*0}K^+$ and the $D^{*+}K^0$ thresholds would contribute significantly. The most refined analysis in the molecular scenario [30], where the parameters of the formalism are constrained by a large bulk of lattice QCD data on singly charmed systems, reports a prediction for the width in the range (104–116) keV. The currently measured upper bound for the width is 3.8 MeV.

It should be stressed that – akin to $q\bar{q}$ mesons – multiquark states also appear in multiplets. An important probe for the structure of hadrons is therefore the spectra, and in particular the SU(3) flavor multiplets within the different scenarios. For example the tetraquark model advocated in Refs. [22, 32] finds that the $D_{s0}^*(2317)^\pm$ should be degenerate with its non-strange partner state $D_0^*(2300)$ in line with the currently available experimental analyses. However, Ref. [33] showed that the recent LHCb data for $B \to D\pi\pi$ [34, 35] call for a significantly lighter lightest non-strange scalar charmed meson as soon as constraints from the chiral symmetry of QCD are employed in the analysis. This claim is in line with the recent lattice QCD study of Ref. [36]. In fact, experimental as well as lattice data turn out to be consistent with the predictions from unitarised chiral perturbation theory pioneered for these systems in Ref. [24]. For more recent calculations see Refs. [30, 37, 38]. Moreover, all these latter calculations predict that there should be in addition an about 300 MeV heavier flavor exotic state, formally a member of a flavor sixtet and absent for $c\bar{q}$ states, that indeed shows up in the above mentioned LHCb data [38] — why this state was not reported in the lattice study of Ref. [39] is explained in Ref. [40] by its being located on a hidden Rieman-sheet. Thus, in this picture the structure that appears as $D_0^*(2300)$ in the *Listings* originates from the interplay of two poles, similar to the $\Lambda(1405)$ in the baryon sector, see 'Pole structure of the $\Lambda(1405)$ region' in this *Review*. Two poles in the non-strange scalar sector are also generated in the tetraquark picture of Ref. [22], but in this work the real parts of the poles are located at 2308 MeV and 2666 MeV, in conflict with the data mentioned above. In the refined analysis of Ref. [32] it is shown, however, that the exact pole locations and even the ordering of the higher multiplets depend on the details of the model.

Lattice QCD allows for predictions of the flavor partner states in the B-sector. The most recent analysis can be found in Ref. [41]. In this work also a comparison with theoretical predictions can be found. Unfortunately an experimental confirmation for those states is difficult with existing facilities. Radiative decays are predicted to be the most prominent decay channels [31], since the above mentioned isospin violation from meson loops is suppressed in the B sector as a consequence of the tiny $B^\pm - B^0$ mass difference.

79.1.2 *The $T_{cs0}^*(2870)$ and $T_{cs1}^*(2900)$*

Manifestly exotic candidates around 2.9 GeV were reported in Refs. [42, 43] by LHCb in the $\bar{D}K$ system. Since the strong interaction preserves the quark flavor and the final state contains an $\bar{s}$ as well as a $\bar{c}$, color neutrality calls for a minimum quark content of $ud\bar{c}\bar{s}$. The explanation for those states include compact tetraquarks [44–46], hadronic molecules with a prominent $D^*\bar{K}^*$ component [47–51], or kinematic effects such as cusps or triangle singularities without nearby poles [52, 53]. The different pictures are contrasted and observable differences between them are discussed in Ref. [54].

79.1.3 *The $T_{c\bar{s}0}^*(2900)^0$ and $T_{c\bar{s}0}^*(2900)^{++}$*

There is a very recent report by LHCb [55] on the observation of a doubly charged open-charm tetraquark candidate together with a neutral partner in the $D_s\pi$ channel, with masses near 2.9 GeV. The results imply two states with $c\bar{s}\bar{u}d$ or $c\bar{s}u\bar{d}$ flavor structures. Although masses and widths are consistent with the T_{cs} states of Refs. [42, 43], the strangeness quantum numbers do not match. The first explanation for those states in coupled-channel studies is based on a kinematic effect such as a cusp [56], while a molecular structure with a dominant D^*K^* component is claimed to be excluded [57].

79.2 Heavy-heavy systems

With the discovery of the $\chi_{c1}(3872)$[1] in $B^\pm \to K^\pm X$ ($X \to J/\psi(1S)\,\pi^+\pi^-$) by Belle [58] in 2003, soon confirmed by BaBar [59], many searches for states beyond the standard $q\bar{q}$ quark model were initiated in the charm and bottom sectors. For an updated collection of the currently available experimental information on multiquark states we refer to 'Spectroscopy of mesons containing two heavy quarks' in this *Review*, and in particular to Table 78.2. Moreover, in the decay $\Lambda_b^0 \to J/\psi(1S)\,K^-p$ the LHCb collaboration has recently reported the observation of new baryons decaying into $J/\psi(1S)\,p$, which are candidates for heavy pentaquark

[1] The $\chi_{c1}(3872)$ is also known as the $X(3872)$. According to the PDG naming scheme, the primary name for a meson expresses its quantum numbers.

states [60,61]. They are discussed in some depth in 'Pentaquarks' in this *Review*.

When restricting ourselves to confirmed states we are faced with several states that do not seem to fit into the mass and quantum number schemes of $q\bar{q}$ quark models. This is clear for the five established charged states ($T_{c\bar{c}1}(3900)^{\pm}$, $T_{c\bar{c}}(4020)^{\pm}$ and $T_{c\bar{c}1}(4430)^{\pm}$ in the charmonium sector, and $T_{b\bar{b}1}(10610)^{\pm}$ and $T_{b\bar{b}1}(10650)^{\pm}$ in the bottomonium sector). The neutral states ($\chi_{c1}(3872)$, $\psi(4230)$, $\psi(4360)$, and $\psi(4660)$)[2] also challenge the quark model since their masses and decay properties are in conflict with expectations. Although so far seen just by a single experiment in a single channel [62,63], the $T_{cc}(3875)$ should not remain unmentioned.

79.2.1 *The* $\chi_{c1}(3872)$

The quantum numbers of the $\chi_{c1}(3872)$ have been determined by LHCb to be $J^{PC} = 1^{++}$, first by assuming zero angular momentum between the $J/\psi(1S)$ and the dipion [64] and then by relaxing this constraint [65]. The $\chi_{c1}(3872)$ cannot be identified with the $\chi_{c1}(2^3P_1)$ since the latter is predicted to lie about 100 MeV higher in mass [66]. Instead, the $X(3940)$ reported by Belle in $e^+e^- \to J/\psi(1S)X$, decaying into $D^*\bar{D}$ but not into $D\bar{D}$ [67] could be the $\chi_{c1}(2^3P_1)$. The $\chi_{c2}(3930)$ 2^3P_2 tensor partner was reported by Belle at 3931 MeV in $\gamma\gamma$ interactions [68].

The $\chi_{c1}(3872)$ lies within 200 keV of the $D^0\bar{D}^{*0}$ threshold and its width is very small — recent Breit-Wigner analyses by LHCb [69, 70] result in an average value of $\Gamma = (1.19 \pm 0.21)$ MeV as indicated in the *Listings*; employing the Flatté formalism of Ref. [71] under the constraint that the $D^*\bar{D}$ decay channel dominates, results in $\Gamma = 0.22^{+0.18}_{-0.19}$ MeV, where the standard convention is applied to use twice the imaginary part of the pole location as width. In the future those values can be refined more by either a direct measurement of the width that should be possible at the planned PANDA experiment [72, 73] or by exploiting the interplay of a triangle singularity and the $\chi_{c1}(3872)$ pole [74–76]. Therefore the most natural explanation for this state is a 1^{++} $D\bar{D}^*$ molecule [77], for which strong isospin breaking is predicted [77, 78], since the distance of the pole of the $\chi_{c1}(3872)$ to the $D^0\bar{D}^{*0}$ threshold is significantly smaller than to the D^+D^{*-} threshold. Indeed, the comparable rates for $\omega J/\psi(1S)$ and $\rho^0 J/\psi(1S)$ are consistent with an interpretation of $\chi_{c1}(3872)$ as an isoscalar $D\bar{D}^*$ molecule, when the different widths of the ρ and ω are taken into account [79]. Similarly, a dominant molecular $D^0\bar{D}^{*0}$ structure in the $\chi_{c1}(3872)$ with further subleading hadronic components is used to explain strong and radiative decays involving $J/\psi(1S)$ and $\psi(2S)$ in the final states [80, 81]. From an effective field theory point of view these radiative transitions are not well suited to identify the molecular admixture in the $\chi_{c1}(3872)$, since there appears a counter term at leading order, diminishing the sensitivity to the long ranged molecular component [82].

A four-quark state $cq\bar{c}\bar{q}'$ is another possible interpretation of the $\chi_{c1}(3872)$ [21] but a charged partner of the $\chi_{c1}(3872)$ has not been observed (e.g. not in $B^- \to \bar{K}^0 X^-$ nor in $B^0 \to K^+X^-$, where $X^- \to J/\psi(1S)\,\pi^-\pi^0$ [83]) – see [84] for a possible explanation of this non-observation within the tetraquark approach assuming specific diquark correlations and the more recent discussion in Ref. [85]. The claim that $\chi_{c1}(3872)$ must be a compact (tetraquark) state, since it is also produced at very high p_T in $\bar{p}p$ collisions [86] and in high multiplicity final states [87], was challenged in [88] and [89], respectively, which in particular stress the importance of rescattering, see also Refs. [90, 91].

The high statistics measurement of the $\chi_{c1}(3872)$ lineshape of Ref. [69] also allowed for an extraction of the effective range for the $D^0\bar{D}^{*0}$ interaction. At face value, the values provided in this publication indicate a large and negative effective range [92], which could be interpreted as a signature of a prominent compact component in the $\chi_{c1}(3872)$ wave function — this follows from the famous Weinberg compositeness criterion [93]. The effect of the one-pion exchange on the effective range turns out to be small [94–97] and should therefore not invalidate the Weinberg-type analysis. However, it was argued in Ref. [98] that once the effect of the large isospin violation as well as the strong correlations between the effective parameters appearing in Ref. [71] are subtracted, the effective range is consistent with a purely molecular $\chi_{c1}(3872)$. There is no consensus yet how to interpret the line shapes of $\chi_{c1}(3872)$.

79.2.2 *The* $\psi(4230)$ *and* $\psi(4360)$

A broad structure, originally called $Y(4260)$, decaying into $J/\psi(1S)\,\pi^+\pi^-$ was reported by BaBar in initial state radiation $e^+e^- \to (\gamma_{\rm ISR})Y(4260)$ [99]. A subsequent measurement with significantly improved precision was reported by BESIII [100], and revealed that the original $Y(4260)$ cannot be described with a simple resonant lineshape. Fitting the BESIII data with two Breit-Wigner distributions leads to a narrower and lighter structure (referred to in the *Listings* as the $\psi(4230)$), but also requires a second state at 4320 MeV. However, note that the $D_1(2420)\bar{D}$ molecular model for the $\psi(4230)$ can describe the same data with just one single pole [101]. How many vector states are in the mass range between 4220 MeV and 4400 MeV is not yet settled, but knowing this is crucial to allow for further progress.

There are no charmonium states expected in this mass region with quantum numbers 1^{--} from quark models using the Cornell type of interaction, although this might not be true for some screened versions thereof – for a recent discussion we refer to Ref. [102]. In addition, a charmonium state at this mass is expected to have significant couplings to one or more of the $\bar{D}^{(*)}D^{(*)}$ channels [103,104], a feature that is not observed for the $\psi(4230)$. This state could be a hybrid charmonium with a spin-1 [105,106] or a spin-0 [107,108] $\bar{c}c$ core. However, provided that the observation of $\psi(4230)$ decay into $h_c(1P)\pi\pi$ by BESIII [109] is confirmed, the hybrid hypothesis would be under pressure, since the spin of the heavy quarks (coupled to zero in the $h_c(1P)$) should be conserved in leading order in the expansion in $(\Lambda_{\rm QCD}/m_c)$. (The individual conservation of the heavy quark spin and the total angular momentum of the light quark cloud is a consequence of the heavy-quark spin symmetry, see 'Heavy-Quark and Soft-Collinear Effective Theory' in this issue of the *Review*.) The same criticism applies to the hadrocharmonium interpretation of the $\psi(4230)$, which describes this state as spin-1 quarkonium surrounded by a light quark cloud [110]. To circumvent the spin-symmetry argument, Ref. [111] argues that $\psi(4230)$ and $\psi(4360)$ could be mixtures of two hadrocharmonia with spin-triplet and spin-singlet heavy quark pairs. The same kind of mixing could also be at work for hybrid structures. Hybrids can also treated employing the Born-Oppenheimer EFT originally suggested in Ref. [112, 113]. Those studies revealed that while the $\psi(4230)$ is in principle a good candidate for a hybrid state [114], its decays are incompatible with this assignment [115].

A dominant $D_1(2420)\bar{D}$ component in the $\psi(4230)$ [116] explains naturally why the $T_{c\bar{c}1}(3900)^{\pm}$ (interpreted by the authors as a $\bar{D}D^*$ bound state) is seen in $\psi(4230) \to \pi^{\mp}T_{c\bar{c}1}(3900)^{\pm}$. A similar mechanism is also found in Ref. [117] linking in addition the $J/\psi(1S)\pi^+\pi^-$ and $\psi(2S)\pi^+\pi^-$ decays of the $\psi(4230)$. Furthermore, a copious production of $\chi_{c1}(3872)$ in $\psi(4230)$ radiative decays was predicted from the prominent $D_1\bar{D}$ component of the $\psi(4230)$ [118], which was confirmed by BESIII [119]. Possible charmonia components both in $\psi(4230)$ and $\chi_{c1}(3872)$ can influence the radiative transition but they are shown to be of subleading order [120]. It was proposed that $\psi(4360)$ as a $D_1\bar{D}^*$ bound state could be the spin partner of the $\psi(4230)$ [121, 122]. In Ref. [123] a dynamical model is presented that identifies the vector states $\psi(4230)$, $\psi(4360)$ and $\psi(4415)$ as $D\bar{D}_1$, $D^*\bar{D}_1$ and $D^*\bar{D}_2$ molecular states, respectively. Moreover, an exotic 0^{--} state is predicted as $D^*\bar{D}_1$ molecule with a mass of 4366 ± 18 MeV and a width of less than 10 MeV.

The tetraquark picture calls for four ground state vector states — once the parameters of the model are fixed from some candidate states in the negative and positive parity sector, states with other quantum numbers can be predicted. Possible scenarios are for instance discussed in Ref. [124] which builds on a tailor-made spin-spin interaction [125] to describe the $\chi_{c1}(3872)$, both $T_{c\bar{c}1}(3900)^{\pm,0}$ and $T_{c\bar{c}}(4020)^{\pm}$ and even the $T_{c\bar{c}1}(4430)^{\pm}$

[2] The $\psi(4230)$, $\psi(4360)$, and $\psi(4660)$ are also known as the $Y(4230)$, $Y(4360)$, and $Y(4660)$, respectively. Before improved mass measurements, the $\psi(4230)$ was originally called the $\psi(4260)$ or $Y(4260)$.

confirmed by Belle [126] and LHCb [127]. This model also explains the copious production of $\chi_{c1}(3872)$ in $\psi(4230)$ radiative decays mentioned above [125, 128]. However, tetraquark models (in most cases based on diquark-antidiquark configurations) tend to predict many additional charged and neutral states which have not yet been discovered. In particular, as for the conventional $\bar{q}q$ structures one should expect nearly degenerate isoscalar and isovector states in analogy to the near degeneracy of $\rho(770)$ and $\omega(782)$. The problem and possible explanations are discussed in some detail in Refs. [84, 85].

Ref. [129] found a sizeable SU(3) flavor octet contribution when analysing the $\pi\pi$ final state from $\psi(4230) \to J/\psi(1S)\pi^+\pi^-$, which is consistent with both a molecular and a tetraquark interpretation of $\psi(4230)$, but at odds with a hybrid or a $\bar{c}c$ interpretation.

79.2.3 *The* $\psi(4660)$

In the mass range above 4600 MeV, the number of poles is also not yet settled. Experimental signals are seen in the $\psi(2S)\pi\pi$, $\Lambda_c^+\bar{\Lambda}_c^-$, $D_s\bar{D}_{s1}$, and $D_s\bar{D}_{s2}^*$ final states. In the *Listings* these structures go into one node, $\psi(4660)$, due to their proximity in parameter values. Moreover, various theoretical works describe these states in a combined analysis [130–132]. The signal in the hidden strangeness mode around 4630 MeV still calls for confirmation and might be yet another realisation of the same state, but there are already speculations about its nature. While Ref. [133] argues in favor of a $D_s^{(*)}\bar{D}_{s1}(2536)$ or $D_s^{(*)}\bar{D}_{s2}(2573)$ [134] molecular nature, Ref. [135] does not confirm these claims. Ref. [136] identifies the structure as P-wave $[cs][\bar{c}\bar{s}]$ tetraquark state. Other explanations of the $\psi(4660)$ include a $\psi(2S)f_0(980)$ molecule [137] and a $\Lambda_c^+\bar{\Lambda}_c^-$ baryonium [130]. Also in this mass range studies of the partner states, driven either by spin or flavor symmetry will be very valuable — see e.g. the predictions in Ref. [138].

79.2.4 *The* $T_{c\bar{c}1}(3900)$, $T_{c\bar{c}}(4020)$, $T_{b\bar{b}1}(10610)$, *and* $T_{b\bar{b}1}(10650)$

The isovector states $T_{c\bar{c}1}(3900)$ and $T_{c\bar{c}}(4020)$, first observed by BESIII [139, 140], decay predominantly into $\bar{D}D^*$ and $\bar{D}^*D^*$, respectively, while the $T_{b\bar{b}1}(10610)$ and $T_{b\bar{b}1}(10650)$, first observed by Belle [141, 142], decay predominantly into $\bar{B}B^*$ and $\bar{B}^*B^*$ [143], respectively, although all four were discovered in the decay mode heavy quarkonium plus pion. This suggests that these states are close relatives and their interactions are connected via heavy quark flavor symmetry. A molecular interpretation for the bottomonium states was proposed shortly after the discovery of the two $T_{b\bar{b}}$ states [144] and also shortly after that of the $T_{c\bar{c}1}(3900)$ [116]. This picture is confirmed within the meson exchange model of Ref. [145]. Decay patterns of $T_{c\bar{c}1}(3900)$ and the two $T_{b\bar{b}}$ were also shown to be consistent with a molecular interpretation [146–148]. However, some of their properties also appear to be consistent with tetraquark structures [149]. If the molecular picture were correct for the $T_{b\bar{b}}$ states, spin symmetry would lead to the existence of spin partner states [150–152], which are still to be found. In Ref. [153] it was shown that the actual pole locations of these partner states would be good probes of one-pion exchange in the molecular potential, which makes the experimental search for those states even more interesting.

79.2.5 *The* $T_{c\bar{c}1}(4200)$ *and* $T_{c\bar{c}1}(4430)$

The heaviest confirmed charged state in the charmonium sector is the $T_{c\bar{c}1}(4430)^{\pm}$ observed by Belle [126]. It is interpreted as hadrocharmonium [110], $\bar{D}_1D^*$ molecule [154], as well as tetraquark [125]. Alternatively, in [155, 156] the $T_{c\bar{c}1}(4430)^{\pm}$ is explained as a cross-channel effect enhanced by a triangle singularity from open charm states. These works were criticised in Ref. [157] where an alternative triangle consisting of a K^*, a π, and the $\psi(4230)$, is proposed to generate the $T_{c\bar{c}1}(4430)$. The Argand diagram shows an anticlockwise circle, in line with the experimental analysis [127], while the one of Ref. [156] shows a clockwise motion. By replacing the $\psi(4230)$ with the $\psi(3770)$, and changing the K^*, one can also interpret the $T_{c\bar{c}1}(4200)$ as a kinematic effect [157]. A possible interpretation of $T_{c\bar{c}1}(3900)$ and $T_{c\bar{c}}(4020)$ as crossed channel effects is put forward in Ref. [158]. It remains to be seen, however, if this kind of explanation is also capable of explaining the observations of these lowest $T_{c\bar{c}}$ states, also at other total energies.

79.2.6 *The* $T_{c\bar{c}\bar{s}1}(4000)$

There is recent evidence for a charged charmonium-like state with strangeness, $T_{c\bar{c}\bar{s}1}(4000)$, from BESIII [159] and LHCb [160]. The possible existence of a strange partner to the $T_{c\bar{c}}$ near the $D_s\bar{D}^*$ thresholds has been predicted in molecular models [161, 162], for tetraquarks [163, 164], for hadrocharmonium structures [164, 165], and as a coupled-channel effect [166]. Later on this state is interpreted in Refs. [167, 168] as a member of the same multiquark octet and in Refs. [169–171] as a member of the same molecular one as the $T_{c\bar{c}1}(3900)$. Ref. [168] is also able to describe the recent LHCb data in the $J/\psi(1S)K^-$ system [160], although the extracted total width for their lowest $T_{c\bar{c}\bar{s}}$ state is an order of magnitude larger than that found by BESIII. Refs. [172,173] claim that both the molecular components and the compact tetraquark core are relevant to describe the $T_{c\bar{c}1}(3900)$ and $T_{c\bar{c}\bar{s}1}(4000)$ resonances. Again, in [174] the $T_{c\bar{c}\bar{s}1}(4000)$ can be explained as a coupled-channel effect producing the enhancement close to threshold.

Ref. [169] comes to the conclusion that an understanding of the experimental data for the $T_{c\bar{c}\bar{s}1}(4000)$ calls for the inclusion of both triangle diagrams as well as a pole term. The authors conclude from their calculations that $T_{c\bar{c}\bar{s}1}(4000)$ and $T_{c\bar{c}1}(3900)$ are members of the same SU(3) multiplet. This conclusion was confirmed in Ref. [175] and the study extended to higher energies. The fit of the experimental data allowed for two solutions, one where the $T_{c\bar{c}}(4020)$ is a spin partner of the mentioned isovector states and one where it is not. Data e.g. for $e^+e^- \to K^+D^{*-}D^{*0}$ is claimed to be decisive which scenario is indeed realised.

It should be stressed that the various scenarios, while describing much of the available data, also make decisive predictions, *e.g.* yet unobserved quantum numbers [124,176]. The forthcoming data on heavy meson spectroscopy from various facilities should provide a much deeper understanding of how QCD forms matter out of quarks and gluons.

79.2.7 *The* $T_{cc}(3875)$

There is a recent report and follow-up by LHCb [62, 63] on the observation of a narrow peak in the $D^0D^0\pi^+$ mass spectrum just below the $D^{*+}D^0$ threshold. The observed state is a candidate for an isoscalar double-charm T_{cc}^+ tetraquark configuration with a quark content of $cc\bar{u}\bar{d}$. Unsuccessful searches in $D^+D^0\pi^+$ and D^+D^+ mass spectra disfavour the isovector assignment. The $D^0\pi^+$ mass distribution indicates that the T_{cc}^+ proceeds through the formation of a D^* in the intermediate state. The additional proximity to the D^*D^0 mass threshold favors the $J^P = 1^+$ assignment. The T_{cc}^+ has a remarkable narrow width and lies very close to the $D^{*+}D^0$ threshold [63], comparable to the properties of the $\chi_{c1}(3872)$ [177].

A first evaluation in the context of QCD sum rules [178] results in mass and width values consistent with the assumption of a compact diquark-antidiquark structure of the T_{cc}^+. A pole analysis performed with $D^0D^0\pi^+ - D^{*+}D^0$ coupled-channels [179] suggests that the T_{cc}^+ has its origin in a $D^{*+}D^0$ virtual state resulting from the attraction in this channel and the coupling to $D^0D^0\pi^+$. The interpretation of the observed T_{cc}^+ as a D^*D molecular structure was pursued in quark models [180–183] and the Bethe-Salpeter framework [184]. Predictions depend on fine model details and are usually accompanied by additional partner states, like an isovector molecule or higher radial excitations. In analogy to the case of the $\chi_{c1}(3872)$ in Ref. [177] the production of T_{cc}^+ in high-energy proton-proton collisions at the LHC is studied. Effects of a charm-meson triangle singularity on the inclusive production of T_{cc}^+ from the rescattering of DD leads to a narrow peak in the $T_{cc}^+\pi^+$ invariant mass distribution. A spin 2 partner of the T_{cc}^+ is predicted in Refs. [182, 183], who's hadronic decays are studied in Ref. [185].

As for the $\chi_{c1}(3872)$ one can employ the effective range deduced from experiment for the effective range in the DD^*-channel as a measure of the nature of the $T_{cc}(3875)$. Also here isospin violations are significant. It turns out that in a calculation where the one-pion exchange is kept fully non-perturbative, its effect on the

effective range is small and positive [183], while it is small and negative when being treated perturbatively [97,186].

First lattice studies are also available for the $T_{cc}(3875)$ [187–189], all performed at pion masses slightly larger than physical such that the D^* and with this also the $T_{cc}(3875)$ are stable. They all find that at these pion masses the T_{cc} is a virtual state. In Ref. [190] it was stressed, however, that all those analyses should be redone, since the proximity of a left-hand cut invalidates the method used.

79.3 Systems containing four heavy quarks

79.3.1 *The $T_{cc\bar{c}\bar{c}}(6900)$*

LHCb reported the observation of pronounced structures in a double-$J/\psi(1S)$ invariant mass distribution [191] thus pointing at states with $cc\bar{c}\bar{c}$ quarks contents. First results on di-$J/\psi(1S)$ and $J/\psi(1S)\psi(2S)$ invariant mass distributions in proton-proton collision data by the CMS [192] and ATLAS [193] Collaborations confirm and extend the resonance structures seen by LHCb. Belle reported on a first search for a double-charmonium state with $e^+e^- \to \eta_c J/\psi(1S)$ near threshold via the ISR process. No significant signal of the double charmonium state is found in several bins of the invariant mass of $\eta_c J/\psi(1S)$ [194]. Recently the COMPASS [195] Collaboration also studied double $J/\psi(1S)$ production in pion scattering off nuclear targets. No significant signatures that could be associated with tetraquarks are found in the double $J/\psi(1S)$ mass spectrum, although the COMPASS data sample is limited.

From quark models the possible existence of bound states like this was discussed already long ago [196,197]. There are now also many model calculations available in the literature. For discussions of those data from the compact tetraquark perspective see Refs. [198–204]. Most of these quark model calculations assign the reported structure to a $cc\bar{c}\bar{c}$ state in the $2S$ multiplet with near-degenerate $J^P = 0^+$, 1^+ and 2^+ configurations. The dominance of a compact tetraquark component in the apparently exotic structure is also supported by the coupled multichannel study of Ref. [205]. The full coupled-channel study of Ref. [206] leads to a rich spectrum of $c\bar{c}$-$c\bar{c}$ states where parts are candidates for the observed double $J/\psi(1S)$ structures. For direct analyses of the data within the tetraquark approach, see, e.g., Ref. [207]. Also QCD sum rule studies of the system were published, but do not give consistent results: For example Ref. [208] interprets the structure at 6900 MeV as a hybrid state, Ref. [209] as a tetraquark, and Ref. [210] states that both molecular and tetraquark interpretations are possible. An alternative view on the LHCb double-$J/\psi(1S)$ data is provided in Refs. [211–213] where the analyses are performed using coupled channel T-matrices. In these works the structures in the data emerge from the interplay of thresholds and resonances with the non-trivial prediction that there should exist, if this dynamical picture were correct, a state located very near the double-$J/\psi(1S)$ threshold which can be searched for experimentally. In Ref. [214] it was shown that a $J/\psi(1S)J/\psi(1S)$ scattering potential sufficiently strong to bind is in fact consistent with our current understanding of $\pi J/\psi(1S)$ scattering as well as the strength of the $\pi\pi$ interactions.

In contrast, Ref. [215,216] explains the double-$J/\psi(1S)$ data as cusps without nearby poles. This claim can be tested experimentally: if this explanation were correct, there should not be any narrow near threshold structure in the channel that generates the cusp, for that would call for a non-perturbative interaction in that channel, as pointed out in Ref. [217].

80. Baryon Decay Parameters

Revised August 2019 by E.D. Commins (UC Berkeley).

80.1 Baryon semileptonic decays

The typical spin-1/2 baryon semileptonic decay is described by a matrix element, the hadronic part of which may be written as:

$$\overline{B}_f \left[f_1(q^2)\gamma_\lambda + i\, f_2(q^2)\sigma_{\lambda\mu}q^\mu + g_1(q^2)\gamma_\lambda\gamma_5 + g_3(q^2)\gamma_5 q_\lambda \right] B_i \ . \tag{80.1}$$

Here B_i and $\overline{B}_f$ are spinors describing the initial and final baryons, and $q = p_i - p_f$, while the terms in f_1, f_2, g_1, and g_3 account for vector, induced tensor ("weak magnetism"), axial vector, and induced pseudoscalar contributions [1]. Second-class current contributions are ignored here. In the limit of zero momentum transfer, f_1 reduces to the vector coupling constant g_V, and g_1 reduces to the axial-vector coupling constant g_A. The latter coefficients are related by Cabibbo's theory [2], generalized to six quarks (and three mixing angles) by Kobayashi and Maskawa [3]. The g_3 term is negligible for transitions in which an $e^\pm$ is emitted, and gives a very small correction, which can be estimated by PCAC [4], for $\mu^\pm$ modes. Recoil effects include weak magnetism, and are taken into account adequately by considering terms of first order in

$$\delta = \frac{m_i - m_f}{m_i + m_f} \ , \tag{80.2}$$

where m_i and m_f are the masses of the initial and final baryons.

The experimental quantities of interest are the total decay rate, the lepton-neutrino angular correlation, the asymmetry coefficients in the decay of a polarized initial baryon, and the polarization of the decay baryon in its own rest frame for an unpolarized initial baryon. Formulae for these quantities are derived by standard means [5] and are analogous to formulae for nuclear beta decay [6]. We use the notation of Ref. [6] in the Listings for neutron beta decay. For comparison with experiments at higher q^2, it is necessary to modify the form factors at $q^2 = 0$ by a "dipole" q^2 dependence, and for high-precision comparisons to apply appropriate radiative corrections [7].

The ratio g_A/g_V may be written as

$$g_A/g_V = |\, g_A/g_V \,| e^{i\phi_{AV}} \ . \tag{80.3}$$

The presence of a "triple correlation" term in the transition probability, proportional to $\mathrm{Im}(g_A/g_V)$ and of the form

$$\boldsymbol{\sigma_i \cdot (p_\ell \times p_\nu)} \tag{80.4}$$

for initial baryon polarization or

$$\boldsymbol{\sigma_f \cdot (p_\ell \times p_\nu)} \tag{80.5}$$

for final baryon polarization, would indicate failure of time-reversal invariance. The phase angle ϕ has been measured precisely only in neutron decay (and in ^{19}Ne nuclear beta decay), and the results are consistent with T invariance.

80.2 Hyperon nonleptonic decays

The amplitude for a spin-1/2 hyperon decaying into a spin-1/2 baryon and a spin-0 meson may be written in the form

$$M = G_F\, m_\pi^2 \cdot \overline{B}_f\, (A - B\gamma_5)\, B_i \ , \tag{80.6}$$

where A and B are constants [1]. The transition rate is proportional to

$$R = 1 + \gamma\, \widehat{\boldsymbol{\omega}}_f \cdot \widehat{\boldsymbol{\omega}}_i + (1-\gamma)(\widehat{\boldsymbol{\omega}}_f \cdot \widehat{\mathbf{n}})(\widehat{\boldsymbol{\omega}}_i \cdot \widehat{\mathbf{n}}) + \alpha(\widehat{\boldsymbol{\omega}}_f \cdot \widehat{\mathbf{n}} + \widehat{\boldsymbol{\omega}}_i \cdot \widehat{\mathbf{n}}) + \beta \widehat{\mathbf{n}} \cdot (\widehat{\boldsymbol{\omega}}_f \times \widehat{\boldsymbol{\omega}}_i) \ , \tag{80.7}$$

where $\widehat{\mathbf{n}}$ is a unit vector in the direction of the final baryon momentum, and $\widehat{\boldsymbol{\omega}}_i$ and $\widehat{\boldsymbol{\omega}}_f$ are unit vectors in the directions of the initial and final baryon spins. (The sign of the last term in the above equation was incorrect in our 1988 and 1990 editions.) The parameters α, β, and γ are defined as

$$\begin{aligned} \alpha &= 2\,\mathrm{Re}(s^* p)/(|\, s\,|^2 + |\, p\,|^2) \ , \\ \beta &= 2\,\mathrm{Im}(s^* p)/(|\, s\,|^2 + |\, p\,|^2) \ , \\ \gamma &= (|\, s\,|^2 - |\, p\,|^2)/(|\, s\,|^2 + |\, p\,|^2) \ , \end{aligned} \tag{80.8}$$

where $s = A$ and $p = |\, \mathbf{p}_f\, | B/(E_f + m_f)$; here E_f and $\mathbf{p}_f$ are the energy and momentum of the final baryon. The parameters α, β, and γ satisfy

$$\alpha^2 + \beta^2 + \gamma^2 = 1 \tag{80.9}$$

If the hyperon polarization is $\mathbf{P}_Y$, the polarization $\mathbf{P}_B$ of the decay baryons is

$$\mathbf{P}_B = \frac{(\alpha + \mathbf{P}_Y \cdot \widehat{\mathbf{n}})\widehat{\mathbf{n}} + \beta(\mathbf{P}_Y \times \widehat{\mathbf{n}}) + \gamma \widehat{\mathbf{n}} \times (\mathbf{P}_Y \times \widehat{\mathbf{n}})}{1 + \alpha \mathbf{P}_Y \cdot \widehat{\mathbf{n}}} \ . \tag{80.10}$$

Here $\mathbf{P}_B$ is defined in the rest system of the baryon, obtained by a Lorentz transformation along $\widehat{\mathbf{n}}$ from the hyperon rest frame, in which $\widehat{\mathbf{n}}$ and $\mathbf{P}_Y$ are defined.

An additional useful parameter ϕ is defined by

$$\beta = (1 - \alpha^2)^{1/2} \sin\!\phi \ . \tag{80.11}$$

In the Listings, we compile α and ϕ for each decay, since these quantities are most closely related to experiment and are essentially uncorrelated. When necessary, we have changed the signs of reported values to agree with our sign conventions. In the Baryon Summary Table, we give α, ϕ, and Δ (defined below) with errors, and also give the value of γ without error.

Time-reversal invariance requires, in the absence of final-state interactions, that s and p be relatively real, and therefore that $\beta = 0$. However, for the decays discussed here, the final-state interaction is strong. Thus

$$s = |\, s\,| e^{i\delta_s} \text{ and } p = |\, p\,| e^{i\delta_p} \ , \tag{80.12}$$

where δ_s and δ_p are the pion-baryon s- and p-wave strong interaction phase shifts. We then have

$$\beta = \frac{-2\,|\, s\,|\,|\, p\,|}{|\, s\,|^2 + |\, p\,|^2} \sin(\delta_s - \delta_p) \ . \tag{80.13}$$

One also defines $\Delta = -\tan^{-1}(\beta/\alpha)$. If T invariance holds, $\Delta = \delta_s - \delta_p$. For $\Lambda \to p\pi^-$ decay, the value of Δ may be compared with the s- and p-wave phase shifts in low-energy $\pi^- p$ scattering, and the results are consistent with T invariance.

81. N and Δ Resonances

Revised August 2019 by V.D. Burkert (Jefferson Lab), V. Crede (Florida State U.), U. Thoma (Bonn U.), L. Tiator (KPH, JGU Mainz) and R.L. Workman (George Washington U.).

81.1 Introduction

The excited states of the nucleon have been studied in a large number of formation and production experiments. Until recently, the Breit-Wigner masses and widths, the pole positions, and the elasticities of the N and Δ resonances in the Baryon Summary Table came largely from partial-wave analyses of πN total, elastic, and charge-exchange scattering data. The most comprehensive analyses were carried out by the Karlsruhe-Helsinki (KH80) [1], Carnegie Mellon-Berkeley (CMB80) [2], and George Washington U (GWU) [3] groups. Partial-wave analyses have also been performed on much smaller πN reaction data sets to get ηN, $K\Lambda$, and $K\Sigma$ branching fractions (see the Listings for references). Other branching fractions come from analyses of $\pi N \to \pi\pi N$ data.

In recent years, a large amount of data on photoproduction of many final states has been accumulated, and these data are beginning to tell us much about the properties of baryon resonances. A survey of data on photoproduction can be found in the proceedings of recent conferences [4] and workshops [5], and in recent reviews [6, 7].

81.2 Naming scheme for baryon resonances

In the past, when nearly all resonance information came from elastic πN scattering, it was common to label resonances with the incoming partial wave $L_{2I,2J}$, as in $\Delta(1232)P_{33}$ and $N(1680)F_{15}$. However, most recent information has come from γN experiments. Therefore, we have replaced $L_{2I,2J}$ with the spin-parity J^P of the state, as in $\Delta(1232)3/2^+$ and $N(1680)5/2^+$; this name gives intrinsic properties of the resonance that are independent of the specific particles and reactions used to study them. This applies equally to all baryons, including Ξ resonances and charm baryons that are not produced in formation experiments. We do not, however, attach the mass or spin-parity to the names of the ground-state ("stable") baryons $N, \Lambda, \Sigma, \Xi, \Omega, \Lambda_c, \cdots$.

81.3 Using the N and Δ listings

Tables 81.1 and 81.2 list all the N and Δ entries in the Baryon Listings and give our evaluation of the overall status and the status channel by channel. Only the established resonances (overall status 3 or 4 stars) are promoted to the Baryon Summary Table. We long ago omitted from the Listings information from old analyses, prior to KH80 and CMB80, which can be found in earlier editions. A rather complete survey of older results was given in our 1982 edition [8].

As a rule, we award an overall status **** or *** only to those resonances which are derived from analyses of data sets that include precision differential cross sections and polarization observables, and are confirmed by independent analyses. All other signals are given ** or * status. New results that are not accompanied by proper error evaluation are less valuable for evaluating star ratings. The following criteria are guidelines for future error analysis.

1. Uncertainties in resonance parameters: The publication should have a detailed discussion on how the uncertainties of parameters were estimated. This requires that the error estimates go beyond the simple fit error as e.g. given by MINUIT, and the robustness of the results should be demonstrated.

2. Fit quality: Concrete measures for the fit quality should be provided. The reduced global χ^2 value of the fit, while useful, is insufficient. Other possibilities include quoting variations of local χ^2 values in kinematic regions where evidence for new resonances, or significantly improved information on resonance parameters, is claimed.

3. Weight factors in observables: Analyses sometimes use weight factors for certain data sets to either increase or reduce their impact on the results. This has been particularly important when polarization observables are involved, which often are sensitive to resonance amplitudes through interferences, but usually have much poorer statistics than differential cross section data. To evaluate sensitivities, the resulting resonance parameters should be checked against variations of the specific weight factors.

Table 81.1: The status of the N resonances and their decays. Sub-threshold decay modes are omitted. Only resonances with an overall status of *** or **** are included in the main Baryon Summary Table.

Claims of evidence for new baryon states must be based on a sufficiently complete set of partial waves in the fit. The robustness of signals must be demonstrated, e.g. by examining the effect of higher partial waves in the fit.

81.4 Properties of resonances

Resonances are defined by poles of the S-matrix, whether in scattering, production or decay matrix elements. These are poles

in the complex plane in s, as discussed in the new review on *Resonances*. As is traditional, we quote here the pole positions in the complex energy $w = \sqrt{s}$ plane. Crucially, the position of the pole of the S-matrix is independent of the process, and the production and decay properties factorize. This is the rationale for listing the pole position first for each resonance. These key properties of the S-matrix pole are in contrast to other quantities related to resonance phenomena, such as Breit-Wigner parameters or any K-matrix pole. Breit-Wigner parameters depend on the formalism used, such as angular-momentum barrier factors, or cut-off parameters, and the assumed or modeled background. However, the accurate determination of pole parameters from the analysis of data on the real energy axis is not necessarily simple, or even straightforward. It requires the implementation of the correct analytic structure of the relevant (often coupled) channels.

In principle, there are two ways to extract pole parameters from experimental data: (i) analytic continuation of theoretical single- or multi-channel models into the complex energy plane or (ii) local expansions of the partial-wave T-matrix amplitudes in the complex energy plane in the vicinity of a pole.

At present, poles are usually extracted using the first method [9–14], but considerable effort has been put into the development of alternate approaches, such as the speed plot [15], time delay [16], N/D method [17], regularization procedure [18], or Padè approximation [19].

Methods of the second type are based on the idea to use first or higher-order derivatives in energy to reduce the importance of, or totally eliminate, the background contribution. One either has to model the background contribution and introduce model dependence, or one is faced with numerical derivatives of single-energy data. In both cases, one reaches almost unsurmountable difficulties.

An alternate way to extract pole parameters from partial waves has been proposed by introducing a Laurent+Pietarinen (L+P) expansion [20–22]

$$T(W) = \sum_{i=1}^{N} \frac{Res_i}{W - W_i} + \sum_{j=1}^{M} \sum_{n=0}^{n_{max}} c_n^j \left(\frac{\alpha_j - \sqrt{x_j - W}}{\alpha_j + \sqrt{x_j - W}}\right)^n , \quad (81.1)$$

where $T(W)$ is a given partial wave amplitude, W_i and Res_i are the N complex pole positions and residues. The background is parameterized with M Pietarinen functions, where α_j are positive range parameters and x_j are real or complex branch points; c_n^j are real expansion coefficients.

The main idea of this procedure is to find the simplest analytic function, with well-defined poles and cuts, regardless of whether they are generated by a theoretical model or some energy-independent procedure. Instead of searching for the function which reproduces the input amplitudes over the complete complex energy plane, on all Riemann sheets, a representation is searched only in a limited complex energy range, near the real axis, which is defined by the radius of convergence of the Laurent decomposition, and which contains the input amplitudes. All details are found in Ref. [21]. Applications of the method can be found in [20–27].

81.5 Photoproduction

A new approach to the nucleon excitation spectrum is provided by dedicated facilities at the Universities of Bonn, Grenoble, and Mainz, and at the national laboratories Jefferson Lab in the US and SPring-8 in Japan. High-precision cross sections and polarization observables for the photoproduction of pseudoscalar mesons provide a data set that is approaching a "complete experiment," one that fully constrains the four complex amplitudes describing the spin-structure of the reaction [28]. A large number of photoproduction reactions has been studied.

In pseudoscalar meson photoproduction, the four independent helicity amplitudes can be expressed in terms of the four CGLN [29] amplitudes allowed by Lorentz and gauge invariance. These amplitudes can be expanded in a series of electric and magnetic multipoles. Except for $J = 1/2$, one electric and one magnetic multipole contributes to each J^P combination.

For a given state, these two amplitudes determine the resonance photo-decay helicity amplitudes $A_{1/2}$ and $A_{3/2}$. As described below, this resonance extraction has been carried out either assuming a Breit-Wigner resonance or at the pole.

If a Breit-Wigner parametrization is used, the $N\gamma$ partial width, Γ_γ, is given in terms of the helicity amplitudes $A_{1/2}$ and $A_{3/2}$ by

$$\Gamma_\gamma = \frac{k_{\rm BW}^2}{\pi} \frac{2m_N}{(2J+1)m_{\rm BW}} \left(|A_{1/2}|^2 + |A_{3/2}|^2 \right) . \quad (81.2)$$

Here m_N and $m_{\rm BW}$ are the nucleon and resonance masses, J is the resonance spin, and $k_{\rm BW}$ is the photon c.m. decay momentum. Most earlier analyses have provided these real quantities $A_{1/2}$ and $A_{3/2}$.

More recent studies have quoted related complex quantities, evaluated at the T-matrix pole. These complex helicity amplitudes, $\tilde{A}_{1/2}$ and $\tilde{A}_{3/2}$, can be cast onto the form

$$\tilde{A}_h = \sqrt{\frac{\pi(2J+1)w_{\rm pole}}{m_N k_{\rm pole}^2}} \frac{Res(T_h(\gamma N \to N\, b))}{\sqrt{Res(T\,(N\, b \to N\, b))}} \quad (81.3)$$

where the residues (Res) are evaluated at the pole position, $w_{\rm pole}$, and $k_{\rm pole}^2 = (w_{\rm pole}^2 - m_N^2)^2/4w_{\rm pole}^2$ [30]. For Breit-Wigner amplitudes, $w_{\rm pole} = m_{\rm BW}$ and $\tilde{A}_h = A_h$. Similar relations for the photo and electro couplings at the pole position can be found in [31, 32].

The determination of eight real numbers from four complex amplitudes (with one overall phase undetermined) requires at least seven independent measurements. At least one further measurement is required to resolve discrete ambiguities that result from the fact that data are proportional to squared amplitudes. Photon beams and nucleon targets can be polarized (with linear or circular polarization $P_\perp$, $P_\odot$ and $\vec{T}$, respectively); the recoil polarization of the outgoing baryon $\vec{R}$ can be measured. The experiments can be divided into three classes: (1) the beam and target are polarized (BT); (2) the beam is polarized and the recoil baryon polarization is measured (BR); (3) the target is polarized and the recoil polarization is measured (TR). Different sign conventions are used in the literature, as summarized in [33].

One of the best studied reactions is $\gamma p \to \Lambda K^+$. Published data include differential cross sections, the beam asymmetry Σ, the target asymmetry T, the recoil polarization P, and the BR double-polarization variables $C_{x'}, C_{z'}, O_{x'}$, and $O_{z'}$. For the photoproduction of pions and etas, off proton and neutron targets, differential cross sections, single- and double-polarization asymmetries have been measured, mainly for pions.

81.6 Electroproduction

Electroproduction of mesons provides information on the internal structure of resonances. The helicity amplitudes are functions of the (squared) momentum transfer $Q^2 = -(e-e')^2$, where e and e' are the 4-momenta of the incident and scattered electron, and a third amplitude, $S_{1/2}$, measures the resonance response to the longitudinal component of the virtual photon. Most data stem from the reactions $e^- p \to e^- n\pi^+$ and $e^- p \to e^- p\pi^0$ but also the reactions $e^- p \to e^- p\eta$, $e^- p \to e^- p\pi^+\pi^-$, and $e^- p \to e^- \Lambda(\Sigma^0)K^+$ have been studied. The data and their interpretation are reviewed in Refs. [34, 35].

The transition to the $\Delta(1232)3/2^+$ is often quantified in terms of the magnetic dipole transition moment M_{1+} (or the magnetic transition form factor $G_{M,Ash}^*(Q^2)$) [36], and the electric and scalar quadrupole transition moments E_{1+} and S_{1+}. Figure 81.1 shows the strength of the $p \to \Delta^+$ transition plotted versus the photon virtuality Q^2. At $Q^2 = 0$, M_{1+} dominates the resonance transition strength. The two amplitudes E_{1+} and S_{1+} imply a quadrupole deformation of the transition to the lowest excited state. The magnitude of $R_{EM} = E_{1+}/M_{1+}$ remains nearly constant, while the magnitude of $R_{SM} = S_{1+}/M_{1+}$ increases rapidly up to 25% at the highest Q^2 value.

Figure 81.2 shows the transverse and scalar helicity amplitudes for the $N(1440)1/2^+$, $N(1520)3/2^-$, and $N(1535)1/2^-$ resonances from JLab [34]. Similar results have been achieved at

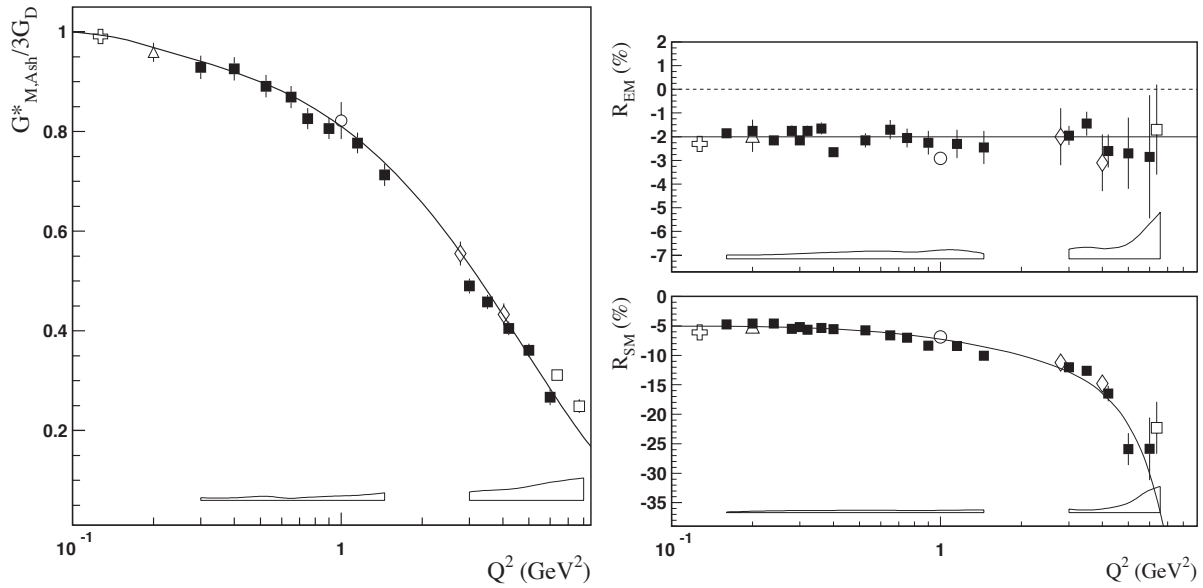

Figure 81.1: Left: The magnetic transition form factor for the $\gamma^* p \to \Delta^+(1232)$ transition versus the photon virtuality Q^2. Right: The electric and scalar quadrupole ratios R_{EM} and R_{SM}. The different symbols are results from different experiments at JLab (squares, diamonds, circle) and MAMI (triangle, cross). The boxes near the horizontal axis indicate model uncertainties of the squares. Curves to guide the eyes.

Mainz [35]. For the states $N(1440)1/2^+$ and $N(1520)3/2^-$, helicity amplitudes and $\pi\Delta$ and ρp decays were determined at JLab in an analysis of $\pi^+\pi^- p$ electroproduction [37]. The data show distinctly different Q^2 dependencies that indicate different internal structures.

The $N(1520)3/2^-$ helicity amplitudes reveal the dominance of its three-quark nature: the $A_{3/2}$ amplitude is large at the photon point and decreases rapidly $\sim Q^{-5}$ with increasing Q^2; $A_{1/2}$ is small at the photon point, increases rapidly with Q^2 and then falls off with $\sim Q^{-3}$. Quantitative agreement with the data is, however, achieved only when meson cloud effects are included.

At high Q^2, both amplitudes for $N(1440)1/2^+$ are qualitatively described by light front quark models [38]: at short distances the resonance behaves as expected from a radial excitation of the nucleon. On the other hand, $A_{1/2}$ changes sign at about $0.6\,\mathrm{GeV}^2$. This remarkable behavior has not been observed before for any nucleon form factor or transition amplitude. Obviously, an important change in the structure occurs when the resonance is probed as a function of Q^2.

The Q^2 dependence of $A_{1/2}$ of the $N(1535)1/2^-$ resonance exhibits the expected Q^{-3} dependence, except for small Q^2 values where meson cloud effects set in.

Figure 81.3 shows the transverse and scalar amplitudes for three states in the 3rd nucleon resonance region, the $\Delta(1620)1/2^-$, the $N(1675)5/2^-$ and $N(1680)5/2^+$. The latter two states have nearly degenerate masses and are parity partners. In the quark model picture, the transverse amplitudes for $N(1675)5/2^-$ on the proton are suppressed due to the Moorhouse selection rule, allowing for a quantitative evaluation of the meson-baryon contributions. The data show significant meson-baryon strength in the $A_{1/2}$ amplitude even at quite high Q^2, while $A_{3/2}$ drops much faster with Q^2. $N(1680)5/2^+$ shows qualitatively the features predicted in constituent quark models, a dominant $A_{3/2}$ at the real photon point that drops rapidly with increasing Q^2, while $A_{1/2}$ becomes the dominant contribution at high Q^2, indicating a switch of the helicity structure in the resonance transition at short distances.

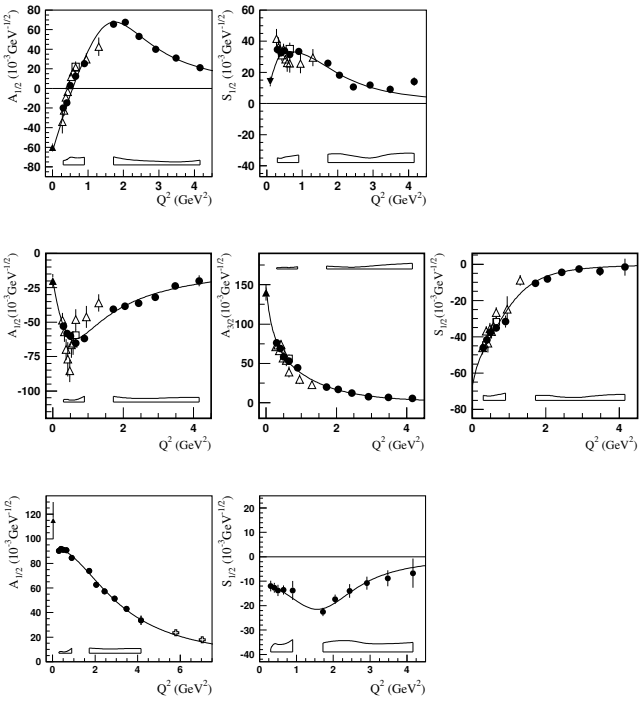

Figure 81.2: Transverse and scalar (longitudinal) helicity amplitudes for $\gamma p \to N(1440)1/2^+$ (top), $\gamma p \to N(1520)3/2^-$ (center), and $\gamma p \to N(1535)1/2^-$ (bottom) as extracted from the JLab/-CLAS data in $n\pi^+$ production (full circles), MAMI/A1 data in $p\pi^0$ production (full down triangle), in $p\pi^+\pi^-$ (open triangles), and combined single and double pion production (open squares). The solid triangle is the PDG 2014 value at $Q^2 = 0$. The open boxes are the model uncertainties of the full circles.

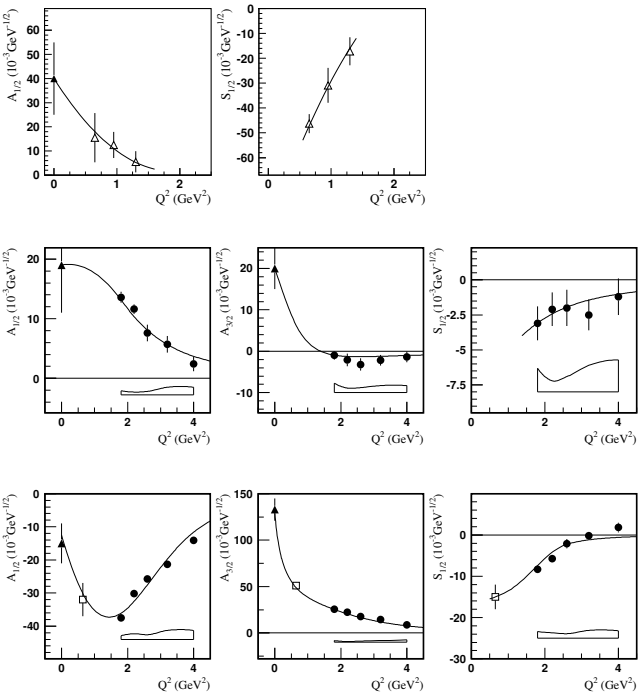

Figure 81.3: Transverse and scalar helicity amplitudes for $\gamma p \to \Delta(1620)1/2^-$ (top), $\gamma p \to N(1675)5/2^-$ (center), and $\gamma p \to N(1680)5/2^+$ (bottom) as extracted from the JLab/CLAS data in $n\pi^+$ production (full circles), $p\pi^+\pi^-$ (open triangles), combined single and double pion production (open square). The solid triangle is the 2014 PDG value at $Q^2 = 0$. The open boxes are the model uncertainties of the full circles. The curves are to guide the eye.

81.7 Partial wave analyses

Several PWA groups are now actively involved in the analysis of the new data. The GWU group maintains a nearly complete database covering reactions from πN and KN elastic scattering to $\gamma N \to N\pi$, $N\eta$, and $N\eta'$. It is presently the only group determining πN elastic amplitudes from scattering data in sliced energy bins. Given the high-precision of photoproduction data already or soon to be collected, the spectrum of N and Δ resonances will in the near future be better known.

Fits to the data are performed by various groups with the aim to understand the reaction dynamics and to identify N and Δ resonances. For practical reasons, approximations have to be made. We mention several analyses here: (1) The Mainz unitary isobar model [39] focuses on the correct treatment of the low-energy domain. Resonances are added to the unitary amplitude as a sum of Breit-Wigner amplitudes. This model also obtains resonance transition form factors and helicity amplitudes from electroproduction [35]. (2) For $N\pi$ electroproduction, the Yerevan/JLab group uses both the unitary isobar model and the dispersion relation approach developed in [38]. A phenomenological model was developed to extract resonance couplings and partial decay widths from exclusive $\pi^+\pi^- p$ electroproduction [37]. (3) Multichannel analyses using K-matrix parameterizations derive background terms from a chiral Lagrangian - providing a microscopical description of the background - (Giessen [40, 41]) or from phenomenology (KSU [42, 43], Bonn-Gatchina [44]). (4.) Several groups (EBAC-Jlab [45, 46], ANL-Osaka [47], Dubna-Mainz-Taipeh [48], Bonn-Jülich [49–51], Valencia [52]) use dynamical reaction models, driven by chiral Lagrangians, which take dispersive parts of intermediate states into account. Several other groups have made important contributions. The Giessen group pioneered multichannel analyses of large data sets on pion- and photo-induced reactions [40, 41]. The Bonn-Gatchina group included recent high-statistics data and reported systematic searches for new baryon resonances in all relevant partial waves. A summary of their results can be found in [44].

82. Λ and Σ Resonances

Revised August 2021 by V.D. Burkert (Jefferson Lab), V. Crede (Florida State U.), E. Klempt (Bonn U.), U. Thoma (Bonn U.), L. Tiator (KPH, JGU Mainz) and R.L. Workman (George Washington U.).

82.1 Introduction

For several decades, there has been very little new experimental data bearing on the properties of Λ and Σ resonances. An exception was the study at JLab of the reactions $\gamma p \to K^+\Sigma^\pm\pi^\mp$ and $\gamma p \to K^+\Sigma^0\pi^0$ [1], which established the spin and parity of the $\Lambda(1405)$ [2]. There was also from BNL new data on the very low energy region of K^-p scattering [3–7]. Otherwise, the field is starved for data. Recent analyses (see below) have improved what we know about the *properties* of the known Λ and Σ resonances, but the *established* resonances are the same ones that were listed in our 1984 edition [8] except for the $\Sigma(2250)$ which we consider 2-star only due to its unkown spin-parity. The 1990 Review [9] gave a full report of the status of Lambda and Sigma hyperons, and included Argand plots from the partial-wave analyses. The 2018 Review [10] has a short survey of the $\Sigma(1670)$-region.

In the last few years, four groups have re-analyzed K^-p reactions using more extensive collections of the old data. These analyses justify an update of the status of the Λ and Σ resonances. Although they have not established any new resonances, they have provided at least some evidence for new states and have given a better understanding of the old ones.

Tables 82.1 and 82.2 give our evaluation of the status, both overall and channel by channel, of each Λ and Σ resonance in the Particle Listings. In making these evaluations, we considered, in addition to the four analyses [11–14], the ratings that predated them. The ratings use a 1- to 4-star system. For more details on the evaluation of the overall star ratings, see [15]. The main Summary Table includes only established states with an overall status of 3 or 4 stars; as has already been noted, these are the same fourteen Λ resonances (including $\Lambda(1116)$) and nine Σ resonances instead of the former ten (including $\Sigma(1193)3/2^+$, and $\Sigma(1385)3/2^+$) that had long been in the Table. In addition, there are seven 1-star and two 2-star Λ's, and fourteen 1-star and three 2-star Σ's in the Particle Listings.

82.2 New analyses

The new analysis progress was pioneered by the Kent group which collected a large fraction of the available data and performed a comprehensive partial wave analysis [11,16]. K^-p scattering into a pseudoscalar meson and an octet baryon is governed by two complex amplitudes; hence four quantities need to be measured to fully construct the amplitudes (up to an arbitrary phase per energy and angular bin). Discussions of complete experiments also generally assume perfect data (no experimental uncertainties); realistic uncertainties further complicate the task of amplitude extraction. Here, the available data are limited to the differential cross section and the target or hyperon recoil polarization P; data on the polarization transfer do not exist. The authors of Ref. [16] overcame this difficulty by using start values for the partial wave amplitudes determined in [17] and/or from an energy-dependent fit and by freezing or releasing sets of amplitudes. The resulting amplitudes were fitted with a unitary multichannel parameterization [11].

The JPAC group presented a coupled-channel fit to the $\bar{K}N$ partial waves derived by the Kent group [13]. The JPAC approach was based on the K-matrix formalism. Special attention was paid to the analytical properties of the amplitudes determined by the square-root unitary branch points and the continuation to the complex angular momentum plane. The fit described the Kent partial waves reasonably well. However, when observables were calculated from their partial-wave amplitudes, significant discrepancies became apparent. The results were therefore not included in the RPP.

The ANL-Osaka group derived the energy-dependent amplitudes in fits to a large subset of the data collected in Ref. [16] and further data sets described in Ref. [18]. Their fits were based on a phenomenological SU(3) Lagrangian [18]. The two ANL-Osaka models agree on the leading contributions but differ significantly in cases with weaker candidates [12].

Table 82.1: The status of the Λ resonances. Only those with an overall status of *** or **** are included in the main Baryon Summary Table. Decay channels other than $N\overline{K}$ and $\Sigma\pi$ are only given for *** and **** resonances.

			Status as seen in —

$\Lambda(2350)$	$9/2^+$	***	***	*	
$\Lambda(2585)$		*	*		

The Bonn-Gatchina (BnGa) group added further (old) data to those analyzed in Ref. [16]. The data set was fitted in a modified K-matrix approach and the resulting amplitudes were compared with those from Refs. [16, 18]. New resonances were found, other states, mostly one and two-star states could not be confirmed; all resonances were tested for their statistical significance. Additional states with any set of quantum numbers were tested and were found to produce only small improvements in the fit [14]. In Ref. [19], properties of the full set of contributing hyperons were reported.

The star ratings of Λ and Σ resonances given in our earlier editions, and the new results from the Kent, ANL-Osaka and BnGa groups were used to update the star rating of the hyperon resonances. In [19], the overall star rating is directly estimated, for [11] we estimate the star rating from the branching-ratio uncertainties. In [12], two solutions are given but no uncertainties for branching ratios. The overall star ratings are based on the evidence for the resonances in the new analyses as well as their consistency including also the results of earlier analyses given in [20]. For further details see also [15].

We decided to remove the three so-called *bumps* $\Sigma(1480)$, $\Sigma(1560)$, $\Sigma(1670)$, and $\Sigma(1690)$ as well as $\Sigma(1620)$ from production experiments. The entries from $\Sigma(1770)1/2^+$ are now listed under $\Sigma(1660)1/2^+$ and $\Sigma(1880)1/2^+$, the entries from $\Sigma(1730)3/2^+$ and $\Sigma(1840)3/2^+$ are now combined to one $\Sigma(1780)3/2^+$. The one-star $\Sigma(2000)1/2^-$ is combined with a new one-star $\Sigma(2160)1/2^-$ to a single one-star $\Sigma(2110)1/2^-$. Apart from $\Lambda(1380)1/2^-$, four further new resonances were included in the Listings: $\Lambda(2070)3/2^+$, $\Lambda(2080)5/2^-$, $\Sigma(2010)3/2^-$, and $\Sigma(2230)3/2^+$, all with one star.

Table 82.2: The status of the Σ resonances. Only those with an overall status of *** or **** are included in the main Baryon Summary Table. Decay channels other than $N\overline{K}$, $\Lambda\pi$ and $\Sigma\pi$ are only given for *** and **** resonances.

82.3 Sign conventions for resonance couplings

In terms of the isospin-0 and isospin-1 elastic scattering amplitudes A_0 and A_1, the amplitude for $K^-p \to \overline{K}^0 n$ scattering is $\pm(A_1 - A_0)/2$, where the sign depends on conventions used in conjunction with the Clebsch-Gordan coefficients (such as, is the baryon or the meson the "first" particle). If this reaction is partial-wave analyzed and if the overall phase is chosen so that, say, the $\Sigma(1775)5/2^-(D_{15})$ amplitude at resonance points along the positive imaginary axis (points "up"), then any Σ at resonance will point "up" and any Λ at resonance will point "down" (along the negative imaginary axis). Thus the phase at resonance determines the isospin. The above ignores background amplitudes in the resonating partial waves.

That is the basic idea. In a similar but somewhat more complicated way, the phases of the $\overline{K}N \to \Lambda\pi$ and $\overline{K}N \to \Sigma\pi$ amplitudes for a resonating wave help determine the SU(3) multiplet to which the resonance belongs. Again, a convention has to be adopted for some overall arbitrary phases: which way is "up"? Our convention is that of Levi-Setti [21] and is shown in Fig. 82.1, which also compares experimental results with theoretical predictions for the signs of several resonances. In the Listings, a + or − sign in front of a measurement of an inelastic resonance coupling indicates the sign (the *absence* of a sign means that the sign is not determined, *not* that it is positive). Also other decay modes can be used to assign a hyperon to a SU(3) multiplet [22, 23]. Modern analyses determine properties of resonances at the pole position. In these analyses, the + or − sign is replaced by a phase. Background amplitudes can lead to significant phase shifts, and an additional phase shift due to rescattering is admitted in some analyses. In comparison to quark model predictions [19,24], three Λ spin doublets can be identified as being mainly SU(3) singlets: the well-known ($\Lambda(1405)1/2^-$, $\Lambda(1520)3/2^-$), the ($\Lambda(2080)5/2^-$, $\Lambda(2100)7/2^-$), and ($\Lambda(2070)3/2^+$, $\Lambda(2110)5/2^+$).

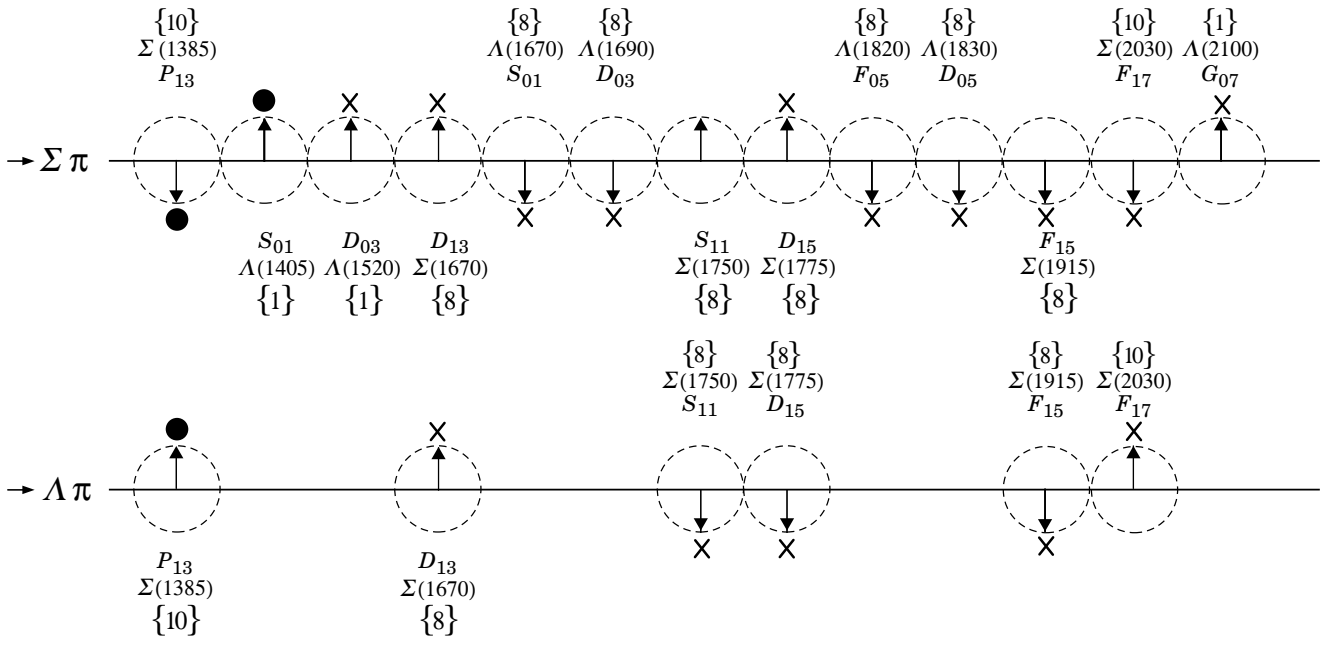

Figure 82.1: The signs of the imaginary parts of resonating amplitudes in the $\overline{K}N \to \Lambda\pi$ and $\Sigma\pi$ channels. The signs of the $\Sigma(1385)$ and $\Lambda(1405)$, marked with a •, are set by convention, and then the others are determined relative to them. The signs required by the SU(3) assignments of the resonances are shown with an arrow, and the experimentally determined signs are shown with an ×.

82.4 The $\Lambda(1405)$

In coupled-channels calculations based on the chiral SU(3) effective field theory, the strongly attractive forces between $N\overline{K}$ and $\Sigma\pi$ generate five poles, one SU(3) singlet pole, two Λ octet poles and two (or one) octet Σ poles (see Section 83). In quark models, these five states are $\Lambda(1405)$, $\Lambda(1670)$, $\Lambda(1800)$, $\Sigma(1620)$,

and $\Sigma(1750)$. The octet states are found 100 to 150 MeV above the corresponding nucleon resonances. In chiral SU(3) effective field theories, at least three of these states are seen in the 1300 to 1600 MeV mass range. The appearance of two Λ poles in this mass range, a narrow SU(3) octet at ∼1420 MeV and a wider SU(3) singlet at ∼1380 MeV, was unexpected. This approach has been pursued by a number of groups; for a summary of the results see our Review 83, "Pole Structure of the $\Lambda(1405)$ Region". In the Listings, we have introduced the $\Lambda(1380)$ as a new candidate resonance (with two stars), named in accordance with its approximate pole position. The second SU(3) octet Λ state is the well-known $\Lambda(1670)$. The masses of the two associated Σ states are uncertain so far, and no new entries are introduced in the Listings.

In traditional approaches only one resonance was seen in this mass region, the narrow state at 1405 MeV. It was reported to be the SU(3) singlet state a long time ago in Ref. [25], in agreement with the quark-model expectations but in contrast to the findings based on coupled-channels calculations within chiral SU(3) effective field theories. In the Listings, the $\Lambda(1405)$ has been retained with its traditional name. In quark models, this state is identified with the SU(3) singlet state, the two Λ octet states with $\Lambda(1670)$ and $\Lambda(1800)$, and the two Σ states with $\Sigma(1620)$ and $\Sigma(1750)$.

82.5 Uncertainties on masses and widths

The uncertainties quoted on resonance parameters from partial-wave analyses are often only statistical, and the parameters can change beyond these uncertainties when a different parametrization of the waves is used. Furthermore, the different analyses use more or less the same data, so it is not really appropriate to treat the different determinations of the resonance parameters as independent or to average them. In any case, the spread of the masses, widths, and branching fractions from the different analyses is certainly a better indication of the uncertainties than are the quoted uncertainties. In the Listings, we usually give a range reflecting the spread of the values rather than a particular value with error.

82.6 Production experiments

Partial-wave analyses of course separate partial waves, whereas a peak in a cross section or an invariant mass distribution usually cannot be disentangled from background and analyzed for its quantum numbers; and more than one resonance may be contributing to the peak. The $\Sigma(1385)$ and $\Lambda(1405)$ lie below the $\overline{K}N$ threshold and nearly everything about $\Sigma(1385)$ is learned from production experiments. Our knowledge on $\Lambda(1405)$ benefits greatly from photoproduction of the three $\Sigma\pi$ charge states [1, 2] and from the precise measurement of the energy shift and width of the kaonic hydrogen atom [26].

Production and formation experiments agree quite well in the case of $\Lambda(1520)$ and results have been combined. Above this mass, no new results on peak hunting have been reported for about 40 years. For these early results, we refer the reader to our earlier editions. In photoproduction with energetic photons [27, 28] or at LHCb [29], hyperons are produced abundantly. So far, no attempt has been made to extract hyperon properties from these data. New data on hyperon spectroscopy can be expected from J-PARC [30], JLAB [31], and the forthcoming PANDA experiment [32].

83. Pole Structure of the $\Lambda(1405)$ Region

Revised June 2021 by T. Hyodo (Tokyo Metropolitan U.) and U.-G. Meißner (Bonn U.; FZ Jülich).

The $\Lambda(1405)$ resonance emerges in the meson-baryon scattering amplitude with the strangeness $S = -1$ and isospin $I = 0$. It is the archetype of what is called a dynamically generated resonance, as pioneered by Dalitz and Tuan [1]. The most powerful and systematic approach for the low-energy regime of the strong interactions is chiral perturbation theory (ChPT), see e.g. Ref. [2]. A perturbative calculation is, however, not applicable to this sector because of the existence of the $\Lambda(1405)$ just below the $\bar{K}N$ threshold. In this case, ChPT has to be combined with a non-perturbative resummation technique, just as in the case of the nuclear forces. By solving the Lippmann-Schwinger equation with the interaction kernel determined by ChPT and using a particular regularization, in Ref. [3] a successful description of the low-energy K^-p scattering data as well as the mass distribution of the $\Lambda(1405)$ was achieved (for further developments, see Ref. [4–7] and references therein).

The study of the pole structure was initiated by Ref. [8], which finds two poles of the scattering amplitude in the complex energy plane between the $\bar{K}N$ and $\pi\Sigma$ thresholds. The spectrum in experiments exhibits one effective resonance shape, while the existence of two poles results in the reaction-dependent lineshape [9]. The origin of this two-pole structure is attributed to the two attractive channels of the leading order interaction in the SU(3) basis (singlet and octet) [9] and in the isospin basis ($\bar{K}N$ and $\pi\Sigma$) [10]. It is remarkable that the sign and the strength of the leading order interaction is determined by a low-energy theorem of chiral symmetry, i.e. the so-called Weinberg-Tomozawa term. The two-pole nature of the $\Lambda(1405)$ is qualitatively different from the case of the N(1440) resonance. Two poles of the N(1440) appear on different Riemann sheets of the complex energy plane separated by the $\pi\Delta$ branch point. These poles reflect a single state, with a nearby pole and a more distant shadow pole. In contrast, the two poles in the $\Lambda(1405)$ region on the same Riemann sheet (where $\pi\Sigma$ channels are unphysical and all other channels physical, correspondingly to the one, connected to the real axis beween the $\pi\Sigma$ and $\bar{K}N$ thresholds) are generated from two attractive forces mentioned above [9, 10].

Recently, various new experimental results on the $\Lambda(1405)$ have become available [4]. Among these, the most striking measurement is the precise determination of the energy shift and width of kaonic hydrogen by the SIDDHARTA collaboration [11,12], which provides a quantitative and stringent constraint on the K^-p amplitude at threshold through the improved Deser formula [13]. Systematic studies with error analyses based on the next-to-leading order ChPT interaction including the SIDDHARTA constraint have been performed by various groups [14–18] All these studies confirm that the new kaonic hydrogen data are compatible with the scattering data above threshold.

The results of the pole positions of $\Lambda(1405)$ in the various approaches are summarized in Table 83.1. We may regard the difference among the calculations as a systematic error, which stems from the various approximations of the Bethe-Salpeter equation, the fitting procedure, and also the inclusion of SU(3) breaking effects such as the choice of the various meson decay constants, and so on. A detailed comparison of the various approaches that enter the table is given in Ref. [19]. A recent analysis including also the $J^P = 1/2^+$ P-wave contribution (and also an explicit $\Sigma(1385)$ $3/2^+$ state) gives results consistent with the findings reported above, with the pole positions at $(1364 - i43)$ MeV and $(1430 - i15)$ MeV, respectively [20].

The main component for the $\Lambda(1405)$ is the pole 1, whose position converges within a relatively small region near the $\bar{K}N$ threshold. On the other hand, the position of the pole 2 shows a sizeable scatter. Detailed studies of the $\pi\Sigma$ spectrum in various reaction processes, together with the precise experimental lineshape (see e.g. the recent precise photoproduction data from the LEPS collaboration [21] and from the CLAS collaboration [22,23], electroproduction data from the CLAS collaboration [24], and proton-proton collision data from COSY [25] and the HADES collaboration [26]), will shed light on the position of the second pole. The $\pi\Sigma$ spectra from the CLAS data are analyzed in Ref. [27] and Ref. [18]. It was shown in Ref. [18] that several solutions, which agree with the scattering data, are ruled out if confronted with the recent CLAS data. The remaining solutions are collected as solution #2 and solution #4 in Table 83.1. The HADES data are analyzed in Ref. [28] and Ref [29]. Although the result of the pole found in Ref. [28] is not compatible with other results, the authors of Ref. [29] invoke the anomalous triangle singularity mechanism to argue that the invariant mass distribution of the $\pi\Sigma$ system is found at lower masses than in other reactions. It is thus desirable to perform more comprehensive analyses of $\pi\Sigma$ spectra together with the systematic error analysis of the scattering data.

Table 83.1: Comparison of the pole positions of $\Lambda(1405)$ in the complex energy plane from next-to-leading order chiral unitary coupled-channel approaches including the SIDDHARTA constraint. The lower two results also include the CLAS photoproduction data.

approach	pole 1 [MeV]	pole 2 [MeV]

84. Pentaquarks

Revised March 2024 by M. Karliner (Tel Aviv U.) and T. Skwarnicki (Syracuse U.).

Experimental searches for pentaquark hadrons comprised of light flavors have a long and vivid history. No undisputed candidates had been found in 50 years. The first wave of claimed observations of pentaquark candidates containing a strange antiquark occurred in the early seventies, see e.g. a review in the 1976 edition of Particle Data Group listings for $Z_0(1780)$, $Z_0(1865)$ and $Z_1(1900)$ [1]. The last mention of these candidates can be found in the 1992 edition [2] with the perhaps prophetic comment "the results permit no definite conclusion - the same story for 20 years. [...] The skepticism about baryons not made of three quarks, and lack of any experimental activity in this area, make it likely that another 20 years will pass before the issue is decided." A decade later, a second wave of observations occurred, possibly motivated by specific theoretical predictions for their existence [3–5]. The evidence for pentaquarks was based on observations of peaks in the invariant mass distributions of their decay products. More data and subsequent more sensitive experiments did not confirm these claims [6]. In the last mention of the best known candidate from that period, $\Theta(1540)^+$, the 2006 Particle Data Group listing [7] included a statement: "The conclusion that pentaquarks in general, and that Θ^+, in particular, do not exist, appears compelling." which well reflected the prevailing mood in the particle physics community until a study of $\Lambda_b^0 \to J/\psi p K^-$ ($J/\psi \to \mu^+\mu^-$) decays by LHCb [8] (charge conjugate modes are implied). From an analysis of 3 fb^{-1} Run 1 data at 7 and 8 TeV at the LHC, the LHCb collaboration reported a significant $J/\psi p$ structure in $\Lambda_b^0 \to J/\psi p K^-$ decays [8]. The exotic character of this structure, with the minimal quark content of $uudc\bar{c}$, was demonstrated in a nearly model-independent way in Ref. [9], where it was shown that the $J/\psi p$ mass ($m_{J/\psi p}$) peak near 4450 MeV was too narrow to be accounted for by $\Lambda^* \to pK^-$ reflections (Λ^* denotes a generic Λ excitation), reinforcing the results from the earlier model-dependent six-dimensional amplitude analysis of invariant masses and decay angles describing the Λ_b^0 decay in the same data [8]. The LHCb 6 fb^{-1} Run 2 LHC data at 13 TeV, together with the improvements in the data selection for both runs, resulted in a nine-fold increase in the number of reconstructed $\Lambda_b^0 \to J/\psi p K^-$ decays (246,000 events) [10] and observation of new narrow $J/\psi p$ structures which were too faint to had been significant in the Run 1 data analysis. A second horizontal band is observed in the Dalitz plot (Fig. 84.1) near 4312 MeV in the $J/\psi p$ mass.

The 4450 MeV structure also appears to consist of two narrower peaks at 4440 and 4457 MeV. Performing a rigorous six-dimensional amplitude analysis of these faint $J/\psi p$ structures is challenging and has not been accomplished yet. Fortunately, the newly observed peaks are so narrow that it is not necessary to construct an amplitude model to prove that these states are not artifacts of interfering Λ^* resonances, as was previously demonstrated in Ref. [9]. Their masses and widths have been characterized by the LHCb (see Table 84.1) from one-dimensional fits to $J/\psi p$ mass distributions, with different levels of suppression of the Λ^* contributions, which peak at the lower pK^- masses (Fig. 84.1). Such analysis is not sensitive to any broad $J/\psi p$ contributions. The histograms analyzed by the LHCb are available in tabular form at https://www.hepdata.net/record/89271.

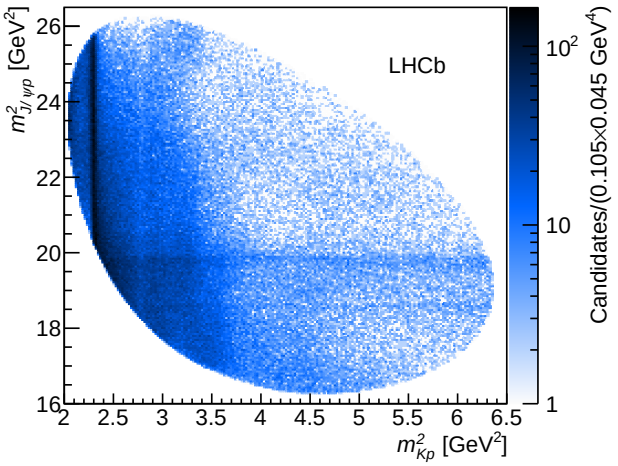

Figure 84.1: Dalitz plot distributions for $\Lambda_b^0 \to J/\psi p K^-$ decays as observed by LHCb.

The fit chosen by the LHCb for the central mass and width values is displayed in Fig. 84.2. The $P_{c\bar{c}}(4312)^+$ state (formerly known as $P_c(4312)^+$) peaks right below the $\Sigma_c^+ \bar{D}^0$ threshold and has statistical significance over 7.6σ. The $P_{c\bar{c}}(4457)^+$ state peaks right below the $\Sigma_c^+ \bar{D}^{*0}$ threshold, while the $P_{c\bar{c}}(4440)^+$ state peaks about 20 MeV below it. The significance of the two-peak versus one-peak hypothesis for the 4450 MeV structure is over 5.4σ, rendering the single peak interpretation of this region obsolete. The six-dimensional amplitude analysis reported in Ref. [8], which in addition to the structure near 4450 MeV, provided also evidence for the broad $P_{c\bar{c}}(4380)^+$ state, is obsolete since it used the single $P_{c\bar{c}}(4450)^+$ state and it lacked the $P_{c\bar{c}}(4312)^+$ state. Furthermore, it used the helicity formalism in which the half-integer spin of the proton was not aligned properly between the different Λ_b^0 decay chains [11, 12]. The newer one-dimensional analysis by LHCb [10] was not sensitive to wide $P_{c\bar{c}}^+$ states. The LHCb result from the six-dimensional amplitude analysis of the Cabibbo suppressed channel $\Lambda_b^0 \to J/\psi p \pi^-$ [13], which contains a statistically marginal evidence for the sum of the $P_{c\bar{c}}^+$ and the $T_{c\bar{c}1}^-$ (formerly known as $Z_c(4200)^-$) contributions, took extensive input from Ref. [8] and, like the $P_{c\bar{c}}(4380)^+$ state, should be treated with caution until the both amplitude analyses are completed on the enlarged data sets with the modified helicity formalism.

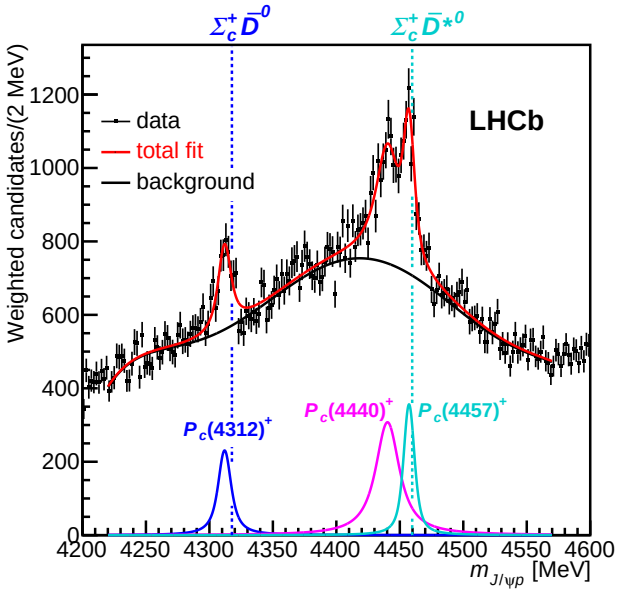

Figure 84.2: Fit to the $J/\psi p$ mass distribution, in which events were weighted to suppress $\Lambda^* \to pK^-$ backgrounds, of three Breit-Wigner functions and a sixth-order polynomial background. This fit was used to determine the central values of the masses and widths of the $P_{c\bar{c}}^+$ states (formerly known as P_c^+) reported by LHCb. The mass thresholds for the $\Sigma_c^+ \bar{D}^0$ and $\Sigma_c^+ \bar{D}^{*0}$ final states are superimposed.

While $\Sigma_c \bar{D}^{(*)}$ states had been predicted [14–17] before the first LHCb results [8], after these results became known, many theoretical groups interpreted the $P_{c\bar{c}}(4450)^+$ and $P_{c\bar{c}}(4380)^+$ states in terms of diquarks and triquarks as building blocks of a compact pentaquark [18–24]. In a different strategy, a tentative attempt has been made to treat the full 5-body dynamics, leading to states below the lowest threshold for spontaneous dissociation [25]. In the first implementation of the former approach [18], the pen-

Table 84.1: Summary of the narrow $P_{c\bar{c}}^+$ (formerly known as P_c^+) properties, interpreted as Breit-Wigner resonances. The central values are based on the fit displayed in Fig. 84.2.

State	M [MeV]	Γ [MeV] (95% CL)	$\mathcal{R}$ [%]
$P_{c\bar{c}}(4312)^+$	$4311.9 \pm 0.7^{+6.8}_{-0.6}$	$9.8 \pm 2.7^{+\ 3.7}_{-\ 4.5}$ (< 27)	$0.30 \pm 0.07^{+0.34}_{-0.09}$
$P_{c\bar{c}}(4440)^+$	$4440.3 \pm 1.3^{+4.1}_{-4.7}$	$20.6 \pm 4.9^{+\ 8.7}_{-10.1}$ (< 49)	$1.11 \pm 0.33^{+0.22}_{-0.10}$
$P_{c\bar{c}}(4457)^+$	$4457.3 \pm 0.6^{+4.1}_{-1.7}$	$6.4 \pm 2.0^{+\ 5.7}_{-\ 1.9}$ (< 20)	$0.53 \pm 0.16^{+0.15}_{-0.13}$

taquark mass splitting was generated mostly by the change of angular momentum between the sub-components (L) from zero to one, which would also make the heavier state narrower and of opposite parity. Explicit modeling of multiquark systems [26] questions if centrifugal barrier factor provides enough width suppression via spatial separation of c and $\bar{c}$ quarks at these masses, as the phase space for $J/\psi p$ decay is very large (more than 400 MeV). Also, the observed mass splitting was too small to be only due to the mechanism proposed in Ref. [18] and required fine-tuning of such models. A variation of this model, in which the heavy (cu) diquark couples with heavy $\bar{c}$ to form colored triquark attracting the light diquark (ud), has been re-implemented for the narrow $P_{c\bar{c}}^+$ states [27]. In this model, the $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ states are accommodated via spin-orbit interactions for the $L = 1$ states, while the $P_{c\bar{c}}(4312)^+$ is one of the $L = 0$ states. However, the mass prediction for the latter is off by (-72 ± 29) MeV [27]. This work was later extended to $SU(3)_F$ [28]. The width dilemma becomes more severe in view of the narrow widths of the newly observed states (Table 84.1), especially for the $L = 0$ $P_{c\bar{c}}(4312)^+$ state, and requires a different origin of potential barrier between c and $\bar{c}$ than angular momentum [27, 29], which remains a subject of theoretical controversy. Measurement of spin-parity of $P_{c\bar{c}}(4312)^+$, $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ will be crucial for testing these and alternative theoretical ideas discussed in the following.

More effective width suppression mechanism is offered by a loosely bound charmed baryon-anticharmed meson molecular model, in which c and $\bar{c}$ can be separated by much larger distances, resulting in a smaller probability of them getting close enough to each other in order to make a J/ψ. Since molecular binding energy cannot be large, such molecules are in S-wave, so it has been realized early on that their masses must be near the sum of the baryon and meson masses and their spin and parity are inherited from their constituent hadrons, see e.g. discussion in [17]. The mass coincidence of the $P_{c\bar{c}}(4312)^+$ and of $P_{c\bar{c}}(4457)^+$ states, with the two related thresholds, $\Sigma_c^+ \bar{D}^0$ and $\Sigma_c^+ \bar{D}^{*0}$, provides very strong experimental evidence in favor of this interpretation. Given how close $P_{c\bar{c}}(4312)^+$ is to the $\Sigma_c^+ \bar{D}^0$ threshold, it might be a virtual rather than a bound state [30]. Since the spins of Σ_c^+ and of $\bar{D}^{*0}$ can be combined in two different ways, the narrow $P_{c\bar{c}}(4440)^+$ peak also finds natural explanation in this physical picture. It cannot be a virtual state since it is sufficiently below the $\Sigma_c^+ \bar{D}^{*0}$ threshold.

It is worth stressing that other baryon-meson combinations, $\Lambda_c^{(*)+} \bar{D}^{(*)0}$ and $\chi_{cJ} p$ are not expected to bind [14, 31]. Before the first pentaquark observation [8] heavy quark symmetry was used to show that, in addition to the three $\Sigma_c \bar{D}^{(*)0}$ states, one expects four $\Sigma_c^* \bar{D}^{(*)0}$ states, for a total of seven [32]. Indeed, additional states at, or below, the $\Sigma_c^{*+} \bar{D}$ and $\Sigma_c^{*+} \bar{D}^*$ thresholds, are expected [33–36]. Since Σ_c^{*+} width is likely around 15 MeV [37], more than the width of either $P_{c\bar{c}}(4312)^+$ or $P_{c\bar{c}}(4457)^+$, it is important to keep in mind that a molecule is typically as broad as the constituents[1] [38–40]. There is no significant evidence for $\Sigma_c^* \bar{D}^{(*)}$ states in the present LHCb data set [10, 41]. Larger data sets are expected from the Upgraded LHCb experiment. For a review on hadronic molecules, and a recent survey in a particular approach, see respectively Refs. [42, 43].

It is useful to consider the $P_{c\bar{c}}(4312)^+$, $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ narrow pentaquarks together with several analogous exotic states with hidden charm and bottom in the meson sector. This provides additional significant motivation for the molecular model. At least five exotic mesons are close to thresholds of two heavy-light mesons: $\chi_{c1}(3872)$ (formerly known as $X(3872)$) [44–47], $T_{b\bar{b}1}(10610)$ and $T_{b\bar{b}1}(10650)$ (formerly $Z_b(10610)$ and $Z_b(10650)$) in the bottomonium sector [48–52] and $T_{c\bar{c}1}(3900)$ (formerly $Z_c(3900)$) [53–57] and $T_{c\bar{c}1}(4020)$ (formerly $Z_c(4020)$) [58–60] in the charmonium sector (see Table II in Ref. [61]; for reviews of experimental information see Ref. [62, 63], as well as *Spectroscopy of Mesons Containing Two Heavy Quarks* and *Heavy Non-$q\bar{q}$ Mesons* in the current Review of Particle Properties. These states share several important features: a) their masses are near thresholds and their spin and parity correspond to S-wave combination of the two mesons; b) they are very narrow, despite very large phase space for decay into quarkonium + pion(s); c) the branching fractions for "fall apart" mode into two mesons are much larger than branching fractions for decay into quarkonium and pion(s). So far, there is no experimental evidence for states at two pseudoscalar thresholds ($D\bar{D}$ and $B\bar{B}$), suggesting that pseudoscalar exchange is essential for binding in meson-meson systems.

The above provide a strong hint that these states are deuteron-like loosely bound states of two heavy mesons [64–72]. It is then natural to conjecture that similar bound states might exist of two heavy baryons [73, 74], or a meson and a baryon or a baryon and an antibaryon, leading to a rather accurate prediction of the $P_{c\bar{c}}(4457)^+$ mass as $3/2^-$ $\Sigma_c \bar{D}^*$ molecule (the mass threshold is 4460 MeV for $\Sigma_c^+ \bar{D}^{*0}$ and 4464 MeV for $\Sigma_c^{++} D^{*-}$) [17, 61], following similar predictions obtained in a wider framework of doubly heavy baryon-meson hadronic molecules, which might include mixtures of various two-hadron states [14–16, 31]. However, single pion exchange is not possible in $\Sigma_c^+ \bar{D}^0$ system. Thus the existence of $P_{c\bar{c}}(4312)^+$ suggests a more general binding mechanism in baryon-meson molecules, e.g. vector or two-pion exchanges, and/or coupled-channel interactions. Two-pion exchange in $D\bar{D}$ system is highly suppressed, because the intermediate state is $D^* \bar{D}^*$, which is 282 MeV heavier than $D\bar{D}$. On the other hand, in the $\Sigma_c \bar{D}$ system the intermediate $\Lambda_c^+ \bar{D}^*$ state is only 25 MeV lighter than $\Sigma_c \bar{D}$, and therefore does not have to suffer significant suppression, providing a possible binding mechanism [75]. In a generic hadronic molecule it is essential that the two hadrons are heavy, in order to minimize the repulsive kinetic energy [73, 74, 76].

Following the initial LHCb discovery [8], several groups carried out a detailed analysis of the $P_{c\bar{c}}^+$ states as hadronic molecules [77–86] followed by further analyses [35, 87–111] after the updated LHCb results [10]. Partial widths of all the allowed decay channels for the $P_{c\bar{c}}$ states have been estimated within a specific model in the molecular picture [112]. The most striking suggestion is that $P_{c\bar{c}}(4312)^+$ decays are totally dominated by the $\Lambda_c^+ \bar{D}^{*0}$ channel. This channel is also suggested to be very prominent in decays of $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$. But other scenarios are possible, as shown by a recent theoretical analysis, allowing for the most general scattering potential of the baryon-meson system consistent with QCD symmetries at leading order in a momentum counting [113]. They found that both large and vanishing transitions to $\Lambda_c^+ \bar{D}^{(*)0}$ channels are allowed. Clearly, experimental determination of the branching fraction of these channels is of high priority.

The $P_{c\bar{c}}$ states have also been-interpreted as so called hadrocharmonium [114], a bound state of relatively compact charmonium states with light hadronic matter. It was proposed that $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ are spin-split $\psi(2S)p$ bound states with $J^P = \frac{1}{2}^-$ and $\frac{3}{2}^-$, while $P_{c\bar{c}}(4312)^+$ is a $\chi_{c0} p$ bound state with $J^P = \frac{1}{2}^+$ [115]. While very interesting from the theoretical point of view, it is not at all clear why the binding energies

[1] This feature gets changed if systems are more deeply bound.

between charmonia and the nucleon should conspire to produce states so close to the $\Sigma_c\bar{D}$ and $\Sigma_c\bar{D}^*$ thresholds. Moreover, the predicted widths of $P_{c\bar{c}}(4440)^+$ and $P_{c\bar{c}}(4457)^+$ are too big by a factor $\sim$ 2-3. One should also keep in mind that the molecular and hadro-charmonium pictures provide opposite predictions for the parity of $P_{c\bar{c}}(4312)^+$. In principle LHCb can check the spin and parity through partial wave analysis, but at present it is not known if systematic uncertainties can be sufficiently reduced to make such an analysis conclusive.

Shortly after the initial experimental discovery it was conjectured that the $P_{c\bar{c}}(4450)^+$ reflects the presence of a triangle singularity near the $\chi_{c1}p$ threshold [116–119]. These explanations are no longer viable, since the $P_{c\bar{c}}(4440)^+$ mass is not at any threshold and the $P_{c\bar{c}}(4312)^+$ and $P_{c\bar{c}}(4457)^+$ peak slightly below the $\Sigma_c^+\bar{D}^0$ and $\Sigma_c^+\bar{D}^{*0}$ thresholds. The $P_{c\bar{c}}(4457)^+$ mass is exactly at $\Lambda_c^{*+}\bar{D}^0$ threshold, but LHCb has demonstrated that the observed peaking is narrower in the data than expected from the triangle-diagram when a realistic width of the excited D_s^- state exchanged in the triangle is used (Supplemental Material in Ref. [10]).

More extensive pre-2019 reviews of some of the theoretical issues can be found in Refs. [120,121]. Two recent relevant reviews are Refs. [122,123].

So far the $P_{c\bar{c}}^+$ states have been observed by only one experiment in only one channel. It is essential to explore other possible experimental channels, such as $P_{c\bar{c}}^+ \to \Lambda_c^+\bar{D}^{(*)0}$, $\eta_c p$ [113]. These channels are however much more experimentally challenging than $P_{c\bar{c}}^+ \to J/\psi p$. Proposals have also been made to search for heavy pentaquarks in photo-production [124–131]. Ref. [132] discusses photoproduction within the string-junction physical picture of the pentaquarks. Photoproduction is also related to recent work on $J/\psi(\eta_c)N$ scattering on the lattice [133] and on computation of $J/\psi(\eta_c)N$ and $\Upsilon(\eta_b)N$ cross sections [134]. In addition, pentaquark production has been discussed in the context of antiproton-deuterium collisions [135], of heavy ion collisions at LHC [136], in pA collisions [137] and in pion-induced processes [138–140]. The GlueX Collaboration reported negative search results for the $P_{c\bar{c}}^+$ states in photo-production at JLAB [141,142], $\gamma p \to (J/\psi \to e^+e^-)p$. Within the large experimental errors and considerable theoretical model dependence these results do not contradict the molecular interpretations of the narrow $P_{c\bar{c}}^+$ states. In particular, vector-meson dominance often assumed in theoretical modelling may not hold for near-threshold J/ψ production, and $\Lambda_c\bar{D}^{(*)0}$ intermediate states may significantly contribute to the $J/\psi p$ production complicating probing for the $P_{c\bar{c}}^+$ states [143,144].

As noted in e.g. [17], bottom analogues of the $P_{c\bar{c}}^+$ might well exist, but experimental search for such states involves very significant challenges. It is therefore hardly surprising that they have not been observed so far. A detailed discussion is beyond the scope of the current review.

The LHCb collaboration obtained a 3.1σ evidence for a $P_{c\bar{c}}^+ \to J/\psi p$ state in the four-dimensional amplitude analysis of about 800 $B_s^0 \to J/\psi p\bar{p}$ ($J/\psi \to \mu^+\mu^-$) decays [145]. The mass of the state, $4337^{+7}_{-4} \pm 2$ MeV, is not compatible with the the $P_{c\bar{c}}(4312)^+$ state at 3.1 standard deviations. The width is relatively small, $29^{+26}_{-12} \pm 14$ MeV. The present data do not provide sufficient discrimination between various J^P assignments. Its mass is about 19 MeV higher than the $\Sigma_c^+\bar{D}^0$ threshold and about 16 MeV lower than the $\chi_{c0}p$ threshold. At present, no specific explanation for this structure has been proposed, but some intriguing ideas have been raised in Ref. [146]. Since the statistical significance of this evidence is marginal, more data are required before this state is considered experimentally established.

Similarly inconclusive 3.1σ evidence for a $P_{c\bar{c}s}^0 \to J/\psi\Lambda$ structure was observed by the LHCb collaboration in the six-dimensional amplitude analysis of about 1750 $\Xi_b^- \to J/\psi\Lambda K^-$ ($J/\psi \to \mu^+\mu^-$, $\Lambda \to p\pi^-$ decays [12]. The strange counterparts of $P_{c\bar{c}}^+$ states have been predicted in both molecular and compact pentaquark models [15,99,101,147–149]. When interpreted as a single peak, its mass, $4458.8 \pm 2.9^{+4.7}_{-1.1}$ MeV, is 15 MeV above the $\Xi_c'^0\bar{D}^0$ threshold and 18 MeV below the $\Xi_c^0\bar{D}^{*0}$ threshold. Its width, $17.3 \pm 6.5^{+8.0}_{-5.7}$ MeV, is relatively narrow, thus plausibly could be interpreted as a loosely bound $\Xi_c^0\bar{D}^{*0}$ state. However, in the latter model two states are expected with J^P equal to $1/2^-$ and $3/2^-$. In fact, the LHCb data are consistent with such hypothesis, under which 4454.9 ± 2.7 MeV ($\Gamma = 7.5 \pm 9.7$ MeV) and 4467.8 ± 3.7 MeV ($\Gamma = 5.2 \pm 5.3$ MeV) mass (width) estimates are obtained (statistical errors only). It is worth noting, that the $SU(3)$ flavor structure of $\Xi_c^0\bar{D}^{*0}$ states is different from that of $\Sigma_c^+\bar{D}^{*0}$ states, since Ξ_c^0 belongs to the charmed baryon triplet, together with Ξ_c^+ and Λ_c^+, where the two light quarks form a spin-zero diquark, unlike Σ_c^+, which together with $\Xi_c'^0$ and Ω_c^0 belongs to the charmed baryon sextet, where the two light quarks form a spin-1 diquark. More data are required to experimentally establish this structure, clarify its composition, and determine the related quantum numbers.

If the two states at 4455 MeV and 4468 MeV indeed correspond to a $\Xi_c^0\bar{D}^{*0}$ molecule, there perhaps exist two other states, corresponding to $\Xi_c'\bar{D}^*$ [15, 99, 101, 147–149], with a mass shifted upwards by approximately $\Xi_c' - \Xi_c$ mass difference [150,151], i.e. about 108 MeV [37].

More recently, the LHCb experiment observed highly significant ($> 14\sigma$) pentaquark state $P_{c\bar{c}s}(4338)^0 \to J/\psi\Lambda$ (formerly known as $P_{cs}(4338)$) in the six-dimensional amplitude analysis of 4620 ± 70 $B^- \to J/\psi\Lambda\bar{p}$ decays [152]. Its mass $4338.2 \pm 0.7 \pm 0.4$ MeV is right at the $\Xi_c\bar{D}$ threshold (Fig. 84.3), its width is narrow $7.0 \pm 1.2 \pm 1.3$ MeV, and its spin is 1/2, with a preference for negative parity, which all fits the molecular model very well. This makes the $P_{c\bar{c}s}(4338)^0$ state a likely $\Xi_c^0\bar{D}^0$ analog of the $P_{c\bar{c}}(4312)^+$ state in $\Sigma_c^0\bar{D}^0$ system. In addition, as in the $P_{c\bar{c}s}(4459)^0$ case, a $\Xi_c'\bar{D}$ state is expected, for a total of three additional strange pentaquarks [151]. Experimental determination whether yet additional $\Xi_c^{(*,\prime)}\bar{D}^{(*)0}$ states actually exist will provide a useful testing ground for the various theoretical approaches which have been used to predict them.

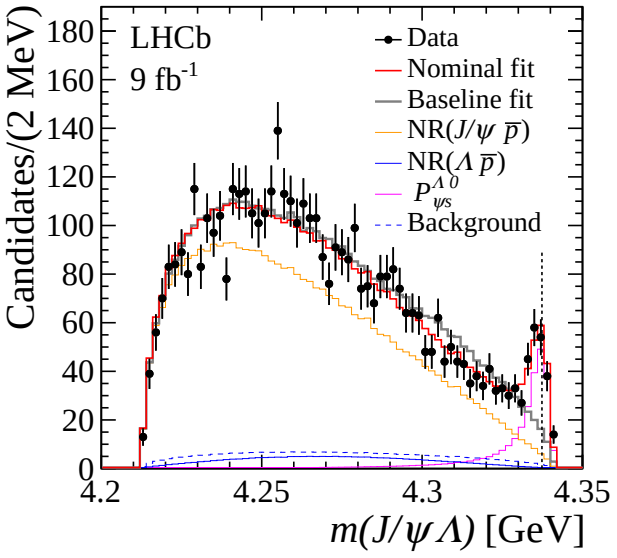

Figure 84.3: Distribution of invariant $J/\psi\Lambda$ mass, with the projection of the amplitude fit model superimposed. The model without the $P_{c\bar{c}s}(4338)^0$ state (labeled as $P_{\psi s}^{\Lambda\,0}$) is also shown in grey. The $\Xi_c^+D^-$ baryon-meson threshold is indicated with a vertical dashed line.

In hidden-charm exotics discussed above, the charmed and the anticharmed quarks can form a charmonium and thereby decouple from the light quarks. The molecular model provides an efficient mechanism to suppress such decays, thus making these states narrow. Compact direct color couplings between quarks are missing an obvious width suppression mechanism, thus could lead to broader states. In fact, there is plenty of evidence for them in form of broader tetraquark mass structures in $J/\psi\phi$ [153–159], $J/\psi\,J/\psi$ [160–162], $T_{c\bar{c}1}(4430)^+ \to \psi(2S)\pi^+$ (formerly

$Z_c(4430)^+$) [163–165] and others, although alternative explanations of these structures have been also proposed. Analogous configurations may also exist for pentaquarks, but there is no firm evidence for them yet.

The hidden-charm exotic states, should not be confused with exotic hadrons containing two heavy quarks, rather than a heavy quark and a heavy antiquark. Decoupling from the light quarks is impossible in exotics which contain two heavy quarks. This has far-reaching consequences. The first tetraquark of the latter type, i.e. containing two heavy quarks, has been reported by LHCb [166, 167]. A comprehensive discussion of tetraquark candidates can be found in the "Heavy non-$Q\bar{Q}$ Mesons" review.

Hypothetical Particles and Concepts

85. Extra Dimensions

Revised August 2023 by Z. Demiragli (Boston U.) and A. Pomarol (U. Autònoma de Barcelona; IFAE).

85.1 Introduction

Proposals for a spacetime with more than three spatial dimensions date back to the 1920s, mainly through the work of Kaluza and Klein, in an attempt to unify the forces of nature [1]. Although their initial idea failed, the formalism that they and others developed is still useful nowadays. Around 1980, string theory proposed again to enlarge the number of space dimensions, this time as a requirement for describing a consistent theory of quantum gravity. The extra dimensions were supposed to be compactified at a scale close to the Planck scale, and thus not testable experimentally in the near future.

A different approach was given by Arkani-Hamed, Dimopoulos, and Dvali (ADD) in their seminal paper in 1998 [2], where they showed that the weakness of gravity could be explained by postulating two or more flat extra dimensions in which only gravity could propagate. The size of these extra dimensions should range between roughly a millimeter and ∼1/TeV, leading to possible observable consequences in current and future experiments. A year later, Randall and Sundrum (RS) [3] found a new possibility using a warped geometry, postulating a five-dimensional Anti-de Sitter (AdS) spacetime with a compactification scale of order 1/TeV. The origin of the smallness of the electroweak scale versus the Planck scale was explained by the gravitational redshift factor present in the warped AdS metric. As in the ADD model, originally only gravity was assumed to propagate in the extra dimensions, although it was soon clear that this was not necessary in warped extra dimensions and also the SM gauge fields [4, 5] and SM fermions [6, 7] could propagate in the five-dimensional spacetime.

The physics of warped extra-dimensional models has an alternative interpretation by means of the AdS/CFT correspondence [8–10]. Models with warped extra dimensions are related to four-dimensional strongly-interacting theories, allowing an understanding of the properties of five-dimensional fields as those of four-dimensional composite states [11]. This approach has opened new directions for tackling outstanding questions in particle physics, such as the flavor problem, grand unification, and the origin of electroweak symmetry breaking or supersymmetry breaking.

85.1.1 *Experimental Constraints*

Constraints on extra-dimensional models arise from astrophysical and cosmological considerations, tabletop experiments exploring gravity at sub-mm distances, and collider experiments. Collider limits on extra-dimensional models are dominated by LHC results, which can be found on the public WWW pages of ATLAS [12] and CMS [13]. This review includes the most recent limits, most of which are published results based on 140 fb^{-1}LHC data collected in 2015-18 at a center-of-mass energy of 13 TeV and legacy results from 20 fb^{-1}of 8 TeV data collected in Run 1. For most of the models, Run 2 results surpass the sensitivity of Run 1.

85.1.2 *Kaluza-Klein Theories*

Field theories with compact extra dimensions can be written as theories in ordinary four dimensions (4D) by performing a Kaluza-Klein (KK) reduction. As an illustration, consider a simple example, namely a field theory of a complex scalar in flat five-dimensional (5D) spacetime. The action will be given by [1]

$$S_5 = -\int d^4x\, dy\, M_5 \left[|\partial_\mu \phi|^2 + |\partial_y \phi|^2 + \lambda_5 |\phi|^4\right] , \qquad (85.1)$$

where y refers to the extra (fifth) dimension. A universal scale M_5 has been extracted in front of the action in order to keep the 5D field with the same mass-dimension as in 4D. This theory is perturbative for energies $E \lesssim \ell_5 M_5/\lambda_5$ where $\ell_5 = 24\pi^3$ [14].

[1] Our convention for the metric is $\eta_{MN} = \mathrm{Diag}(-1, 1, 1, 1, 1)$.

Let us now consider that the fifth dimension is compact with the topology of a circle S^1 of radius R, which corresponds to the identification of y with $y + 2\pi R$. In such a case, the 5D complex scalar field can be expanded in a Fourier series:

$$\phi(x, y) = \frac{1}{\sqrt{2\pi R M_5}} \sum_{n=-\infty}^{\infty} e^{iny/R} \phi^{(n)}(x) , \qquad (85.2)$$

that, inserted in Eq. (85.1) and integrating over y, gives

$$S_5 = S_4^{(0)} + S_4^{(n)} , \qquad (85.3)$$

where

$$S_4^{(0)} = -\int d^4x \left[|\partial_\mu \phi^{(0)}|^2 + \lambda_4 |\phi^{(0)}|^4\right] , \qquad (85.4)$$

and,

$$S_4^{(n)} = -\int d^4x \sum_{n\neq 0} \left[|\partial_\mu \phi^{(n)}|^2 + \left(\frac{n}{R}\right)^2 |\phi^{(n)}|^2\right] + \text{quartic interactions} . \qquad (85.5)$$

The $n = 0$ mode self-coupling is given by

$$\lambda_4 = \frac{\lambda_5}{2\pi R M_5} . \qquad (85.6)$$

The above action corresponds to a 4D theory with a massless scalar $\phi^{(0)}$, referred to as the zero mode, and an infinite tower of massive modes $\phi^{(n)}$ with $n > 0$, known as KK modes. The KK reduction thus allows a treatment of 5D theories as 4D field theories with an infinite number of fields. At energies smaller than $1/R$, the KK modes can be neglected, leaving the zero-mode action of Eq. (85.4). The strength of the interaction of the zero-mode, given by Eq. (85.6), decreases as R increases. Thus, for a large extra dimension $R \gg 1/M_5$, the massless scalar is very weakly coupled.

85.2 Large Extra Dimensions for Gravity

85.2.1 *The ADD Scenario*

The ADD scenario [2, 15] (for a review see, for example, [16]) assumes a $D = 4 + \delta$ dimensional spacetime, with δ compactified spatial dimensions. The apparent weakness of gravity arises since it propagates in the higher-dimensional space. The SM is assumed to be localized in a 4D subspace, a 3-brane, as can be found in certain string theory constructions [17, 18]. Gravity is described by the Einstein-Hilbert action in $D = 4 + \delta$ spacetime dimensions

$$S_D = -\frac{\bar{M}_D^{2+\delta}}{2} \int d^4x d^\delta y \sqrt{-g}\, \mathcal{R} + \int d^4x \sqrt{-g_{\rm ind}}\, \mathcal{L}_{\rm SM} , \qquad (85.7)$$

where x labels the ordinary four coordinates, y the δ extra coordinates, g refers to the determinant of the D-dimensional metric whose Ricci scalar is defined by $\mathcal{R}$, and $\bar{M}_D$ is called the reduced Planck scale of the D-dimensional theory. In the second term of Eq. (85.7), which gives the gravitational interactions of SM fields, the D-dimensional metric reduces to the induced metric on the 3-brane where the SM fields propagate. The extra dimensions are assumed to be flat and compactified in a volume V_δ. As an example, consider a toroidal compactification of equal radii R and volume $V_\delta = (2\pi R)^\delta$. After a KK reduction, one finds that the fields that couple to the SM are the spin-2 gravitational field $G_{\mu\nu}(x, y)$ and a tower of spin-0 KK graviscalars [19]. The graviscalars, however, only couple to SM fields through the trace of the energy-momentum tensor, resulting in weaker couplings to the SM fields. The Fourier expansion of the spin-2 field is given by

$$G_{\mu\nu}(x, y) = G_{\mu\nu}^{(0)}(x) + \frac{1}{\sqrt{V_\delta}} \sum_{\vec{n}\neq 0} e^{i\vec{n}\cdot\vec{y}/R} G_{\mu\nu}^{(\vec{n})}(x) , \qquad (85.8)$$

where $\vec{y} = (y_1, y_2, ..., y_\delta)$ are the extra-dimensional coordinates and $\vec{n} = (n_1, n_2, ..., n_\delta)$. Eq. (85.8) contains a massless state,

the 4D graviton $G^{(0)}_{\mu\nu}$, and its KK tower $G^{(\vec{n})}_{\mu\nu}$ with masses $m^2_{\vec{n}} = |\vec{n}|^2/R^2$. At energies below $1/R$ the action is that of the zero mode

$$S^{(0)}_4 = -\frac{\bar{M}_D^{2+\delta}}{2}\int d^4x\, V_\delta \sqrt{-g^{(0)}}\,\mathcal{R}^{(0)} + \int d^4x \sqrt{-g^{(0)}_{\rm ind}}\,\mathcal{L}_{\rm SM}\,, \tag{85.9}$$

where we can identify the 4D reduced Planck mass, $M_P \equiv 1/\sqrt{8\pi G_N} \simeq 2.4\times 10^{18}$ GeV, as a function of the D-dimensional parameters:

$$M_P^2 = V^\delta \bar{M}_D^{2+\delta} \equiv R^\delta M_D^{2+\delta}\,. \tag{85.10}$$

Fixing M_D at around the electroweak scale $M_D \sim$ TeV to avoid introducing a new mass scale in the model, Eq. (85.10) gives a prediction for R:

$$\delta = 1, 2, ..., 6 \;\rightarrow\; R \sim 10^9 \text{ km}\,, 0.5 \text{ mm}\,, ...\,, 0.1 \text{ MeV}^{-1}\,. \tag{85.11}$$

The option $\delta = 1$ is clearly ruled out, as it leads to modifications of Newton's law at solar system distances. However this is not the case for $\delta \geq 2$, and possible observable consequences can be sought in present and future experiments.

Consistency of the model requires a stabilization mechanism for the radii of the extra dimensions, to the values shown in Eq. (85.11). The fact that we need $R \gg 1/M_D$ leads to a new hierarchy problem, the solution of which might require imposing supersymmetry in the extra-dimensional bulk (for the case of two extra dimensions see for example [20]).

85.2.2 *Tests of the Gravitational Force Law at Sub-mm Distances*

The KK modes of the graviton give rise to deviations from Newton's law of gravitation for distances $\lesssim R$. Such deviations are usually parameterized by a modified Newtonian potential of the form

$$V(r) = -G_N \frac{m_1 m_2}{r}\left[1 + \alpha\, e^{-r/\lambda}\right]\,. \tag{85.12}$$

For a 2-torus compactification, $\alpha = 16/3$ and $\lambda = R$. Searches for deviations from Newton's law of gravitation have been performed in several experiments [21–24]. From Ref. [23] we have the constraint $R < 30\mu$m at 95% CL for $\delta = 2$, corresponding to $M_D > 4.0$ TeV. We see then that bounds from Newton's law deviations are already pushing the scale M_D beyond the TeV for two extra dimensions.

85.2.3 *Astrophysical and Cosmological Constraints*

The light KK gravitons could be copiously produced in stars, carrying away energy. Ensuring that the graviton luminosity is low enough to preserve the agreement of stellar models with observations provides powerful bounds on the scale M_D. The most stringent bound arises from supernova SN1987A, giving $M_D > 27$ (2.4) TeV for $\delta = 2$ (3) [25]. After a supernova explosion, most of the KK gravitons stay gravitationally trapped in the remnant neutron star. The requirement that neutron stars are not excessively heated by KK decays into photons leads to $M_D > 1700$ (76) TeV for $\delta = 2$ (3) [26].

Cosmological constraints are also quite stringent [27]. To avoid overclosure of the Universe by relic gravitons one needs $M_D > 7$ TeV for $\delta = 2$. Relic KK gravitons decaying into photons contribute to the cosmic diffuse gamma radiation, from which one can derive the bound $M_D > 100$ TeV for $\delta = 2$.

We must mention however that bounds coming from the decays of KK gravitons into photons can be reduced if we assume that KK gravitons decay mainly into other non-SM states. This could happen, for example, if there were other 3-branes with hidden sectors residing on them [15].

85.2.4 *Collider Signals*

85.2.4.1 *Graviton and Other Particle Production*

Although each KK graviton has a purely gravitational coupling, suppressed by $1/M_P$, inclusive processes in which one sums over the almost continuous spectrum of available gravitons have cross sections suppressed only by powers of M_D. Processes involving gravitons are therefore detectable in collider experiments if $M_D \sim$ TeV. A number of experimental searches for evidence of large extra dimensions have been performed at colliders, and interpreted in the context of the ADD model.

One signature arises from direct graviton emission. By making a derivative expansion of Einstein gravity, one can construct an effective theory, valid for energies much lower than M_D, and use it to make predictions for graviton-emission processes at colliders [19, 28, 29]. Gravitons produced in the final state would escape detection, giving rise to missing transverse momentum ($p_{\rm T}^{\rm miss}$). The results quoted below are 95% CL lower limits on M_D for a range of values of δ between 2 and 6, with more stringent limits corresponding to lower δ values.

At hadron colliders, experimentally sensitive channels include the jet (j) + $p_{\rm T}^{\rm miss}$ and γ + $p_{\rm T}^{\rm miss}$ final states. ATLAS (CMS) j + $p_{\rm T}^{\rm miss}$ results with 139 (137) fb^{-1} of 13 TeV data provide limits of $M_D > 5.9 - 11.2$ TeV [30] ($M_D > 5.5 - 10.7$ TeV [31]). For these analyses, both experiments are assuming leading order (LO) cross sections. Since the effective theory is only valid for energies much less than M_D, the results are quoted for the full space, and include the information that suppressing the graviton cross section by a factor $M_D^4/\hat{s}^2$ for $\sqrt{\hat{s}} > M_D$, where $\sqrt{\hat{s}}$ is the parton-level center-of-mass energy of the hard collision, weakens the limits on M_D by a negligible amount for $\delta = 2$ (∼3% for $\delta = 6$). Less stringent limits are obtained by CMS [32] from analysis of 36 fb^{-1}of 13 TeV data in the γ + $p_{\rm T}^{\rm miss}$ final state ($M_D > 2.85 - 2.90$ TeV for $\delta = 3 - 6$). The analogous ATLAS search [33] uses full Run 2 statistics but does not quote ADD interpretation of the results.

In models in which the ADD scenario is embedded in a string theory at the TeV scale [18], we expect the string scale M_s to be smaller than M_D, and therefore expect production of string resonances at the LHC [34]. A result from CMS analyzing the dijet invariant mass distribution for 137 fb^{-1}of 13 TeV data excludes string resonances that decay predominantly to $q + g$ with masses below 7.9 TeV [35]. ATLAS dijet analysis [36] provides their results in the context of model-independent limits on the cross section times acceptance for generic resonances of a variety of possible widths, from which one can deduce similar lower mass limits ∼ 8 TeV for string resonances decaying to $q + g$.

85.2.4.2 *Virtual graviton effects*

One can also search for virtual graviton effects, the calculation of which however depends on the ultraviolet cut-off of the theory and is therefore very model dependent. In the literature, several different formulations exist [19,29,37] for the dimension-eight operator for gravity exchange at tree level:

$$\mathcal{L}_8 = \pm\frac{4}{M_{TT}^4}\left(T_{\mu\nu}T^{\mu\nu} - \frac{1}{\delta+2}T^\mu_\mu T^\nu_\nu\right), \tag{85.13}$$

where $T_{\mu\nu}$ is the energy-momentum tensor and M_{TT} is related to M_D by some model-dependent coefficient [38]. The relations with the parametrization of Refs. [37] and [19] are, respectively, $M_{TT} = M_S$ and $M_{TT} = (2/\pi)^{1/4}\Lambda_T$. The experimental results below are given as 95% CL lower limits on M_{TT}, including in some cases the possibility of both constructive or destructive interference, depending on the sign chosen in Eq. (9).

The most stringent limits arise from LHC analyses of the dijet angular distribution. Using 35.9 fb^{-1}of 13 TeV data, CMS [39] obtains results that correspond to an approximate limit of $M_{TT} \gtrsim 9$ TeV.

The next most restrictive results come from the analyses of diphoton ($M_{TT} > 6.1$ TeV from ATLAS [40] and $M_{TT} > 7.0$ TeV from CMS [41]) and dilepton mass spectra ($M_{TT} > 6.5$ TeV from CMS [42]). The complete Run 2 (139 fb^{-1}) analysis of ATLAS di-lepton data [43] does not quote the limits on ADD.

At the one-loop level, gravitons can also generate dimension-six operators with coefficients that are also model dependent. Experimental bounds on these operators can also give stringent constraints on M_D [38].

85.2.4.3 *Black Hole Production*

The physics at energies $\sqrt{s} \sim M_D$ is sensitive to the details of the unknown quantum theory of gravity. Nevertheless, in the transplanckian regime, $\sqrt{s} \gg M_D$, one can rely on a semiclassical description of gravity to obtain predictions. An interesting feature

of transplanckian physics is the creation of black holes [44,45] (for a review see, for example, [46]). A black hole is expected to be formed in a collision in which the impact parameter is smaller than the Schwarzschild radius [47]:

$$R_S = \frac{1}{M_D}\left[\frac{2^\delta \pi^{(\delta-3)/2}}{\delta+2}\Gamma\left(\frac{\delta+3}{2}\right)\frac{M_{BH}}{M_D}\right]^{1/(\delta+1)}, \quad (85.14)$$

where M_{BH} is the mass of the black hole, which would roughly correspond to the total energy in the collision. The cross section for black hole production can be estimated to be of the same order as the geometric area $\sigma \sim \pi R_S^2$. For $M_D \sim$ TeV, this gives a production of $\sim 10^7$ black holes at the $\sqrt{s} = 14$ TeV LHC with an integrated luminosity of 30 fb^{-1} [44,45]. A black hole would provide a striking experimental signature since it is expected to thermally radiate with a Hawking temperature $T_H = (\delta+1)/(4\pi R_S)$, and therefore would evaporate democratically into all SM states. Nevertheless, given the present constraints on M_D, the LHC will not be able to reach energies much above M_D. This implies that predictions based on the semiclassical approximation could receive sizable modifications from model-dependent quantum-gravity effects.

The most stringent limits on microscopic black holes arise from LHC searches which observed no excesses above the SM background in high-multiplicity final states. The results are usually quoted as model-independent limits on the cross section for new physics in the final state and kinematic region analyzed. These results can then be used to provide constraints of models of low-scale gravity and weakly-coupled string theory. In addition, limits are sometimes quoted on particular implementations of models, which are used as benchmarks to illustrate the sensitivity.

A CMS analysis [48] of multi-object final states using 36 fb^{-1}of 13 TeV data, excludes semiclassical black holes below masses of up to 10.1 TeV for $M_D = 2$ TeV and $\delta = 6$. Analogous Run 2 ATLAS analysis [49], using 3.0 fb^{-1}of 13 TeV data, excludes black hole masses up to 9.0 − 9.7 TeV, depending on M_D, for $\delta = 6$. Another ATLAS search [50] for an excess of events with multiple high transverse momentum objects, including charged leptons and jets, using 3.2 fb^{-1}of 13 TeV data, excludes semiclassical black holes below masses of ~ 8.7 TeV for $M_D = 2$ TeV and $\delta = 6$.

A complementary approach is to look for jet extinction at high transverse momenta, as we expect hard short distance scattering processes to be highly suppressed at energies above M_D [51]. The CMS analysis [52] of inclusive jet p_T spectrum in 10.7 fb^{-1}of 8 TeV data set a lower limit of 3.3 TeV on the extinction mass scale.

For black hole masses near M_D, the semi-classical approximation is not valid, and one could instead expect quantum black holes (QBH) that decay primarily into two-body final states [53]. In the context of both ADD model with $\delta = 6$ the QBHs have been searched in few final state analysis (based on 2.3 fb^{-1} [54]), dijet [36,39,55], (same and different flavor) dilepton [56–60], photon+jet [61,62] and lepton+jet [63] channels by both ATLAS and CMS experiments. The Run 2 results at 13 TeV provide lower limits on QBH masses of up-to 9.4 TeV in an ADD model with $\delta = 6$. The strongest constraints are from dijet searches.

In weakly-coupled string models the semiclassical description of gravity fails in the energy range between M_s and M_s/g_s^2 where stringy effects are important. In this regime one expects, instead of black holes, the formation of string balls, made of highly excited long strings, that could be copiously produced at the LHC for $M_s \sim$ TeV [64], and would evaporate thermally at the Hagedorn temperature giving rise to high-multiplicity events. The same analyses used to search for black holes can be interpreted in the context of string balls. For example, for the case of $\delta = 6$ with $M_s = M_D/1.26 = 3$ TeV, the ATLAS multiple high transverse momentum object analysis [49] excludes string balls with masses below 6.5 to 9.0 TeV for values of $0.2 < g_s < 0.8$. The CMS multi-object analysis [48] studies string ball production in two scenarios, both assuming $\delta = 6$. For the constant $g_s = 0.2$ and $1 < M_s < 3.5$ TeV the string ball masses below 7.2 to 9.4 TeV are excluded, while at constant $M_s = 3.6$ TeV and $0.2 < g_s < 0.4$ masses below 7.2 to 8.1 TeV are excluded.

85.3 TeV-Scale Extra Dimensions

85.3.1 *Warped Extra Dimensions*

The RS model [3] is the most attractive setup of warped extra dimensions at the TeV scale, since it provides an alternative solution to the hierarchy problem. The RS model is based on a 5D theory with the extra dimension compactified in an orbifold, S^1/Z_2, a circle S^1 with the extra identification of y with $-y$. This corresponds to the segment $y \in [0, \pi R]$, a manifold with boundaries at $y = 0$ and $y = \pi R$. Let us now assume that this 5D theory has a cosmological constant in the bulk Λ, and on the two boundaries Λ_0 and $\Lambda_{\pi R}$. The action is given by

$$S_5 = -\int d^4x\, dy \Big\{ \sqrt{-g}\left[\frac{1}{2}M_5^3\mathcal{R} + \Lambda\right] + \sqrt{-g_0}\,\delta(y)\Lambda_0 + \sqrt{-g_{\pi R}}\,\delta(y-\pi R)\Lambda_{\pi R}\Big\}, \quad (85.15)$$

where g_0 and $g_{\pi R}$ are the values of the determinant of the induced metric on the two respective boundaries. Einstein's equations can be solved, giving in this case the metric

$$ds^2 = a(y)^2 dx^\mu dx^\nu \eta_{\mu\nu} + dy^2\,, \quad a(y) = e^{-ky}\,, \quad (85.16)$$

where $k = \sqrt{-\Lambda/6M_5^3}$. Consistency of the solution requires $\Lambda_0 = -\Lambda_{\pi R} = -\Lambda/k$. The metric in Eq. (85.16) corresponds to a 5D AdS space. The factor $a(y)$ is called the "warp" factor and determines how 4D scales change as a function of the position in the extra dimension. In particular, this implies that energy scales for 4D fields localized at the boundary at $y = \pi R$ are redshifted by a factor $e^{-k\pi R}$ with respect to those localized at $y = 0$. For this reason, the boundaries at $y = 0$ and $y = \pi R$ are usually referred to as the ultraviolet (UV) and infrared (IR) boundaries, respectively.

As in the ADD case, we can perform a KK reduction and obtain the low-energy effective theory of the 4D massless graviton. In this case we obtain

$$M_P^2 = \int_0^{\pi R} dy\, e^{-2ky} M_5^3 = \frac{M_5^3}{2k}\left(1 - e^{-2k\pi R}\right). \quad (85.17)$$

Taking $M_5 \sim k \sim M_P$, we can generate an IR-boundary scale of order $ke^{-k\pi R} \sim$ TeV for an extra dimension of radius $R \simeq 11/k$. Mechanisms to stabilize R to this value have been proposed [65,66] that, contrary to the ADD case, do not require introducing any new small or large parameter. Therefore a natural solution to the hierarchy problem can be achieved in this framework if the Higgs field, whose vacuum expectation value (VEV) is responsible for electroweak symmetry breaking, is localized at the IR-boundary where the effective mass scales are of order TeV. The radion field is generically heavy in models with a stabilized R. Nevertheless, it has been recently discussed that under some conditions a naturally light radion can arise [67–70]. In these cases the radion is identified with the dilaton, the Nambu-Goldstone boson associated to the spontaneous breaking of scale invariance, and its mass can be naturally below $ke^{-k\pi R} \sim$ TeV.

In the RS model [3], all the SM fields were assumed to be localized on the IR-boundary. Nevertheless, for the hierarchy problem, only the Higgs field has to be localized there. SM gauge bosons and fermions can propagate in the 5D bulk [4–7] (for a review see, for example, [71, 72]). By performing a KK reduction from the 5D action of a gauge boson, we find [4, 5]

$$\frac{1}{g_4^2} = \int_0^{\pi R} dy\, \frac{1}{g_5^2} = \frac{\pi R}{g_5^2}\,, \quad (85.18)$$

where g_D ($D = 4, 5$) is the gauge coupling in D-dimensions. Therefore the 4D gauge couplings can be of order one, as is the case of the SM, if one demands $g_5^2 \sim \pi R$. Using $kR \sim 10$ and $g_4 \sim 0.5$, one obtains the 5D gauge coupling

$$g_5 \sim 4/\sqrt{k}\,. \quad (85.19)$$

Boundary kinetic terms for the gauge bosons can modify this relation, allowing for larger values of $g_5\sqrt{k}$.

Fermions propagating in a warped extra dimension have 4D massless zero-modes with wavefunctions which vary as $f_0 \sim exp[(1/2-c_f)ky]$, where $c_f k$ is their 5D mass [7,73]. Depending on the free parameter $c_f k$, fermions can be localized either towards the UV-boundary ($c_f > 1/2$) or IR-boundary ($c_f < 1/2$). Since the Higgs boson is localized on the IR-boundary, one can generate exponentially suppressed Yukawa couplings by having the fermion zero-modes localized towards the UV-boundary, generating naturally the light SM fermion spectrum [7]. A large overlap with the wavefunction of the Higgs is needed for the top quark, in order to generate its large mass, thus requiring it to be localized towards the IR-boundary. In conclusion, the large mass hierarchies present in the SM fermion spectrum can be easily obtained in warped models via suitable choices of the order-one parameters c_f [74]. In these scenarios, deviations in flavor physics from the SM predictions are expected to arise from flavor-changing KK gluon couplings [75], putting certain constraints on the parameters of the models and predicting new physics effects to be observed in B-physics processes (see, for example, [76,77]).

The masses of the KK states can also be calculated. One finds [7]

$$m_n \simeq \left(n + \frac{\alpha}{2} - \frac{1}{4}\right) \pi k e^{-\pi k R}\,, \qquad (85.20)$$

where $n = 1, 2, ...$ and $\alpha = \{|c_f - 1/2|, 0, 1\}$ for KK fermions, KK gauge bosons and KK gravitons, respectively. Their masses are of order $ke^{-\pi kR} \sim$ TeV (for this reason we refer to these scenarios as TeV-scale extra dimensions). The first KK state of the gauge bosons would be the lightest, while gravitons are expected to be the heaviest.

85.3.1.1 *Models of Electroweak Symmetry Breaking*

Theories in warped extra dimensions can be used to implement symmetry breaking at low energies by boundary conditions (for a review see, for example, [78]). For example, for a $U(1)$ gauge symmetry in the 5D bulk, this can be easily achieved by imposing a Dirichlet boundary condition on the IR-boundary for the gauge-boson field, $A_\mu|_{y=\pi R} = 0$. This makes the zero-mode gauge boson get a mass, given by $m_A = g_4\sqrt{2k/g_5^2}\, e^{-\pi kR}$. A very different situation occurs if the Dirichlet boundary condition is imposed on the UV-boundary, $A_\mu|_{y=0} = 0$. In this case the zero-mode gauge boson disappears from the spectrum. Finally, if a Dirichlet boundary condition is imposed on the two boundaries, one obtains a massless 4D scalar corresponding to the fifth component of the 5D gauge boson, A_5. Thus, different scenarios can be implemented by appropriately choosing the 5D bulk gauge symmetry, $\mathcal{G}_5$, and the symmetries to which it reduces on the UV and IR-boundary, $\mathcal{H}_{UV}$ and $\mathcal{H}_{IR}$, respectively. In all cases the KK spectrum comes in representations of the group $\mathcal{G}_5$.

Among the most interesting scenarios are those called gauge-Higgs unified models, where the Higgs boson appears as the fifth component of a 5D gauge boson, A_5. The Higgs mass is protected by the 5D gauge invariance and can only get a nonzero value from non-local one-loop effects [79]. To guarantee the relation $M_W^2 \simeq M_Z^2 \cos^2\theta_W$, a custodial $SU(2)_V$ symmetry is needed in the bulk and IR-boundary [80]. The simplest realization [81,82] has

$$\begin{aligned} \mathcal{G}_5 &= SU(3)_c \times SO(5) \times U(1)_X, \\ \mathcal{H}_{IR} &= SU(3)_c \times SO(4) \times U(1)_X, \\ \mathcal{H}_{UV} &= G_{SM}. \end{aligned}$$

The Higgs boson gets a potential at the one-loop level that triggers a VEV, breaking the electroweak symmetry. In these models there is a light Higgs boson whose mass can be around 125 GeV, as required by the discovered Higgs boson [83]. This state, as will be explained in Sec. 85.3.2, behaves as a composite pseudo-Nambu-Goldstone boson with couplings that deviate from the SM Higgs [84]. The present experimental determination of the Higgs couplings at the LHC, that agrees with the SM predictions, put important constraints on these scenarios [83]. The lightest KK modes of the model are color fermions with charges $Q = -1/3, 2/3$ and $5/3$ [85].

85.3.1.2 *Constraints from Electroweak Precision Tests*

Models in which the SM gauge bosons propagate in 1/TeV-sized extra dimensions give generically large corrections to electroweak observables. When the SM fermions are confined on a boundary these corrections are universal and can be parameterized by four quantities: $\widehat{S}$, $\widehat{T}$, W and Y, as defined in Ref. [86]. For warped models, where the 5D gauge coupling of Eq. (85.19) is large, the most relevant parameter is $\widehat{T}$, which gives the bound $m_{KK} \gtrsim 10$ TeV [71]. When a custodial symmetry is imposed [80], the main constraint comes from the $\widehat{S}$ parameter, requiring $m_{KK} \gtrsim 3$ TeV, independent of the value of g_5. Corrections to the $Zb_L\bar{b}_L$ coupling can also be important [71], especially in warped models for electroweak symmetry breaking as the ones described above.

85.3.1.3 *Kaluza-Klein Searches*

The main prediction of 1/TeV-sized extra dimensions is the presence of a discretized KK spectrum, with masses around the TeV scale, associated with the SM fields that propagate in the extra dimension.

In the RS model [3], only gravity propagates in the 5D bulk. Experimental searches have been performed for the lightest KK graviton through its decay to a variety of SM particle-antiparticle pairs. The results are usually interpreted in the plane of the dimensionless coupling k/M_P versus m_1, where M_P is the reduced Planck mass defined previously and m_1 is the mass of the lightest KK excitation of the graviton. Since the AdS curvature $\sim k$ cannot exceed the cut-off scale of the model, which is estimated to be $\ell_5^{1/3} M_5$ [38], one must demand $k \ll \sqrt{2\ell_5} M_P \simeq 40 M_P$. The most stringent limits currently arise from LHC searches for resonances in the dilepton and diphoton final states, using 13 TeV collisions. Searches with the $\gamma\gamma$ final state are an especially powerful approach, given that these final states have a branching fraction twice that of any individual lepton flavor. The CMS analysis [41] of 36 fb^{-1}of 13 TeV data excludes KK gravitons below 2.3 to 4.6 TeV, depending on the value of the coupling k/M_P, which is varied between 0.01 and 0.2, while ATLAS [87] uses the full 139 fb^{-1}and provides a lower limit on the KK graviton mass of 4.5 TeV for the coupling parameter 0.1. The CMS [42] dilepton analyses, combining results from the ee and $\mu\mu$ channels, exclude KK gravitons with masses 2.47–4.78 TeV for k/M_P values of 0.01–0.1. The ATLAS [88] analysis of 139 fb^{-1}of Run 2 data does not include a RS KK graviton interpretation of the results. Less stringent limits on the KK graviton mass can be derived from analyses of the dijet [35, 36, 89, 90], HH [91–99], and VV [100–104] final states, where V can represent either a W or Z boson.

In addition, both ATLAS and CMS experiments directly search for heavy radions, with masses above 1 TeV where the dominant decay mode is to pairs of bosons. The main production mechanism is gluon fusion. ATLAS [102] (CMS [105]) excludes radion masses below 3.2 TeV (3.1 TeV) for a radion decaying into WW, ZZ. Radions are also searched in final states with pairs of Higgs bosons HH [91, 94, 96, 97, 99, 106], and dijet final states [107] with additional gluons. Bounds for a light radion (1 keV–10 GeV mass range) can be found in [108].

In warped extra-dimensional models in which the SM fields propagate in the 5D bulk, the couplings of the KK graviton to $ee/\mu\mu/\gamma\gamma$ are suppressed [109], and the above bounds do not apply. Furthermore, the KK graviton is the heaviest KK state (see Eq. (85.20)), and therefore experimental searches for KK gauge bosons and fermions are more appropriate discovery channels in these scenarios. For the scenarios discussed above in which only the Higgs boson and the top quark are localized close to the IR-boundary, the KK gauge bosons mainly decay into top quarks, longitudinal W/Z bosons, and Higgs bosons. Couplings to light SM fermions are suppressed by a factor $g/\sqrt{g_5^2 k} \sim 0.2$ [7] for the value of Eq. (85.19) that is considered from now on. Searches have been made for evidence of the lightest KK excitation of the gluon, through its decay to $t\bar{t}$ pairs. The searches take into account the natural KK gluon width, which is typically $\sim 15\%$ of its mass. The decay of a heavy particle to $t\bar{t}$ would tend to produce highly boosted top (anti-)quarks in the final state. Products of the subsequent top decays would therefore tend to be close to each other in the detector. In the case of $t \to Wb \to jjb$ decays, the three

jets could overlap with one another and not be individually reconstructed with the standard jet algorithms, while $t \to Wb \to \ell\nu b$ decays could result in the lepton failing standard isolation requirements due to its proximity to the b-jet; in both cases, the efficiency for properly reconstructing the final state would fall as the mass of the original particle increases. To avoid the loss in sensitivity which would result, a number of techniques, known generally as top quark tagging [110, 111], have been developed to reconstruct and identify highly boosted top quarks, for example by using a single wide jet to contain all the decay products of a hadronic top decay. The large backgrounds from QCD jets can then be reduced by requiring the jet mass be consistent with that of a top quark, and also by examining the substructure of the wide jet for indication that it resulted from the hadronic decay of a top quark. These techniques are key to extending to very high masses the range of accessible resonances decaying to $t\bar{t}$ pairs. While the ATLAS search in 139 fb^{-1}of Run 2 data [112] does not provide a KK interpretation, dedicated analysis from CMS [113] of 36 fb^{-1} of 13 TeV data combines di-lepton, lepton-plus-jet, and all-hadronic $t\bar{t}$ decays and excludes KK gluons with masses below 4.55 TeV. ATLAS uses all-hadronic [114] and lepton-plus-jet [115] final states to exclude KK gluons up to 3.4 and 3.8 TeV respectively with 36fb^{-1}of 13 TeV data. The results are not directly comparable between the two LHC experiments, since they employ in their respective analyses different implementations of the theoretical model. For masses between 3 and 5 TeV, the cross-section limits are around 20 fb for CMS analysis of 36 fb^{-1}and 30 fb (4 fb) for ATLAS analyses of 36 (139) fb^{-1}.

A gauge boson KK excitation could be also sought through its decay to longitudinal W/Z bosons. Recent analyses from ATLAS [116] (and CMS [117]) with 139 (137) fb^{-1}of 13 TeV data searching for heavy vector resonances decaying to a W or Z boson and a Higgs in the $q\bar{q}b\bar{b}$ final state have set a lower limit on the mass of these KK of 3.2 (3.7) TeV (warped models are equivalent to the Model B considered in the analyses with $g_V \sim g_5\sqrt{k}$). The decay to a pair of intermediate vector bosons has also been exploited to search for KK gravitons in models in which the SM fields propagate in the 5D bulk. The analyses typically reconstruct hadronic W/Z decays using variants of the boosted techniques mentioned previously. An ATLAS analysis [118] combines leptonic and hadronic final states from the KK graviton decay $G^* \to VV$, where V can represent either a W or Z boson, exclude KK gravitons with masses below 2.3 TeV, for a value of $k/M_P = 1$. CMS VV analyses [105, 119, 120] using 137 fb^{-1}of 13 TeV data also exclude KK gravitons with masses below 1.8 TeV in the context of bulk gravitons for a maximum value of $k/M_P = 0.5$.

The lightest KK states are, in certain models, the partners of the top quark. For example, in 5D composite Higgs models these are colored states with charges $Q = -1/3, 2/3$ and $5/3$ (arising from $SU(2)_L$ doublets with $Y = 7/6, 1/6$), and masses expected to be below the TeV [85]. They can be either singly or pair-produced, and mainly decay into a combination of W/Z with top/bottom quarks [121–124]. An exhaustive review of these searches can be found in Ref. [125]. Of particular note, the $Q = 5/3$ state decays mainly into $W^+t \to W^+W^+b$, giving a very clean signature of a pair of same-sign leptons in the final state. An analysis by ATLAS [126] searching in the lepton-plus-jets final state for evidence of pair production of the $Q = 5/3$ state provides a lower mass limit of 1.25 TeV. A CMS analysis [127] searching for pair production of the $Q = 5/3$ state using both lepton-plus-jets and same sign lepton final states excludes masses below 1.3 TeV. Similarly, searches for single production of the $Q = 5/3$ state [128], also excludes masses up to 0.9 to 1.5 TeV depending on the model parameters. Both LHC experiments have searched for pair production of vector-like quarks T and B of charges $Q = 2/3$ and $-1/3$ respectively, assuming the allowable decays are $T \to Wb/Zt/Ht$ and $B \to Wt/Zb/Hb$. In each case, it is assumed the branching fractions of the three decay modes sum to unity, but the individual branching fractions, which are model-dependent, are allowed to vary within this constraint. Both ATLAS [129–131] and CMS [132,133] obtain lower limits on the mass of the T and B vector-like quarks up to 1.5 TeV and 1.6 TeV respectively.

Analyses from ATLAS [134–138] and CMS [128, 139–142] also search for a single top partner and single bottom partner production, the cross section for which is model-dependent [143] but does not carry the kinematic penalty for producing two heavy objects.

85.3.2 *Connection with Strongly Coupled Models via the AdS/CFT Correspondence*

The AdS/CFT correspondence [8] provides a connection between warped extra-dimensional models and strongly-coupled theories in ordinary 4D. Although the exact connection is only known for certain cases, the AdS/CFT techniques have been very useful to obtain, at the qualitative level, a 4D holographic description of the various phenomena in warped extra-dimensional models [11, 72].

The connection goes as follows. The physics of the bulk AdS$_5$ models can be interpreted as that of a 4D conformal field theory (CFT) which is strongly coupled. The extra-dimensional coordinate y plays the role of the renormalization scale μ of the CFT by means of the identification $\mu \equiv ke^{-ky}$. Therefore the UV-boundary corresponds in the CFT to a UV cut-off scale at $\Lambda_{UV} = k \sim M_P$, breaking explicitly conformal invariance, while the IR-boundary can be interpreted as a spontaneous breaking of the conformal symmetry at energies $ke^{-k\pi R} \sim$ TeV. Fields localized on the UV-boundary are elementary fields external to the CFT, while fields localized on the IR-boundary and KK states corresponds to composite resonances of the CFT. Furthermore, local gauge symmetries in the 5D models, $\mathcal{G}_5$, correspond to global symmetries of the CFT, while the UV-boundary symmetry can be interpreted as a gauging of the subgroup $\mathcal{H}_{UV}$ of $\mathcal{G}_5$ in the CFT. Breaking gauge symmetries by IR-boundary conditions corresponds to the spontaneous breaking $\mathcal{G}_5 \to \mathcal{H}_{IR}$ in the CFT at energies $\sim ke^{-k\pi R}$. Using this correspondence one can easily derive the 4D massless spectrum of the compactified AdS$_5$ models. One also has the identification $k^3/M_5^3 \approx 16\pi^2/N^2$ and $g_5^2 k \approx 16\pi^2/N^r$ ($r = 1$ or 2 for CFT fields in the fundamental or adjoint representation of the gauge group), where N plays the role of the number of colors of the CFT. Therefore the weak-coupling limit in AdS$_5$ corresponds to a large-N expansion in the CFT.

Following the above AdS/CFT dictionary one can understand the RS solution to the hierarchy problem from a 4D viewpoint. The equivalent 4D model is a CFT with a TeV mass gap and a Higgs boson emerging as a composite state. In the particular case where the Higgs is the fifth-component of the gauge-boson, A_5 [144], this corresponds to models, similar to those proposed in Ref. [145–148], where the Higgs is a composite pseudo-Nambu-Goldstone boson arising from the spontaneous breaking $\mathcal{G}_5 \to \mathcal{H}_{IR}$ in the CFT. The AdS/CFT dictionary tells us that KK states must behave as composite resonances. For example, if the SM gauge bosons propagate in the 5D bulk, the lowest KK $SU(2)_L$-gauge boson must have properties similar to those of the Technirho ρ_T [125] with a coupling to longitudinal W/Z bosons given by $g_5\sqrt{k} \approx g_{\rho_T}$, while the coupling to elementary fermions is $g^2/\sqrt{g_5^2 k} \approx g^2 F_{\rho_T}/M_{\rho_T}$.

Fermions in compactified AdS$_5$ also have a simple 4D holographic interpretation. The 4D massless mode described in Sec. 85.3.1 corresponds to an external fermion ψ_i linearly coupled to a fermionic CFT operator $\mathcal{O}_i$: $\mathcal{L}_{\rm int} = \lambda_i \bar{\psi}_i \mathcal{O}_i + h.c.$. The dimension of the operator $\mathcal{O}_i$ is related to the 5D fermion mass according to $\mathrm{Dim}[\mathcal{O}_i] = |c_f + 1/2| - 1$. Therefore, by varying c_f one varies $\mathrm{Dim}[\mathcal{O}_i]$, making the coupling λ_i irrelevant ($c_f > 1/2$), marginal ($c_f = 1/2$) or relevant ($c_f < 1/2$). When irrelevant, the coupling is exponentially suppressed at low energies, and then the coupling of ψ_i to the CFT (and eventually to the composite Higgs) is very small. When relevant, the coupling grows in the IR and become as large as g_5 (in units of k), meaning that the fermion is as strongly coupled as the CFT states [81]. In this latter case ψ_i behaves as a composite fermion.

85.3.3 *Linear dilaton geometry*

The warp factor $a(y)$ in Eq. (85.16) can be different from the exponential considered above, giving rise to a different KK mass spectrum. A particularly interesting case is the linear dilaton geometry [149] where the KK states become very narrowly-spaced. These scenarios can also be understood in 4D via the clockwork mechanism [150], and for this reason are usually referred to as

Clockwork/Linear Dilaton (CW/LD) models. The collider phenomenology becomes different in these models since the decay of the narrowly-spaced KK spectrum appears as a periodic signal in the invariant mass of the decaying products. An excellent detector resolution is needed in order to resolve these KK modes which can be done by looking at 2 electrons or 2 photons in the final state. A search for this type of KK gravitons decaying into ee [151] and $\gamma\gamma$ [151, 152] put bounds for M_5 in the range of 10 TeV to 1 TeV for values of the lightest KK graviton mass (referred as k in [151, 152]) in the range of few TeVs.

85.3.4 *Flat Extra Dimensions*

Models with quantum gravity at the TeV scale, as in the ADD scenario, can have extra (flat) dimensions of 1/TeV size, as happens in string scenarios (see, for example, [153]). All SM fields may propagate in these extra dimensions, leading to the possibility of observing their corresponding KK states.

A simple example is to assume that the SM gauge bosons propagate in a flat five-dimensional orbifold S^1/Z_2 of radius R, with the fermions localized on a 4D boundary. The KK gauge bosons behave as sequential SM gauge bosons with a coupling to fermions enhanced by a factor $\sqrt{2}$ [153]. The experimental limits on such sequential gauge bosons could therefore be recast as limits on KK gauge bosons. Such an interpretation of the ATLAS 7 TeV dilepton analysis [154] yielded the bound $1/R > 4.16$ TeV, while a CMS 8 TeV search with a lepton and missing transverse energy in the final state [155] give $1/R > 3.4$ TeV. Indirect bounds from LEP2 require however $1/R \gtrsim 6$ TeV [86, 156], a bound that can considerably improve in the future by high-energy measurements of the dilepton invariant mass spectrum from Drell-Yan processes at the LHC [157]. More recent LHC limits on leptonically decaying gauge bosons [88, 158–162] are not interpreted as bounds on $1/R$ by the collaborations, but the published results allow for independent derivation of such bounds.

An alternative scenario, known as Universal Extra Dimensions (UED) [163] (for a review see, for example, [164]), assumes that all SM fields propagate universally in a flat orbifold S^1/Z_2 with an extra Z_2 parity, called KK-parity, that interchanges the two boundaries. In this case, the lowest KK state is stable and is a Dark Matter candidate. At colliders, the KK particles would have to be created in pairs, and would then cascade decay to the lightest KK particle, which would be stable and escape detection. The UED mass-spectrum depends not only on the extra-dimensional radius R, but also on the cut-off of the 5D theory Λ, since quantum corrections sensitive to ΛR induce mass-splittings between the KK states. Experimental signatures, such as jets or leptons and $p_{\mathrm{T}}^{\mathrm{miss}}$, would be similar to those of typical R-parity conserving SUSY searches. An interpretation of the recent LHC experimental SUSY searches for UED models has been presented in Refs. [165,166]. A lower bound $1/R > 1.4 - 1.5$ TeV was derived for ΛR in the range $5 - 35$ [165]. A recent analysis is given in Ref. [167] where it is shown that the minimal UED model is ruled out when LHC data is combined with Dark Matter relic density data. Extensions to the minimal UED model where boundary terms are included can however be compatible with experiments [167].

Finally, realistic models of electroweak symmetry breaking can also be constructed with flat extra spatial dimensions, similarly to those in the warped case, requiring, however, the presence of sizeable boundary kinetic terms [168]. There is also the possibility of breaking supersymmetry by boundary conditions [169]. Models of this type could explain naturally the presence of a Higgs boson lighter than $M_D \sim$ TeV (see, for example, [170–172]).

86. W'-Boson Searches

Revised September 10, 2023 by B.A. Dobrescu (FNAL) and S. Willocq (U. Massachusetts).

The W' boson is a massive hypothetical particle of spin 1 and electric charge ± 1, which is a color singlet and is predicted in various extensions of the Standard Model (SM).

86.1 W' couplings to quarks and leptons

The Lagrangian terms describing the couplings of a W'^{+} boson to fermions are given by

$$\frac{W'^{+}_{\mu}}{\sqrt{2}}\left[\overline{u}_i\left(C^R_{q_{ij}}P_R+C^L_{q_{ij}}P_L\right)\gamma^\mu d_j+\overline{\nu}_i\left(C^R_{\ell_{ij}}P_R+C^L_{\ell_{ij}}P_L\right)\gamma^\mu e_j\right]. \tag{86.1}$$

Here, u, d, ν, and e are the SM fermions in the mass eigenstate basis, $i, j = 1, 2, 3$ label the fermion generation, and $P_{R,L} = (1 \pm \gamma_5)/2$. The coefficients $C^L_{q_{ij}}$, $C^R_{q_{ij}}$, $C^L_{\ell_{ij}}$, and $C^R_{\ell_{ij}}$ are complex dimensionless parameters. If $C^R_{\ell_{ij}} \neq 0$, then the ith generation includes a right-handed neutrino. Using this notation, the SM W couplings are $C^L_q = gV_{\rm CKM}$, $C^L_\ell = g \approx 0.63$ and $C^R_q = C^R_\ell = 0$.

Unitarity considerations imply that the W' boson is associated with a spontaneously-broken gauge symmetry. This is true even when it is a composite particle (*e.g.* $\rho^{\pm}$-like bound states [1]) if its mass is much smaller than the compositeness scale, or a Kaluza-Klein mode in theories where the W boson propagates in extra dimensions [2]. The simplest extension of the electroweak gauge group that includes a W' boson is $SU(2)_1 \times SU(2)_2 \times U(1)$, but larger groups are encountered in some theories. A generic property of these gauge theories is that they also include a Z' boson [3]; the W'-to-Z' mass ratio is often a free parameter.

A tree-level mass mixing may be induced between the electrically-charged gauge bosons. Upon diagonalization of their mass matrix, the W-to-Z mass ratio and the couplings of the observed W boson are shifted from the SM values. Their measurements imply that the mixing angle, θ_+, between the gauge eigenstates must be smaller than about 10^{-2} [4]. In certain theories the mixing is negligible (*e.g.*, due to a new parity [5]), even when the W' mass is near the electroweak scale. Note that $SU(2)$ gauge invariance suppresses the kinetic mixing between the W and W' bosons (in contrast to the case of a Z' boson [3]).

The W' coupling to WZ is fixed by Lorentz and gauge invariances, and to leading order in θ_+ is given by [6]

$$\frac{g\,\theta_+\,i}{\cos\theta_W}\left[W'^{+}_{\mu}\left(W^-_\nu Z^{\nu\mu}+Z_\nu W^{-\mu\nu}\right)+Z^\nu W^{-\mu}W'^{+}_{\nu\mu}\right]+\text{H.c.}, \tag{86.2}$$

where $W^{\mu\nu} \equiv \partial^\mu W^\nu - \partial^\nu W^\mu$, etc. The θ_W dependence shown here corrects the one given in Ref. [7], which has been referred to as the Extended Gauge Model by the experimental collaborations. The W' coupling to Wh^0, where h^0 is the SM Higgs boson, is

$$-\,\xi_h\, g_{W'}\, M_W\; W'^{+}_{\mu}\, W^{\mu-} h^0 + \text{H.c.}, \tag{86.3}$$

where $g_{W'}$ is the gauge coupling of the W' boson, and the coefficient ξ_h satisfies $\xi_h \leq 1$ in simple Higgs sectors [6].

In models based on the "left-right symmetric" gauge group [8], $SU(2)_L \times SU(2)_R \times U(1)_{B-L}$, the SM fermions that couple to the W boson transform as doublets under $SU(2)_L$ while the other fermions transform as doublets under $SU(2)_R$. Consequently, the W' boson couples primarily to right-handed fermions; its coupling to left-handed fermions arises due to the θ_+ mixing, so that C^L_q is proportional to the CKM matrix and its elements are much smaller than the diagonal elements of C^R_q. Generically, C^R_q does not need to be proportional to $V_{\rm CKM}$.

There are many other models based on the $SU(2)_1 \times SU(2)_2 \times U(1)$ gauge symmetry. In the "alternate left-right" model [9], all the couplings shown in Eq. (86.1) vanish, but there are some new fermions such that the W' boson couples to pairs involving a SM fermion and a new fermion. In the "ununified SM" [10], the left-handed quarks are doublets under one $SU(2)$, and the left-handed leptons are doublets under a different $SU(2)$, leading to a mostly leptophobic W' boson: $C^L_{\ell_{ij}} \ll C^L_{q_{ij}}$ and $C^R_{\ell_{ij}} = C^R_{q_{ij}} = 0$. Fermions of different generations may also transform as doublets under different $SU(2)$ gauge groups [11]. In particular, the couplings to third generation quarks may be enhanced [12].

It is also possible that the W' couplings to SM fermions are highly suppressed. For example, if the quarks and leptons are singlets under one $SU(2)$ [13], then the couplings are proportional to the tiny mixing angle θ_+. Similar suppressions may arise if some vectorlike fermions mix with the SM fermions [14].

Gauge groups that embed the electroweak symmetry, such as $SU(3)_W \times U(1)$ or $SU(4)_W \times U(1)$, also include one or more W' bosons [15].

86.2 Collider searches

At hadron colliders, W' bosons can be detected through resonant pair production of fermions (f and f') or electroweak bosons with a net electric charge equal to ± 1. When W' has a width much smaller than its mass ($\Gamma_{W'}/M_{W'} \lesssim 7\%$), the contribution of the s-channel W' exchange to the total rate for $pp \to f\bar{f}'X$, where X is any final state, may be approximated by the branching fraction $B(W' \to f\bar{f}')$ times the production cross section [16], which may be written as

$$\sigma\left(pp \to W'X\right) \simeq \frac{\pi}{6s}\sum_{i,j}\left[(C^L_{q_{ij}})^2+(C^R_{q_{ij}})^2\right] w_{ij}\left(M^2_{W'}/s, M_{W'}\right). \tag{86.4}$$

The functions w_{ij} include the information about proton structure, and are given to leading order in α_s by

$$w_{ij}(z,\mu) = \int_z^1 \frac{dx}{x}\left[u_i(x,\mu)\,\overline{d}_j\left(\frac{z}{x},\mu\right)+\overline{u}_i(x,\mu)\,d_j\left(\frac{z}{x},\mu\right)\right], \tag{86.5}$$

where $u_i(x,\mu)$ and $d_i(x,\mu)$ are the parton distributions inside the proton at the factorization scale μ and parton momentum fraction x for the up- and down-type quarks of the ith generation, respectively. QCD corrections to W' production are sizable (they also include quark-gluon initial states), but preserve the above factorization of couplings at next-to-leading order [17].

The most commonly studied W' signal consists of a high-momentum electron or muon and large missing transverse momentum. The signal transverse mass distribution forms a Jacobian peak with its endpoint at $M_{W'}$ (see Fig. 1 (top) of Ref. [18]). Given that the branching fractions for $W' \to e\nu$ and $W' \to \mu\nu$ could be very different, the results in these channels should be presented separately. Searches in these channels often implicitly assume that the left-handed couplings vanish (no interference between W and W'), and that the right-handed neutrino is light compared to the W' boson and escapes the detector. An example of parameter values that satisfy these assumptions is $C^R_q = gV_{\rm CKM}$, $C^R_\ell = g$, $C^L_q = C^L_\ell = 0$, which define a model that preserves lepton universality and predicts the same total cross section as the Sequential SM used in many W' searches. However, if a W' boson were discovered and the final state fermions have left-handed helicity, then the effects of $W - W'$ interference could be observed [22], providing information about the W' couplings. The effects of the W' width on interference are discussed in Ref. [23].

In the $e\nu$ channel, the ATLAS and CMS collaborations set limits on the W' production cross section times branching fraction $\sigma \times B$ (and thus indirectly on the W' couplings). These limits are set for $M_{W'}$ in the $0.15 - 7$ TeV range and are based on approximately 140 fb^{-1} at $\sqrt{s} = 13$ TeV [18,19], with the most stringent limits reproduced in Fig. 86.1. ATLAS sets the strongest mass limit $M_{W'} > 6.0$ TeV in the Sequential SM (all limits in this mini-review are at the 95% CL). The coupling limits are much weaker for $M_{W'} < 150$ GeV, a range last explored with the Tevatron at $\sqrt{s} = 1.8$ TeV [24].

In the $\mu\nu$ channel, ATLAS and CMS set rate limits for $M_{W'}$ in the $0.15-7$ TeV range [18,19], with the strongest mass lower limit of 5.6 TeV in the Sequential SM set by CMS [19] using 138 fb^{-1} of $\sqrt{s} = 13$ TeV data, as shown in Fig. 86.1. When combined with the $e\nu$ channel assuming lepton universality, the upper limit on the $\sqrt{s} = 13$ TeV cross section times branching fraction to $\ell\nu$ varies between 0.05 and 2.1 fb for $M_{W'}$ values between 1 and 6 TeV [18]. Only weak limits on $W' \to \mu\nu$ exist for $M_{W'} < 150$ GeV [25]. Note that masses of the order of the electroweak

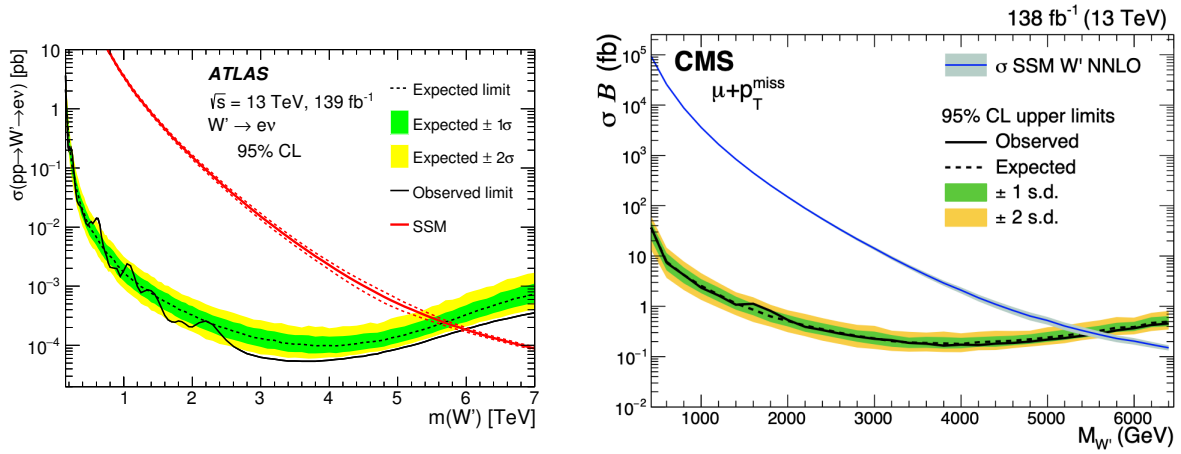

Figure 86.1: Upper limit on $\sigma(pp \to W'X) \times B(W' \to \ell\nu)$ in the $e\nu$ channel from ATLAS [18] (left) and the $\mu\nu$ channel from CMS [19] (right). The red (black) line shows the theoretical prediction in the Sequential SM in the $e\nu$ ($\mu\nu$) channel.

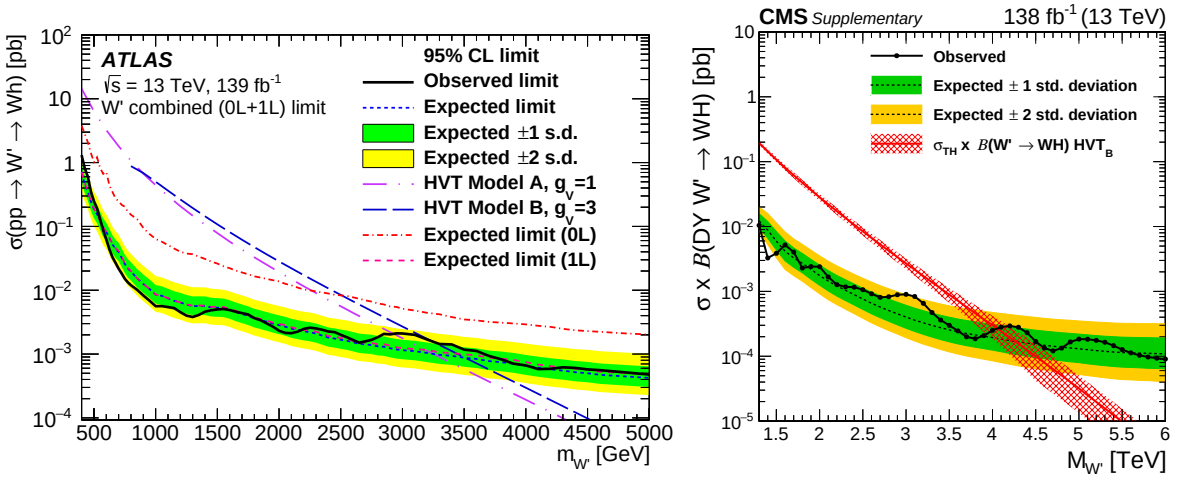

Figure 86.2: Upper limits on W' production cross section times branching fraction into a W and a SM Higgs boson decaying into heavy-flavor quarks, from ATLAS [20] (left) and CMS [21] (right).

scale are interesting from a theoretical point of view, while lepton universality does not necessarily apply to a W' boson.

Searches for $W' \to \tau\nu$ have been performed at 13 TeV by CMS with 138 fb^{-1} [26], and by ATLAS with 139 fb^{-1} [27]. Limits are set on $\sigma \times B$ for $M_{W'}$ between 0.5 and 6 TeV. A mass lower limit of 5.0 TeV is set in the Sequential SM, and the upper limit on the cross section times branching fraction to $\tau\nu$ at 13 TeV varies between 0.4 and 9 fb for $M_{W'}$ values between 1 and 5 TeV [27].

The W' decay into a charged lepton and a right-handed neutrino, ν_R, may also be followed by the ν_R decay through a virtual W' boson into a charged lepton and two quark jets. The CMS [28] and ATLAS [29] searches in the $eejj$ and $\mu\mu jj$ channels have set limits at $\sqrt{s} = 13$ TeV on the cross section times branching fractions as a function of the ν_R mass and of $M_{W'}$. No requirement is placed on the charge of the lepton pair. A related W' search in the $\tau\tau jj$ channel with hadronic τ decays was also performed by CMS [30].

The $t\bar{b}$ channel is particularly important because a W' boson that couples only to right-handed fermions cannot decay to leptons when the right-handed neutrinos are heavier than $M_{W'}$. Additional motivations are provided by a W' boson with enhanced couplings to the third generation [12], and by a leptophobic W' boson. The usual signature for $W' \to t\bar{b}$ consists of a leptonically-decaying W boson and two b-jets. Recent studies have also incorporated the fully hadronic decay channel for $M_{W'} \gg m_t$ with the use of jet substructure techniques to tag highly boosted top-jets. For a detailed discussion of this channel, see Ref. [31].

Searches for dijet resonances may be used to set limits on $W' \to q\bar{q}'$. ATLAS [32] and CMS [33] provide similar coverage in the $\sim 1.5-8$ TeV mass range with 139 and 137 fb^{-1} of data, respectively, collected at $\sqrt{s} = 13$ TeV. Interpretation in terms of W' decays with 139 fb^{-1} of 13 TeV data yields a W' mass lower limit of 4.0 TeV in the Sequential SM [32]. For masses in the range $\sim 0.5-1.5$ TeV, analyses based on jets reconstructed online provide the best sensitivity because they circumvent trigger bandwidth limitations [34, 35]. For W' masses below ~ 0.5 TeV, the best limits are set in novel analyses exploiting boosted technologies and initial state radiation [36–39]. Cross-section limits for W' masses below ~ 1.5 TeV can be derived from the dijet limits on Z' bosons summarized in Ref. [3].

In some theories [5] the W' couplings to SM fermions are suppressed by discrete symmetries. W' production then occurs in pairs, through a photon or Z boson. The decay modes are model-dependent and often involve other new particles. The ensuing collider signals arise from cascade decays and often include missing transverse momentum or boosted multi-jet topologies. Even when single production of W' is large enough, it is possible that its main decay mode is into a new particle and a SM one. An example is a search performed by CMS [40] for W' decays into a vector-like quark and a top or a bottom quark. The final state studied in this analysis involves a boosted SM Higgs or Z boson, as well as a $t\bar{t}$ or $b\bar{b}$ pair, with all heavy particles decaying into

jets. Another example is a search performed by ATLAS [41] for W' decays into a W boson and a Z' boson, the latter decaying into a jet pair.

Searches for WZ resonances at the LHC have focused on the process $pp \to W' \to WZ$ with the production mainly from $u\bar{d} \to W'$, assuming SM-like couplings to quarks. ATLAS and CMS have set upper limits on the $W'WZ$ coupling for $M_{W'}$ in the $0.2-5.0$ TeV range with a combination of fully leptonic, semi-leptonic and fully hadronic channels with $\sim 36-139$ fb^{-1} at 13 TeV [42–44] (see also Ref. [31]). Recent constraints with 138–139 fb^{-1} at 13 TeV were also set in individual channels by ATLAS [45–47] and CMS [21, 48–50]. The strongest lower limit on the W' mass is set by ATLAS [46] in the semi-leptonic channel with a lower limit on $M_{W'}$ of 3.9 TeV [46] in the context of the Heavy Vector Triplet (HVT) weakly-coupled scenario A [51]. A similar result is obtained by CMS in the fully-hadronic channel [21]. A fermiophobic W' boson that couples to WZ may be produced at hadron colliders in association with a Z boson, or via WZ fusion. This would give rise to $(WZ)Z$ and $(WZ)jj$ final states [52]. Results of the search for the latter are reported in Refs. [21, 42, 46, 48, 50].

W' bosons have also been searched for in final states with a W boson and a SM Higgs boson in the channels $W \to \ell\nu$ or $W \to q\bar{q}'$ and $h^0 \to b\bar{b}$ by ATLAS [20, 53] and CMS [21, 50] with 138–139 fb^{-1} at $\sqrt{s} = 13$ TeV. CMS also searched for W' bosons in the $q\bar{q}'\tau\tau$ final state [54]. Cross-section limits are set for W' masses between 0.4 and 6.0 TeV. The most stringent upper limit on the cross section is set by the ATLAS analysis with $W \to \ell\nu$ at low $M_{W'}$ and the CMS analysis with $W \to q\bar{q}'$ at high $M_{W'}$, as shown in Fig. 86.2.

At lepton colliders, W' bosons may be produced in pairs via their photon coupling, which is model independent. At LEP-II, although dedicated searches for W' bosons have not been performed, the large cross section for $e^+e^- \to \gamma^* \to W'^+W'^-$ and small backgrounds suggest that any W' is ruled out up to the kinematic limit, $M_{W'} < \sqrt{s}/2 \approx 105$ GeV, for most decay modes. Sensitivity to $M_{W'}$ above $\sqrt{s}$ could be achieved [55] using the $e^+e^- \to \gamma\nu\bar{\nu}$ process via a t-channel W' exchange, if the W' coupling to $e\nu$ is large enough.

86.3 Low-energy constraints

The properties of W' bosons are also constrained by measurements of processes at energies much below $M_{W'}$. The bounds on $W - W'$ mixing [4] are mostly due to the change in W properties compared to the SM. Limits on deviations in the ZWW couplings provide a leading constraint for fermiophobic W' bosons [14].

Constraints arising from low-energy effects of W' exchange are strongly model-dependent. If the W' couplings to quarks are not suppressed, then box diagrams involving a W and a W' boson contribute to neutral meson-mixing. In the case of W' couplings to right-handed quarks as in the left-right symmetric model, the limit from $K_L - K_S$ mixing is severe: $M_{W'} > 2.9$ TeV for $C_q^R = gV_{\rm CKM}$ [56]. However, if no correlation between the W' and W couplings is assumed, then the limit on $M_{W'}$ may be significantly relaxed [57].

W' exchange also contributes at tree level to various low-energy processes. In particular, it would impact the measurement of the Fermi constant G_F in muon decay, which in turn would change the predictions of many other electroweak processes. A recent test of parity violation in polarized muon decay [58] has set limits of about 600 GeV on $M_{W'}$, assuming W' couplings to right-handed leptons as in left-right symmetric models and a light ν_R. There are also W' contributions to the neutron electric dipole moment, β decays, and other processes [4].

If right-handed neutrinos have Majorana masses, then there are tree-level contributions to neutrinoless double-beta decay, and a limit on $M_{W'}$ versus the ν_R mass may be derived [59]. For ν_R masses below a few GeV, the W' boson contributes to leptonic and semileptonic B meson decays, so that limits may be placed on various combinations of W' parameters [57]. For ν_R masses below $\sim$30 MeV, the most stringent constraints on $M_{W'}$ are due to the limits on ν_R emission from supernovae [60].

87. Z'-Boson Searches

Revised September 2023 by B.A. Dobrescu (FNAL) and S. Willocq (U. Massachusetts).

The Z' boson is a massive, electrically-neutral and color-singlet hypothetical particle of spin 1. This particle is predicted in many extensions of the Standard Model (SM) and has been the object of extensive phenomenological studies [1].

87.1 Z' boson couplings

The couplings of a Z' boson to the first-generation fermions are given by

$$Z'_\mu \left(g_u^L\, \overline{u}_L \gamma^\mu u_L + g_d^L\, \overline{d}_L \gamma^\mu d_L + g_u^R\, \overline{u}_R \gamma^\mu u_R + g_d^R\, \overline{d}_R \gamma^\mu d_R + g_\nu^L\, \overline{\nu}_L \gamma^\mu \nu_L + g_e^L\, \overline{e}_L \gamma^\mu e_L + g_e^R\, \overline{e}_R \gamma^\mu e_R \right), \tag{87.1}$$

where u, d, ν, e are the quark and lepton fields in the mass eigenstate basis, and the coefficients g_u^L, g_d^L, g_u^R, g_d^R, g_ν^L, g_e^L, g_e^R are real dimensionless parameters. If the Z' couplings to quarks and leptons are generation-independent, then these seven parameters describe the couplings of the Z' boson to all SM fermions. More generally, however, the Z' couplings to fermions are generation-dependent, in which case Eq. (87.1) may be written with generation indices i, $j = 1$, 2, 3 labeling the quark and lepton fields, and with the seven coefficients promoted to 3×3 Hermitian matrices (*e.g.*, $g_{e\,ij}^L\, \overline{e}_L^i \gamma^\mu e_L^j$, where e_L^2 is the left-handed muon, etc.).

The parameters describing the Z' boson interactions with quarks and leptons are subject to some theoretical constraints. Quantum field theories that include a heavy spin-1 particle are well behaved at high energies only if that particle is a gauge boson associated with a spontaneously broken gauge symmetry. Quantum effects preserve the gauge symmetry only if the couplings of the gauge boson to fermions satisfy the anomaly equations [2]. Furthermore, the fermion charges under the new gauge symmetry are constrained by the requirement that the quarks and leptons get masses from gauge-invariant interactions with the Higgs fields.

The relation between the couplings displayed in Eq. (87.1) and the gauge charges $z_{f\,i}^L$ and $z_{f\,i}^R$ of the fermions $f = u, d, \nu, e$ involves the unitary 3×3 matrices V_f^L and V_f^R that transform the gauge eigenstate fermions f_L^i and f_R^i, respectively, into the mass eigenstates. The Z' couplings also depend on the mixings of the new gauge boson in the gauge eigenstate basis ($\tilde{Z}'_\mu$). The main mixings are a kinetic mixing $(-\chi/2) B^{\mu\nu} \tilde{Z}'_{\mu\nu}$ with the hypercharge gauge boson B^μ (χ is a dimensionless parameter), and a mass mixing $\delta M^2\, \tilde{Z}^\mu \tilde{Z}'_\mu$ with the linear combination ($\tilde{Z}_\mu$) of neutral bosons that couples as the SM Z boson [3]. Since both the kinetic and mass mixings shift the mass and couplings of the Z boson, electroweak measurements impose upper limits on χ and $\delta M^2/(M_{Z'}^2 - M_Z^2)$ of the order of 10^{-3} [4]. Keeping only linear terms in these two small quantities, the couplings of the mass-eigenstate Z' boson are given by

$$g_{f\,ij}^L = g_z V_{f\,ii'}^L\, z_{f\,i'}^L \left(V_f^L\right)^\dagger_{i'j} + \frac{e}{c_W} \left(\frac{s_W \chi M_{Z'}^2 + \delta M^2}{2 s_W \left(M_{Z'}^2 - M_Z^2\right)} \sigma_f^3 - \epsilon\, Q_f \right), \tag{87.2}$$

$$g_{f\,ij}^R = g_z V_{f\,ii'}^R\, z_{f\,i'}^R \left(V_f^R\right)^\dagger_{i'j} - \frac{e}{c_W}\, \epsilon\, Q_f, \tag{87.3}$$

where g_z is the new gauge coupling, Q_f is the electric charge of f, e is the electromagnetic gauge coupling, s_W and c_W are the sine and cosine of the weak mixing angle, $\sigma_f^3 = +1$ for $f = u, \nu$ and $\sigma_f^3 = -1$ for $f = d, e$, and

$$\epsilon = \frac{\chi \left(M_{Z'}^2 - c_W^2 M_Z^2\right) + s_W \delta M^2}{M_{Z'}^2 - M_Z^2}. \tag{87.4}$$

The interaction of the Z' boson with a pair of W bosons has the form

$$\left[i \left(W_\mu^- Z'_\nu - W_\nu^- Z'_\mu \right) \partial^\mu W^{+\nu} + \text{H.c.} \right] + i \left(W_\mu^+ W_\nu^- - W_\nu^+ W_\mu^- \right) \partial^\mu Z'^\nu \tag{87.5}$$

with a coefficient of order $M_W^2/M_{Z'}^2$ [5]. The Z' also couples to one SM Higgs boson and one Z boson, $Z'_\mu Z^\mu\, h^0$, with a coefficient of order M_Z.

87.2 Z' models

A simple origin of a Z' boson is a new $U(1)'$ gauge symmetry. In that case, the matricial equalities $z_u^L = z_d^L$ and $z_\nu^L = z_e^L$ are required by the SM $SU(2)_W$ gauge symmetry. Given that the $U(1)'$ interaction is not asymptotically free, the theory may be well-behaved at high energies (*e.g.*, by embedding $U(1)'$ in a non-Abelian gauge group) only if the charges are commensurate numbers, *i.e.* any ratio of charges is a rational number. Satisfying the anomaly equations [6] with rational numbers is highly nontrivial, and typically new fermions charged under $U(1)'$ are necessary.

If the couplings are generation-independent ($V_f^{L,R}$ are then unit matrices in Eq. (87.2)) and the mixings of $\tilde{Z}'$ are negligible, then there are five commensurate couplings: g_u^R, g_d^R, g_e^R, g_q^L ($q = u$ or d), g_l^L ($l = \nu$ or e). Four sets of charges are displayed in Table 87.1, each of them spanned by a free parameter x [6]. The first set, labeled $B - xL$, has charges proportional to the baryon number minus x times the lepton number. These charges allow all SM Yukawa couplings to the Higgs doublet which is neutral under $U(1)_{B-xL}$, so that there is no tree-level $\tilde{Z} - \tilde{Z}'$ mixing. For $x = 1$ one recovers the $U(1)_{B-L}$ group, which is non-anomalous in the presence of one "right-handed neutrino" (a chiral fermion that is a singlet under the SM gauge group) per generation. For $x \neq 1$, it is necessary to include some fermions that are vectorlike (*i.e.* their mass terms are gauge invariant) with respect to the electroweak gauge group and chiral with respect to $U(1)_{B-xL}$. In the particular cases $x = 0$ or $x \gg 1$, the Z' is leptophobic or quark-phobic, respectively.

The second set, $U(1)_{10+x\bar{5}}$, has charges that commute with the representations of the $SU(5)$ grand unified group. Here x is related to the mixing angle between the two $U(1)$ bosons encountered in the $E_6 \to SU(5) \times U(1) \times U(1)$ symmetry breaking patterns of grand unified theories [1,7]. With these charges, two Higgs doublets are typically required to generate masses for both up- and down- type fermions. This set leads to $\tilde{Z} - \tilde{Z}'$ mass mixing at tree level, such that for a Z' mass close to the electroweak scale, the measurements at the Z-pole require some fine tuning between the charges and VEVs of the two Higgs doublets. Vectorlike quarks charged under the electroweak gauge group are required (except for $x = -3$) to make this set anomaly free. The particular cases $x = -3, 1, -1/2$ are usually labeled $U(1)_\chi$, $U(1)_\psi$, and $U(1)_\eta$, respectively. Under the third set, $U(1)_{d-xu}$, the weak-doublet quarks are neutral, and the ratio of u_R and d_R charges is $-x$. For $x = 1$, this is the "right-handed" group $U(1)_R$. For $x = 0$, the charges are those of the E_6-inspired $U(1)_I$ group, which requires new quarks and leptons. Other generation-independent sets of $U(1)'$ charges are given in Ref. [8].

In the absence of new fermions charged under the SM group, the most general generation-independent charge assignment is $U(1)_{q+xu}$, which is a linear combination of hypercharge and $B-L$. Many other anomaly-free solutions exist if generation-dependent charges are allowed. An example is $B - xL_e - yL_\mu + (y-3)L_\tau$, with x, y free parameters. This allows all fermion masses to be generated by Yukawa couplings to a single Higgs doublet, without inducing tree-level flavor-changing neutral current (FCNC) processes. There are also lepton-flavor dependent charges that allow neutrino masses to arise only from operators of high dimensionality [9].

If the $SU(2)_W$-doublet quarks have generation-dependent $U(1)'$ charges, then the mass eigenstate quarks have flavor off-diagonal couplings to the Z' boson (see Eq. (87.1), and note that $V_u^L \left(V_d^L\right)^\dagger$

Table 87.1: Examples of generation-independent $U(1)'$ charges for quarks and leptons. The parameter x is an arbitrary rational number. Gauge anomaly cancellation requires certain new fermions [6].

fermion	$U(1)_{B-xL}$	$U(1)_{10+x\bar{5}}$	$U(1)_{d-xu}$	$U(1)_{q+xu}$
(u_L, d_L)	$1/3$	$1/3$	0	$1/3$
u_R	$1/3$	$-1/3$	$-x/3$	$x/3$
d_R	$1/3$	$-x/3$	$1/3$	$(2-x)/3$
(ν_L, e_L)	$-x$	$x/3$	$(-1+x)/3$	-1
e_R	$-x$	$-1/3$	$x/3$	$-(2+x)/3$

is the CKM matrix). These are severely constrained by measurements of FCNC processes, which in this case are mediated at tree-level by Z' boson exchange [10]. The constraints are relaxed if the first and second generation charges are the same, although they are increasingly tightened by the measurements of B meson properties [11]. If only the $SU(2)_W$-singlet quarks have generation-dependent $U(1)'$ charges, there is more freedom in adjusting the flavor off-diagonal couplings because the $V^R_{u,d}$ matrices are not observable in the SM.

The anomaly equations for $U(1)'$ could be circumvented only if there is an axion with certain dimension-5 couplings to the gauge bosons. However, such a scenario violates unitarity unless the quantum field theory description breaks down at a scale near $M_{Z'}$ [12]. It is possible, though, that the SM fermions are not charged under the $U(1)'$, but have mass mixing with some vectorlike fermions which are charged under $U(1)'$, implying that the physical fermions have couplings to the Z' [13]. For example, if the only SM quarks that have large mixings with some vectorlike quarks are the b quarks, then the only currently known particles that couple to the Z' would be the physical b quarks.

Z' bosons may also arise from larger gauge groups. These may extend the electroweak group, as in $SU(2)\times SU(2)\times U(1)$, or may embed the electroweak group, as in $SU(3)_W \times U(1)$ [14]. If the larger group is spontaneously broken down to $SU(2)_W \times U(1)_Y \times U(1)'$ at a scale $v_\star \gg M_{Z'}/g_z$, then the above discussion applies up to corrections of order $M^2_{Z'}/(g_z v_\star)^2$. For $v_\star \sim M_{Z'}/g_z$, additional gauge bosons have masses comparable to $M_{Z'}$, including at least a W' boson [14]. If the larger gauge group breaks together with the electroweak symmetry directly to the electromagnetic $U(1)_{\rm em}$, then the left-handed fermion charges are no longer correlated ($z^L_u \neq z^L_d$, $z^L_\nu \neq z^L_e$) and a $Z'W^+W^-$ coupling is induced.

If the electroweak gauge bosons propagate in extra dimensions, then their Kaluza-Klein (KK) excitations include a series of Z' boson pairs. Each of these pairs can be associated with a different $SU(2)\times U(1)$ gauge group in four dimensions. The properties of the KK particles depend strongly on the extra dimensional theory [15]. For example, in universal extra dimensions there is a parity that forces all couplings of Eq. (87.1) to vanish in the case of the lightest KK bosons, while allowing couplings to pairs of fermions involving a SM and a heavy vectorlike fermion. There are also 4-dimensional gauge theories (*e.g.* little Higgs with T parity) with Z' bosons exhibiting similar properties. By contrast, in a warped extra dimension, the couplings of Eq. (87.1) may be sizable even when SM fields propagate along the extra dimension.

Z' bosons may also be composite particles. For example, in confining gauge theories [16], the ρ-like bound state is a spin-1 boson that may be interpreted as arising from a spontaneously broken gauge symmetry [17].

87.3 Non-resonant Z' signatures at colliders

In the presence of the couplings shown in Eq. (87.1), the Z' boson may be produced in the s-channel at colliders, and would decay to pairs of fermions. The decay width into a pair of electrons is given by

$$\Gamma\left(Z' \to e^+e^-\right) \simeq \left[\left(g^L_e\right)^2 + \left(g^R_e\right)^2\right] \frac{M_{Z'}}{24\pi}, \qquad (87.6)$$

where small corrections from electroweak loops are not included. The decay width into $q\bar{q}$ is similar, except for an additional color factor of 3, QCD radiative corrections, and fermion mass corrections. Thus, one may compute the Z' branching fractions in terms of the couplings of Eq. (87.1). However, other decay channels, such as WW or a pair of new particles, could have large widths and need to be added to the total decay width.

As mentioned above, there are theories in which the Z' couplings are controlled by a discrete symmetry that forbids decays into a pair of SM particles. Typically, such theories involve several new particles, which may be produced only in pairs and undergo cascade decays through Z' bosons, leading to signals involving missing transverse momentum. Given that the cascade decays depend on the properties of new particles other than the Z' boson (see, *e.g.* Ref. [18]), this case is not discussed further here.

The Z' contribution to the cross sections for $e^+e^- \to f\bar{f}$ proceeds through an s-channel Z' exchange (when $f = e$, there are also t- and u-channel exchanges). For $M_{Z'} < \sqrt{s}$, the Z' appears as an $f\bar{f}$ resonance in the radiative return process where photon emission tunes the effective center-of-mass energy to $M_{Z'}$. The agreement between the LEP-II measurements and the SM predictions implies that either the Z' couplings are smaller than or of order 10^{-2}, or else $M_{Z'}$ is above 209 GeV, the maximum energy of LEP-II. In the latter case, the Z' exchange may be approximated up to corrections of order $s/M^2_{Z'}$ by the contact interactions

$$\frac{g_z^2}{M^2_{Z'} - s}\left[\bar{e}\gamma_\mu\left(z^L_e P_L + z^R_e P_R\right)e\right]\left[\bar{f}\gamma^\mu\left(z^L_f P_L + z^R_f P_R\right)f\right], \qquad (87.7)$$

where $P_{L,R}$ are chirality projection operators, and the relation between Z' couplings and charges (see Eq. (87.2) in the limit where the mass and kinetic mixings are neglected) is used, assuming generation-independent charges. The four LEP collaborations have set limits on the coefficients of such operators for all possible chiral structures and for various combinations of fermions [19]. Thus, one may derive bounds on $(M_{Z'}/g_z)|z^L_e z^L_f|^{-1/2}$ and the analogous combinations of LR, RL and RR charges, which are typically on the order of a few TeV. LEP-II limits were derived [6] on the four sets of charges shown in Table 87.1.

Somewhat stronger bounds can be set on $M_{Z'}/g_z$ for specific sets of Z' couplings if the effects of several operators (87.7) are combined. Dedicated analyses by the LEP collaborations have set limits on Z' bosons for particular values of the gauge coupling (see section 3.5 of Ref. [19]). For example, $M_{Z_{\rm SSM}} > 1.76$ TeV for a "sequential" Z' of same couplings as the SM Z boson, while $M_{Z_\chi} > 0.785$ TeV for the Z' associated with $U(1)_\chi$ assuming a unification condition for the gauge coupling.

87.4 Searches at hadron colliders

Z' bosons with couplings to quarks (see Eq. (87.1)) may be produced at hadron colliders in the s-channel and would show up as resonances in the invariant mass distribution of the decay products. The cross section for producing a Z' boson at the LHC, which then decays to some $f\bar{f}$ final state, takes the form [22]

$$\sigma\left(pp \to Z'X \to f\bar{f}X\right) \simeq \frac{\pi}{6\,s}\sum_q c^f_q\, w_q\left(s, M^2_{Z'}\right) \qquad (87.8)$$

for flavor-diagonal couplings to quarks. Here, we have neglected the interference with the SM contribution to $f\bar{f}$ production, which is a good approximation for a narrow Z' resonance (deviations from the narrow width approximation are discussed in Ref. [23]). The coefficients

$$c^f_q = \left[\left(g^L_q\right)^2 + \left(g^R_q\right)^2\right] B(Z' \to f\bar{f}) \qquad (87.9)$$

contain all the dependence on the Z' couplings, while the functions w_q include all the information about parton distributions and QCD corrections [6, 8]. This factorization holds exactly to NLO and the deviations from it induced at NNLO are very small. Note that the w_u and w_d functions are substantially larger than the w_q functions for the other quarks. Eq. (87.8) also applies to

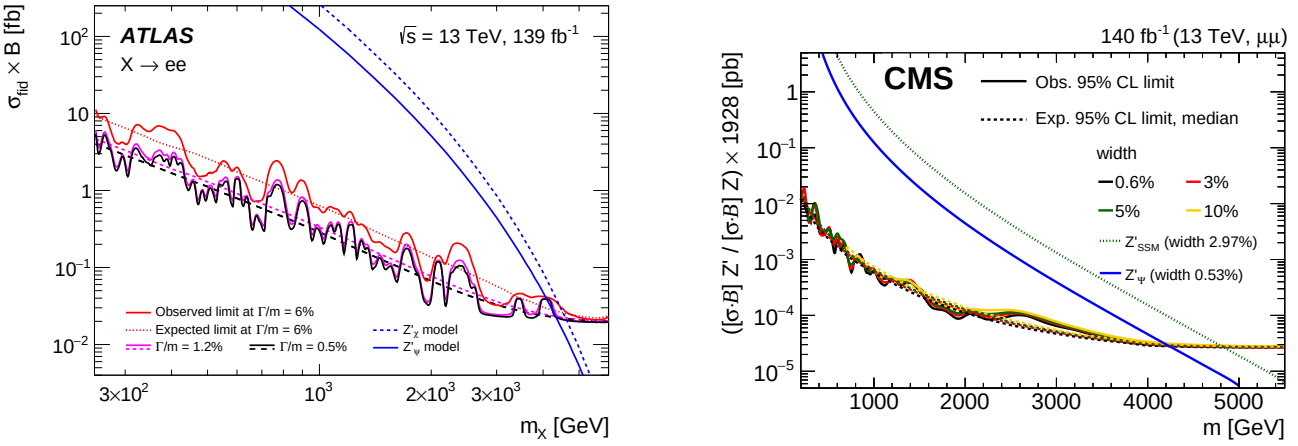

Figure 87.1: Upper limits on the cross section for Z' production times the branching fraction for $Z' \to e^+e^-$ (left panel, set by ATLAS [20]) or $Z' \to \mu^+\mu^-$ (right panel, set by CMS [21]) as a function of $M_{Z'}$. The lines labeled by Z'_ψ and Z'_χ are theoretical predictions for the $U(1)_{10+x\bar{5}}$ models in Table 87.1 with $x = -3$ and $x = +1$, respectively, for g_z fixed by an E_6 unification condition. The $Z'_{\rm SSM}$ line corresponds to Z' couplings equal to those of the Z boson.

the Tevatron, except for changing the pp initial state to $p\bar{p}$, which implies that the $w_q(s, M^2_{Z'})$ functions are replaced by some other functions $\bar{w}_q((1.96\,\text{TeV})^2, M^2_{Z'})$.

It is common to present results of Z' searches as limits on the cross section versus $M_{Z'}$ (see for example Fig. 87.1). An alternative is to plot exclusion curves for fixed $M_{Z'}$ values in the $c^f_u - c^f_d$ planes, allowing a simple derivation of the mass limit within any Z' model. CMS upper limits in the $c^\ell_u - c^\ell_d$ plane ($\ell = e$ or μ) for different $M_{Z'}$ are shown in Ref. [21] (for Tevatron limits, see Refs. [8, 24]).

The discovery of a dilepton resonance at the LHC would determine the Z' mass and width. A measurement of the total cross section would define a band in the $c^\ell_u - c^\ell_d$ plane. Angular distributions can be used to measure several combinations of Z' parameters (angular distributions were used in Ref. [25] to improve the Tevatron sensitivity). Even though the original quark direction in a pp collider is unknown, the leptonic forward-backward asymmetry $A^\ell_{\rm FB}$ can be extracted from the kinematics of the dilepton system, and is sensitive to parity-violating couplings. A fit to the Z' rapidity distribution can distinguish between the couplings to up and down quarks. These measurements, combined with off-peak observables, have the potential to differentiate among various Z' models [26]. In some cases, $A^\ell_{\rm FB}$ may provide discovery sensitivity that is competitive with the mass distribution [27]. The spin of the Z' boson may be determined from angular distributions [28].

Searches for Z' decays into e^+e^- and $\mu^+\mu^-$ by the ATLAS and CMS collaborations [20, 21] have set 95% C.L. upper cross-section limits as low as 0.02 fb (see Fig. 87.1), with the mass lower limits in specific models as high as 4.9 TeV in a single channel. Cross section limits in the dimuon channel for low mass regions, below 200 GeV but not near the Z mass, have been set at the LHC by CMS [29, 30] and LHCb [31].

The $Z' \to \tau^+\tau^-$ decay has been searched for by ATLAS with 36 fb^{-1} of 13 TeV data [32], and a limit $M_{Z'} > 2.4$ TeV has been set in the case of a sequential Z'. Limits on heavy scalars in the $\tau^+\tau^-$ final state, set by ATLAS [33] and CMS [34] with the full Run 2 datasets, can be recast into limits on Z'. Limits in the flavor-violating leptonic final states have also been reported by ATLAS [35] and CMS [36] at 13 TeV, for resonances in the $e^\pm\mu^\mp$, $e^\pm\tau^\mp$ and $\mu^\pm\tau^\mp$ channels.

Final states with higher background, jj, $b\bar{b}$ and $t\bar{t}$, are also important as they probe various combinations of Z' couplings to quarks. Besides the improved sensitivity at masses of several TeV, the LHC searches in the dijet channel have been also extended to masses as low as 10 GeV, through the use of new techniques involving boosted topologies and initial state radiation [37]. Limits from such Z' searches in hadronic final states are summarized in Fig. 87.2.

Searches for the $Z' \to b\bar{b}$ decay have been performed for two production mechanisms. ATLAS [39] and CMS [40] searched for $b\bar{b}$ resonances using the full Run 2 datasets, setting limits under the assumption that the Z' boson couples to light quarks and thus is produced in the s-channel. The CMS upper limit on the cross-section times the $Z' \to b\bar{b}$ branching fraction decreases from 40 fb at $M_{Z'} = 1.8$ TeV to 0.4 fb at $M_{Z'} = 8$ TeV. The ATLAS search covered the 1.3 TeV – 5 TeV mass range, setting a lower mass limit of 2.7 TeV for the Z'_{SSM}. Independent of any other couplings, if the Z' couples to the b quark, then it can be produced in association with a $b\bar{b}$ pair, and it decays to a second $b\bar{b}$ pair, which forms a resonance. The cross-section limit for that process, set by ATLAS [41] with 103 fb^{-1} of 13 TeV data, is between 0.1 and 0.2 pb for $M_{Z'}$ in the 1.3 – 3 TeV range. For a vector coupling g_b of Z' to b quarks, *i.e*, $g^L_{d\,33} = g^R_{d\,33} = g_b$ using the notation of Eq. (87.1), the limit is $M_{Z'} > 1.45$ TeV when $g_b = 1$.

Another search that depends on the Z' couplings to the b quark for production (more precisely, for a $b\bar{b}$, $s\bar{b}$ or $b\bar{s}$ initial state) was performed by CMS [42], under the assumption that the Z' boson decays into a muon pair. Searches for the $Z' \to t\bar{t}$ decay are discussed in Ref. [16].

Heavy resonances decaying into Zh^0 with $Z \to \ell^+\ell^-$, $\nu\bar{\nu}$ or $q\bar{q}$ and $h^0 \to b\bar{b}$ have been studied by ATLAS [43,44] and CMS [45,46] using the full 13 TeV dataset. CMS also searched for Z' bosons in the $q\bar{q}\tau\tau$ final state [47]. The most stringent constraint on Z' production in the context of the Heavy Vector Triplet (HVT) model weakly-coupled scenario A [48] is set in the semi-leptonic channel, with a mass lower limit of 3.5 TeV [45].

Searches for a Z' boson lighter than the SM Z and which couples to leptons have been performed in the 4-lepton final state. ATLAS [49] and CMS [50] focused on the Z decays into a muon pair followed by the radiation of a narrow Z' boson which decays itself into a muon pair. A related CMS search [51] for Z decays into four leptons, but without requiring that a pair of leptons form a narrow resonance, was used to set limits on Z' couplings to electrons or muons as a function of mass, which are relevant for large widths. ATLAS [52] considered the $h^0 \to ZZ'$ and $h^0 \to Z'Z'$ processes followed by the leptonic decays of both spin-1 bosons.

The $pp \to Z'X \to W^+W^-X$ process has also been searched for at the LHC. The channel where the Z' boson is produced through its couplings to quarks, and the W bosons decay hadronically, has been explored using boosted techniques to analyze the 13 TeV data [46, 53–55] with a mass lower limit of 3.5 TeV in the HVT model A [54]. A search in the $e\nu\mu\nu$ final state sets cross-section limits at lower Z' mass [56]. The Z' boson may also be produced through its couplings to W bosons [57], which has been explored with the use of forward jets consistent with a vector boson fusion event topology [46, 54, 55]. The latter process provides a test of

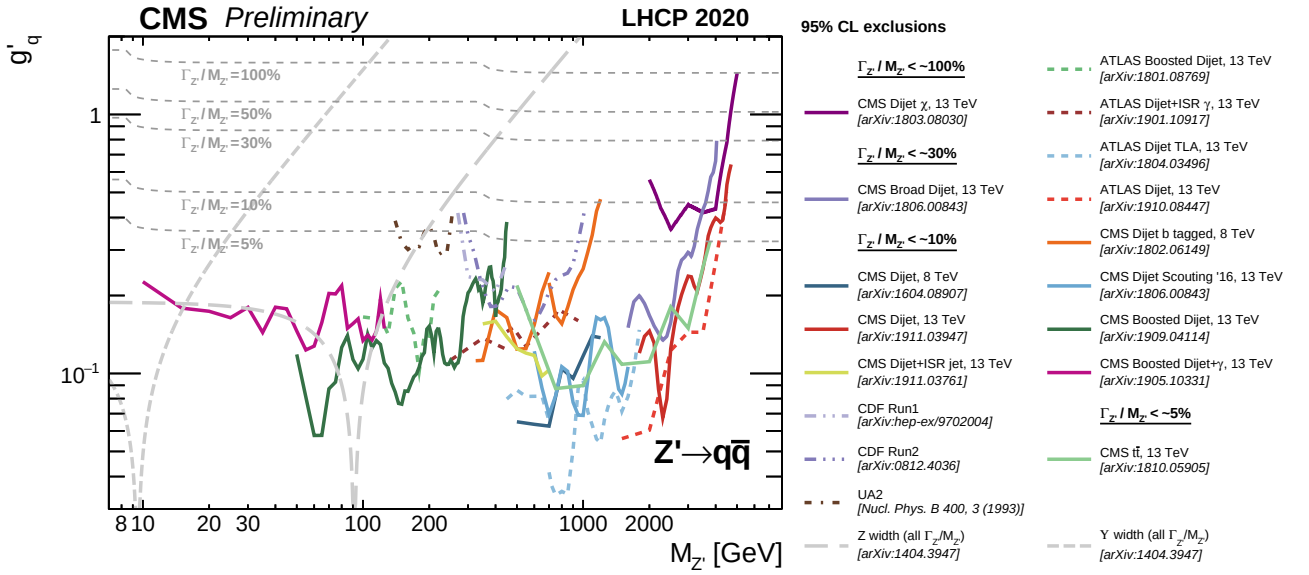

Figure 87.2: Upper limits on the Z' coupling to quarks as a function of $M_{Z'}$ based on various searches performed by the ATLAS, CMS, CDF, and UA2 experiments [38].

fermiophobic Z' models.

At the Tevatron, the CDF and DØ collaborations have searched for Z' bosons in the e^+e^- [58], $\mu^+\mu^-$ [59], $e^\pm\mu^\mp$ [60], $\tau^+\tau^-$ [61], $t\bar{t}$ [62], jj [63] and W^+W^- [64] final states. These limits have been mostly superseded by the LHC results.

87.5 Low-energy constraints

Z' boson properties are also constrained by a variety of low-energy experiments [65]. Polarized electron-nucleon scattering and atomic parity violation are sensitive to electron-quark contact interactions, which get contributions from Z' exchange that can be expressed in terms of the couplings introduced in Eq. (87.1) and M'_Z. Further corrections to the electron-quark contact interactions are induced in the presence of $\tilde{Z}-\tilde{Z}'$ mixing because of the shifts in the Z couplings to quarks and leptons [3]. Deep-inelastic neutrino-nucleon scattering is similarly affected by Z' bosons. Other low-energy observables are discussed in [4]. Viable models with Z' bosons much lighter than the Z boson have been constructed, despite many additional experimental constraints [66]. Limits on the Z' coupling to leptons in the mass range 0.02–10.2 GeV have been set in e^+e^- collisions by BaBar [67], assuming a dark photon, *i.e.*, a Z' boson whose couplings arise only from the kinetic mixing with the hypercharge gauge boson.

In some models, the lower limits on $M_{Z'}$ set by low-energy data are above 1 TeV. For example, $M_{Z_\chi} > 1.1$ TeV and $M_{Z_\eta} > 0.43$ TeV assuming that the Higgs sectors consist of electroweak doublets and singlets only [4], while the gauge coupling is fixed by an $SO(10)$ unification condition for $U(1)_\chi$ and $U(1)_\eta$. For more general models, see Refs. [1, 6, 68]. The mass bounds from direct searches at the LHC [20, 21] exceed the electroweak constraints by a factor of three or more for the models mentioned here. This conclusion could change if the collider bounds are weakened by exotic decay channels [69].

Although the LHC data are most constraining for many Z' models, one should be careful in assessing the relative reach of various experiments given the freedom in Z' couplings. For example, a Z' coupled to $B-yL_\mu+(y-3)L_\tau$ has implications for the muon $g-2$, neutrino oscillations or τ decays, and would be hard to see in processes involving first-generation fermions. Moreover, the combination of LHC searches and low-energy measurements could allow a precise determination of the Z' parameters [70].

88. Supersymmetry, Part I (Theory)

Revised August 2023 by B.C. Allanach (DAMTP, Cambridge U.) and H.E. Haber (UC Santa Cruz).

88.1 Introduction

Supersymmetry (SUSY) is a generalization of the space-time symmetries of quantum field theory that transforms fermions into bosons and vice versa [1]. The existence of such a non-trivial extension of the Poincaré symmetry of ordinary quantum field theory was initially surprising, and its form is highly constrained by theoretical principles [2]. SUSY also provides a framework for the unification of particle physics and gravity [3–5] at the Planck energy scale, $M_{\rm P} \sim 10^{19}$ GeV, where the gravitational interactions become comparable in strength to the gauge interactions. Moreover, supersymmetry can stabilize the hierarchy between the energy scale that characterizes electroweak symmetry breaking, $M_{\rm EW} \sim 100$ GeV, and the Planck scale [6–9] against large radiative corrections. The stability of this large gauge hierarchy with respect to radiative quantum corrections is not possible to maintain in the Standard Model (SM) without an unnatural fine-tuning of the parameters of the fundamental theory at the Planck scale. In contrast, in a supersymmetric extension of the SM, it is possible to maintain the gauge hierarchy while providing a natural framework for elementary scalar fields.

If supersymmetry were an exact symmetry of nature, then particles and their superpartners, which differ in spin by half a unit, would be degenerate in mass. Since superpartners have not (yet) been observed, supersymmetry must be a broken symmetry. Nevertheless, the stability of the gauge hierarchy can still be maintained if the SUSY breaking is soft [10,11], and the corresponding SUSY-breaking mass parameters are no larger than a few TeV. Whether this is still plausible in light of recent SUSY searches at the LHC (see Sec. 89) will be discussed in Sec. 88.7.

In particular, soft-SUSY-breaking terms of the Lagrangian involve combinations of fields with total mass dimension of three or less, with some restrictions on the dimension-three terms as elucidated in Ref. [10]. The impact of the soft terms becomes negligible at energy scales much larger than the size of the SUSY-breaking masses. Thus, a theory of weak-scale supersymmetry, where the effective scale of supersymmetry breaking is tied to the scale of electroweak symmetry breaking, provides a natural framework for the origin and the stability of the gauge hierarchy [6–9].

At present, there is no unambiguous experimental evidence for the breakdown of the SM at or below the TeV scale. The expectations for new TeV-scale physics beyond the SM are based primarily on three theoretical arguments. First, in a theory with an elementary scalar field of mass m and interaction strength λ (*e.g.*, a quartic scalar self-coupling, the square of a gauge coupling or the square of a Yukawa coupling), the stability with respect to quantum corrections requires the existence of an energy cutoff roughly of order $(16\pi^2/\lambda)^{1/2}m$, beyond which new physics must enter [12]. A significantly larger energy cutoff would require an unnatural fine-tuning of parameters that govern the effective low-energy theory. Applying this argument to the SM leads to an expectation of new physics at the TeV scale [9].

Second, the unification of the three SM gauge couplings at a very high energy close to the Planck scale is possible if new physics beyond the SM (which modifies the running of the gauge couplings above the electroweak scale) is present. The minimal supersymmetric extension of the SM, where superpartner masses lie below a few TeV, provides an example of successful gauge coupling unification [13].

Third, the existence of dark matter that makes up approximately one quarter of the energy density of the universe, cannot be explained within the SM of particle physics [14]. Remarkably, a stable weakly-interacting massive particle (WIMP) whose mass and interaction rate are governed by new physics associated with the TeV-scale can be consistent with the observed density of dark matter (this is the so-called WIMP miracle, which is reviewed in Ref. [15]). The lightest supersymmetric particle (LSP), if stable, is a promising (although not the unique) candidate for the dark matter [16–20]. Further aspects of dark matter can be found in Sec. 27.

88.2 Structure of the MSSM

The minimal supersymmetric extension of the SM (MSSM) consists of the fields of the two-Higgs-doublet extension of the SM and the corresponding superpartner fields [21–25]. A particle and its superpartner together form a supermultiplet. The corresponding field content of the supermultiplets of the MSSM and their gauge quantum numbers are shown in Table 88.1. The electric charge $Q = T_3 + \frac{1}{2}Y$ is determined in terms of the third component of the weak isospin (T_3) and the U(1) weak hypercharge (Y).

The gauge supermultiplets consist of the gluons and their gluino fermionic superpartners and the SU(2)×U(1) gauge bosons and their gaugino fermionic superpartners. The matter supermultiplets consist of three generations of left-handed quarks and leptons and their scalar superpartners (squarks and sleptons, collectively referred to as sfermions), and the corresponding antiparticles. The Higgs supermultiplets consist of two complex Higgs doublets, their higgsino fermionic superpartners, and the corresponding antiparticles. The enlarged Higgs sector of the MSSM constitutes the minimal structure needed to guarantee the cancellation of gauge anomalies [27] generated by the higgsino superpartners that can appear as internal lines in triangle diagrams with three external electroweak gauge bosons. Moreover, without a second Higgs doublet, one cannot generate mass for both "up"-type and "down"-type quarks (and charged leptons) in a way consistent with the underlying SUSY [28–30].

In the most elegant treatment of SUSY, spacetime is extended to superspace which consists of the spacetime coordinates and new anticommuting fermionic coordinates θ and $\theta^\dagger$ [25,31,32]. Each supermultiplet is represented by a superfield that is a function of the superspace coordinates. The fields of a given supermultiplet (which are functions of the spacetime coordinates) are coefficients of the θ and $\theta^\dagger$ expansion of the corresponding superfield.

Vector superfields contain the gauge-boson fields and their gaugino partners. Chiral superfields contain the spin-0 and spin-

Table 88.1: The fields of the MSSM and their representations under the SU(3)×SU(2)×U(1) gauge group are listed. For simplicity, only one generation of quarks and leptons is exhibited. For each lepton, quark, and Higgs supermultiplet (each denoted by a hatted upper-case letter), there is a corresponding antiparticle multiplet of charge-conjugated fermions and their associated scalar partners [26].

Field Content of the MSSM						
Super-multiplets	Super-field	Bosonic fields	Fermionic partners	SU(3)	SU(2)	U(1)
gluon/gluino	$\hat{V}_8$	g	$\widetilde{g}$	8	1	0
gauge boson/	$\hat{V}$	$W^\pm$, W^0	$\widetilde{W}^\pm$, $\widetilde{W}^0$	1	3	0
gaugino	$\hat{V}'$	B	$\widetilde{B}$	1	1	0
slepton/	$\hat{L}$	$(\widetilde{\nu}_L, \widetilde{e}^-_L)$	$(\nu, e^-)_L$	1	2	-1
lepton	$\hat{E}^c$	$\widetilde{e}^+_R$	e^c_L	1	1	2
squark/	$\hat{Q}$	$(\widetilde{u}_L, \widetilde{d}_L)$	$(u, d)_L$	3	2	1/3
quark	$\hat{U}^c$	$\widetilde{u}^*_R$	u^c_L	$\bar{3}$	1	$-4/3$
	$\hat{D}^c$	$\widetilde{d}^*_R$	d^c_L	$\bar{3}$	1	2/3
Higgs boson/	$\hat{H}_d$	(H^0_d, H^-_d)	$(\widetilde{H}^0_d, \widetilde{H}^-_d)$	1	2	-1
higgsino	$\hat{H}_u$	(H^+_u, H^0_u)	$(\widetilde{H}^+_u, \widetilde{H}^0_u)$	1	2	1

1/2 fields of the matter or Higgs supermultiplets. A general supersymmetric Lagrangian is determined by three functions of the chiral superfields [4]: the superpotential, the Kähler potential, and the gauge kinetic function (which can be appropriately generalized to accommodate higher derivative terms [33]). Minimal forms for the Kähler potential and gauge kinetic function, which generate canonical kinetic energy terms for all the fields, are required for renormalizable globally supersymmetric theories. A renormalizable superpotential, which is at most cubic in the chiral superfields, yields supersymmetric Yukawa couplings and mass terms. A combination of gauge invariance and SUSY produces couplings of gaugino fields to matter (or Higgs) fields and their corresponding superpartners. The (renormalizable) MSSM Lagrangian is then constructed by including all possible supersymmetric interaction terms (of dimension four or less) that satisfy SU(3)×SU(2)×U(1) gauge invariance and B–L conservation (where B = baryon number and L = lepton number). Finally, the most general soft-supersymmetry-breaking terms consistent with these symmetries are added [10, 11, 34].

Although the MSSM is the focus of much of this review, there is some motivation for considering non-minimal supersymmetric extensions of the SM [35]. For example, extra structure is needed to generate non-zero neutrino masses as discussed in Sec. 88.8. In addition, in order to address some theoretical issues and tensions associated with the MSSM, it has been fruitful to introduce one additional singlet Higgs superfield. The resulting next-to-minimal supersymmetric extension of the Standard Model (NMSSM) [36] is briefly considered in Sec. 88.4–88.7 and 88.9. Finally, one is always free to add additional fields to the SM along with the corresponding superpartners. However, only certain choices for the new fields (*e.g.*, the addition of complete SU(5) multiplets) will preserve the successful gauge coupling unification of the MSSM. Some examples will be briefly mentioned in Sec. 88.9.

88.2.1 *R-parity and the lightest supersymmetric particle*

The (renormalizable) SM Lagrangian possesses an accidental global B–L symmetry due to the fact that B and L-violating operators composed of SM fields must have dimension $d = 5$ or larger [37]. Consequently, B and L-violating effects are suppressed by $(M_{\rm EW}/M)^{d-4}$, where M is the characteristic mass scale of the physics that generates the corresponding higher dimensional operators. Indeed, values of M of order the grand unification scale or larger may be responsible for the observed (approximate) stability of the proton and suppression of neutrino masses. Unfortunately, these results are not guaranteed in a generic supersymmetric extension of the SM. For example, it is possible to construct gauge invariant supersymmetric dimension-four B and L-violating operators made up of fields of SM particles and their superpartners. Such operators, if simultaneously present in the theory, would typically yield a proton decay rate many orders of magnitude larger than the current experimental bound. It is for this reason that B–L conservation is *imposed* on the supersymmetric Lagrangian when defining the MSSM, which is sufficient for eliminating all B and L-violating operators of dimension $d \leq 4$.

As a consequence of the B–L symmetry, the MSSM possesses a multiplicative R-parity invariance, where $R = (-1)^{3(B-L)+2S}$ for a particle of spin S [38]. This implies that all the particles of the SM have even R-parity, whereas the corresponding superpartners have odd R-parity. The conservation of R-parity in scattering and decay processes has a critical impact on supersymmetric phenomenology. For example, any initial state in a scattering experiment will involve ordinary (R-even) particles. Consequently, it follows that supersymmetric particles must be produced in pairs. In general, these particles are highly unstable and decay into lighter states. Moreover, R-parity invariance also implies that the LSP is absolutely stable, and must eventually be produced at the end of a decay chain initiated by the decay of a heavy unstable supersymmetric particle. In order to be consistent with cosmological constraints, a stable LSP is almost certainly electrically and color neutral [18]. Consequently, the LSP in an R-parity-conserving theory is weakly interacting with ordinary matter, *i.e.*, it behaves like a stable heavy neutrino and will escape collider detectors without being directly observed. Thus, the canonical signature for conventional R-parity-conserving supersymmetric theories is missing (transverse) momentum, due to the escape of the LSP. Moreover, as noted in Sec. 88.1 and reviewed in Refs. [19] and [20], the stability of the LSP in R-parity-conserving SUSY makes it a promising candidate for dark matter.

The possibility of relaxing the R-parity invariance of the MSSM (which would generate new B and/or L-violating interactions) will be addressed in Sec. 88.8.2. However, note that in R-parity violating (RPV) models, the LSP is no longer stable and thus would not be a viable candidate for the dark matter (unless its lifetime was significantly longer than the age of the universe). In such scenarios, one has to look elsewhere to explain the origin of dark matter.

88.2.2 *The goldstino and gravitino*

In the MSSM, SUSY breaking is accomplished by including the most general renormalizable soft-SUSY-breaking terms consistent with the SU(3)×SU(2)×U(1) gauge symmetry and R-parity invariance. These terms parameterize our ignorance of the fundamental mechanism of supersymmetry breaking. If supersymmetry breaking occurs spontaneously, then a massless Goldstone fermion called the goldstino ($\widetilde{G}_{1/2}$) must exist. The goldstino would then be the LSP, and could play an important role in supersymmetric phenomenology [39].

However, the goldstino degrees of freedom are physical only in models of spontaneously-broken global SUSY. If SUSY is a local symmetry, then the theory must incorporate gravity; the resulting

theory is called supergravity [5, 40]. In models of spontaneously-broken supergravity, the goldstino is "absorbed" by the gravitino ($\widetilde{G}$), the spin-3/2 superpartner of the graviton, via the super-Higgs mechanism [41]. Consequently, the goldstino is removed from the physical spectrum and the gravitino acquires a mass (denoted by $m_{3/2}$). If $m_{3/2}$ is smaller than the mass of the lightest superpartner of the SM particles, then the gravitino is the LSP.

In processes with center-of-mass energy $E \gg m_{3/2}$, one can employ the goldstino–gravitino equivalence theorem [42], which implies that the interactions of the helicity $\pm\frac{1}{2}$ gravitino (whose properties approximate those of the goldstino) dominate those of the helicity $\pm\frac{3}{2}$ gravitino. The interactions of gravitinos with other light fields can be described by a low-energy effective Lagrangian that is determined by fundamental principles [43].

88.2.3 *Hidden sectors and the structure of SUSY breaking*

It is very difficult (perhaps impossible) to construct a realistic model of spontaneously-broken weak-scale supersymmetry where the supersymmetry breaking arises solely as a consequence of the interactions of the particles of the MSSM. A more successful scheme posits a theory with at least two distinct sectors: a visible sector consisting of the particles of the MSSM [34] and a sector where SUSY breaking is generated. It is often (but not always) assumed that particles of the hidden sector are neutral with respect to the SM gauge group. The effects of the hidden sector supersymmetry breaking are then transmitted to the MSSM by some mechanism (often involving the mediation by particles that comprise an additional messenger sector). Two theoretical scenarios that exhibit this structure are gravity-mediated and gauge-mediated SUSY breaking.

Supergravity models provide a natural mechanism for transmitting the SUSY breaking of the hidden sector to the particle spectrum of the MSSM. In models of gravity-mediated SUSY breaking, gravity is the messenger of supersymmetry breaking [44–48]. More precisely, supersymmetry breaking is mediated by effects of gravitational strength (*i.e.* suppressed by inverse powers of the Planck mass). The soft-SUSY-breaking parameters with dimensions of mass arise as model-dependent multiples of the gravitino mass $m_{3/2}$. In this scenario, $m_{3/2}$ is of order the electroweak-symmetry-breaking scale, while the gravitino couplings are roughly gravitational in strength [3, 49].[1]

Under certain theoretical assumptions that govern the structure of the Kähler potential (the so-called sequestered form introduced in Ref. [51]), SUSY breaking is due entirely to the super-conformal (super-Weyl) anomaly, which is common to all supergravity models [51]. In particular, gaugino masses are radiatively generated at one-loop, and squark and slepton squared-mass matrices are flavor-diagonal. In sequestered scenarios, sfermion squared-masses arise at two-loops, which implies that gluino and sfermion masses are of the same order of magnitude. This approach is called anomaly-mediated SUSY breaking (AMSB). Indeed, anomaly mediation is more generic than originally conceived, and provides a ubiquitous source of SUSY breaking [52]. However in the simplest formulation of AMSB as applied to the MSSM, the squared-masses of the sleptons are negative (known as the tachyonic slepton problem). It may be possible to cure this otherwise fatal flaw in non-minimal extensions of the MSSM [53]. Alternatively, one can assert that anomaly mediation is not the sole source of SUSY breaking in the sfermion sector. In non-sequestered scenarios, sfermion squared-masses can arise at tree-level, in which case squark masses would be parametrically larger than the loop-suppressed gaugino masses [54].

In gauge-mediated supersymmetry breaking (GMSB), gauge forces transmit the supersymmetry breaking to the MSSM. A typical structure of such models involves a hidden sector where SUSY is broken, a messenger sector consisting of particles (messengers) with nontrivial SU(3)×SU(2)×U(1) quantum numbers, and the visible sector consisting of the fields of the MSSM [55–58]. The direct coupling of the messengers to the hidden sector generates a supersymmetry-breaking spectrum in the messenger sector. Supersymmetry breaking is then transmitted to the MSSM via the virtual exchange of the messenger fields. In models of direct gauge mediation, there is no separate hidden sector. In particular, the sector in which the SUSY breaking originates includes fields that carry nontrivial SM quantum numbers, which allows for the direct transmission of SUSY breaking to the MSSM [59].

In models of gauge-mediated SUSY breaking with a minimal Kähler potential, the gravitino is the LSP [16], as its mass can range from a few eV (in the case of low SUSY breaking scales) up to a few GeV (in the case of high SUSY breaking scales). In particular, the gravitino is a potential dark matter candidate (for a review and guide to the literature, see Ref. [20]). The couplings of the helicity $\pm\frac{1}{2}$ components of $\widetilde{G}$ to the particles of the MSSM (which approximate those of the goldstino as previously noted in Sec. 88.2.2) are significantly stronger than gravitational strength and amenable to experimental collider analyses.

The mass ranges of the gravitino in either gravity-mediated or gauge-mediated SUSY breaking are further constrained by cosmological considerations [60, 61]. In particular, there is a danger of over-abundance of gravitinos if it is the dark matter or, if it decays before nucleosynthesis, modifications to the successful predictions of light element abundances. Avoiding these cosmological gravitino problems imposes strong constraints on gravity-mediated and gauge-mediated SUSY breaking models.

The concept of a hidden sector is more general than SUSY. Hidden valley models [62] posit the existence of a hidden sector of new particles and interactions that are very weakly coupled to particles of the SM. The impact of a hidden valley on supersymmetric phenomenology at colliders can be significant if the LSP lies in the hidden sector [63].

88.2.4 *SUSY and extra dimensions*

Approaches to SUSY breaking have also been developed in the context of theories in which the number of spatial dimensions is greater than three. In particular, a number of SUSY-breaking mechanisms have been proposed that are inherently extra-dimensional [64]. The size of the extra dimensions can be significantly larger than $M_{\rm P}^{-1}$; in some cases of order $(\text{TeV})^{-1}$ or even larger (see, *e.g.*, Sec. 85 and Ref. [65]).

For example, in one approach the fields of the MSSM live on some brane (a lower-dimensional manifold embedded in a higher-dimensional spacetime), while the sector of the theory that breaks SUSY lives on a second spatially-separated brane. Two examples of this approach are AMSB [51] and gaugino-mediated SUSY breaking [66]. In both cases, SUSY breaking is transmitted through fields that live in the bulk (the higher-dimensional space between the two branes). This setup has some features in common with both gravity-mediated and gauge-mediated SUSY breaking (*e.g.*, hidden and visible sectors and messengers).

Since a higher dimensional theory must be compactified to four spacetime dimensions, one can also generate a source of SUSY breaking by employing boundary conditions on the compactified space that distinguish between fermions and bosons. This is the so-called Scherk-Schwarz mechanism [67]. The phenomenology of such models can be strikingly different from that of the usual MSSM [68].

88.2.5 *Split-SUSY*

If SUSY is not connected with the origin of the electroweak scale, it may still be possible that some remnant of the superparticle spectrum survives down to the TeV-scale or below. This is the idea of split-SUSY [69,70], in which scalar superpartners of the quarks and leptons are significantly heavier than 1 TeV, whereas the fermionic superpartners of the gauge and Higgs bosons have masses on the order of 1 TeV or below. With the exception of a single light neutral scalar whose properties are practically indistinguishable from those of the SM Higgs boson, all other Higgs bosons are also assumed to be very heavy. Among the supersymmetric particles, only the fermionic superpartners may be kinematically accessible at the LHC.

In models of split SUSY, the top squark masses cannot be arbitrarily large, as these parameters enter in the radiative corrections to the mass of the observed Higgs boson [71–73]. In the MSSM, a Higgs boson mass of 125 GeV (see Sec. 11) implies an upper bound

[1] However, such a gravitino typically plays no direct role in supersymmetric phenomenology at colliders (except perhaps indirectly in the case where the gravitino is the LSP [50]).

on the top squark mass scale in the range of 10 to 10^8 TeV [74–76], depending on the value of the ratio of the two neutral Higgs field vacuum expectation values, although this mass range can be somewhat extended by varying other relevant MSSM parameters. In some approaches, gaugino masses are one-loop suppressed relative to the sfermion masses, corresponding to the so-called mini-split SUSY spectrum [72,77]. The higgsino mass scale may or may not be likewise suppressed depending on the details of the model [78].

The SUSY breaking required to produce such a split-SUSY spectrum would destabilize the gauge hierarchy, and thus would not provide an explanation for the scale of electroweak symmetry breaking. Nevertheless, models of split-SUSY can account for the dark matter (which is assumed to be the LSP gaugino or higgsino) and gauge coupling unification, thereby preserving two of the desirable features of weak-scale SUSY. Finally, as a consequence of the very large squark and slepton masses, neutral flavor changing and CP-violating effects, which can be problematic in models with TeV-scale SUSY-breaking masses, are sufficiently reduced to avoid conflict with experimental observations.

88.3 Parameters of the MSSM

The parameters of the MSSM are conveniently described by considering separately the supersymmetry-conserving and the supersymmetry-breaking sectors. A careful discussion of the conventions used here in defining the tree-level MSSM parameters can be found in Refs. [25, 79, 80]. For simplicity, consider first the case of one generation of quarks, leptons, and their scalar superpartners.

88.3.1 *The SUSY-conserving parameters*

The parameters of the supersymmetry-conserving sector consist of: (i) gauge couplings, g_s, g, and g', corresponding to the SM gauge group SU(3)×SU(2)×U(1) respectively; (ii) a supersymmetry-conserving higgsino mass parameter μ; and (iii) Higgs-fermion Yukawa couplings, λ_u, λ_d, and λ_e, of one generation of left- and right-handed quarks and leptons, and their superpartners to the Higgs bosons and higgsinos. Because there is no right-handed neutrino/sneutrino in the MSSM as defined here, a Yukawa coupling λ_ν is not included. The complex μ parameter and Yukawa couplings enter via the most general renormalizable R-parity-conserving superpotential,

$$W_{\rm MSSM} = \lambda_d \hat{H}_d \hat{Q} \hat{D}^c - \lambda_u \hat{H}_u \hat{Q} \hat{U}^c + \lambda_e \hat{H}_d \hat{L} \hat{E}^c + \mu \hat{H}_u \hat{H}_d \,, \quad (88.1)$$

where the superfields are defined in Table 1 and the gauge group indices are suppressed. More explicitly, the so-called "μ-term" can be written out as $\mu\epsilon^{ab}(\hat{H}_u)_a(\hat{H}_d)_b$ with an implicit sum over repeated indices, where ϵ^{ab} is used to tie together the SU(2) weak isospin indices $a, b \in \{1, 2\}$ in a gauge-invariant way (where $\epsilon^{12} = -\epsilon^{21} = 1$ and $\epsilon^{11} = \epsilon^{22} = 0$). Likewise, the term $\hat{H}_u \hat{Q} \hat{U}^c$ can be written out as $\epsilon^{ab}(\hat{H}_u)_a \hat{Q}_{ib} (\hat{U}^c)^i$, where $i \in \{1, 2, 3\}$ is the SU(3) color index. Finally, $\hat{H}_d \hat{Q} \hat{D}^c$ can be written out as $\epsilon^{ab}(\hat{H}_d)_a \hat{Q}_{ib} (\hat{D}^c)^i$, with an analogous expression for $\hat{H}_d \hat{L} \hat{E}^c$.

88.3.2 *The SUSY-breaking parameters*

The supersymmetry-breaking sector contains the following sets of parameters: (i) three complex gaugino Majorana mass parameters, M_3, M_2, and M_1, associated with the SU(3), SU(2), and U(1) subgroups of the SM; (ii) five sfermion squared-mass parameters, $M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, $M^2_{\widetilde{D}}$, $M^2_{\widetilde{L}}$, and $M^2_{\widetilde{E}}$, corresponding to the five electroweak gauge multiplets, *i.e.*, superpartners of the left-handed fields $(u, d)_L$, u^c_L, d^c_L, $(\nu, e^-)_L$, and e^c_L, where the superscript c indicates a charge-conjugated fermion field [26]; and (iii) three Higgs-squark-squark and Higgs-slepton-slepton trilinear interaction terms, with complex coefficients $T_U \equiv \lambda_u A_U$, $T_D \equiv \lambda_d A_D$, and $T_E \equiv \lambda_e A_E$ (which define the "A-parameters"), following the notation employed in Ref. [80]. It is conventional to separate out the factors of the Yukawa couplings in defining the A-parameters [3, 25] (originally motivated by a simple class of gravity-mediated SUSY-breaking models). If the A-parameters are parametrically of the same order (or smaller) relative to other SUSY-breaking mass parameters, then in most cases only the third generation A-parameters will be phenomenologically relevant.

Finally, we have (iv) two real squared-mass parameters, $m^2_{H_d}$ and $m^2_{H_u}$ (also called m^2_1 and m^2_2, respectively, in the literature), and one complex squared-mass parameter, $m^2_{12} \equiv \mu B$ (the latter defines the "B-parameter"), which appear in the MSSM tree-level scalar Higgs potential [30],

$$V = (m^2_{H_d} + |\mu|^2) H_d^\dagger H_d + (m^2_{H_u} + |\mu|^2) H_u^\dagger H_u + (m^2_{12} H_u H_d + \text{h.c.}) + \frac{1}{8}(g^2 + g'^2)(H_d^\dagger H_d - H_u^\dagger H_u)^2 + \frac{1}{2} g^2 |H_d^\dagger H_u|^2 \,, \quad (88.2)$$

where the SU(2)-invariant combination of the complex doublet scalar fields H_u and H_d that appears in Eq. (88.2) is given by $H_u H_d \equiv \epsilon^{ab}(H_u)_a (H_d)_b = H_u^+ H_d^- - H_u^0 H_d^0$. Note that the quartic Higgs couplings are related to the gauge couplings g and g' as a consequence of SUSY. The breaking of the SU(2)×U(1) electroweak symmetry group to $\mathrm{U(1)_{EM}}$ is only possible after incorporating the SUSY-breaking Higgs squared-mass parameters $m^2_{H_d}$, $m^2_{H_u}$ (which can be negative) and m^2_{12}. After minimizing the Higgs scalar potential, these three squared-mass parameters can be re-expressed in terms of the two Higgs vacuum expectation values, $\langle H_d^0 \rangle \equiv v_d/\sqrt{2}$ and $\langle H_u^0 \rangle \equiv v_u/\sqrt{2}$, and the CP-odd Higgs mass m_A [cf. Eqs. (88.4) and (88.5) below]. One is always free to rephase the Higgs doublet fields such that v_d and v_u (also called v_1 and v_2, respectively, in the literature) are both real and positive.

The quantity, $v_d^2 + v_u^2 = 4m_W^2/g^2 = (2G_F^2)^{-1/2} \simeq (246 \text{ GeV})^2$, is fixed by the Fermi constant, G_F, whereas the ratio

$$\tan\beta = v_u/v_d \quad (88.3)$$

is a free parameter such that $0 < \beta < \pi/2$. By employing the tree-level conditions resulting from the minimization of the scalar potential, one can eliminate the diagonal and off-diagonal Higgs squared-masses in favor of $m_Z^2 = \frac{1}{4}(g^2 + g'^2)(v_d^2 + v_u^2)$, the CP-odd Higgs mass m_A and the parameter $\tan\beta$,

$$\sin 2\beta = \frac{2m^2_{12}}{m^2_{H_d} + m^2_{H_u} + 2|\mu|^2} = \frac{2m^2_{12}}{m_A^2} \,, \quad (88.4)$$

$$\frac{1}{2} m_Z^2 = -|\mu|^2 + \frac{m^2_{H_d} - m^2_{H_u} \tan^2\beta}{\tan^2\beta - 1} \,. \quad (88.5)$$

One must also guard against the existence of charge and/or color breaking global minima due to non-zero vacuum expectation values for the squark and charged slepton fields. This possibility can be avoided if the A-parameters are not unduly large [45, 81, 82]. Additional constraints must also be respected to avoid the possibility of directions in scalar field space in which the full tree-level scalar potential can become unbounded from below [82]. A computer program has been developed to calculate vacuum stability bounds in general models at the one-loop level [83], and has been applied to the MSSM in Ref. [84].

Note that SUSY-breaking mass terms for the fermionic superpartners of the scalar fields and non-holomorphic trilinear scalar interactions (*i.e.*, interactions that mix scalar fields and their complex conjugates) have not been included above in the soft-SUSY-breaking sector. These terms can potentially destabilize the gauge hierarchy [10] in models with a gauge-singlet superfield. The latter is not present in the MSSM; hence as noted in Ref. [11], these so-called non-standard soft-SUSY-breaking terms are benign. The phenomenological impact of non-holomorphic soft SUSY-breaking terms has been reconsidered in Refs. [85–87]. However, in the most common approaches to constructing a fundamental theory of SUSY-breaking, the coefficients of these terms (which have dimensions of mass) are significantly suppressed compared to the TeV-scale [88]. Consequently, we follow the usual approach and omit these terms from further consideration.

88.3.3 *MSSM-124*

The total number of independent physical parameters that define the MSSM (in its most general form) is quite large, primarily due to the soft-supersymmetry-breaking sector. In particular, in the case of three generations of quarks, leptons, and their superpartners, $M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, $M^2_{\widetilde{D}}$, $M^2_{\widetilde{L}}$, and $M^2_{\widetilde{E}}$ are hermitian 3×3

matrices, and A_U, A_D, and A_E are complex 3×3 matrices. In addition, M_1, M_2, M_3, B, and μ are in general complex parameters. Finally, as in the SM, the Higgs-fermion Yukawa couplings, λ_f (f=u, d, and e), are complex 3×3 matrices that are related to the quark and lepton mass matrices via: $M_f = \lambda_f v_f/\sqrt{2}$, where $v_e = v_d$ [with v_u and v_d as defined above Eq. (88.3)].

However, not all these parameters are physical. Some of the MSSM parameters can be eliminated by expressing interaction eigenstates in terms of the mass eigenstates, with an appropriate redefinition of the MSSM fields to remove unphysical degrees of freedom. The analysis of Ref. [89] shows that the MSSM possesses 124 independent real degrees of freedom. Of these, 18 correspond to SM parameters (including the QCD vacuum angle $\theta_{\rm QCD}$), one corresponds to a Higgs sector parameter (the analogue of the SM Higgs mass), and 105 are genuinely new parameters of the model. The latter include: five real parameters and three CP-violating phases in the gaugino/higgsino sector, 21 squark and slepton (sfermion) masses, 36 real mixing angles to define the sfermion mass eigenstates, and 40 CP-violating phases that can appear in sfermion interactions. The most general parameterization of the R-parity-conserving MSSM (without additional theoretical assumptions) will be denoted henceforth as MSSM-124 [90].

88.4 The supersymmetric-particle spectrum

The supersymmetric particles (sparticles) differ in spin by half a unit from their SM partners. The superpartners of the gauge and Higgs bosons are fermions, whose names are obtained by appending "ino" to the end of the corresponding SM particle name. The gluino is the color-octet Majorana fermion partner of the gluon with mass $M_{\widetilde{g}} = |M_3|$. The superpartners of the electroweak gauge and Higgs bosons (the gauginos and higgsinos) can mix due to SU(2)×U(1) breaking effects. As a result, the physical states of definite mass are parameter dependent linear combinations of the charged or neutral gauginos and higgsinos, called charginos and neutralinos, respectively (sometimes collectively called electroweakinos). The neutralinos are Majorana fermions, which can lead to some distinctive phenomenological signatures [91,92]. The superpartners of the quarks and leptons are spin-zero bosons: the squarks, charged sleptons, and sneutrinos, respectively. A complete set of Feynman rules for the sparticles of the MSSM can be found in Refs. [93,94]. The MSSM Feynman rules also are implicitly contained in a number of amplitude generation and Feynman diagram software packages (see *e.g.*, Refs. [95–97]).

It should be noted that all mass formulae quoted below in this Section are tree-level results. Radiative loop corrections will modify these results and must be included in any precision study of supersymmetric phenomenology [98]. Beyond tree level, the definition of the supersymmetric parameters becomes convention-dependent. For example, one can define physical couplings or running couplings, which differ beyond the tree level. This provides a challenge to any effort that attempts to extract supersymmetric parameters from data. The SUSY Les Houches Accord (SLHA) [80,99] has been adopted, which establishes a set of conventions for specifying generic file structures for supersymmetric model specifications and input parameters, supersymmetric mass and coupling spectra, and decay tables. These provide a universal interface between spectrum calculation programs, decay packages, and high energy physics event generators.

88.4.1 *The charginos and neutralinos*

The mixing of the charged gauginos ($\widetilde{W}^\pm$) and charged higgsinos ($\widetilde{H}_u^+$ and $\widetilde{H}_d^-$) is described (at tree-level) by a 2×2 complex mass matrix [100, 101],

$$M_C \equiv \begin{pmatrix} M_2 & \frac{1}{\sqrt{2}} g v_u \\ \frac{1}{\sqrt{2}} g v_d & \mu \end{pmatrix} . \qquad (88.6)$$

To determine the physical chargino states and their masses, one must perform a singular value decomposition [102] of the complex matrix M_C [25, 103]:

$$U^* M_C V^{-1} = \mathrm{diag}(M_{\tilde{\chi}_1^+}\,,\, M_{\tilde{\chi}_2^+})\,, \qquad (88.7)$$

where U and V are unitary matrices, and the right-hand side of Eq. (88.7) is the diagonal matrix of (real non-negative) chargino masses. Explicit formulae for the singular value decomposition of M_C can be found in Ref. [104]. The physical chargino states are denoted by $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^\pm$. These are linear combinations of the charged gaugino and higgsino states determined by the matrix elements of U and V [100, 101] The chargino masses correspond to the singular values [102] of M_C, *i.e.*, the positive square roots of the eigenvalues of $M_C^\dagger M_C$:

$$M^2_{\tilde{\chi}_1^+,\tilde{\chi}_2^+} = \frac{1}{2}\Big\{ |\mu|^2 + |M_2|^2 + 2m_W^2 \mp \sqrt{\left(|\mu|^2 + |M_2|^2 + 2m_W^2\right)^2 - 4|\mu M_2 - m_W^2 \sin 2\beta|^2} \Big\}, \qquad (88.8)$$

in a convention where v_u and v_d are real and positive, and where the states are ordered such that $M_{\tilde{\chi}_1^+} \leq M_{\tilde{\chi}_2^+}$. The relative phase of μ^* and M_2 is physical and potentially observable [105].

The mixing of the neutral gauginos ($\widetilde{B}$ and $\widetilde{W}^0$) and neutral higgsinos ($\widetilde{H}_d^0$ and $\widetilde{H}_u^0$) is described (at tree-level) by a 4×4 complex symmetric mass matrix [100, 101],

$$M_N \equiv \begin{pmatrix} M_1 & 0 & -\frac{1}{2}g' v_d & \frac{1}{2}g' v_u \\ 0 & M_2 & \frac{1}{2} g v_d & -\frac{1}{2} g v_u \\ -\frac{1}{2}g' v_d & \frac{1}{2} g v_d & 0 & -\mu \\ \frac{1}{2}g' v_u & -\frac{1}{2} g v_u & -\mu & 0 \end{pmatrix} . \qquad (88.9)$$

To determine the physical neutralino states and their masses, one must perform an Autonne-Takagi factorization [102,106] (also called Takagi diagonalization in Refs. [25,103,107]) of the complex symmetric matrix M_N:

$$W^T M_N W = \mathrm{diag}(M_{\tilde{\chi}_1^0}\,,\, M_{\tilde{\chi}_2^0}\,,\, M_{\tilde{\chi}_3^0}\,,\, M_{\tilde{\chi}_4^0})\,, \qquad (88.10)$$

where W is a unitary matrix (which is called N^{-1} in Refs. [21,30]) and the right-hand side of Eq. (88.10) is the diagonal matrix of (real non-negative) neutralino masses. The physical neutralino states are denoted by $\widetilde{\chi}_i^0$ (for $i = 1, \ldots, 4$), where the states are ordered such that $M_{\tilde{\chi}_1^0} \leq M_{\tilde{\chi}_2^0} \leq M_{\tilde{\chi}_3^0} \leq M_{\tilde{\chi}_4^0}$. The $\widetilde{\chi}_i^0$ are the linear combinations of the neutral gaugino and higgsino states determined by the matrix elements of W. The neutralino masses correspond to the singular values of M_N, *i.e.*, the positive square roots of the eigenvalues of $M_N^\dagger M_N$. Exact formulae for these masses can be found in Refs. [108, 109]. A numerical algorithm for determining the mixing matrix W has been given in Ref. [110].

If a chargino or neutralino state approximates a particular gaugino or higgsino state, it is convenient to employ the corresponding nomenclature. Specifically, if $|M_1|$ and $|M_2|$ are small compared to m_Z and $|\mu|$, then the lightest neutralino $\widetilde{\chi}_1^0$ would be nearly a pure photino, $\widetilde{\gamma}$, the superpartner of the photon. If $|M_1|$ and m_Z are small compared to $|M_2|$ and $|\mu|$, then the lightest neutralino would be nearly a pure bino, $\widetilde{B}$, the superpartner of the weak hypercharge gauge boson. If $|M_2|$ and m_Z are small compared to $|M_1|$ and $|\mu|$, then the lightest chargino pair and neutralino would constitute a triplet of roughly mass-degenerate pure winos, $\widetilde{W}^\pm$, and $\widetilde{W}_3^0$, the superpartners of the weak SU(2) gauge bosons. Finally, if $|\mu|$ and m_Z are small compared to $|M_1|$ and $|M_2|$, then the lightest chargino pair and neutralino would be nearly pure higgsino states, the superpartners of the Higgs bosons. Each of the above cases leads to a strikingly different phenomenology.

In the NMSSM, an additional Higgs singlet superfield is added to the MSSM. This superfield comprises two real Higgs scalar degrees of freedom and an associated neutral higgsino degree of freedom. Consequently, there are five neutralino mass eigenstates that are obtained by a Takagi-diagonalization of the 5×5 neutralino mass matrix. In many cases, the fifth neutralino state is dominated by its SU(2)×U(1) singlet component, and thus is very weakly coupled to the SM particles and their superpartners.

88.4.2 *The squarks and sleptons*

For a given Dirac fermion f, there are two superpartners, $\widetilde{f}_L$ and $\widetilde{f}_R$, where the L and R subscripts simply identify the scalar partners that are related by SUSY to the left-handed and right-handed fermions, $f_{L,R} \equiv \frac{1}{2}(1 \mp \gamma_5)f$, respectively. (There is no $\widetilde{\nu}_R$ in the MSSM.) However, $\widetilde{f}_L$–$\widetilde{f}_R$ mixing is possible, in which case $\widetilde{f}_L$ and $\widetilde{f}_R$ are not mass eigenstates. For three generations of squarks, one must diagonalize 6×6 matrices corresponding to the basis $(\widetilde{q}_{iL}, \widetilde{q}_{iR})$, where $i = 1, 2, 3$ are the generation labels. For simplicity, only the one-generation case is illustrated in detail below.

Using the notation of the third family, the one-generation tree-level squark squared-mass matrix is given by [25, 111],

$$\mathcal{M}^2 = \begin{pmatrix} M^2_{\widetilde{Q}} + m_q^2 + L_q & m_q X_q^* \\ m_q X_q & M^2_{\widetilde{R}} + m_q^2 + R_q \end{pmatrix} , \tag{88.11}$$

where

$$X_q \equiv A_q - \mu^*(\cot\beta)^{2T_{3q}} , \tag{88.12}$$

and $T_{3q} = \frac{1}{2}$ $[-\frac{1}{2}]$ for $q = t$ $[b]$. The diagonal squared-masses are governed by soft-SUSY-breaking squared-masses $M^2_{\widetilde{Q}}$ and $M^2_{\widetilde{R}} \equiv M^2_{\widetilde{U}}$ $[M^2_{\widetilde{D}}]$ for $q = t$ $[b]$, the corresponding quark masses m_t $[m_b]$ and the electroweak correction terms:

$$\begin{aligned} L_q &\equiv (T_{3q} - e_q \sin^2\theta_W) m_Z^2 \cos 2\beta , \\ R_q &\equiv e_q \sin^2\theta_W \, m_Z^2 \cos 2\beta , \end{aligned} \tag{88.13}$$

where $e_q = \frac{2}{3}$ $[-\frac{1}{3}]$ for $q = t$ $[b]$. The off-diagonal squark squared-masses are proportional to the corresponding quark masses and depend on $\tan\beta$, the soft-SUSY-breaking A-parameters and the higgsino mass parameter μ. Assuming that the A-parameters are parametrically of the same order (or smaller) relative to other SUSY-breaking mass parameters, it then follows that the first and second generation $\widetilde{q}_L$–$\widetilde{q}_R$ mixing is smaller than that of the third generation where mixing can be enhanced by factors of m_t and $m_b \tan\beta$.

In the case of third generation $\widetilde{q}_L$–$\widetilde{q}_R$ mixing, the squark mass eigenstates (usually denoted by $\widetilde{q}_1$ and $\widetilde{q}_2$, with $m_{\tilde{q}_1} < m_{\tilde{q}_2}$) are determined by diagonalizing the 2×2 matrix $\mathcal{M}^2$ given by Eq. (88.11). The corresponding squared-masses and mixing angle are given by [111]:

$$\begin{aligned} m^2_{\tilde{q}_{1,2}} &= \frac{1}{2}\left[\mathrm{Tr}\,\mathcal{M}^2 \mp \sqrt{(\mathrm{Tr}\mathcal{M}^2)^2 - 4\det\mathcal{M}^2} \right] , \\ \sin 2\theta_{\tilde{q}} &= \frac{2m_q|X_q|}{m^2_{\tilde{q}_2} - m^2_{\tilde{q}_1}} . \end{aligned} \tag{88.14}$$

The one-generation results above also apply to the charged sleptons, with the obvious substitutions: $q \to \ell$ with $T_{3\ell} = -\frac{1}{2}$ and $e_\ell = -1$, and the replacement of the SUSY-breaking parameters: $M^2_{\widetilde{Q}} \to M^2_{\widetilde{L}}$, $M^2_{\widetilde{D}} \to M^2_{\widetilde{E}}$, and $A_q \to A_\tau$. For the neutral sleptons, $\widetilde{\nu}_R$ does not exist in the MSSM, so $\widetilde{\nu}_L$ is a mass eigenstate.

In the case of three generations, the SUSY-breaking scalar-squared masses $[M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, $M^2_{\widetilde{D}}$, $M^2_{\widetilde{L}}$, and $M^2_{\widetilde{E}}]$ and the A-parameters $[A_U$, A_D, and $A_E]$ are now 3×3 matrices as noted in Sec. 88.3.3. The diagonalization of the 6×6 squark mass matrices yields $\widetilde{f}_{iL}$–$\widetilde{f}_{jR}$ mixing. In practice, since the $\widetilde{f}_L$–$\widetilde{f}_R$ mixing is appreciable only for the third generation, this additional complication can often be neglected (although see Ref. [112] for examples in which the mixing between the second and third generation squarks is relevant).

88.5 The supersymmetric Higgs sector

Consider first the MSSM Higgs sector [29, 30, 113]. Despite the large number of potential CP-violating phases among the MSSM-124 parameters, the tree-level MSSM Higgs potential given by Eq. (88.2) is automatically CP-conserving. This follows from the fact that the only potentially complex parameter (m^2_{12}) of the MSSM Higgs potential can be chosen real and positive by rephasing the Higgs fields, in which case $\tan\beta$ is a real positive parameter. Consequently, the physical neutral Higgs scalars are CP-eigenstates (at tree-level). The MSSM Higgs sector contains five physical spin-zero particles: a charged Higgs boson pair ($H^\pm$), two CP-even neutral Higgs bosons (denoted by h^0 and H^0 where $m_h < m_H$), and one CP-odd neutral Higgs boson (A^0). The discovery of a SM-like Higgs boson at the LHC with a mass of 125 GeV (see Sec. 11) strongly suggests that this state should be identified with h^0, although the possibility that the 125 GeV state should be identified with H^0 cannot yet be completely ruled out [114].

In the NMSSM [36], the scalar component of the singlet Higgs superfield adds two additional neutral states to the Higgs sector. In this model, the tree-level Higgs sector can exhibit explicit CP-violation. If CP is conserved, then the two extra neutral scalar states are CP-even and CP-odd, respectively. These states can potentially mix with the neutral Higgs states of the MSSM. If scalar states exist that are dominantly singlet, then they are weakly coupled to SM gauge bosons and fermions through their small mixing with the MSSM Higgs scalars. Consequently, it is possible that one (or both) of the singlet-dominated states is considerably lighter than the Higgs boson that was observed at the LHC.

88.5.1 *The tree-level Higgs sector*

The tree-level properties of the Higgs sector are determined by the Higgs potential given by Eq. (88.2). The quartic interaction terms are manifestly supersymmetric (although these are modified by SUSY-breaking effects at the loop level). In general, the quartic couplings arise from two sources: (i) the supersymmetric generalization of the scalar potential (the so-called "F-terms"), and (ii) interaction terms related by SUSY to the coupling of the scalar fields and the gauge fields, whose coefficients are proportional to the corresponding gauge couplings (the so-called "D-terms").

In the MSSM, F-term contributions to the quartic Higgs self-couplings are absent. As a result, the strengths of the MSSM quartic Higgs interactions are fixed in terms of the gauge couplings, as noted below Eq. (88.2). Consequently, all the tree-level MSSM Higgs-sector parameters depend only on two quantities: $\tan\beta$ [defined in Eq. (88.3)] and one Higgs mass usually taken to be m_A. For example, the tree-level squared mass of the charged Higgs boson is given by

$$m^2_{H^\pm} = m_A^2 + m_W^2 , \tag{88.15}$$

where $m_A^2 = m^2_{H_d} + m^2_{H_u} + 2|\mu|^2$ [cf. Eq. (88.5)] and

$$H^\pm = H_d^\pm \sin\beta + H_u^\pm \cos\beta \, , \; A = \sqrt{2}\left(\mathrm{Im}\, H_d^0 \sin\beta + \mathrm{Im}\, H_u^0 \cos\beta \right) . \tag{88.16}$$

The CP-even scalar mass eigenstate fields h and H are identified by diagonalizing the 2×2 squared-mass matrix

$$\mathcal{M}^2 = \begin{pmatrix} m_A^2 \sin^2\beta + m_Z^2 \cos^2\beta & -(m_A^2 + m_Z^2)\sin\beta\cos\beta \\ -(m_A^2 + m_Z^2)\sin\beta\cos\beta & m_A^2\cos^2\beta + m_Z^2\sin^2\beta \end{pmatrix} . \tag{88.17}$$

In particular,

$$h = -(\sqrt{2}\,\mathrm{Re}\, H_d^0 - v_d)\sin\alpha + (\sqrt{2}\,\mathrm{Re}\, H_u^0 - v_u)\cos\alpha , \tag{88.18}$$

$$H = (\sqrt{2}\,\mathrm{Re}\, H_d^0 - v_d)\cos\alpha + (\sqrt{2}\,\mathrm{Re}\, H_u^0 - v_u)\sin\alpha , \tag{88.19}$$

with corresponding tree-level squared masses,

$$m^2_{H,h} = \frac{1}{2}\left(m_A^2 + m_Z^2 \pm \sqrt{(m_A^2 + m_Z^2)^2 - 4m_Z^2 m_A^2 \cos^2 2\beta} \right) , \tag{88.20}$$

and mixing angle α given by

$$\cos\alpha = \sqrt{\frac{m_A^2\sin^2\beta + m_Z^2\cos^2\beta - m_h^2}{m_H^2 - m_h^2}} , \tag{88.21}$$

in a convention where $|\alpha| \leq \pi/2$. However, because the off-diagonal elements of $\mathcal{M}^2$ are negative, it follows that $-\pi/2 \leq$

$\alpha \leq 0$ [104]. In light of Eq. (88.20), the tree-level mass of the lighter CP-even Higgs boson is bounded [29, 30],

$$m_h \leq m_Z |\cos 2\beta| \leq m_Z \,. \tag{88.22}$$

This bound can be substantially modified when radiative corrections are included, as discussed in Sec. 88.5.2.

In the NMSSM, we set $\mu = 0$ in Eq. 88.1 and then add two additional terms to the superpotential,

$$W_{\rm NMSSM} \supset \lambda \hat{H}_u \hat{H}_d \hat{S} + \frac{1}{3}\kappa \hat{S}^3 \,, \tag{88.23}$$

where $\hat{S}$ is a singlet Higgs superfield. In the NMSSM as defined here, all terms in $W_{\rm NMSSM}$ are cubic in the superfields due to the presence of a discrete $\mathbb{Z}_3$ symmetry. An effective μ-term is generated, $\mu_{\rm eff} = \lambda \langle S \rangle$, where $\langle S \rangle$ is the vacuum expectation value of the scalar field component of $\hat{S}$. Moreover, due to the term proportional to λ in Eq. 88.23, there is now an F-term contribution to the quartic Higgs self-couplings. Consequently, the tree-level bound for the mass of the lightest CP-even MSSM Higgs boson is modified [115],

$$m_h^2 \leq m_Z^2 \cos^2 2\beta + \frac{1}{2}\lambda^2 v^2 \sin^2 2\beta \,, \tag{88.24}$$

where $v \equiv (v_u^2 + v_d^2)^{1/2} = 246$ GeV. By requiring that λ remain finite after renormalization-group evolution up to the Planck scale, one finds that λ is constrained to lie below about 0.7–0.8 at the electroweak scale [36] (although larger values of λ have also been considered in Ref. [116]).

The tree-level Higgs couplings to gauge bosons and the Higgs boson self-couplings are governed by the electroweak gauge couplings and the parameter $\cos(\beta - \alpha)$. Explicitly,

$$\cos(\beta - \alpha) = \frac{m_Z^2 \sin 2\beta \cos 2\beta}{\sqrt{(m_H^2 - m_h^2)(m_H^2 - m_Z^2 \cos^2 2\beta)}} \,. \tag{88.25}$$

Note that $\cos(\beta - \alpha) \to 0$ in the limit of $m_H \gg m_h$, m_Z. In this *decoupling limit* [117], the properties of h coincide with those of the SM Higgs boson. In light of the LHC Higgs data [118, 119], which are compatible with the SM predictions (see Sec. 11), one can conclude that if h is identified with the observed Higgs boson then H, A and $H^\pm$ must be substantially heavier (most likely of order 500 GeV or larger [120]).

The tree-level Higgs-quark and Higgs-lepton interactions of the MSSM are derived from the superpotential given in Eq. (88.1). The corresponding Higgs-fermion Yukawa couplings can be expressed in terms of the fermion masses and the separate parameters $\cos(\beta - \alpha)$ and $\tan\beta$. In particular, the Higgs sector of the MSSM is a Type-II two-Higgs doublet model [121], in which one Higgs doublet (H_d) couples exclusively to the right-handed down-type quark (or lepton) fields and the second Higgs doublet (H_u) couples exclusively to the right-handed up-type quark fields. Consequently, the diagonalization of the fermion mass matrices simultaneously diagonalizes the matrix of Yukawa couplings, resulting in flavor-diagonal tree-level couplings of the neutral Higgs bosons h^0, H^0 and A^0 to quark and lepton pairs. One can again check that in the decoupling limit where $\cos(\beta - \alpha) \to 0$, the couplings of h reduce to those of the SM.

88.5.2 *The radiatively-corrected Higgs sector*

When radiative corrections are incorporated, additional parameters of the supersymmetric model enter via virtual supersymmetric particles that appear in loops. The impact of these corrections can be significant [122]. The qualitative behavior of these radiative corrections can be most easily seen in the large top-squark mass limit, where in addition, both the splitting of the two diagonal entries and the off-diagonal entries of the top-squark squared-mass matrix [Eq. (88.11)] are small in comparison to the geometric mean of the two top-squark squared-masses, $M_{\rm S}^2 \equiv M_{\widetilde{t}_1} M_{\widetilde{t}_2}$. In this case (assuming $\rm m_A > m_Z$), the predicted upper bound for m_h is approximately given by [123]

$$m_h^2 \lesssim m_Z^2 \cos^2 2\beta + \frac{3g^2 m_t^4}{8\pi^2 m_W^2}\left[\ln\left(\frac{M_{\rm S}^2}{m_t^2}\right) + \frac{X_t^2}{M_{\rm S}^2}\left(1 - \frac{X_t^2}{12 M_{\rm S}^2}\right)\right], \tag{88.26}$$

where $X_t \equiv A_t - \mu \cot\beta$ [cf. Eq. (88.12)] is proportional to the off-diagonal entry of the top-squark squared-mass matrix (where for simplicity, A_t and μ are taken to be real). The Higgs mass upper limit specified by Eq. (88.26) is saturated when $\tan\beta$ is large (*i.e.*, $\cos^2 2\beta \sim 1$) and $X_t = \sqrt{6}\, M_S$, which defines the so-called maximal mixing scenario.

In applying the radiatively corrected MSSM Higgs sector to the analysis of LHC Higgs data, the authors of Refs. [124, 125] suggested that a reasonable approximation would consist of retaining the leading corrections employed in deriving Eq. (88.26), while discarding all other subleading terms. This procedure was implemented by simply replacing $\mathcal{M}_{22}^2 \to \mathcal{M}_{22}^2 + \Delta\mathcal{M}_{22}^2$ in the 22 element of the CP-even Higgs squared-mass matrix given in Eq. (88.17), since $\Delta\mathcal{M}_{22}^2$ contains the leading contributions that govern the Higgs mass radiative corrections. One can now rediagonalize the CP-even Higgs squared-mass matrix and determine $\Delta\mathcal{M}_{22}^2$ in terms of the parameters m_A, $\tan\beta$ and the *measured* Higgs mass (*e.g.*, $m_h \simeq 125$ GeV, if h is identified with the observed Higgs boson). This framework was dubbed the hMSSM in Ref. [124].

Although the hMSSM can be readily applied to LHC data to derive interesting constraints on the MSSM Higgs sector, it can lead to results that are not robust in a more general MSSM parameter scan. Indeed, a more complete treatment of the radiative corrections can yield results that cannot be accounted for by the hMSSM framework. Examples of benchmark points of the MSSM parameter space that cannot be reproduced by the hMSSM analysis are discussed in 11.6.1.1.

The set of approximations employed in obtaining Eq. (88.26) somewhat overestimates the value of m_h. The most complete treatment of the MSSM Higgs mass radiative corrections, which incorporate renormalization group improvement, the two loop, and the leading three-loop contributions [73, 126], yields a predicted value of m_h shown in Fig. 88.1, as a function of X_t (assumed for simplicity to be real).

In the NMSSM with $m_h \simeq 125$ GeV, the dominant radiative correction to Eq. (88.24) is the same as the one given in Eq. (88.26). However, in contrast to the MSSM, one does not need as large a boost from radiative corrections to achieve a Higgs mass of 125 GeV in certain regimes of the NMSSM parameter space (*e.g.*, $\tan\beta \sim 2$ and $\lambda \sim 0.7$ [127]).

88.6 Restricting the MSSM parameter freedom

In Sections 88.4 and 88.5, we surveyed the parameters that comprise the MSSM-124. However, the MSSM-124 is not a phenomenologically viable theory over much of its parameter space. In particular, a generic point of the MSSM-124 parameter space exhibits: (i) no conservation of the separate lepton numbers L_e, L_μ, and L_τ; (ii) unsuppressed flavor-changing neutral currents (FCNCs); and (iii) new sources of CP violation that are inconsistent with the experimental bounds.

In addition, one-loop radiative corrections can introduce CP-violating effects in the Higgs sector that depend on some of the CP-violating phases among the MSSM-124 parameters [128]. This phenomenon is most easily understood in a scenario where $m_A \ll M_S$ (i.e., all five physical Higgs states are significantly lighter than the SUSY breaking scale). In this case, one can integrate out the heavy superpartners to obtain a low-energy effective theory with two Higgs doublets. The resulting effective two-Higgs doublet model will now contain all possible Higgs self-interaction terms (both CP-conserving and CP-violating) and Higgs-fermion interactions (beyond those of Type-II) that are consistent with electroweak gauge invariance [129].

For example, the MSSM contains new sources of CP violation [130]. Indeed, for TeV-scale sfermion and gaugino masses, some combinations of the complex phases of the gaugino-mass parameters, the A-parameters, and μ must be less than about 10^{-2}–10^{-3} to avoid generating electric dipole moments for the

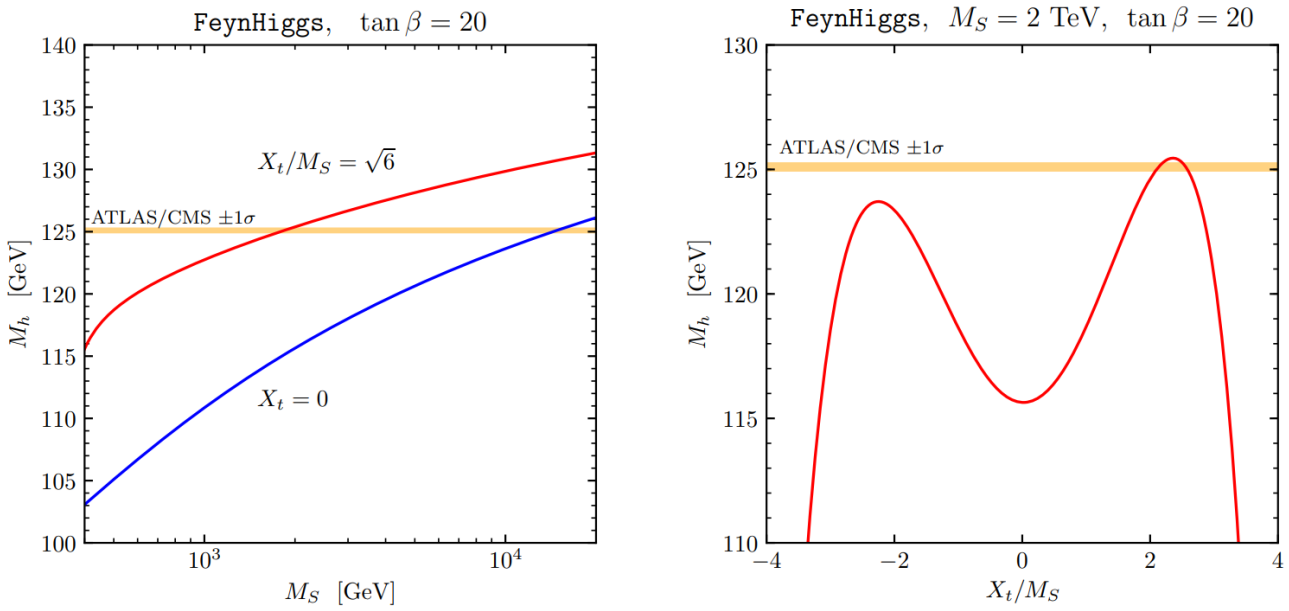

Figure 88.1: The lighter CP-even Higgs mass in the MSSM as a function of a common SUSY mass parameter M_S and of the stop mixing parameter X_t (normalized to M_S). Figure taken from Ref. [73].

neutron, electron, and atoms [131–133] in conflict with observed data [134, 135]. The rarity of FCNCs [136–138] places additional constraints on the off-diagonal matrix elements of the squark and slepton soft-SUSY-breaking squared-masses and A-parameters (see Sec. 88.3.3).

The MSSM-124 is also theoretically incomplete as it provides no explanation for the fundamental origin of the supersymmetry-breaking parameters. The successful unification of the MSSM gauge couplings at a grand unified mass scale $M_{\rm GUT}$, close to the Planck scale [7, 70, 139–141],

$$g_s(M_{\rm GUT}) = g(M_{\rm GUT}) = \sqrt{\frac{5}{3}}\, g'(M_{\rm GUT}), \qquad (88.27)$$

suggests that the high-energy structure of the theory may be considerably simpler than its low-energy realization.[2] In a top-down approach, the dynamics that governs the theory at high energies is used to derive the effective broken-supersymmetric theory at the TeV scale.

In this Section, we examine a number of theoretical frameworks that potentially yield phenomenologically viable regions of the MSSM-124 parameter space. The resulting supersymmetric particle spectrum is then a function of a relatively small number of input parameters. This is accomplished by imposing a simple structure on the soft SUSY-breaking parameters at a common high-energy scale M_X (typically chosen to be the Planck scale, M_P, the grand unified theory scale, $M_{\rm GUT}$, or the messenger scale, $M_{\rm mess}$). These serve as initial conditions for the MSSM renormalization group equations (RGEs), which are given in the two-loop approximation in Ref. [142]. An automated program to compute RGEs for the MSSM and other supersymmetric models of new physics has been developed in Ref. [143]. Solving these equations numerically, one can then derive the low-energy MSSM parameters relevant for phenomenology. A number of software packages exist that numerically calculate the spectrum of supersymmetric particles, consistent with theoretical conditions on SUSY breaking at high energies and some experimental data at low energies [73, 144].

[2] Generically, the normalization of the U(1) hypercharges exhibited in Table 88.1 is a matter of convention. In particular, the U(1) hypercharges can be rescaled by absorbing the scaling factor into a redefinition of the hypercharge gauge coupling g'. However, the embedding of the hypercharge U(1) generator into the Lie algebra of a grand unified simple gauge group fixes the normalization of the U(1) hypercharges and results in the rescaled hypercharge gauge coupling shown in Eq. (88.27).

Examples of viable frameworks are provided by models of gravity-mediated, anomaly-mediated, and gauge-mediated SUSY breaking. In some of these approaches, one of the diagonal Higgs squared-mass parameters is driven negative by renormalization group evolution [145]. In such models, electroweak symmetry breaking is generated radiatively, and the resulting electroweak symmetry-breaking scale is intimately tied to the scale of low-energy SUSY breaking.

88.6.1 *Gaugino mass relations*

One prediction of many supersymmetric grand unified models is the unification of the (tree-level) gaugino mass parameters[3] at some high-energy scale, M_X,

$$M_1(M_X) = M_2(M_X) = M_3(M_X) = m_{1/2}\,. \qquad (88.28)$$

Due to renormalization group running, in the one-loop approximation the effective low-energy gaugino mass parameters (at the electroweak scale) are related,

$$M_3 = (g_s^2/g^2)M_2 \simeq 3.5 M_2\ , \qquad M_1 = (5g'^2/3g^2)M_2 \simeq 0.5 M_2. \qquad (88.29)$$

Eq. (88.29) can arise more generally in gauge-mediated SUSY-breaking models where the gaugino masses are generated at the messenger scale $M_{\rm mess}$ (which typically lies significantly below the unification scale where the gauge couplings unify). In this case, the gaugino mass parameters are proportional to the corresponding squared gauge couplings at the messenger scale.

When Eq. (88.29) is satisfied, the chargino and neutralino masses and mixing angles depend only on three unknown parameters: the gluino mass, μ, and $\tan\beta$. It then follows that the lightest neutralino must be heavier than 46 GeV due to the non-observation of charginos at LEP [147]. If in addition $|\mu| \gg |M_1| \gtrsim m_Z$, then the lightest neutralino is nearly a pure bino, an assumption often made in supersymmetric particle searches at colliders. Although Eq. (88.29) is often assumed in many phenomenological studies, a truly model-independent approach would take the gaugino mass parameters M_1, M_2, and M_3 to be independent parameters to be determined by experiment. Indeed, an approximately massless neutralino *cannot* be ruled out at present by a model-independent analysis [148].

It is possible that the tree-level masses of the gauginos are zero. In this case, the gaugino mass parameters arise at one-loop and

[3] Non-universal gaugino mass parameters can also be a viable option in grand unified models with non-minimal gauge kinetic functions [146].

do not satisfy Eq. (88.29). For example, the gaugino masses in AMSB models arise entirely from a model-independent contribution derived from the super-conformal anomaly [51, 149]. In this case, Eq. (88.29) is replaced (in the one-loop approximation) by:

$$M_i \simeq \frac{b_i g_i^2}{16\pi^2} m_{3/2}\,, \tag{88.30}$$

where $m_{3/2}$ is the gravitino mass and the b_i are the coefficients of the MSSM gauge beta-functions corresponding to the corresponding U(1), SU(2), and SU(3) gauge groups, $(b_1, b_2, b_3) = (\frac{33}{5}, 1, -3)$. Eq. (88.30) yields $M_1 \simeq 2.8 M_2$ and $M_3 \simeq -8.3 M_2$, which implies that the lightest chargino pair and neutralino comprise a nearly mass-degenerate triplet of winos, $\widetilde{W}^\pm$, $\widetilde{W}^0$ (cf. Table 1), over most of the MSSM parameter space. For example, if $|\mu| \gg m_Z, |M_2|$, then Eq. (88.30) implies that $M_{\widetilde{\chi}^\pm} \simeq M_{\widetilde{\chi}^0_1} \simeq M_2$ [150]. Alternatively, one can construct an AMSB model where $|\mu|, m_Z \ll M_2$, which yields an LSP that is an approximate higgsino state [151]. In both cases, the corresponding supersymmetric phenomenology differs significantly from the standard phenomenology based on Eq. (88.29) [152, 153].

Finally, it should be noted that the unification of gaugino masses (and scalar masses) can be accidental. In particular, the energy scale where unification takes place may not be directly related to any physical scale. One version of this phenomenon has been called mirage unification and can occur in certain theories of fundamental SUSY breaking [154].

88.6.2 *Constrained versions of the MSSM: mSUGRA, CMSSM, etc.*

In the minimal supergravity (mSUGRA) framework [3–5, 25, 44–46], the minimal form of the Kähler potential is employed, which yields standard kinetic energy terms for the MSSM fields [48]. As a result, the soft supersymmetry-breaking parameters at the high-energy scale M_X take a particularly simple form in which the scalar squared-masses and the A-parameters are flavor-diagonal and universal [46]:

$$\begin{aligned}
&M^2_{\widetilde{Q}}(M_X) = M^2_{\widetilde{U}}(M_X) = M^2_{\widetilde{D}}(M_X) = m_0^2 \mathbf{1}\,,\\
&M^2_{\widetilde{L}}(M_X) = M^2_{\widetilde{E}}(M_X) = m_0^2 \mathbf{1}\,,\\
&m_1^2(M_X) = m_2^2(M_X) = m_0^2\,,\\
&A_U(M_X) = A_D(M_X) = A_E(M_X) = A_0 \mathbf{1}\,,
\end{aligned} \tag{88.31}$$

where $\mathbf{1}$ is a 3×3 identity matrix in generation space. As in the SM, this approach exhibits minimal flavor violation (see *e.g.* Refs. [155, 156]), whose unique source is the nontrivial flavor structure of the Higgs-fermion Yukawa couplings. The gaugino masses are also unified according to Eq. (88.28).

Renormalization group evolution is then used to derive the values of the supersymmetric parameters at the low-energy (electroweak) scale. For example, to compute squark masses, one should use the low-energy values for $M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, and $M^2_{\widetilde{D}}$ in Eq. (88.11). Through the renormalization group running with boundary conditions specified in Eq. (88.29) and Eq. (88.31), one can show that the low-energy values of $M^2_{\widetilde{Q}}$, $M^2_{\widetilde{U}}$, and $M^2_{\widetilde{D}}$ depend primarily on m_0^2 and $m_{1/2}^2$. A number of useful approximate analytic expressions for superpartner masses in terms of the mSUGRA parameters can be found in Ref. [157].

One can count the number of independent parameters in the mSUGRA framework. In addition to 18 SM parameters (excluding the Higgs mass), one must specify m_0, $m_{1/2}$, A_0, the Planck-scale values for μ and B-parameters (denoted by μ_0 and B_0), and the gravitino mass $m_{3/2}$. Without additional model assumptions, $m_{3/2}$ is independent of the parameters that govern the mass spectrum of the superpartners of the SM [46]. In principle, A_0, B_0, μ_0, and $m_{3/2}$ can be complex, although in the mSUGRA approach, these parameters are taken to be real for simplicity.

As previously noted, renormalization group evolution is used to compute the low-energy values of the mSUGRA parameters, which then fixes all the parameters of the low-energy MSSM. In particular, the two Higgs vacuum expectation values (or equivalently, m_Z and $\tan\beta$) can be expressed as a function of the Planck-scale supergravity parameters. In light of Eq. (88.4) and Eq. (88.5), a common procedure is to determine μ_0 and B_0 in terms of m_Z and $\tan\beta$ [the sign of μ_0, denoted $\mathrm{sgn}(\mu_0)$ below, is not fixed in this process]. In this case, the MSSM spectrum and its interaction strengths are fixed by five parameters:

$$m_0\,,\ A_0\,,\ m_{1/2}\,,\ \tan\beta\,,\ \text{and}\ \mathrm{sgn}(\mu_0)\,, \tag{88.32}$$

and an independent gravitino mass $m_{3/2}$ (in addition to the 18 parameters of the SM). In Ref. [158], this framework was dubbed the constrained minimal supersymmetric extension of the SM (CMSSM). Additional relations such as $B_0 = A_0 - m_0$ and $m_{3/2} = m_0$ comprise the original mSUGRA proposal [44, 48, 159].

One can also relax the universality of scalar masses by decoupling the squared-masses of the Higgs bosons and the squarks/sleptons. This leads to the non-universal Higgs mass models (NUHMs), thereby adding one or two new parameters to the CMSSM depending on whether the diagonal Higgs scalar squared-mass parameters ($m^2_{H_d}$ and $m^2_{H_u}$) are set equal (NUHM1 [160]) or taken to be independent (NUHM2 [161]) at the high energy scale M_X. Clearly, this modification preserves the minimal flavor violation of the mSUGRA approach. Nevertheless, the mSUGRA approach and its NUHM generalizations are probably too simplistic. Theoretical considerations suggest that the universality of Planck-scale soft SUSY-breaking parameters is not generic [162]. In particular, effective operators at the Planck scale exist that do not respect flavor universality, and it is difficult to find a theoretical principle that would forbid them.

In the framework of supergravity, if anomaly mediation is the sole source of SUSY breaking, then the gaugino mass parameters, diagonal scalar squared-mass parameters, and the SUSY-breaking trilinear scalar interaction terms (proportional to $\lambda_f A_F$) are determined in terms of the beta functions of the gauge and Yukawa couplings and the anomalous dimensions of the squark and slepton fields [51, 149, 153]. As noted in Sec. 88.2.3, this approach yields tachyonic sleptons in the MSSM unless additional sources of SUSY breaking are present. In the minimal AMSB (mAMSB) scenario, a universal squared-mass parameter, m_0^2, is added to the AMSB expressions for the diagonal scalar squared-masses [153]. Thus, the mAMSB spectrum and its interaction strengths are determined by four parameters, m_0^2, $m_{3/2}$, $\tan\beta$ and $\mathrm{sgn}(\mu_0)$.

The mAMSB scenario appears to be ruled out based on the observed value of the Higgs boson mass, assuming an upper limit on M_S of a few TeV, since the mAMSB constraint on A_F implies that the maximal mixing scenario cannot be achieved [cf. Eq. (88.26)]. Indeed, under the stated assumptions, the mAMSB Higgs mass upper bound lies below the observed Higgs mass value [163]. Thus within the AMSB scenario, either an additional SUSY-breaking contribution to $\lambda_f A_F$ and/or new ingredients beyond the MSSM are required.

88.6.3 *Gauge-mediated SUSY breaking*

In contrast to models of gravity-mediated SUSY breaking, the flavor universality of the fundamental soft SUSY-breaking squark and slepton squared-mass parameters is guaranteed in gauge-mediated SUSY breaking (GMSB) because the supersymmetry breaking is communicated to the sector of MSSM fields via gauge interactions [56, 58]. In GMSB models, the mass scale of the messenger sector (or its equivalent) is sufficiently below the Planck scale such that the additional SUSY-breaking effects mediated by supergravity can be neglected.

In the minimal GMSB approach, there is one effective mass scale, Λ, that determines all low-energy scalar and gaugino mass parameters through loop effects, while the resulting A-parameters are suppressed. In addition, the minimal form of the Kähler potential is employed. In order that the resulting superpartner masses be of order 1 TeV, one must have $\Lambda \sim \mathcal{O}(100\ \text{TeV})$. The origin of the μ and B-parameters is model-dependent, and lies somewhat outside the purview of gauge-mediated SUSY breaking [164].

The simplest GMSB models appear to be ruled out based on the observed value of the Higgs boson mass. Due to suppressed A pa-

rameters, it is difficult to boost the contributions of the radiative corrections in Eq. (88.26) to obtain a Higgs mass as large as 125 GeV. However, this conflict can be alleviated in more complicated GMSB models [165]. To analyze these generalized GMSB models, it has been especially fruitful to develop model-independent techniques that encompass all known GMSB models [166]. These techniques are well-suited for a comprehensive analysis [167] of the phenomenological profile of gauge-mediated SUSY breaking.

The gravitino is the LSP in minimal GMSB models, as noted in Sec. 88.2.3. As a result, the next-to-lightest supersymmetric particle (NLSP) now plays a crucial role in the phenomenology of supersymmetric particle production and decays. Note that unlike the LSP, the NLSP can be charged. In GMSB models, the most likely candidates for the NLSP are $\tilde{\chi}_1^0$ and $\widetilde{\tau}_R^{\pm}$. The NLSP will decay into its superpartner plus a gravitino (*e.g.*, $\tilde{\chi}_1^0 \to \gamma\widetilde{G}$, $\tilde{\chi}_1^0 \to Z\widetilde{G}$, $\tilde{\chi}_1^0 \to h^0\widetilde{G}$ or $\widetilde{\tau}_1^{\pm} \to \tau^{\pm}\widetilde{G}$), with lifetimes and branching ratios that depend on the model parameters. There are also GMSB scenarios in which there are several nearly degenerate co-NLSPs, any one of which can be produced at the penultimate step of a supersymmetric decay chain [168]. For example, in the slepton co-NLSP case, all three right-handed sleptons are close enough in mass and thus can each play the role of the NLSP.

Different choices for the identity of the NLSP and its decay rate lead to a variety of distinctive supersymmetric phenomenologies [58,169]. For example, a long-lived $\tilde{\chi}_1^0$-NLSP that decays outside collider detectors leads to supersymmetric decay chains with missing energy in association with leptons and/or hadronic jets (this case is indistinguishable from the standard phenomenology of the $\tilde{\chi}_1^0$-LSP). On the other hand, if $\tilde{\chi}_1^0 \to \gamma\widetilde{G}$ is the dominant decay mode, and the decay occurs inside the detector, then nearly *all* supersymmetric particle decay chains would produce a photon. In contrast, in the case of a $\widetilde{\tau}_1^{\pm}$-NLSP, the $\widetilde{\tau}_1^{\pm}$ would either be long-lived or would decay inside the detector into a τ-lepton plus missing energy.

A number of attempts have been made to address the origins of the μ and B-parameters in GMSB models based on the field content of the MSSM (see, *e.g.*, Refs. [164, 170]). An alternative approach is to consider GMSB models based on the NMSSM [171]. The vacuum expectation value of the additional singlet Higgs superfield can be used to generate effective μ and B-parameters [172]. Such models provide an alternative GMSB framework for achieving a Higgs mass of 125 GeV, while still being consistent with LHC bounds on supersymmetric particle masses.

88.6.4 *The phenomenological MSSM*

Any of the theoretical assumptions described in the previous three subsections must be tested experimentally and could turn out to be wrong. To facilitate the exploration of MSSM phenomena in a more model-independent way while respecting the constraints noted at the beginning of this Section, the phenomenological MSSM (pMSSM) has been introduced [173].

The pMSSM is governed by 19 independent real supersymmetric parameters: the three gaugino mass parameters M_1, M_2 and M_3, the Higgs sector parameters m_A and $\tan\beta$, the Higgsino mass parameter μ, five sfermion squared-mass parameters for the degenerate first and second generations ($M^2_{\underset{\sim}{Q}}$, $M^2_{\underset{\sim}{U}}$, $M^2_{\underset{\sim}{D}}$, $M^2_{\underset{\sim}{L}}$ and $M^2_{\underset{\sim}{E}}$), the five corresponding sfermion squared-mass parameters for the third generation, and three third-generation A-parameters (A_t, A_b and A_τ). The first and second generation A-parameters are typically neglected in pMSSM studies, as their phenomenological consequences are negligible in most applications. One counterexample arises when considering the A_μ dependence of the anomalous magnetic moment of the muon, which can be as significant as other contributions due to superpartner mediated radiative corrections [174]. Since its initial proposal, the pMSSM approach has been extended to include a 20th parameter, A_μ [175]. It also has been further extended to include CP-violating SUSY-breaking parameters in Ref. [176].

The 19-parameter pMSSM is often further constrained to expedite scans over the parameter space. For example, in Ref. [177], the number of pMSSM parameters is reduced to ten by assuming one common squark squared-mass parameter for the first two generations, a second common squark squared-mass parameter for the third generation, a common (charged) slepton squared-mass parameter and a common third generation A parameter. In Ref. [178] an eleven parameter pMSSM is defined by allowing for a different stau squared-mass parameter from that of the first two generation charged sleptons. Other applications of the pMSSM approach (with a reduced pMSSM parameter space) to supersymmetric particle searches, and a discussion of the implications for past and future LHC and dark matter studies can be found in Refs. [177, 179, 180].

88.6.5 *Simplified models*

As Sec. 89 demonstrates, experiments present their searches for supersymmetric particles primarily in terms of simplified models. Simplified models for supersymmetric searches [181] are defined mostly by the empirical objects and kinematic variables involved in the search. Their interpretation by an experimental collaboration usually involves only a small number of supersymmetric particles (often two or three). Other supersymmetric particles are assumed to play no role (this may happen by virtue of them being too heavy to be produced). Experimental bounds from non-observation of a signal are usually presented in terms of the physical masses of the supersymmetric particles involved. Bounds may be presented on the relevant supersymmetric particle masses assuming certain values for the branching ratio of certain supersymmetric particle decays, or as an upper bound on the signal production cross-section as a function of the relevant supersymmetric particle masses.

For example, consider a search for hadronic jets plus missing transverse momentum. One can match such a search to the simplified model of squark pair production followed by the subsequent decay of each squark into a quark (which appears as a jet) and a neutralino LSP that produces the missing transverse momentum, *i.e.* $\tilde{q}\tilde{q} \to (q\tilde{\chi}_1^0)(q\tilde{\chi}_1^0)$. Excluded cross-sections resulting from the non-observation of a signal (which in this case could consist of some specified minimum value of missing transverse momentum and at least two hard jets) may be exhibited in the squark mass versus LSP mass plane.

Simplified models have the apparent advantage that they have fewer free parameters than more complete supersymmetric models, whose greater number of free parameters makes it difficult to present excluded regions in any generality. If limits are quoted on supersymmetric particle masses without reference to the signal production cross-section from a simplified model analysis, then there is a potential pitfall—namely, mass limits can differ from those obtained in full models because there may be contributions to the signal coming from processes involving supersymmetric particles other than those assumed. For example, in the $\tilde{q}\tilde{q} \to q\tilde{\chi}_1^0 q\tilde{\chi}_1^0$ process mentioned above, the simplified model analysis does not account for the interference with tree-level t-channel gluino contributions. Nevertheless, simplified model bounds quoted purely in terms of supersymmetric particle masses may still approximately hold over sizable regions of parameter space of more complete models, within which the simplified model is embedded. When simplified model limits are phrased as bounds on signal cross-sections, the aforementioned pitfall is sidestepped. Simplified models thus remain an efficient tool for organizing and presenting the results of supersymmetric particle searches. A comparison between supersymmetric particle search constraints in the context of simplified models and the corresponding constraints obtained in the more complete pMSSM can be found in Ref. [182].

88.7 Experimental data confronts the MSSM

At present, there is no significant evidence for weak-scale SUSY from the data analyzed by the LHC experiments. Recent LHC data have been employed in ruling out the existence of colored supersymmetric particles (primarily the gluino and the first generation of squarks) with masses below about 2 TeV (see Fig. 89.14). Moreover, given that the mass of the observed Higgs boson is 125 GeV, the results exhibited in Fig. 88.1 tend to favor a mass scale of the top squarks somewhat above 2 TeV. However, the precise mass limits are very model dependent. For example, as Fig. 89.13 demonstrates, regions of the pMSSM parameter space can be identified in which lighter squarks and gluinos below 1 TeV cannot be

definitely ruled out. Under the assumption of gaugino mass unification [cf. Eq. (88.29)], LHC searches result in a lower bound on neutralino and chargino masses of roughly 200 GeV. It is difficult to place general bounds on neutralino and chargino masses, since the limit in terms of masses from direct searches tends to be particularly model dependent. Nevertheless, one must confront the tension that exists between the theoretical expectations for the magnitude of the SUSY-breaking parameters and the non-observation of supersymmetric phenomena at colliders.

88.7.1 *Naturalness constraints and the little hierarchy*

In Sec. 88.1, weak-scale SUSY was motivated as a natural solution to the hierarchy problem, which could provide an understanding of the origin of the electroweak symmetry-breaking scale without a significant fine-tuning of the fundamental parameters that govern the MSSM. In this context, the weak scale soft supersymmetry-breaking masses must be generally of the order of 1 TeV or below [183]. This requirement is most easily seen in the determination of m_Z by the scalar potential minimum condition. In light of Eq. (88.5), to avoid the fine-tuning of MSSM parameters, the soft SUSY-breaking squared-masses $m^2_{H_d}$ and $m^2_{H_u}$ and the higgsino squared-mass $|\mu|^2$ should all be roughly of $\mathcal{O}(m_Z^2)$. Many authors have proposed quantitative measures of fine-tuning [183–188]. One of the simplest measures is the one advocated by Barbieri and Giudice [183] (which was also introduced previously in Ref. [184]),

$$\Delta_i \equiv \left| \frac{\partial \ln m_Z^2}{\partial \ln p_i} \right| , \qquad \Delta \equiv \max\, \Delta_i \,, \tag{88.33}$$

where the p_i are the MSSM parameters at the high-energy scale M_X, which are set by the fundamental SUSY-breaking dynamics. The theory is more fine-tuned as Δ becomes larger. However, different measures of fine-tuning yield quantitatively different results; in particular, calculating minimal fine-tuning based on the high-scale parameters [as defined in Eq. (88.33)] yields a difference by a factor ~ 10 to fine-tuning based on TeV-scale parameters [189, 190].

One can apply the fine-tuning measure to any explicit model of SUSY breaking. For example, in the approaches discussed in Sec. 88.6, the p_i are parameters of the model at the energy scale M_X where the soft SUSY-breaking operators are generated by the dynamics of SUSY breaking. Renormalization group evolution then determines the values of the parameters appearing in Eq. (88.5) at the electroweak scale. In this way, Δ is sensitive to all the SUSY-breaking parameters of the model (see *e.g.* Ref. [191]). The computation of Δ is often based on Eq. (88.5), which is a tree-level condition. However, the fine-tuning measure obtained at tree level can be somewhat reduced in value when loop corrections are included while remaining consistent with all experimental constraints [87, 192].

One way of taking fine-tuning into account in fits to data using Bayesian statistics is to have a prior probability distribution proportional to $1/\Delta$ [193] so that fine-tuning is balanced against the fit to empirical data. In such a Bayesian approach, it is important to choose the prior probability distribution carefully, since prior probability densities that are flat in one set of variables may not be flat in another, more fundamental set. One can in fact derive a different measure of fine-tuning resulting from a Jacobian factor when transforming to other variables.[4] By comparing the results of several Bayesian fits with different (but reasonable) prior probability distributions, one can assess the robustness of the fit with respect to their variation, mitigating for subjectivity in the interpretation of the fine-tuning measure.

As anticipated, there is a tension between the present experimental lower limits on the masses of colored supersymmetric particles [195,196] and the expectation that supersymmetry-breaking is associated with the electroweak symmetry-breaking scale. Moreover, this tension is exacerbated [197] by the observed value of the Higgs mass ($m_h \simeq 125$ GeV), which is not far from the MSSM upper bound ($m_h \lesssim 135$ GeV) [which depends on the top-squark mass and mixing as noted in Sec. 88.5.2]. If $M_{\rm SUSY}$ characterizes the scale of supersymmetric particle masses, then one would crudely expect $\Delta \sim M^2_{\rm SUSY}/m_Z^2$. For example, if $M_{\rm SUSY} \sim 1$ TeV then one expects a $\Delta^{-1} \sim 1\%$ fine-tuning of the MSSM parameters to achieve the observed value of m_Z. This separation of the electroweak symmetry-breaking and SUSY-breaking scales is an example of the little hierarchy problem [198, 199].

The fine-tuning parameter Δ can depend quite sensitively on the structure of the SUSY-breaking dynamics, such as the value of M_X and relations among SUSY-breaking parameters in the fundamental high energy theory [200]. For example, in so-called focus point SUSY models [187, 201], all squark masses can be as heavy as 5 TeV *without* significant fine-tuning. This can be attributed to a focusing behavior of the renormalization group evolution when certain relations hold among the high-energy values of the scalar squared-mass SUSY-breaking parameters. Although the focus point region of the CMSSM still yields an uncomfortably high value of Δ due to the observed Higgs mass of 125 GeV, one can achieve moderate values of Δ in models with NUHM2 boundary conditions for the scalar masses [197].

Among the colored superpartners, the third generation squarks typically have the most significant impact on the naturalness constraints [202], while their masses are the least constrained by the LHC data. Hence, in the absence of any relation between third generation squarks and those of the first two generations, the naturalness constraints due to present LHC data can be considerably weaker than those obtained in the CMSSM. Indeed, models with first and second generation squark masses in the multi-TeV range do not necessarily require significant fine tuning. Such models have the added benefit that undesirable FCNCs mediated by squark exchange are naturally suppressed [203]. Other MSSM mass spectra that are compatible with moderate fine tuning have been considered in Refs. [200] and [204].

The lower bounds on squark and gluino masses may not be as large as suggested by the experimental analyses based on the CMSSM or simplified models. For example, mass bounds for the gluino and the first and second generation squarks based on the CMSSM can often be evaded in alternative or extended MSSM models, *e.g.*, compressed SUSY [205] and stealth SUSY [206]. Moreover, the experimental upper limits for the third generation squark masses (which have a more direct impact on the fine-tuning measure) are weaker than the corresponding mass limits for other colored supersymmetric states.

Among the uncolored superpartners, the higgsinos are typically the most impacted by the naturalness constraints. Eq. (88.5) suggests that the masses of the two neutral higgsinos and charged higgsino pair (which are governed by $|\mu|$) should not be significantly larger than m_Z to avoid an unnatural fine-tuning of the supersymmetric parameters, which would imply the existence of light higgsinos (whose masses are not well constrained, as they are difficult to detect directly at the LHC due to their soft decay products). However, it may be possible to avoid the conclusion that $\mu \sim \mathcal{O}(m_Z)$ if additional correlations among the SUSY breaking mass parameters and μ are present. Such a scenario can be realized in models in which the boundary conditions for SUSY breaking are generated by approximately conformal strong dynamics. For example, in the so-called scalar-sequestering model of Ref. [207], values of $|\mu| > 1$ TeV can be achieved while naturally maintaining the observed value of m_Z.

Finally, one can also consider extensions of the MSSM in which the degree of fine-tuning is relaxed. For example, it has already been noted in Sec. 88.5 that it is possible to accommodate the observed Higgs mass more easily in the NMSSM due to contributions to m_h^2 proportional to the parameter λ^2. This means that one does not have to rely on a large contribution from radiative corrections to boost the Higgs mass sufficiently above its tree-level bound. This allows for smaller top squark masses, which are more consistent with the demands of naturalness. The reduction of the fine-tuning in various NMSSM models was initially advocated in Ref. [208], and subsequently treated in more detail in Refs. [116, 209]. Naturalness can also be relaxed in extended su-

[4] For example, one may consider the parameters μ and m_{12}^2 to be more fundamental than $\tan\beta$ and M_Z. In this case, one would choose a flat prior probability distribution in μ and m_{12}^2 rather than in $\tan\beta$ and M_Z [186, 194]. The Jacobian factor is then obtained from Eq. (88.4) and Eq. (88.5).

persymmetric models with vector-like quarks [210] and in gauge extensions of the MSSM [211].

The experimental absence of any new physics beyond the SM at the LHC suggests that the principle of naturalness is presently under significant stress [212]. Nevertheless, one must be very cautious when drawing conclusions about the viability of weak-scale SUSY to explain the origin of electroweak symmetry breaking, since different measures of fine-tuning noted above can lead to different assessments [189, 190]. Moreover, the maximal value of Δ that determines whether weak-scale SUSY is a fine-tuned model (should it be $\Delta \sim 10?$ $100?$ $1000?$) is ultimately subjective. Thus, it is premature to conclude that weak-scale SUSY is on the verge of exclusion. It might be possible to sharpen the upper bounds on superpartner masses based on naturalness arguments, which ultimately will either confirm or refute the weak scale SUSY hypothesis [213]. Of course, if evidence for supersymmetric phenomena in the multi-TeV regime were to be established at a future collider facility (with an energy reach beyond the LHC [214]), it would be viewed as a spectacularly successful explanation of the large gauge hierarchy between the (multi-)TeV scale and Planck scale. In this case, the remaining little hierarchy, characterized by the somewhat large value of the fine-tuning parameter Δ discussed above, would be regarded as a less pressing issue.

88.7.2 *Indirect constraints on supersymmetric models*

While direct empirical searches for supersymmetric particles provide various limits on their properties, indirect constraints can depend more sensitively on details of the whole model. The cold dark matter relic density inferred from cosmological fits to observational data is one such example of an indirect constraint. In supersymmetric models where the LSP is stable (and thus is a dark matter candidate), its thermally-produced relic density depends upon the scattering of various supersymmetric particles into dark matter particles and SM particles. The resulting relic density can depend sensitively on the masses of the non-LSP supersymmetric particles as well as on the mass of the LSP. In a typical model, an appreciable region of the parameter space is ruled out because it yields an overabundance of dark matter (see for example Ref. [215] for a fit to a seven parameter version of the pMSSM). However, subsequent tweaks to the supersymmetric model that yield an unstable LSP, such as the introduction of R-parity violating effects, can mean that the relic density no longer constrains the parameter space.

There are a number of indirect constraints based on low-energy measurements that are sensitive to the effects of new physics via supersymmetric loop effects. For example, the virtual exchange of supersymmetric particles can contribute to the muon anomalous magnetic moment, $a_\mu \equiv \frac{1}{2}(g-2)_\mu$, as reviewed in Ref. [216]. The SM prediction for a_μ, which employs dispersion relations and low energy e^+e^- scattering data to determine the hadronic corrections [217], exhibits a deviation of 5σ from the experimentally observed value [218]. The deviation of Ref. [217] from the measured value of a_μ [218] is difficult to accommodate in the constrained models of Sec. 88.6.2 and 88.6.3 given the present sparticle mass bounds [196]. Nevertheless, such a deviation can be consistent in the context of a more general version of the MSSM [219].

However, the Budapest-Marseille-Wupertal (BMW) lattice determination of the leading hadronic contribution to the muon magnetic moment obtained in Ref. [220] yields a significantly smaller deviation from the SM prediction [221]. Indeed, there is a tension of almost 4σ between the BMW lattice calculation and the corresponding dispersive estimate based on the same e^+e^- data, as stated in Ref. [222] where the relevant references are cited. Moreover, Ref. [222] notes that crucial parts of the BMW calculation have recently been cross checked by other lattice groups. In addition, various tensions exist among the relevant sets of e^+e^- scattering data that are used in the dispersive estimate, some of which have appeared after the publication of Ref. [217]. Thus, the deviation of the measured value of a_μ from the corresponding SM prediction still needs to be clarified.

The precision of the measured value of a_μ is not sensitive to the experimental error associated with the measured value of the fine structure constant, α. In contrast, the comparison of the SM prediction with the experimental measurement of the anomalous magnetic moment of the electron, a_e, depends critically on the value of α. Using the experimentally determined value of α given in Ref. [223] yields a SM prediction for a_e that is 2.4σ above its measured value [224]. However, this previous determination of α is in tension at the 5σ level with a more recent measurement of the fine structure constant [225]. The latter yields a SM prediction for a_e that is 1.6σ below its measured value [225].

Measurements of the fine structure constant, a_e and a_μ jointly constrain the pMSSM parameter space [226] due to shifts originating from supersymmetric loop effects. In particular, if the supersymmetric interpretation of the deviation in the measured value of a_μ from its SM prediction is combined with the experimental limits on the electron electric dipole moment [135], then the resulting upper bounds on MSSM CP-violating phases are even more constraining [227] than previously noted at the beginning of Sec. 88.6.

Flavor transitions in radiative, leptonic and semi-leptonic b quark decays [228] provide a fertile ground for physics beyond the SM. For example, the rare inclusive decay $b \to s\gamma$ is a sensitive probe of the virtual effects of new physics beyond the SM. The experimental measurements of $B \to X_s + \gamma$ [229] are in agreement with the theoretical SM predictions of Ref. [230]. Since supersymmetric loop corrections can contribute an observable shift from the SM predictions, the absence of any significant deviation places useful constraints on the MSSM parameter space [231].

The rare decays $B_s \to \mu^+\mu^-$ and $B_d \to \mu^+\mu^-$ are especially sensitive to supersymmetric loop effects, with some loop contributions scaling as $\tan^6\beta$ when $\tan\beta \gg 1$ [232]. At present, a combination [233] of the measurements of these rare decay modes [234] is in slight tension at the 1.6σ level with the predicted SM rates [235]. Such a tension can be resolved by the aforementioned supersymmetric loop effects [232].

Several tensions exist between SM predictions and measurements of some other experimental observables that probe $b \to s\mu^+\mu^-$ transitions, although the level of tension depends upon the theoretical treatment of the SM analysis. In a certain angular distribution parameter (denoted by P_5') extracted from $B^0 \to K^{*0}\mu^+\mu^-$ decays, the tension is around the 4σ level [236]. An even larger discrepancy is observed in a combination of angular distributions and rates derived from $B^\pm \to K^\pm\mu^+\mu^-$ and $B^0 \to K^0\mu^+\mu^-$ [237]. Finally, there is a 3.6σ deviation in the branching ratio of $B_s \to \phi\mu^+\mu^-$ for di-muon invariant mass squared values between 1.1 GeV^2 and 6.0 GeV^2 [238]. Finally, a recent measurement of $B^+ \to K^+\nu\bar{\nu}$ by the Belle II Collaboration [239] obtained a branching fraction that is roughly four times larger than the SM prediction [240], corresponding to 2.7σ above the SM expectation. However, it is unlikely that this result can be attributed to new contributions from the MSSM [241], as the latter are expected to be negligible in comparison with the SM.

The decays $B^\pm \to \tau^\pm\nu_\tau$ and $\overline{B} \to D^{(*)}\tau^-\overline{\nu}_\tau$ are noteworthy, since in models with extended Higgs sectors such as the MSSM, these processes possess tree-level charged Higgs exchange contributions that can compete with the dominant W-exchange. As Sec. 72 shows, experimental measurements of $B^\pm \to \tau^\pm\nu_\tau$ are currently consistent with SM expectations [242]. The BaBar Collaboration measured values of the rates for $\overline{B} \to D\tau^-\overline{\nu}_\tau$ and $\overline{B} \to D^*\tau^-\overline{\nu}_\tau$ [243] which exhibited a combined 3.4σ discrepancy from the SM predictions, which was also not compatible with the Type-II Higgs Yukawa couplings employed by the MSSM. Subsequent measurements by the LHCb and Belle Collaborations were compatible with the BaBar measurements although they displayed less deviation from the SM expectations; the combined difference between the measured values of the $\overline{B} \to D\tau^-\overline{\nu}_\tau$ and $\overline{B} \to D^*\tau^-\overline{\nu}_\tau$ decay rates relative to the corresponding SM values has a significance of 3.3 standard deviations [244].

In summary, although there are a few hints of possible deviations from the SM in B decays, none of the discrepancies by themselves are significant enough to conclusively imply the existence of new physics beyond the SM. Moreover, the absence of evidence for sizable deviations in other B-physics observables from their SM predictions can place useful constraints on the MSSM parameter space [138, 195, 245, 246].

The CDF Collaboration has reported a measurement of the W

boson mass [247] that is 7σ above the SM prediction. Supersymmetric models have been shown to be able to accommodate the measured value by the CDF Collaboration at the 2σ level [248]. However, other measurements, including a more recent determination by ATLAS Collaboration [249], are consistent with SM predictions for m_W (see Sec. 10 for further details).

88.8 Massive neutrinos in weak-scale SUSY

In the minimal version of the SM and its supersymmetric extension, there are no right-handed neutrinos, and Majorana mass terms for the left-handed neutrinos are absent. However, given the overwhelming evidence for neutrino masses and mixing (see Sec. 14 and [250]), any viable model of the fundamental particles must provide a mechanism for generating neutrino masses [251]. In extended supersymmetric models, various mechanisms exist for producing massive neutrinos [252]. Although one can devise models for generating massive Dirac neutrinos [253], the most common approaches for incorporating neutrino masses are based on L-violating supersymmetric extensions of the MSSM, which generate massive Majorana neutrinos. Two classes of L-violating supersymmetric models will now be considered.

88.8.1 *The supersymmetric seesaw*

Neutrino masses can be incorporated into the SM by introducing SU(3)×SU(2)×U(1) singlet right-handed neutrinos (ν_R) whose mass parameters are very large, typically near the grand unification scale. In addition, one must also include a standard Yukawa couplings between the lepton doublets, the Higgs doublet, and ν_R. The Higgs vacuum expectation value then induces an off-diagonal ν_L–ν_R mass on the order of the electroweak scale. Diagonalizing the neutrino mass matrix (in the three-generation model) yields three superheavy neutrino states, and three very light neutrino states that are identified with the light neutrinos observed in nature. This is the seesaw mechanism [254].

It is straightforward to construct a supersymmetric generalization of the seesaw model of neutrino masses [255,256] by promoting the right-handed neutrino field to a superfield $\widehat{N}^c = (\widetilde{\nu}_R\,;\,\nu_R)$. Integrating out the heavy right-handed neutrino supermultiplet yields a new term in the superpotential [cf. Eq. (88.1)] of the form

$$W_{\rm seesaw} = \frac{f}{M_R}(\widehat{H}_U\widehat{L})(\widehat{H}_U\widehat{L})\,, \tag{88.34}$$

where M_R is the mass scale of the right-handed neutrino sector and f is a dimensionless constant. Note that lepton number is broken by two units by Eq. (88.34), which implies that R-parity invariance is preserved. The supersymmetric analogue of the Majorana neutrino mass term in the sneutrino sector leads to sneutrino–antisneutrino mixing phenomena [256, 257]. In addition, new Higgs-slepton interaction terms can probe the structure of the supersymmetric seesaw model [258]. The right-handed sneutrino that resides in $\widehat{L}$ also provides an intriguing dark matter candidate [259].

The SUSY Les Houches Accord [80,99], mentioned at the end of the introduction to Sec. 88.4, has been extended to the supersymmetric seesaw (and other extensions of the MSSM) in Ref. [260].

88.8.2 *R-parity-violating SUSY*

It is possible to incorporate massive neutrinos in renormalizable supersymmetric models while retaining the minimal particle content of the MSSM by relaxing the assumption of R-parity invariance. The most general R-parity-violating model involving the MSSM spectrum introduces many new parameters to both the SUSY-conserving and the SUSY-breaking sectors [80, 261]. Each new interaction term violates either B or L conservation. For example, starting from the MSSM superpotential given in Eq. (88.1) [suitably generalized to three generations of quarks, leptons and their superpartners], consider the effect of adding the following new terms:

$$\begin{aligned} W_{\rm RPV} =& (\lambda_L)_{pmn}\widehat{L}_p\widehat{L}_m\widehat{E}^c_n + (\lambda'_L)_{pmn}\widehat{L}_p\widehat{Q}_m\widehat{D}^c_n \\ &+ (\lambda_B)_{pmn}\widehat{U}^c_p\widehat{D}^c_m\widehat{D}^c_n + (\mu_L)_p\widehat{H}_u\widehat{L}_p\,, \end{aligned} \tag{88.35}$$

where p, m, and n are generation indices, and gauge group indices are suppressed. Eq. (88.35) yields new scalar-fermion Yukawa couplings consisting of all possible combinations involving two SM fermions and one scalar superpartner.

Note that the term in Eq. (88.35) proportional to λ_B violates B, while the other three terms violate L. The L-violating term in Eq. (88.35) proportional to μ_L is the RPV analog of the $\mu\widehat{H}_u\widehat{H}_d$ term of the MSSM superpotential, in which the $Y = -1$ Higgs/higgsino supermultiplet $\widehat{H}_d$ is replaced by the slepton/lepton supermultiplet $\widehat{L}_p$.

Phenomenological constraints derived from data on various low-energy B- and L-violating processes can be used to establish limits on each of the coefficients $(\lambda_L)_{pmn}$, $(\lambda'_L)_{pmn}$, and $(\lambda_B)_{pmn}$ taken one at a time [261, 262]. If more than one coefficient is simultaneously non-zero, then the limits are in general more complicated [263]. All possible RPV terms cannot be simultaneously present and unsuppressed; otherwise the proton decay rate would be many orders of magnitude larger than the present experimental bound. One way to avoid proton decay is to impose B or L invariance (either one alone would suffice). Otherwise, one must accept the requirement that certain RPV coefficients must be extremely suppressed.

One particularly interesting class of RPV models is one in which B is conserved, but L is violated. It is possible to enforce baryon number conservation (and the stability of the proton), while allowing for lepton-number-violating interactions by imposing a discrete $\mathbb{Z}_3$ baryon triality symmetry on the low-energy theory [264], in place of the standard $\mathbb{Z}_2$ R-parity. Since the distinction between the Higgs and matter supermultiplets is lost in RPV models where L is violated, the mixing of sleptons and Higgs bosons, the mixing of neutrinos and neutralinos, and the mixing of charged leptons and charginos are now possible, leading to more complicated mass matrices and mass eigenstates than in the MSSM. The treatment of neutrino masses and mixing in this framework can be found, *e.g.*, in Ref. [265].

Alternatively, one can consider imposing a lepton parity such that all lepton superfields are odd [264, 266]. In this case, only the B-violating term in Eq. (88.35) survives, and L is conserved. Models of this type have been considered in Ref. [267]. Since L is conserved in these models, the mixing of the lepton and Higgs superfields is forbidden. Moreover, neutrino masses (and mixing) are not generated if lepton parity is an exact symmetry. However, one expects that lepton parity cannot be exact due to quantum gravity effects. Remarkably, the standard $\mathbb{Z}_2$ R-parity and the $\mathbb{Z}_3$ baryon triality are stable with respect to quantum gravity effects, as they can be identified as residual discrete symmetries that arise from spontaneously broken non-anomalous gauge symmetries [264].

The symmetries employed above to either remove or suppress R-parity violating operators were flavor independent. In contrast, there exist a number of motivated scenarios based on flavor symmetries that can also yield the suppression as required by the experimental data (*e.g.*, see Ref. [268]).

The supersymmetric phenomenology of the RPV models exhibits features that are distinct from that of the MSSM [261]. The LSP is no longer stable, which implies that not all supersymmetric decay chains must yield missing-energy events at colliders. A comprehensive examination of the phenomenology of the MSSM extended by a single R-parity violating coupling at the unification scale and its implications for LHC searches has been given in Ref. [269]. As an example, the sparticle mass bounds obtained in searches for R-parity-conserving SUSY can be considerably relaxed in certain RPV models due to the absence of large missing transverse momentum signatures [270]. This can alleviate some of the tension with naturalness (introduced in Sec. 88.7.1).

Nevertheless, the loss of the missing-energy signature is often compensated by other striking signals (which depend on which R-parity-violating parameters are dominant). For example, supersymmetric particles in RPV models can be singly produced (in contrast to R-parity-conserving models where supersymmetric particles must be produced in pairs). The phenomenology of pair-produced supersymmetric particles is also modified in RPV models due to new decay chains not present in R-parity-conserving SUSY models [261].

In RPV models with lepton number violation (these include

weak-scale SUSY models with baryon triality mentioned above), both $\Delta L = 1$ and $\Delta L = 2$ phenomena are allowed, leading to neutrino masses and mixing [271], neutrinoless double-beta decay [272], sneutrino-antisneutrino mixing [273], and resonant s-channel production of sneutrinos in e^+e^- collisions [274] and in charged sleptons in $p\bar{p}$ and pp collisions [275], respectively.

88.9 Extensions beyond the MSSM

Extensions of the MSSM have been proposed to solve a variety of theoretical problems [35]. One such problem involves the μ parameter of the MSSM. Although μ is a SUSY-*preserving* parameter, it must be of order the effective SUSY-breaking scale of the MSSM to yield a consistent supersymmetric phenomenology [276]. Any natural solution to the so-called μ-problem must incorporate a symmetry that enforces $\mu = 0$ and a small symmetry-breaking parameter that generates a value of μ that is not parametrically larger than the effective SUSY-breaking scale [277]. A number of proposed mechanisms in the literature (*e.g.*, see Ref. [276–278]) provide concrete examples of a natural solution to the μ-problem of the MSSM.

In extensions of the MSSM, other compelling solutions to the μ-problem are possible. For example, one can replace μ by the vacuum expectation value of a new SU(3)×SU(2)×U(1) singlet scalar field, as noted below Eq. 88.23. This is the NMSSM, which yields phenomena that were briefly discussed in Sections 88.4–88.7. The NMSSM superpotential consists only of trilinear terms whose coefficients are dimensionless. There are some advantages to extending the NMSSM further to the 'USSM' [107] by adding a new broken U(1) gauge symmetry [279], under which the singlet field is charged.

Alternatively, one can consider a generalized version of the NMSSM (called the GNMSSM in Ref. [209]), where all possible renormalizable terms in the superpotential are allowed, which yield new supersymmetric mass terms (analogous to the μ term of the MSSM). A discussion of the parameters of the GNMSSM can be found in Ref. [80]. Although the GNMSSM does not solve the μ-problem, it does exhibit regions of parameter space in which the degree of fine-tuning is relaxed, as discussed in Sec. 88.7.1.

The generation of the μ-term may be connected with the solution to the strong CP problem [280]. Models of this type, which include new gauge singlet fields that are charged under the Peccei-Quinn (PQ) symmetry [281], were first proposed in Ref. [276]. The breaking of the PQ symmetry is thus intimately tied to SUSY breaking, while naturally yielding a value of μ that is of order the electroweak symmetry breaking scale [282].

All supersymmetric models discussed so far in this review possess self-conjugate fermions—the Majorana gluinos and neutralinos. However, it is possible to add additional chiral superfields in the adjoint representation. The spin-1/2 components of these new superfields can pair up with the gauginos to form Dirac gauginos [283, 284]. Such states appear in models of so-called supersoft SUSY breaking [285], in some generalized GMSB models [286], and in R-symmetric SUSY models [287, 288]. Such approaches often lead to improved naturalness and/or significantly relaxed flavor constraints. The implications of models of Dirac gauginos on the observed Higgs boson mass and its properties are addressed in Ref. [289].

For completeness, we briefly note other MSSM extensions considered in the literature. These include an enlarged electroweak gauge group beyond SU(2)×U(1) [290]; the addition of new Higgs supermultiplets beyond the doublets and singlets of the MSSM/NMSSM [291]; and/or the addition of new (possibly exotic) matter supermultiplets [210, 292, 293] such as vector-like fermions and their superpartners.

89. Supersymmetry, Part II (Experiment)

Revised August 2023 by M. D'Onofrio (Liverpool U.) and F. Moortgat (CERN; Ghent U.).

89.1 Introduction

Supersymmetry (SUSY), a transformation relating fermions to bosons and vice versa [1–9] is one of the most compelling possible extensions of the Standard Model of particle physics (SM).

On theoretical grounds SUSY is motivated as a generalization of space-time symmetries. A low-energy realization of SUSY, *i.e.*, SUSY at the TeV scale, is, however, not a necessary consequence. Instead, low-energy SUSY is motivated by the possible cancellation of quadratic divergences in radiative corrections to the Higgs boson mass [10–15]. Furthermore, it is intriguing that a weakly interacting, (meta)stable supersymmetric particle might make up some or all of the dark matter in the Universe [16–18]. In addition, SUSY predicts that gauge couplings, as measured experimentally at the electroweak scale, unify at an energy scale $\mathcal{O}(10^{16})$ GeV ("GUT scale") near the Planck scale [19–25].

In the minimal supersymmetric extension to the Standard Model, the so called MSSM [11, 26, 27], a supersymmetry transformation relates every chiral fermion and gauge boson in the SM to a supersymmetric partner with half a unit of spin difference, but otherwise with the same properties (such as mass) and quantum numbers. The MSSM Higgs sector contains two doublets, which give mass to the up-type and down-type quarks, respectively. After electroweak symmetry breaking, five Higgs bosons arise, of which two are charged. The supersymmetric partners of chiral fermions are squarks ($\tilde{q}$) and sleptons ($\tilde{\ell}$, $\tilde{\nu}$), and the "gauginos" for gauge bosons. The supersymmetric partners of the Higgs doublets are known as "higgsinos." The weak gauginos and higgsinos mix, giving rise to charged mass eigenstates called "charginos" ($\tilde{\chi}^{\pm}$), and neutral mass eigenstates called "neutralinos" ($\tilde{\chi}^0$). These are often collectively referred to as electroweakinos (EWkinos). The SUSY partners of the gluons are known as "gluinos" ($\tilde{g}$). The fact that such particles are not yet observed leads to the conclusion that, if supersymmetry is realized, it is a broken symmetry. A description of SUSY in the form of an effective Lagrangian with only "soft" SUSY breaking terms and SUSY particle masses of the order of TeV maintains the cancellation of quadratic divergences of soft SUSY breaking scalar mass squared parameters.

The phenomenology of SUSY is to a large extent defined by the SUSY breaking mechanism and the SUSY breaking scale. These determine the SUSY particle masses, the mass hierarchy, the field contents of physical particles, and their decay modes. In addition, phenomenology crucially depends on whether the multiplicative quantum number of R-parity [27], $R = (-1)^{3(B-L)+2S}$, where B and L are baryon and lepton numbers and S is the spin, is conserved or violated. If R-parity is conserved, SUSY particles (sparticles), which have odd R-parity, are produced in pairs and the decays of each SUSY particle must involve an odd number of lighter SUSY particles. The lightest SUSY particle (LSP) is then stable and often assumed to be a weakly interacting massive particle (WIMP). If R-parity is violated, new terms λ_{ijk}, λ'_{ijk} and λ''_{ijk} appear in the superpotential, where ijk are generation indices; λ-type couplings appear between lepton superfields only, λ''-type are between quark superfields only, and λ'-type couplings connect the two. R-parity violation implies lepton and/or baryon number violation. More details of the theoretical framework of SUSY are discussed elsewhere in this volume [28].

The discovery of a Higgs boson with a mass around 125 GeV imposes constraints on SUSY models, which are discussed elsewhere [28, 29]. Low-energy data from flavor physics experiments, high-precision electroweak observables as well as astrophysical data also impose strong constraints on the allowed SUSY parameter space. Recent examples of such data include measurements of the rare B-meson decay $B_s \to \mu^+\mu^-$ [30–32], measurements of the anomalous magnetic moment of the muon [33, 34], and accurate determinations of the cosmological dark matter relic density constraint [35, 36].

Indirect constraints can be more sensitive to higher SUSY mass scales than experiments searching for direct sparticle production at colliders, but the interpretation of these results is often strongly model dependent. In contrast, direct searches for sparticle production at collider experiments, which are the main topic of this review, are less subject to interpretation ambiguities and therefore they play a crucial role in the search for SUSY. Further discussion on indirect constraints can be found in 88.7.2.

89.2 Overview of the experimental search programme

The electron-positron collider LEP was operational at CERN between 1989 and 2000. In the initial phase, center-of-mass energies around the Z-peak were probed, but after 1995 the LEP experiments collected a significant amount of luminosity at higher center-of-mass energies, some 235 pb^{-1} per experiment at $\sqrt{s} \geq 204$ GeV, with a maximum $\sqrt{s}$ of 209 GeV. Searches for new physics at e^+e^- colliders benefit from the clean experimental environment and the fact that momentum balance can be measured not only in the plane transverse to the beam, but also in the direction along the beam (up to the beam pipe holes), defined as the longitudinal direction. Searches at LEP are dominated by the data samples taken at the highest center-of-mass energies.

The CDF and D0 experiments at the Tevatron, a proton-antiproton collider at a center-of-mass energy of up to 1.96 TeV, had an extensive search program for supersymmetric particles. CDF and D0 collected integrated luminosities between 10 and 11 fb^{-1} each up to the end of collider operations in 2011.

The electron-proton collider HERA provided collisions to the H1 and ZEUS experiments between 1992 and 2007, at a center-of-mass energy up to 318 GeV. A total integrated luminosity of approximately 0.5 fb^{-1} was collected by each experiment. Since at HERA baryons collide with leptons, SUSY searches typically look for R-parity violating production of single SUSY particles.

The Large Hadron Collider (LHC) at CERN started proton-proton operation at a center-of-mass energy of 7 TeV in 2010. By the end of 2011 the ATLAS and CMS experiments had collected about 5 fb^{-1} of integrated luminosity each, and the LHCb experiment had collected approximately 1 fb^{-1}. In 2012, the LHC operated at a center-of-mass energy of 8 TeV, and ATLAS and CMS collected approximately 20 fb^{-1} each, whereas LHCb collected 2 fb^{-1}. In 2015, the LHC started Run 2, with a center-of-mass energy of 13 TeV. At the end of Run 2 in November 2018, ATLAS and CMS had both collected approximately 140 fb^{-1}, and LHCb had collected almost 6 fb^{-1}. The Run 3 of the LHC started in July 2022 with a center-of-mass energy of 13.6 TeV. Almost 70 fb^{-1} of data have been collected by ATLAS and CMS at the time of writing (August 2023), and LHCb collected around 1.3 fb^{-1}.

At the LHC, cross sections of QCD-mediated processes are the largest achievable at colliders, which is reflected in the higher sensitivity for SUSY particles carrying color charge, squarks and gluinos, with respect to LEP, Tevatron and HERA. In particular, proton-proton collisions at the LHC differ from proton-antiproton collisions at the Tevatron in the sense that there are no valence anti-quarks in the proton, and that gluon-initiated processes play a more dominant role. The increased center-of-mass energy of the LHC compared to the Tevatron significantly extends the kinematic reach for SUSY searches. This is reflected foremost in the sensitivity for squarks and gluinos, but also for SUSY particles produced via electroweak processes.

In this review we report results of direct searches for SUSY particles at colliders up to August 2023, mostly covering data analyses at the ATLAS and CMS experiments with reference to results from LEP, HERA and the Tevatron. For more details on LEP and Tevatron constraints, see earlier PDG reviews [37]. Analyses on the Run 3 datasets are still in progress hence the results reported for ATLAS and CMS are based on Run 1 and Run 2 data. Results are categorized depending on the targeted SUSY particles, the nature of their production and decays, and the assumption on R-parity. Brief summaries of search techniques and approaches adopted for interpretation of the results are given in Section 89.3 and 89.4, respectively. Sections 89.5-89.8 focus on results for promptly-decaying gluinos and first and second generation squarks, top and bottom squarks, electroweakinos (charginos,

neutralinos) and sleptons. Limits obtained for sparticle masses assuming R-parity violating models are also reported. Results of dedicated searches for long-lived (LL) SUSY particles are reported in Section 89.9. Finally, Section 89.10 provides examples of global reinterpretations of SUSY searches.

89.3 Experimental search techniques

Large background contributions from Standard Model processes pose challenges to the trigger and analysis. Such backgrounds are dominated by multijet production processes, including, particularly at the LHC, those of top quark production, as well as jet production in association with vector bosons. The proton's momentum is shared between its parton constituents, and in each collision only a fraction of the total center-of-mass energy is available in the hard parton-parton scattering. Since the parton momenta in the longitudinal direction are not known on an event-by-event basis, use of momentum conservation constraints in an analysis is restricted to the transverse plane, leading to the definition of transverse variables, such as the missing transverse momentum, and the transverse mass.

Under the assumption of R-parity conservation (RPC), the typical SUSY search signature for squarks and gluinos at hadron colliders contains high-p_{T} jets, which are produced in the decay chains of heavy squarks and gluinos, and significant missing transverse momentum originating from the two LSPs produced at the end of the decay chains, which escape experimental detection. Electroweakino decays are often characterised by the presence of leptons, for instance from W and Z bosons in the decay chain, plus missing transverse momentum. Standard Model backgrounds with missing transverse momentum include leptonic W/Z-boson decays, associated production of jets and a Z-boson decaying into neutrinos, semi-leptonic heavy-flavor decays to neutrinos, top-quark pair production with one or both W bosons decaying leptonically, and multijet events that may be affected by instrumental effects such as jet mis-measurement.

Selection variables designed to separate the SUSY signal from the Standard Model backgrounds include transverse variables such as H_{T}, $E_{\mathrm{T}}^{\mathrm{miss}}$, and m_{eff}. The quantities H_{T} and $E_{\mathrm{T}}^{\mathrm{miss}}$ refer to the measured transverse energy and the missing transverse momentum in the event, respectively. They are usually defined as the scalar sum of the transverse jet momenta or of the transverse energies of calorimeter clusters measured in the event (H_{T}), or the magnitude ($E_{\mathrm{T}}^{\mathrm{miss}}$) of the negative vector sum of transverse momenta of reconstructed objects like jets and leptons in the event ($\vec{p}_{\mathrm{T}}^{\,\mathrm{miss}}$). The quantity m_{eff} is referred to as the effective mass of the event and is defined as $m_{\mathrm{eff}} = H_{\mathrm{T}} + E_{\mathrm{T}}^{\mathrm{miss}}$. The peak of the m_{eff} distribution for SUSY signal events correlates with the SUSY mass scale, in particular with the mass difference between the primary produced SUSY particle and the LSP [38], whereas the Standard Model backgrounds dominate at low m_{eff}. An additional reduction of multijet backgrounds can be achieved by demanding isolated leptons or photons in the final states; in such events the lepton or photon transverse momentum may be added to H_{T} or m_{eff} for further signal-background separation. Other kinematic variables and approaches developed to increase the sensitivity to pair production of heavy sparticles with TeV-scale masses focusing on the kinematics of their decays are the α_{T} [39–43], *razor* [44], *stransverse mass* (m_{T2}) [45], and *contransverse mass* (m_{CT}) [46] variables. The *super-razor* [47] and *recursive jigsaw reconstruction* [48] techniques are topological event reconstruction methods also used in searches for sparticles with masses in the TeV-range. In case massive, unstable SM particles such as top quarks, vector bosons or the Higgs boson arise in the decay chain, dedicated procedures are employed for their reconstruction and identification. If these are produced with a significant boost, their decay products will typically overlap and become collimated (boosted) in the direction of the parent particle. Their hadronic decay products can be reconstructed as a single large-radius jet (see studies from ATLAS [49]), and *jet-substructure* [50] techniques can be adopted. Machine-learning (ML) approaches are also used to identify and classify hadronic decays of highly Lorentz-boosted bosons and top quarks, see as example recent studies from CMS [51].

Most analyses still use simple combinations of selections on kinematic variables (often referred to as *cut-and-count* analyses) and exploit multiple signal regions defined by categorizing events on the basis of several variables and their correlations. An example is provided in Fig. 89.1 from Ref. [52]: 39 signal regions are set to search for top squarks in events with one lepton, jets and missing transverse momentum. Regions depend on jet multiplicities, reconstructed top-quark candidates and thresholds applied to the most discriminant variables used for optimisation.

In recent years, shape analyses or analyses using more sophisticated techniques, e.g. machine learning, have been also developed. ML techniques often allow analyses to better capture the complexity of the events and achieve improved sensitivity with respect to counting experiments. For example, Boosted Decision Trees (BDTs) allow analyses to exploit simultaneously the discriminating power of multiple variables and that of correlations among objects in the events. Deep Neural Networks (NN) are also employed for objects reconstruction and to use directly detector-recorded energies and momenta of produced particles instead of first deriving a restricted set of physical variables. Among others, currently in use are Convolutional NN for image classification techniques, Recurrent NN, parametric NN and Generative Adversarial Networks.

Variables and approaches reported above are also used in searches for R-parity violating (RPV) SUSY models where signal events are often characterised by the presence of multiple leptons and/or jets, and little or no missing transverse momentum. However, if R-parity violating couplings are small, sparticles might be long-lived and may travel macroscopic distances before decaying. Similarly, long lifetimes may be due to small mass splittings, as in the case of pure higgsino/wino scenarios, or to heavy mediators, as in Split SUSY models [53, 54]. The identification of long-lived particles requires dedicated tools and their signatures can be very diverse. At the LHC, customized techniques (also based on NN) have been developed, for example, to reconstruct significantly displaced decay vertices or short track segments, and to identify tracks with atypical properties or unusual ionization, small and localized deposits of energy inside of the calorimeters without associated tracks, or stopped particles that decay out of time with collisions. For an overview, see Ref. [55].

89.4 Interpretation of search results

Since the mechanism by which SUSY is broken is unknown, a general approach to SUSY via the most general soft SUSY breaking Lagrangian adds a significant number of new free parameters. For the minimal supersymmetric standard model, MSSM, *i.e.*, the model with the minimal particle content, these comprise 105 new real degrees of freedom. A phenomenological analysis of SUSY searches leaving all these parameters free is not feasible. For the practical interpretation of SUSY searches at colliders several approaches are taken to reduce the number of free parameters.

One approach is to assume a SUSY breaking mechanism and lower the number of free parameters through the assumption of additional constraints. Before the start of the LHC, interpretations of experimental results were often performed in constrained models of gravity mediated [56, 57], gauge-mediated [58–60], and anomaly mediated [61, 62] SUSY breaking. The most popular model was the constrained MSSM (CMSSM) [56, 63, 64], which in the literature is also referred to as minimal supergravity, or MSUGRA. These constrained SUSY models are theoretically well motivated and provide a rich spectrum of experimental signatures. However, with universality relations imposed on the soft SUSY breaking parameters, they do not cover all possible kinematic signatures and mass relations of SUSY. Furthermore, the Higgs mass measurement from LHC Run 1, together with other collider and non-collider measurements, limits substantially the allowed SUSY parameter space for these models. This indicates that very constrained models like the CMSSM are no longer good benchmark scenarios to solely characterize the results of SUSY searches at the LHC and efforts have been made to complement them with more flexible approaches.

A broader and more comprehensive subset of the MSSM can be studied via the so-called phenomenological-MSSM, or pMSSM [65–68]. It is derived from the MSSM, using experimental data to eliminate parameters that are free in principle but have

	N_J	t_{mod}	M_{lb} [GeV]

C	≥ 4	≤ 0	≤ 175
D	≥ 4	≤ 0	> 175
E	≥ 4	0–10	≤ 175
F	≥ 4	0–10	> 175
G	≥ 4	> 10	≤ 175
H	≥ 4	> 10	> 175

Figure 89.1: Example of multiple signal regions set for a typical SUSY search at the LHC. For definition of regions and acronyms specific for this search, see corresponding paper.

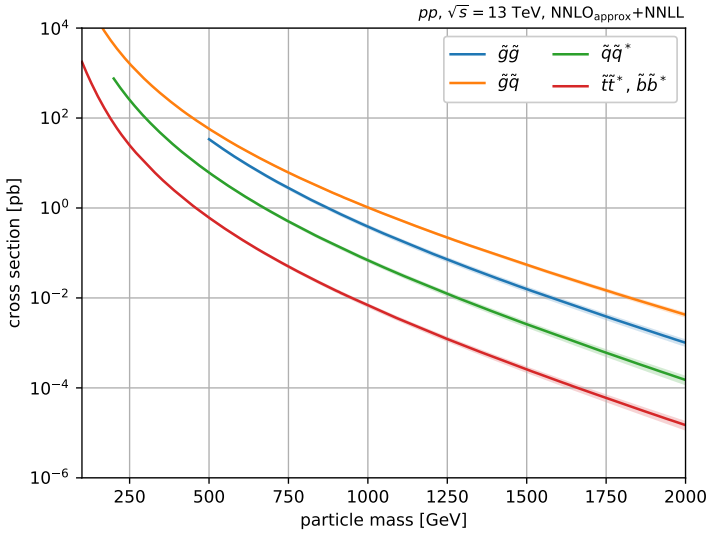

Figure 89.2: Cross sections for pair production of gluinos and squarks as a function of their mass at the LHC for a center-of-mass energy of 13 TeV. They are calculated at approximately next-to-next-to-leading-order (NNLO) including the resummation of soft gluon emission at the next-to-next-to-leading logarithmic accuracy.

already been highly constrained by measurements of *e.g.*, flavor mixing and CP-violation. This effective approach reduces the number of free parameters in the MSSM to typically 19 or even less, making it a practical compromise between the full MSSM and highly constrained models such as the CMSSM.

Even less dependent on fundamental assumptions are interpretations in terms of so-called simplified models [69–72]. Such models assume a limited set of SUSY particle production and decay modes and leave open the possibility to vary masses and other parameters freely. Therefore, simplified models enable comprehensive studies of individual SUSY topologies, and are useful for optimization of the experimental searches over a wide parameter space without limitations on fundamental kinematic properties such as masses, production cross sections, and decay modes.

As a consequence, ATLAS and CMS have adopted simplified models as the primary framework to provide interpretations of their searches. In addition to using simplified models that describe prompt decays of SUSY particles, the experiments are now also focusing more on the use of simplified models that allow for decays of long-lived SUSY particles as they can arise in different SUSY scenarios (see Section 89.9 for further discussion). Today, almost every individual search provides interpretations of their results in one or several simplified models that are characteristic of SUSY topologies probed by the analysis.

While simplified models are very convenient for the interpretation of individual SUSY production and decay topologies, care must be taken when applying these limits to more complex SUSY spectra. In particular, the branching ratio of SUSY particles into a specific final state is often assumed to be 100% and in many of the quoted limits the LSP is assumed to be massless. Therefore, simplified model limits should be seen as an approximation of the constraints that can be placed on sparticle masses in more complex SUSY spectra. Only on a case-by-case basis can it be determined whether the limit of a given simplified model represents a good approximation of the true underlying constraint that can be applied on a sparticle mass in a complex SUSY spectrum.

In the following, we will point out explicitly the assumptions that have entered the limits when quoting interpretations from simplified models.

Since none of the searches performed so far have shown significant excess above the SM background prediction, the interpretation of the presented results are exclusion limits on SUSY parameter space. Unless stated differently, all quoted exclusion limits are at the 95% confidence level. Finally, we note that many of the recent publications by ATLAS and CMS also present results in terms of model-independent limits such that their discovery potential is statistically quantified independently on a particular model.

89.5 Exclusion limits on gluino, first and second generation squark masses in RPC scenarios

Colored SUSY particles such as squarks and gluinos are produced via the strong interaction and have the highest cross sections at hadron colliders. Limits on squark masses of the order 100 GeV have been set by the LEP experiments [73], in the decay to quark plus neutralino, and for a mass difference between squark and quark plus neutralino of typically at least a few GeV. However, hadron collider experiments are able to set much more stringent mass limits.

The main production mechanisms at hadron colliders are squark-squark, squark-gluino and gluino-gluino production; when "squark" is used "antisquark" is also implied. Pair production usually involves both the s-channel and t-channel parton-parton interactions. However, since there is a negligible amount of bottom and top quark content in the proton, top and bottom squark production proceeds through s-channel diagrams only. Experimental analyses of squark and/or gluino production typically assume the first and second generation squarks to be approximately degenerate in mass. Cross section calculations at the center-of-mass energy of 13 TeV shown in Fig. 89.2 (from Ref. [74]) assume mass degeneracy of left- and right-handed u, d, s, c squarks. Other sparticle masses are considered decoupled, *i.e.* their masses are assumed to have a very high value (above 10 TeV). The LHC experiments also provide simplified model limits on individual first or second generation squarks. Top and bottom squarks have the same production cross section, identical to that of a single light squark.

In this section, we focus on results assuming R-parity conservation. Limits set by the Tevatron experiments on the gluino mass assume the framework of the CMSSM, with $\tan\beta = 5$ (CDF) or $\tan\beta = 3$ (D0). Furthermore, the common trilinear term A_0 is set to 0 and the higgsino mass term μ is assumed to be less than 0. The resulting lower mass limits are about 310 GeV for all squark masses, or 390 GeV for the case $m_{\tilde{q}} = m_{\tilde{g}}$ [75, 76].

ATLAS and CMS limits on the gluino mass have been established in the framework of simplified models. Assuming only gluino pair production, three main primary decay chains of the gluino have been considered by the LHC experiments for interpretations of their search results. The first decay chain, $\tilde{g} \to q\bar{q}\tilde{\chi}_1^0$, assumes gluino mediated production of first and second generation squarks (on-shell or off-shell) which leads to four light flavor quarks in the final state. Therefore, inclusive all-hadronic analyses searching for multijet plus $E_{\mathrm{T}}^{\mathrm{miss}}$ final states are utilized to put limits on this simplified model. These limits are derived as a function of the gluino and neutralino (LSP) mass. As shown in Fig. 89.3 (left)the CMS collaboration [77] excludes in this simplified model gluino masses below approximately 2.1 TeV for a light neutralino mass below about 600 GeV. In scenarios where neutralinos are not very light, the efficiency of the analyses is reduced by the fact that jets are less energetic, and there is less missing transverse momentum in the event. This leads to weaker limits when the mass difference $\Delta m = m_{\tilde{g}} - m_{\tilde{\chi}_1^0}$ is reduced. For example, for neutralino masses above about 1.2 TeV no limit on the gluino mass can be set for this decay chain. Therefore, limits on gluino masses are strongly affected by the assumption of the neutralino mass. Similar results for this simplified model have been obtained by ATLAS [78]. A second simplified model postulates a decay chain where $\tilde{g} \to q\bar{q}W\tilde{\chi}_1^0$, assuming that the intermediate (on-shell or off-shell) squark is left-handed and decays to a chargino and a quark, with the chargino decaying to a W boson and the LSP. This leads to two W bosons and four light flavor quarks plus $E_{\mathrm{T}}^{\mathrm{miss}}$ in the final state. Both leptonic and hadronic decays of the W can be considered. In this scenario, the ATLAS collaboration [79, 80] excludes gluino masses below approximately 2.2 TeV for a sufficiently light neutralino and assuming the chargino mass is halfway between the gluino and neutralino mass, see Fig. 89.3 (right). Again, for neutralino masses above about 1.2 TeV, there exists no limit on the gluino mass for this decay chain. A similar reach has been obtained by the CMS collaboration [81, 81, 82], where the most recent results are obtained using novel algorithms based on deep neutral networks that identify hadronically decaying W bosons.

Gluino decays are not limited to first and second generation squarks: another important decay chain of the gluino considered for interpretation in simplified models is $\tilde{g} \to b\bar{b}\tilde{\chi}_1^0$. In this case the decay is mediated via bottom squarks and thus leads to four jets originating from b-quarks and $E_{\mathrm{T}}^{\mathrm{miss}}$ in the final state. For this topology as well, inclusive all-hadronic searches provide the highest sensitivity. In this case, the use of secondary vertex reconstruction for the identification of jets originating from the b-quarks in the event provides a powerful handle to reject SM background contributions. Therefore, in addition to a multijet plus $E_{\mathrm{T}}^{\mathrm{miss}}$ signature these searches also require between 1 and 4 jets to be tagged as b-jets. As shown in Fig. 89.4 (left), for this simplified model CMS [77] excludes gluino masses below ≈ 2.3 TeV for a sufficiently light neutralino, while for neutralino masses above ≈ 1.5 TeV no limit on the gluino mass can be set. Comparable limits for this simplified model are provided by searches from ATLAS [83, 84], with the most recent results pushing the boundary of gluino masses to 2.44 TeV in the case of a massless neutralino.

If kinematically allowed, decays of gluinos to top squarks via $\tilde{g} \to \tilde{t}t$ are also possible. This defines the next important simplified model characterizing gluino pair production, $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$, which leads to a "four tops" final state, $ttttt\tilde{\chi}_1^0\tilde{\chi}_1^0$. The topology of this decay is very rich in different experimental signatures: as many as four isolated leptons, four b-jets, several light flavor quark jets, and significant missing transverse momentum from the neutrinos in the W decay and from the two neutralinos. As shown in Fig. 89.4 (right), the ATLAS search [83] rules out gluinos with masses below ≈ 2.4 TeV for light neutralinos in this model. For neutralino masses above ≈ 1.4 TeV, no limit can be placed on the gluino mass. The CMS multiple b-jet search [85] and the search in full-hadronic events using identification techniques for boosted top-quarks in the final state [86] result in gluino mass limits of ≈ 2.3 TeV.

Assuming gluinos to be heavier than squarks, squarks will predominantly decay to a quark and a neutralino or chargino, if kinematically allowed. The decay may involve the lightest neutralino (typically the LSP) or chargino, but, depending on the masses and couplings of the gauginos and on the handedness of the squarks, may involve heavier neutralinos or charginos. For pair production of first and second generation squarks, the simplest decay modes involve two jets and missing transverse momentum, with potential extra jets stemming from initial state or final state radiation (ISR/FSR) or from decay modes with longer decay chains (cascades). In cascades, isolated photons or leptons may appear from the decays of sparticles such as neutralinos or charginos.

Limits on first and second generation squark masses set by the Tevatron experiments assume the CMSSM, and amount to lower limits of about 380 GeV for all gluino masses, or 390 GeV for the case $m_{\tilde{q}} = m_{\tilde{g}}$ [75, 76]. At the LHC, limits on squark masses have been set using up to approximately 140 fb^{-1} of data at 13 TeV. Interpretations in simplified models typically characterize squark pair production considering only one decay chain at the time for the squark, for instance $\tilde{q} \to q\tilde{\chi}_1^0$. It is usually assumed that the left and right-handed $\tilde{u}$, $\tilde{d}$, $\tilde{s}$ and $\tilde{c}$ squarks are degenerate in mass. Furthermore, it is assumed that the mass of the gluino is very high (above 10 TeV) and thus contributions of the corresponding t-channel diagrams to squark pair production are negligible. Therefore, the total production cross section

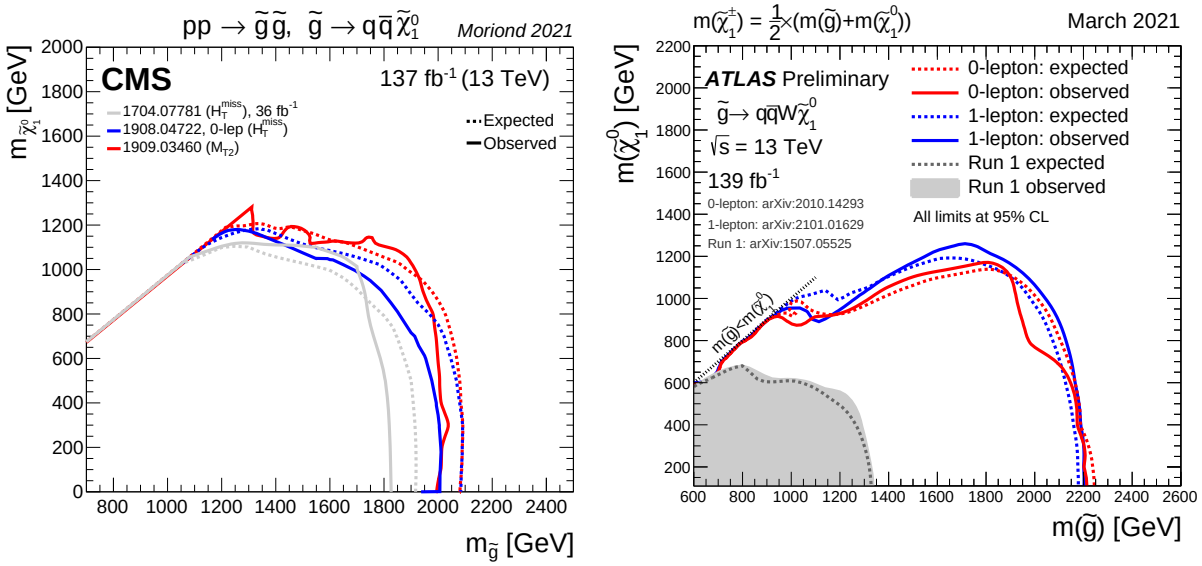

Figure 89.3: Lower mass limits, at 95% C.L., on gluino pair production for various decay chains in the framework of simplified models. Left: $\tilde{g} \to q\bar{q}\tilde{\chi}_1^0$, result of the CMS collaboration. Right: $\tilde{g} \to q\bar{q}W\tilde{\chi}_1^0$, result of the ATLAS collaboration.

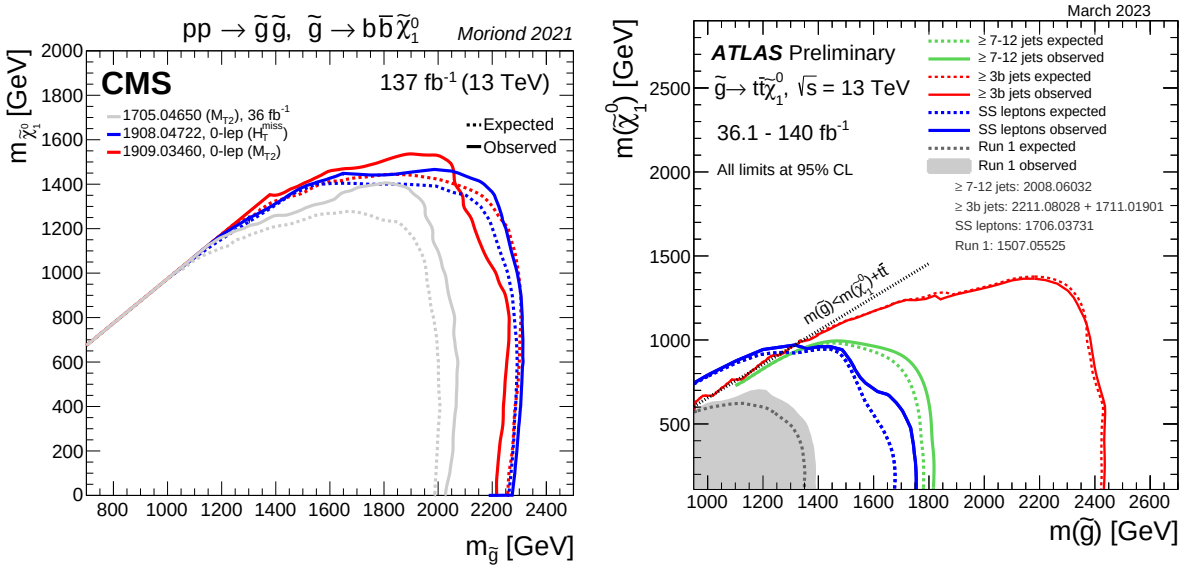

Figure 89.4: Lower mass limits, at 95% C.L., on gluino pair production for various decay chains in the framework of simplified models. Left: $\tilde{g} \to b\bar{b}\tilde{\chi}_1^0$. Right: $\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$. Results from the CMS and ATLAS collaborations.

for this simplified model is eight times the production cross section of an individual squark (e.g. $\tilde{u}_L$). Under these assumptions, CMS obtains a lower squark mass limit of ≈ 1.75 TeV for light neutralinos [85], as shown in Fig. 89.5 (left). Only for neutralino masses below ≈ 800 GeV can any squark masses be excluded. Searches for new physics in monojet channels are sensitive to very compressed scenarios, and masses up to 900 GeV are excluded for $\Delta m = m_{\tilde{q}}, m_{\tilde{\chi}_1^0} \approx 5$ GeV [87].

If the assumption of mass degenerate first and second generation squarks is dropped and only the production of a single light squark is assumed, the limits weaken significantly. For example, the CMS limit on degenerate squarks of 1750 GeV for light neutralinos drops to ≈ 1300 GeV for pair production of a single light squark, and for neutralinos heavier than ≈ 600 GeV no squark mass limit can be placed. It should be noted that this limit is not a result of a simple scaling of the above mentioned mass limits assuming eight-fold mass degeneracy but it also takes into account that for an eight times lower production cross section the analyses must probe kinematic regions of phase space that are closer to the ones of SM background production.

A summary of results of the ATLAS searches also targeting more complicated decay chains, where e.g. intermediate bosons are produced as well, can be seen in Fig. 89.5 (right). Depending on the topology, the exclusion limit can reach up to ≈ 2 TeV (this value is only reached in gaugino-mediated simplified models [88]). Recent results include a search in two-opposite-sign, same=flavor dilepton final state events [89] targeting squarks decaying through the next-to-lightest neutralino via a slepton or a Z boson and exclude mass up to ≈ 1550 GeV for a massless neutralino. Squarks decaying via charginos and next-to-lightest neutralinos in long decay chains including W and Z bosons are constrained with searches for same-sign dilepton or three-lepton final state events [90]: in this case, masses up to ≈ 1.7 TeV are excluded.

For single light squarks ATLAS also reports results of a dedicated search for pair production of scalar partners of charm quarks [91]. Assuming that the scalar-charm state exclusively decays into a charm quark and a neutralino, scalar-charm masses

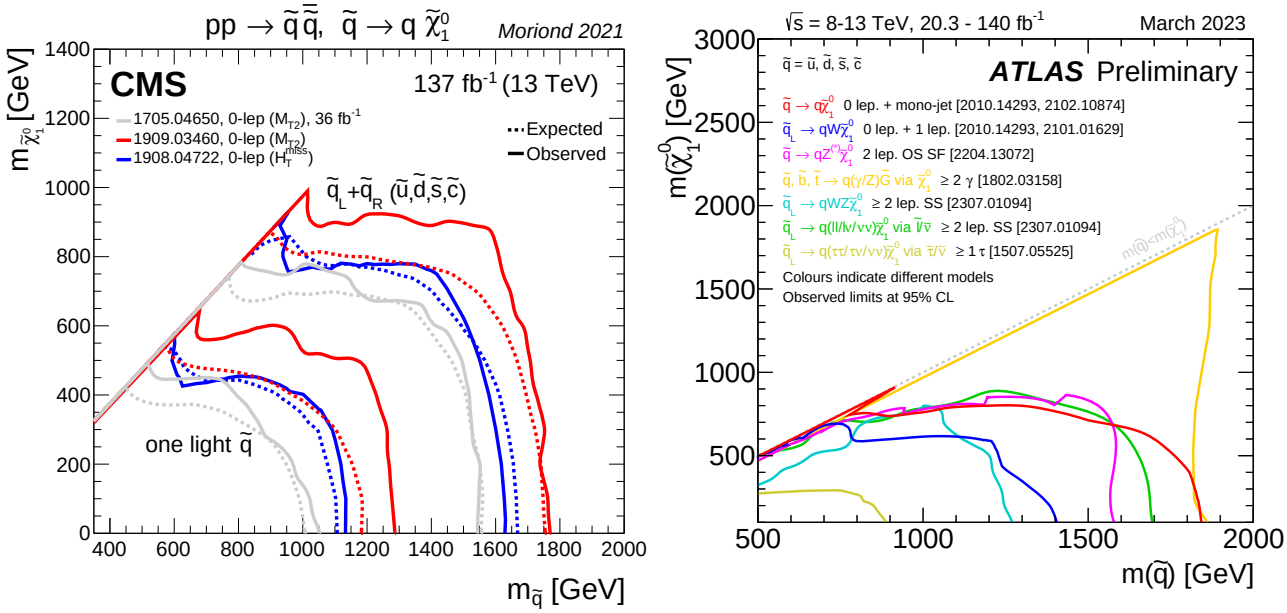

Figure 89.5: Left: 95% C.L. exclusion contours in the framework of simplified models assuming a single decay chain of $\tilde{q} \to q\tilde{\chi}_1^0$, obtained by the CMS collaboration. Right: Assuming more complicated decay chains including W or Z bosons, obtained by the ATLAS collaboration.

up to 800 GeV are excluded for neutralino masses below 260 GeV.

Table 89.1: Summary of squark mass and gluino mass limits using different interpretation approaches assuming R-parity conservation. Masses in this table are provided in GeV. Further details about the assumptions and analyses from which these limits are obtained are discussed in the corresponding sections of the text.

Model	Assumption	$m_{\tilde{q}}$	$m_{\tilde{g}}$
Simplified models $\tilde{g}\tilde{g}$			
$\tilde{g} \to q\bar{q}\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	-	≈ 2300
	$m_{\tilde{\chi}_1^0} > \approx 1200$	-	no limit
$\tilde{g} \to b\bar{b}\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	-	≈ 2440
	$m_{\tilde{\chi}_1^0} > \approx 1600$	-	no limit
$\tilde{g} \to t\bar{t}\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	-	≈ 2400
	$m_{\tilde{\chi}_1^0} > \approx 1400$	-	no limit
Simplified models $\tilde{q}\bar{q}$			
$\tilde{q} \to q\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	≈ 1900	-
	$m_{\tilde{\chi}_1^0} > \approx 800$	no limit	-
$\tilde{u}_L \to q\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} = 0$	≈ 1300	-
	$m_{\tilde{\chi}_1^0} > \approx 600$	no limit	-

A summary of the most important squark and gluino mass limits for different interpretation approaches assuming R-parity conservation is shown in Table 89.1. For gluino masses rather similar limits of about 2.3 – 2.4 TeV are obtained from different model assumptions, indicating that the LHC is indeed probing direct gluino production at the TeV scale and beyond. However, for neutralino masses above approximately 1.2 to 1.6 TeV, even in the best case scenarios, ATLAS and CMS searches do not place any limits on the gluino mass. Limits on direct squark production, on the other hand, depend strongly on the chosen model. For neutralino masses above ≈ 600 GeV no limits on any direct squark pair production scenario are placed by the LHC.

89.6 Exclusion limits on bottom and top squarks masses in RPC scenarios

Besides placing stringent limits on first and second generation squark masses, the LHC experiments also search for the production of third generation squarks. SUSY at the TeV-scale is often motivated by naturalness arguments, most notably as a solution to cancel quadratic divergences in radiative corrections to the Higgs boson mass. In this context, the most relevant terms for SUSY phenomenology arise from the interplay between the masses of the third generation squarks and the Yukawa coupling of the top quark to the Higgs boson. This motivates a potential constraint on the masses of the top squarks and the left-handed bottom squark. Due to the large top quark mass, significant mixing between $\tilde{t}_L$ and $\tilde{t}_R$ is expected, leading to a lighter mass state $\tilde{t}_1$ and a heavier mass state $\tilde{t}_2$. In the MSSM, the lightest top squark ($\tilde{t}_1$) can be the lightest squark.

Bottom squarks are expected to decay predominantly to $b\tilde{\chi}_1^0$ giving rise to the characteristic multi b-jet and E_T^{miss} signature. Direct production of bottom squark pairs has been searched for at the Tevatron and at the LHC. Limits from the Tevatron are $m_{\tilde{b}} > 247$ GeV for a massless neutralino [92,93]. ATLAS has set a lower limit of $m_{\tilde{b}} > 1250$ GeV for massless neutralinos in this model [94] exploiting the two b-jets and missing transverse momentum analysis. For $m_{\tilde{\chi}_1^0} \approx 800$ GeV or higher no limit can be placed on direct bottom squark pair production in this simplified model. Limits from CMS are comparable [85]. Reinterpretations of the monojet analysis results can be used to constrain very compressed scenarios, with exclusion of masses up to 550 GeV in case of $\Delta m = m_{\tilde{b}} - m_{\tilde{\chi}_1^0} \approx 5$ GeV [87]. Further bottom squark decay modes have also been searched for by ATLAS [95–97] and CMS [77,98,99], for instance targeting more complex decay chains that include Higgs bosons in the cascade.

The top squark decay modes depend on the SUSY mass spectrum, and on the $\tilde{t}_L$-$\tilde{t}_R$ mixture of the top squark mass eigenstate. If kinematically allowed, the two-body decays $\tilde{t} \to t\tilde{\chi}_1^0$ (which requires $m_{\tilde{t}} - m_{\tilde{\chi}_1^0} > m_t$) and $\tilde{t} \to b\tilde{\chi}^{\pm}$ (which requires $m_{\tilde{t}} - m_{\tilde{\chi}^{\pm}} > m_b$) are expected to dominate. If not, the top squark decay may proceed either via the two-body decay $\tilde{t} \to c\tilde{\chi}_1^0$ or through $\tilde{t} \to bf\bar{f}'\tilde{\chi}_1^0$ (where f and $\bar{f}'$ denote a fermion-antifermion pair with appropriate quantum numbers). For $m_{\tilde{t}} - m_{\tilde{\chi}_1^0} > m_b$ the latter decay chain represents a four-body decay with a W boson,

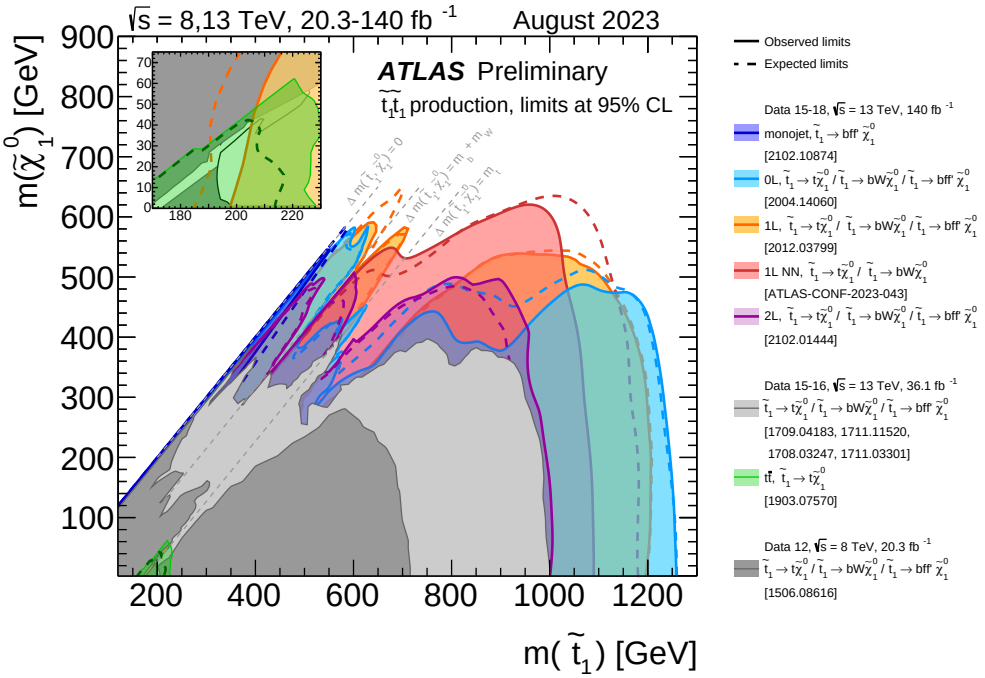

Figure 89.6: A summary of the 95% C.L. exclusion contours in the stop-neutralino mass plane for various possible decay chains, including two-, three- and four-body decays, as obtained in dedicated analyses by ATLAS.

charged Higgs $H^{\pm}$, slepton $\tilde{\ell}$, or light flavor squark $\tilde{q}$, exchange. If the exchanged W boson and/or sleptons are kinematically allowed to be on-shell, the three-body decays $\tilde{t} \to Wb\tilde{X}_1^0$ and/or $\tilde{t} \to b\nu\tilde{\ell}(\tilde{\nu}\ell)$ will become dominant. For further discussion on top squark decays see for example Ref. [100].

Limits from LEP on the $\tilde{t}_1$ mass are $m_{\tilde{t}} > 96$ GeV in the charm plus neutralino final state, and > 93 GeV in the lepton, b-quark and sneutrino final state [73].

The Tevatron experiments have performed a number of searches for top squarks, often assuming direct pair production. In the $b\ell\tilde{\nu}$ decay channel, and assuming a 100% branching fraction, limits are set as $m_{\tilde{t}} > 210$ GeV for $m_{\tilde{\nu}} < 110$ GeV and $m_{\tilde{t}} - m_{\tilde{\nu}} > 30$ GeV, or $m_{\tilde{t}} > 235$ GeV for $m_{\tilde{\nu}} < 50$ GeV [101, 102]. In the $\tilde{t} \to c\tilde{X}_1^0$ decay mode, a top squark with a mass below 180 GeV is excluded for a neutralino lighter than 95 GeV [103, 104]. In both analyses, no limits on the top squark can be set for heavy sneutrinos or neutralinos. In the $\tilde{t} \to b\tilde{X}_1^{\pm}$ decay channel, searches for a relatively light top squark have been performed in the dilepton final state [105, 106]. The CDF experiment sets limits in the $\tilde{t} - \tilde{X}_1^0$ mass plane for various branching fractions of the chargino decay to leptons and for two values of $m_{\tilde{X}_1^{\pm}}$. For $m_{\tilde{X}_1^{\pm}} = 105.8$ GeV and $m_{\tilde{X}_1^0} = 47.6$ GeV, top squarks between 128 and 135 GeV are excluded for W-like leptonic branching fractions of the chargino.

The LHC experiments have improved these limits substantially and developed dedicated searches for all potential top-squark decay mode. This is well depicted in Fig. 89.6, where a summary of the limits on the top squark mass are reported for the single decay chain of $\tilde{t} \to t\tilde{X}_1^0$ as well as for the three-body and four-body decay modes. Interpretations are carried out in simplified models hence care must be taken when interpreting these limits in the context of more complete SUSY models.

The most important searches for the top squark decay topology are dedicated searches requiring zero or one isolated lepton, modest $E_{\mathrm{T}}^{\mathrm{miss}}$, and four or more jets out of which at least one jet must be reconstructed as a b-jet [52, 77, 85, 86, 107–109]. For example, using an all-hadronic analysis, CMS excludes top squarks with masses below about 1300 GeV in this model for light neutralinos, while for $m_{\tilde{X}_1^0} > 700$ GeV no limits can be provided [86]. Equivalent constraints are set by the ATLAS all-hadronic search [107].

Analyses targeting final state events characterised by the presence of one lepton (electron or muon) have similar albeit lower sensitivity in the $\tilde{t} \to t\tilde{X}_1^0$ decay mode, see for instance the recent ATLAS result [109] using NN methods.

Single and di-lepton analyses are most sensitive to models where the top squark decay exclusively proceeds via the chargino mediated decay chain $\tilde{t} \to b\tilde{X}_1^{\pm}$, $\tilde{X}_1^{\pm} \to W^{\pm(*)}\tilde{X}_1^0$. In this case, top squark mass exclusion limits vary strongly with the assumptions made on the $\tilde{t} - \tilde{X}_1^{\pm} - \tilde{X}_1^0$ mass hierarchy. For example, for $m_{\tilde{X}_1^{\pm}} = (m_{\tilde{t}} + m_{\tilde{X}_1^0})/2$, a stop mass below ≈ 1150 GeV for a light $\tilde{X}_1^0$ is excluded by CMS, while no limit can be placed for $m_{\tilde{X}_1^0} > 550$ GeV [52]. These limits, however, can weaken significantly when other assumptions about the mass hierarchy or the decay of the charginos are imposed [52, 110–112].

Other analyses with zero, one or two leptons target this kinematic region [113–119], also providing sensitivity in the case of alternative decay modes of the top squark, *i.e.* including tau sleptons [112, 120–122] or Higgs and Z bosons in the decay chain [123].

If the decays $\tilde{t} \to t\tilde{X}_1^0$ and $\tilde{t} \to b\tilde{X}_1^{\pm}$, $\tilde{X}_1^{\pm} \to W^{\pm(*)}\tilde{X}_1^0$ are kinematically forbidden, the decay chains $\tilde{t} \to Wb\tilde{X}_1^0$ and $\tilde{t} \to c\tilde{X}_1^0$ can become important. The one-lepton ATLAS search [108] provides for the kinematic region $m_{\tilde{t}} - m_{\tilde{X}^{\pm}} > m_b + m_W$ lower limits on the top squark mass of ≈ 700 GeV for a neutralino lighter than ≈ 570 GeV, as also shown in Fig. 89.6. For the kinematic region in which even the production of real W bosons is not allowed, ATLAS and CMS improve the Tevatron limit on $\tilde{t} \to c\tilde{X}_1^0$ substantially. Based on a monojet analysis [87] ATLAS excludes top squark masses below $m_{\tilde{X}_1^0} \approx 550$ GeV along the kinematic boundary for the $\tilde{t} \to c\tilde{X}_1^0$ decay. The ATLAS monojet analysis also places similar boundaries for the other decay chain relevant in this phase region, $\tilde{t} \to bff'\tilde{X}_1^0$. Other analyses, such as the search in events with one leptons and jets, are also sensitive to this decay mode: the ATLAS one-lepton analysis excludes up to ≈ 650 GeV for $\Delta m = m_{\tilde{t}}, m_{\tilde{X}_1^0} \approx 50$ GeV [108]. The CMS collaboration uses the hadronic searches [86, 114, 116] to place constraints on stop decay into charm-quark and excludes $m_{\tilde{t}} \approx 630$ GeV for $\Delta m = m_{\tilde{t}}, m_{\tilde{X}_1^0} \approx 50$ GeV [86]. Constraints are also set in case of

$\tilde{t} \to bf\bar{f}'\tilde{\chi}_1^0$, with CMS excluding masses up to 480 and 700 GeV for $\Delta m = m_{\tilde{t}}, m_{\tilde{\chi}_1^0} \approx 10$ and 80 GeV, respectively [124].

Table 89.2: Summary of bottom and top squark mass limits using different interpretation approaches assuming R-parity conservation. Masses in this table are provided in GeV. Further details about the assumptions and analyses from which these limits are obtained are discussed in the corresponding sections of the text.

Model	Assumption	$m_{\tilde{q}}$
$\tilde{b} \to b\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0}$ =0	$\approx$ 1250
	$m_{\tilde{\chi}_1^0} > \approx$ 700	no limit
$\tilde{t} \to t\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0}$ =0	$\approx$ 1300
	$m_{\tilde{\chi}_1^0} > \approx$ 600	no limit
$\tilde{t} \to b\tilde{\chi}_1^\pm$	$m_{\tilde{\chi}_1^0}$ =0	$\approx$ 1150
$(m_{\tilde{\chi}_1^\pm} = (m_{\tilde{t}} - m_{\tilde{\chi}_1^0})/2)$	$m_{\tilde{\chi}_1^0} > \approx$ 550	no limit
$\tilde{t} \to Wb\tilde{\chi}_1^0$	$m_{\tilde{\chi}_1^0} < \approx$ 570	$\approx$ 700
$(m_W < m_{\tilde{t}} - m_{\tilde{\chi}^0} < m_t)$		
$\tilde{t} \to c\tilde{\chi}_1^0$	$m_{\tilde{t}} - m_{\tilde{\chi}_1^0} \approx 50$	$\approx$ 630
	$m_{\tilde{t}} \approx m_{\tilde{\chi}_1^0}$	$\approx$ 550
$\tilde{t} \to bff'\tilde{\chi}_1^0$	$m_{\tilde{t}} - m_{\tilde{\chi}_1^0} \approx 50$	$\approx$ 650
$(m_{\tilde{t}} - m_{\tilde{\chi}^0} < m_W)$	$m_{\tilde{t}} \approx m_{\tilde{\chi}_1^0}$	$\approx$ 550

In general, the variety of top squark decay chains in the phase space region where $\tilde{t} \to t\tilde{\chi}_1^0$ is kinematically forbidden represents a challenge for the experimental search program but more data and refined analyses in Run 2 have further improved the sensitivity in this difficult but important region of SUSY parameter space, and more is expected for future Runs of the LHC. Precision SM measurements can also provide important insights to such challenging regions. For instance, analyses of $t\bar{t}$ spin correlations can be used to set constraints on top squark masses close to the top-quark mass. ATLAS [125] excludes the mass region between 150 and 230 GeV for kinematically allowed values of the neutralino mass. CMS [126] results cover a similar mass range.

89.7 Exclusion limits on the masses of charginos, neutralinos and sleptons in RPC scenarios

Charginos, neutralinos and sleptons are produced through electroweak interactions and their cross sections depend on the assumptions made for mass and mixing parameters.

Charginos and neutralinos carry no color charge and the mixing of the charged wino and higgsino states (for charginos), and the neutral bino, wino and higgsino states (for neutralinos), is determined by a limited number of parameters. For charginos these are the wino mass parameter M_2, the higgsino mass parameter μ, and $\tan\beta$, and for neutralinos these are the same parameters plus the bino mass parameter M_1. If one of the parameters M_1, M_2 or μ is substantially smaller than the others, the chargino/neutralino composition would be dominated by specific states, which are referred to as bino-like ($M_1 \ll M_2, \mu$), wino-like ($M_2 \ll M_1, \mu$), or higgsino-like ($\mu \ll M_1, M_2$). If gaugino mass unification at the GUT scale is assumed, a relation between M_1 and M_2 at the electroweak scale follows: $M_1 = 5/3 \tan^2\theta_W M_2 \approx 0.5 M_2$, with θ_W the weak mixing angle. The largest production rates at hadron machines are obtained when the LSP is bino-like and the lightest chargino and next-to-lightest neutralino are wino-like, forming an approximately mass degenerate SU(2) triplet. If the higgsino mass is much smaller than the gaugino masses, the two lightest neutralinos and the lightest chargino form an approximately mass degenerate Dirac SU(2) doublet, production rates are lower and the mass spectrum is compressed.

In models with slepton and gaugino mass unification at the GUT scale, the superpartner of the right-handed lepton, $\tilde{\ell}_R$, is expected to be lighter than the left-handed one, $\tilde{\ell}_L$. Cross sections depend on the L-R mixing which in turn depends on the mass of the fermion and other parameters. For tau sleptons there may be considerable mixing between the L and R states, leading to a significant mass difference between the lighter $\tilde{\tau}_1$ and the heavier $\tilde{\tau}_2$.

Fig. 89.7 [127,128] (see also Ref. [74] for further details) shows typical production cross sections at hadron colliders for electroweakinos under various assumptions and considering a center-of-mass energy of 13 TeV. For masses of several hundreds of GeV, they are at least two orders of magnitude smaller than for colored SUSY particles. Thanks to the large data samples collected at the LHC, the sensitivity of LEP and Tevatron searches for direct chargino/neutralino or slepton production has been surpassed in several regions of SUSY parameter space.

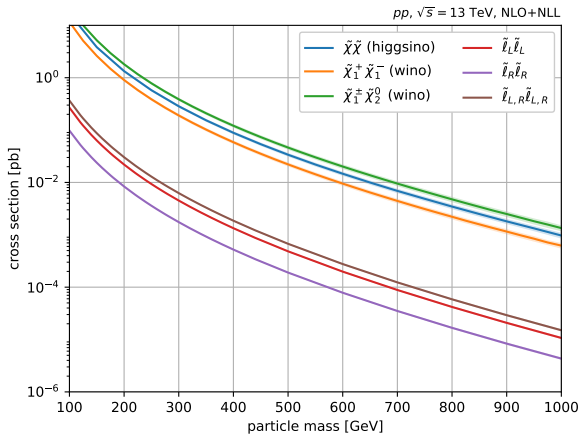

Figure 89.7: Cross sections for pair production of charginos, neutralinos and sleptons calculated for 13 TeV centre-of-mass energy at NLO plus next-to-leading-log (NLL) precision. Wino-like $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ and $\tilde{\chi}_1^+\tilde{\chi}_1^-$ productions are calculated in a limit of mass-degenerate $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$, light bino $\tilde{\chi}_1^0$, and with all the other sparticles assumed to be heavy and decoupled. Higgsino-like cross sections assume mass-degenerate $\tilde{\chi}_1^\pm$, $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^0$. For slepton pair cross sections, left(right)-handed only or 50% mixed states are considered.

89.7.1 *Exclusion limits on chargino masses*

The lightest chargino $\tilde{\chi}_1^\pm$ is searched for either considering pair production, or through associated production of $\tilde{\chi}_1^\pm$ and the next-to-lightest neutralino, $\tilde{\chi}_2^0$, if they are assumed to be degenerate in mass. If kinematically allowed, two body decay modes such as $\tilde{\chi}^\pm \to \tilde{f}\bar{f}'$ (including $\ell\tilde{\nu}$ and $\tilde{\ell}\nu$) are dominant. If not, three-body decays $\tilde{\chi}^\pm \to f\bar{f}'\tilde{\chi}_1^0$, mediated through virtual W bosons or sfermions, become dominant. If sfermions are heavy, the W mediation dominates, and $f\bar{f}'$ are distributed with branching fractions similar to W decay products (barring phase space effects for small mass gaps between $\tilde{\chi}^\pm$ and $\tilde{\chi}^0$). If, on the other hand, sleptons are light enough to play a significant role in the decay, leptonic final states will be enhanced.

At LEP, $\tilde{\chi}_1^+\tilde{\chi}_1^-$ is the dominant production process. Charginos have been searched for in fully-hadronic, semi-leptonic and fully leptonic decay modes [129, 130]. A general lower limit on the lightest chargino mass of 103.5 GeV is derived, except in corners of phase space with low electron sneutrino mass, where destructive interference in chargino production, or two-body decay modes, play a role. The limit is also affected if the mass difference between $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ is small; dedicated searches for such scenarios set a lower limit of 92 GeV.

At the Tevatron, charginos have been searched for via associated production of $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ [131, 132]. Decay modes involving multilepton final states provide the best discrimination against the large multijet background. Analyses have looked for at least three charged isolated leptons, for two leptons with missing transverse momentum, or for two leptons with the same charge. Depending

on the $(\tilde{\chi}_1^\pm - \tilde{\chi}_1^0)$ and/or $(\tilde{\chi}_2^0 - \tilde{\chi}_1^0)$ mass differences, leptons may have soft transverse momentum.

At the LHC, the search strategy is similar to that at the Tevatron but it also exploits the large datasets collected to target missing momentum and fully-hadronic final states and consider $\tilde{\chi}_1^+\tilde{\chi}_1^-$ production only i.e. releasing the assumption of $\tilde{\chi}_1^\pm, \tilde{\chi}_2^0$ mass degeneracy. Furthermore, compressed SUSY spectra are searched for considering low-momentum leptons recoiling against an ISR jet.

Chargino pair production is searched for in the dilepton plus missing momentum final state. In a simplified model interpretation of the results where only the $\tilde{\chi}_1^+\tilde{\chi}_1^-$ process is considered and assuming mediation of the chargino decay by light sleptons ($\tilde{e}$ and $\tilde{\mu}$), ATLAS [133] and CMS [134] set limits on the chargino mass up to 1 TeV for massless LSPs, but no limits on the chargino mass can be set for $\tilde{\chi}_1^0$ heavier than 480 GeV. Limits are fairly robust against variation of the slepton mass, unless the mass gap between sparticles becomes small enough that the charged lepton has a too low-momentum to be reconstructed. For decays mediated through $\tilde{\tau}$ or $\tilde{\nu}_\tau$, limits of 630 GeV are set by ATLAS [135] for LSPs not heavier than 200 GeV. The CMS experiment provides similar limits [136].

In case slepton masses are higher than the mass of the chargino, searches are performed for charginos decaying via a W boson. ATLAS sets limits on this kind of simplified models [133] for pure-wino charginos: masses below 420 GeV are excluded for massless LSPs, but no limits are set for LSPs heavier than 120 GeV. In the challenging case where the difference between chargino and LSP masses is close to that of the W boson, dedicated searches have been carried out by ATLAS [137], excluding chargino masses up to 140 GeV. Searches have also been carried out in the single lepton final state. ATLAS excludes chargino masses between 260 and 520 GeV for a massless LSP [138].

Further extension of the sensitivity in the high-mass region is achieved by ATLAS [139] and CMS [140] exploiting the large branching ratio of fully-hadronic final states and the identification of boosted W bosons through large-radius jets and jet substructure information. Considering only wino-like chargino pair production in case of a massless LSP, ATLAS excludes a region between 630 GeV and 760 GeV, while CMS excludes between 290 GeV and 670 GeV. No limits are set for LSP masses above 200 GeV.

Several final states characterised by the presence of missing transverse momentum are studied to set limits on the chargino mass through $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ associated production. Usually, wino-like $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ and bino-like $\tilde{\chi}_1^0$ are assumed with $m_{\tilde{\chi}_1^\pm} = m_{\tilde{\chi}_2^0}$, leaving $m_{\tilde{\chi}_1^\pm}$ and $m_{\tilde{\chi}_1^0}$ free. Again, the branching fraction of leptonic final states is determined by the slepton masses. If the decay is predominantly mediated by a light $\tilde{\ell}_\mathrm{L}$, i.e. $\tilde{\ell}_\mathrm{R}$ is assumed to be heavy, the three charged-lepton flavors will be produced in equal amounts, and a multi-lepton signature is favored. It is assumed that $\tilde{\ell}_\mathrm{L}$ and sneutrino masses are equal, and diagrams with sneutrinos are included. In this scenario, ATLAS [141] and CMS [142] exclude chargino masses below 1450 GeV for massless LSPs; no limits are set for LSP masses above 1 TeV. If the decay is dominated by a light $\tilde{\ell}_\mathrm{R}$, the chargino cannot be a pure wino but needs to have a large higgsino component, preferring the decays to tau leptons. Limits are set in various scenarios. If, like for $\tilde{\ell}_\mathrm{L}$, a flavor-democratic scenario is assumed (τ-enriched scenario), CMS sets limits of 1150 GeV on the chargino mass for massless LSPs, but under the assumption that both $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ decay leads to tau leptons in the final state (τ-dominated scenario), the chargino mass limit deteriorates to 970 GeV for massless LSPs [142]. ATLAS assumes a simplified model in which staus are significantly lighter than the other sleptons and search for a similar multi-tau final state, setting a lower limit on the chargino mass of 760 GeV in this model [135].

If sleptons are heavy, the chargino is assumed to decay to a W boson plus LSP, and the $\tilde{\chi}_2^0$ into Z plus LSP (WZ searches) or H plus LSP (WH searches). Searches for the WZ channel exploit events with either two same-sign leptons or three leptons, a single lepton, or with no leptons (all-hadronic). If $\tilde{\chi}_2^0$ decays through a Higgs boson with $m_H = 125$ GeV, search strategies depend on the SM-like Higgs decay modes and branching fractions. Higgs bosons in the final state are identified by either two jets originating from bottom quarks ($h \to b\bar{b}$), two photons ($h \to \gamma\gamma$), or leptons from the WW, ZZ or $\tau\tau$ decay modes. Interpretations are also provided in scenarios where the $\tilde{\chi}_2^0$ does not decay exclusively into a Z or H boson and the LSP.

ATLAS has searched for $\tilde{\chi}_1^\pm\tilde{\chi}_2^0$ production in events with three leptons and missing momentum and wino-like chargino masses below 640 GeV are excluded for massless LSPs [143]. Results have also been reported for searches including same-sign lepton signal regions [144] and single lepton searches [138]. Limits are reduced in case of higgsino-like scenarios, with exclusion down to 210 GeV. CMS [142] excludes chargino masses below 650 GeV for massless LSPs using events with two leptons of the same sign, or with three or more leptons targeting final states with W and Z bosons. No constraints are set for $\tilde{\chi}_1^0$ masses above 300 GeV.

Additional constraints on the chargino mass are placed exploiting all-hadronic analyses. A wino-like (higgsino-like) chargino with mass up to 1060 (900) GeV is excluded by ATLAS [139] when the LSP mass is below 400 (240) GeV and the mass splitting is larger than 400 (450) GeV. CMS [140] excludes wino-like charginos with mass up to 970 GeV for massless LSP.

Searches exploiting the presence of b-jets are most sensitive in the high-mass chargino region if $\tilde{\chi}_2^0$ decays through a Higgs boson, while analyses targeting photon pair or leptonic decays provide the best sensitivity in the region of low masses. CMS [145] sets lower limits on the chargino mass up to 820 GeV for massless LSPs, but vanish for LSP masses above 350 GeV using events with at least one lepton and missing transverse momentum in the final state. Similar sensitivity is achieved by the ATLAS analyses [146–148].

In both the wino region (a characteristic of anomaly-mediated SUSY breaking models) and the higgsino region of the MSSM, the mass splitting between $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_1^0$ is small. The chargino decay products are very soft and may escape detection. These compressed spectra are hard to detect, and have triggered dedicated search strategies. ATLAS [149] and CMS [150] have performed searches for charginos and neutralinos in a compressed mass spectrum using initial state radiation and two or three low-momentum (soft) leptons. For wino-like charginos, assuming degenerate $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$, exclusion contours in the chargino-mass versus $\Delta m(\tilde{\chi}_1^\pm - \tilde{\chi}_1^0)$ plane are derived. As an example, such charginos are excluded by CMS (ATLAS) below 280 (240) GeV for $\Delta m(\tilde{\chi}_1^\pm - \tilde{\chi}_1^0) = 10$ GeV. Considering the higgsino model, the masses probed by CMS reach up to 215 GeV for a mass difference of 7.5 GeV and 150 GeV in the highly compressed region with a mass difference of 3 GeV. CMS has also searched for chargino-pair production through vector-boson-fusion [151], also targeting compressed mass spectra. Assuming degenerate $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$, charginos with a mass below 112 GeV are excluded for $\Delta m(\tilde{\chi}_1^\pm - \tilde{\chi}_1^0) = 1$ GeV. CMS has published further searches for such compressed spectra with a soft tau lepton [152].

89.7.2 *Exclusion limits on neutralino masses*

In a considerable part of the MSSM parameter space, and in particular when demanding that the LSP carries no electric or color charge, the lightest neutralino $\tilde{\chi}_1^0$ is the LSP. If R-parity is conserved, such a $\tilde{\chi}_1^0$ is stable. Since it is weakly interacting, it will typically escape detectors unseen. Limits on the invisible width of the Z boson apply to neutralinos with a mass below 45.5 GeV, but depend on the Z-neutralino coupling. Such a coupling could be small or even absent; in such a scenario there is no general lower limit on the mass of the lightest neutralino [153]. In models with gaugino mass unification and sfermion mass unification at the GUT scale, a lower limit on the neutralino mass is derived from limits from direct searches, notably for charginos and sleptons, and amounts to 47 GeV [154]. Assuming a constrained model like the CMSSM, this limit increases to 50 GeV at LEP; however the strong constraints now set by the LHC increase such CMSSM-derived $\tilde{\chi}_1^0$ mass limits to well above a few hundred GeV (the latest reinterpretation only uses Run 1 data and indicates 200 GeV [155–

157]).

In gauge-mediated SUSY breaking models (GMSB), the LSP is typically a gravitino, and the phenomenology is determined by the nature of the next-to-lightest supersymmetric particle (NLSP). A NLSP neutralino will decay to a gravitino and a SM particle whose nature is determined by the neutralino composition. Final states with two high p_{T} photons and missing momentum are searched for, and interpreted in gauge mediation models with bino-like neutralinos [158–164].

Assuming the production of at least two neutralinos per event, neutralinos with large non-bino components can also be searched for by their decay in final states with missing momentum plus any two bosons out of the collection γ, Z, H. A number of searches at the LHC have tried to cover the rich phenomenology predicted by the general gauge mediation model (GGM) where $\tilde{\chi}_1^0$ might decay with various BR in the Z and H decay modes [98, 147, 161, 165–175]. As an example, strong constraints for decay modes involving Z and H bosons arise from full-hadronic searches on higgsino-like scenarios: ATLAS [139] excludes higgsino production with decays into a massless gravitino LSP in a mass range between 450 (500) GeV and 940 (850) GeV assuming BR = 1 (0.5) for the Z plus gravitino decay mode. Assuming only H plus gravitino decays, CMS [176] excludes a higgsino mass range between 175 GeV and 1025 GeV. Assuming a mix of γ, Z, H decays, a CMS search [164] in the photonic final state excludes higgsinos up to 1.05 TeV.

Heavier neutralinos, in particular $\tilde{\chi}_2^0$, have been searched for in their decays to the lightest neutralino plus a γ, a Z boson or a Higgs boson. Limits on electroweak production of $\tilde{\chi}_2^0$ plus $\tilde{\chi}_1^\pm$ from all-hadronic, same-sign dilepton and trilepton analyses have been discussed in the section on charginos; the assumption of equal mass of $\tilde{\chi}_2^0$ and $\tilde{\chi}_1^\pm$ make the limits on chargino masses apply to $\tilde{\chi}_2^0$ as well. Multilepton analyses have also been used to set limits on $\tilde{\chi}_2^0\tilde{\chi}_3^0$ production; assuming equal mass and decay through light sleptons, limits are set up to 680 GeV for massless LSPs [177]. Again, compressed spectra with small mass differences between the heavier neutralinos and the LSP form the most challenging region.

In $\tilde{\chi}_2^0$ decays to $\tilde{\chi}_1^0$ and a lepton pair, the lepton pair invariant mass distribution may show a structure that can be used to measure the $\tilde{\chi}_2^0 - \tilde{\chi}_1^0$ mass difference in case of a signal [38]. This structure, however, can also be used in the search strategy itself, as demonstrated by ATLAS [178, 179] and CMS [98, 180].

Fig. 89.8 summarizes some of the most recent results from ATLAS and CMS for chargino pair or chargino and next-to-lightest neutralino pair productions comparing results obtained with various assumptions. The limits on weak gauginos in simplified models are also summarized in Table 89.3. Only results for promptly decaying charginos and neutralinos are included: limits from searches focusing on long-lived particle scenarios are reported in Section 89.9. A combination of several searches for the electroweak production of winos, binos, higgsinos, and sleptons has also been recently been presented by CMS [181].

Interpretations of the search results outside simplified models, such as in the phenomenological MSSM [182–187], show that the simplified model limits can translate into accurate constraints but must also be interpreted with care. Electroweak gauginos in models that are compatible with the relic density of dark matter in the Universe, for example, have particularly tuned mixing parameters and mass spectra, which are not always captured by the simplified models used.

Table 89.3: Summary of weak gaugino mass limits in simplified models, assuming R-parity conservation. Masses in the table are provided in GeV. Further details about assumptions and corresponding analyses are discussed in the text. Details on constraints for compressed scenarios from soft-lepton searches are not represented in the table.

Assumption	m_χ
$\tilde{\chi}_1^\pm$, all $\Delta m(\tilde{\chi}_1^\pm, \tilde{\chi}_1^0)$	> 92
$\tilde{\chi}_1^\pm$ $\Delta m > 5$, $m_{\tilde{\nu}} > 300$	> 103.5
$\tilde{\chi}_1^\pm$, $m_{(\tilde{\ell},\tilde{\nu})} = (m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_1^0})/2$	
$m_{\tilde{\chi}_1^0} \approx 0$	> 1000
$\tilde{\chi}_1^\pm$, $m_{\tilde{\chi}_1^0} > 480$	no LHC limit
$\tilde{\chi}_1^\pm$, $m_{\tilde{\ell}} > m_{\tilde{\chi}_1^\pm}$	
$m_{\tilde{\chi}_1^0} \approx 0$	> 420 and $290 - 760$
$\tilde{\chi}_1^\pm$, $m_{\tilde{\chi}_1^0} > 120$	no LHC limit
$m_{\tilde{\chi}_1^\pm} = m_{\tilde{\chi}_2^0}$, $m_{\tilde{\ell}_{\mathrm{L}}} = (m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_1^0})/2$	
$m_{\tilde{\chi}_1^0} \approx 0$	> 1450
$m_{\tilde{\chi}_1^0} > 1000$	no LHC limit
$m_{\tilde{\chi}_1^\pm} = m_{\tilde{\chi}_2^0}$, $m_{\tilde{\ell}_{\mathrm{R}}} = (m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_1^0})/2$	flavor-democratic
$m_{\tilde{\chi}_1^0} \approx 0$	> 1150
$m_{\tilde{\chi}_1^0} > 700$	no LHC limit
$m_{\tilde{\chi}_1^\pm} = m_{\tilde{\chi}_2^0}$, $m_{\tilde{\tau}} = (m_{\tilde{\chi}_1^\pm} + m_{\tilde{\chi}_1^0})/2$	$\tilde{\tau}$-dominated
$m_{\tilde{\chi}_1^0} \approx 0$	> 970
$m_{\tilde{\chi}_1^0} > 450$	no LHC limit
$m_{\tilde{\chi}_1^\pm} = m_{\tilde{\chi}_2^0}$, $m_{\tilde{\ell}} > m_{\tilde{\chi}_1^\pm}$, BF$(WZ) = 1$	
$m_{\tilde{\chi}_1^0} \approx 0$	> 960
$m_{\tilde{\chi}_1^0} > 300$	no LHC limit
$m_{\tilde{\chi}_1^\pm} = m_{\tilde{\chi}_2^0}$, $m_{\tilde{\ell}} > m_{\tilde{\chi}_1^\pm}$, BF$(WH) = 1$	
$m_{\tilde{\chi}_1^0} \approx 0$, wino-like $\tilde{\chi}_1^\pm$	> 1060
$m_{\tilde{\chi}_1^0} \approx 0$, higgsino-like $\tilde{\chi}_1^\pm$	> 900
$m_{\tilde{\chi}_1^0} > 400(240)$	no LHC limit wino(higgsino)-like

89.7.3 *Exclusion limits on slepton masses*

The most model-independent searches for selectrons, smuons and staus originate from the LEP experiments [188]. Smuon production only takes place via s-channel γ^*/Z exchange. Search results are often quoted for $\tilde{\mu}_{\mathrm{R}}$, since it is typically lighter than $\tilde{\mu}_{\mathrm{L}}$ and has a weaker coupling to the Z boson; limits are therefore conservative. Decays are expected to be dominated by $\tilde{\mu}_{\mathrm{R}} \to \mu\tilde{\chi}_1^0$, leading to two non-back-to-back muons and missing momentum. Slepton mass limits are calculated in the MSSM under the assumption of gaugino mass unification at the GUT scale, and depend on the mass difference between the smuon and $\tilde{\chi}_1^0$. A $\tilde{\mu}_{\mathrm{R}}$ with a mass below 94 GeV is excluded for $m_{\tilde{\mu}_{\mathrm{R}}} - m_{\tilde{\chi}_1^0} > 10$ GeV. The selectron case is similar to the smuon case, except that an additional production mechanism is provided by t-channel neutralino exchange. The $\tilde{e}_{\mathrm{R}}$ lower mass limit is 100 GeV for $m_{\tilde{\chi}_1^0} < 85$ GeV. Due to the t-channel neutralino exchange, $\tilde{e}_{\mathrm{R}}\tilde{e}_{\mathrm{L}}$ pair production was possible at LEP, and a lower limit of 73 GeV was set on the selectron mass regardless of the neutralino mass by scanning over MSSM parameter space [189]. The potentially large mixing between $\tilde{\tau}_{\mathrm{L}}$ and $\tilde{\tau}_{\mathrm{R}}$ not only makes the $\tilde{\tau}_1$ light, but can also make its coupling to the Z boson small. LEP lower limits on the $\tilde{\tau}$ mass range between 87 and 93 GeV depending on the $\tilde{\chi}_1^0$ mass, for $m_{\tilde{\tau}} - m_{\tilde{\chi}_1^0} > 7$ GeV [188].

At the LHC, pair production of sleptons is not only heavily suppressed with respect to pair production of colored SUSY particles but the cross section is also almost two orders of magnitude smaller than the one of pair production of charginos and neutralinos. With the full data sets of Run 1 and Run 2, however, ATLAS and CMS have surpassed the sensitivity of the LEP analyses under certain assumptions.

ATLAS and CMS have searched for direct production of selectron pairs and smuon pairs at the LHC, with each slepton decaying to its corresponding SM partner lepton and the $\tilde{\chi}_1^0$ LSP. In simplified models, ATLAS [133] and CMS [180] set lower mass limits on sleptons of 700 GeV for degenerate $\tilde{\ell}_{\mathrm{L}}$ and $\tilde{\ell}_{\mathrm{R}}$, for a massless $\tilde{\chi}_1^0$ and assuming equal selectron and smuon masses, as shown in Fig. 89.9. The limits deteriorate with increasing $\tilde{\chi}_1^0$ mass due to decreasing missing momentum and lepton momentum. As a consequence, no limits are set for $\tilde{\chi}_1^0$ masses above 400 GeV. Limits are also derived without the assumption of slepton mass degeneracy [133, 190]. A dedicated search for sleptons with small mass difference between $\tilde{\ell}$ and $\tilde{\chi}_1^0$ is performed by ATLAS [149] demanding

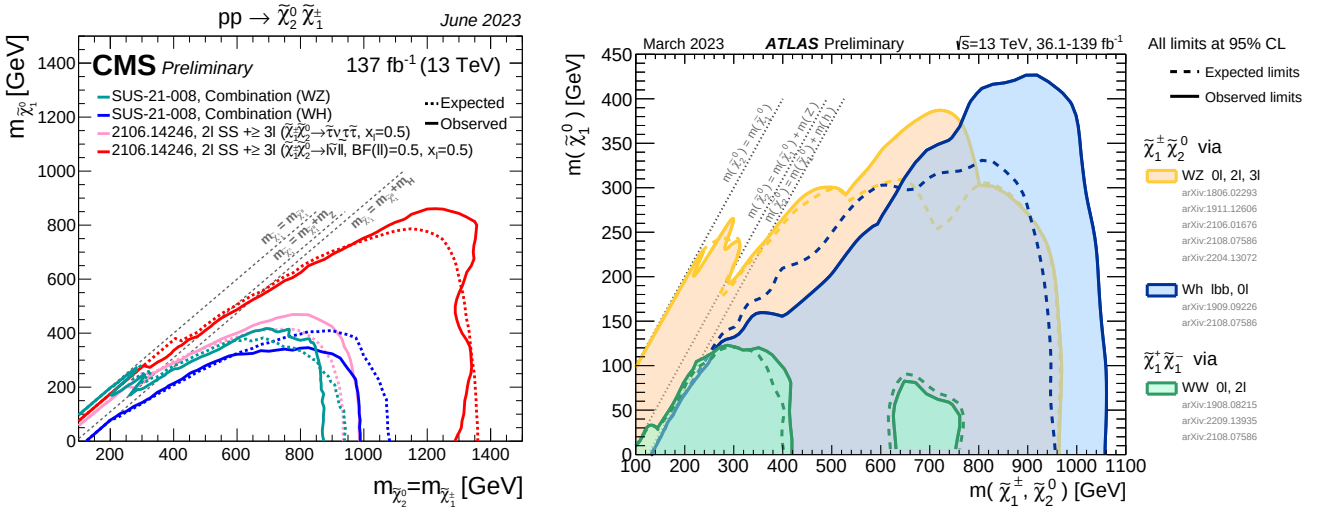

Figure 89.8: LHC exclusion limits on chargino and neutralino masses in a number of simplified models. Left: CMS limits on chargino and neutralino masses for pair production of charginos, pair production of heavier neutralinos, or pair production of chargino and neutralino, under a variety of assumptions including light sleptons mediating the decays. Right: ATLAS limits on chargino and neutralino masses for pair production of chargino and neutralino, under the assumption of decoupled sleptons, and chargino/neutralino decay through on- or off-shell W and Z or H.

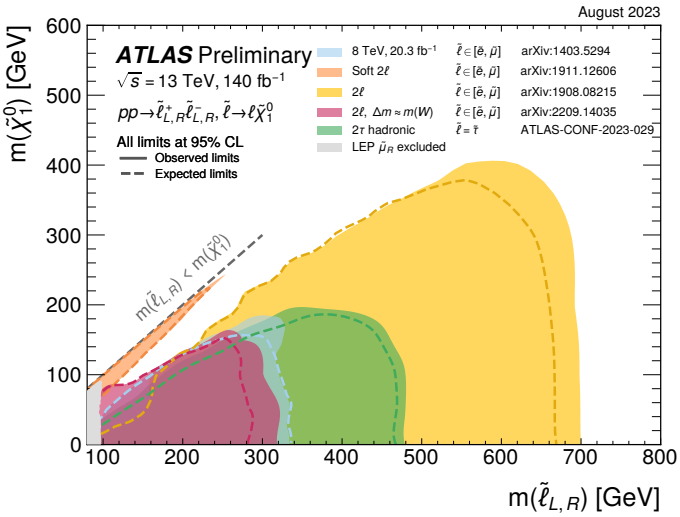

Figure 89.9: LHC exclusion limits on slepton (selectron, smuon and stau) masses, assuming equal masses of selectrons and smuons, degeneracy of $\tilde{\ell}_{\rm L}$ and $\tilde{\ell}_{\rm R}$, and a 100% branching fraction for $\tilde{\ell} \to \ell\tilde{\chi}_1^0$.

the presence of ISR jets. Although no sensitivity is achieved for intermediate mass differences between the slepton and the LSP, slepton masses up to 260 GeV are excluded for slepton-LSP mass differences of 10-20 GeV. ATLAS [137] followed up with a dedicated search in the challenging regime where the mass difference between the slepton and the LSP is close to the W mass. Sleptons with masses up to 150 GeV are excluded for a mass-splitting between the sleptons and the LSP of 50 GeV.

ATLAS and CMS have also searched for $\tilde{\tau}$-pair production. In simplified models, ATLAS excludes $\tilde{\tau}$ masses between 120 and 390 GeV assuming light $\tilde{\chi}_1^0$, combining the production of degenerate left- and right-handed $\tilde{\tau}$s [191]. The CMS analysis [192] covers lower masses and closes the mass gap with LEP. In a search for hadronic final states, CMS [193] excludes purely left-handed $\tilde{\tau}$s with masses between 115 and 340 GeV for massless LSP. A recent ATLAS search [194] for stau pair production in the fully hadronic final state excludes, for a massless LSP, degenerate left- and right-handed $\tilde{\tau}$s with masses up to 480 GeV, purely left-handed $\tilde{\tau}$s with masses up to 410 GeV and purely right-handed $\tilde{\tau}$s with masses up to 330 GeV.

In gauge-mediated SUSY breaking models, sleptons can be (co-)NLSPs, *i.e.*, the next-to-lightest SUSY particles and almost degenerate in mass, decaying to a lepton and a gravitino. This decay can either be prompt, or the slepton can have a non-zero lifetime. Combining several analyses, lower mass limits on $\tilde{\mu}_{\rm R}$ of 96.3 GeV and on $\tilde{e}_{\rm R}$ of 66 GeV are set for all slepton lifetimes at LEP [195]. In a considerable part of parameter space in these models, the $\tilde{\tau}$ is the NLSP. The LEP experiments have set lower limits on the mass of such a $\tilde{\tau}$ between 87 and 97 GeV, depending on the $\tilde{\tau}$ lifetime. ATLAS and CMS have searched for final states with τs, jets and missing transverse momentum, and have interpreted the results in GMSB models setting limits on the model parameters [196, 197]. CMS has interpreted a multilepton analysis in terms of limits on gauge mediation models with slepton NLSP [198]. CDF has put limits on gauge mediation models at high $\tan\beta$ and slepton NLSP using an analysis searching for like-charge light leptons and taus [199].

The invisible width of the Z boson puts a lower limit on the

sneutrino mass of about 45 GeV. Tighter limits are derived from other searches, notably for gauginos and sleptons, under the assumption of gaugino and sfermion mass universality at the GUT scale, and amount to approximately 94 GeV in the MSSM [200].

The limits on sleptons in simplified models are summarized in Table 89.4.

Table 89.4: Summary of slepton mass limits from LEP and LHC, assuming R-parity conservation and 100% branching fraction for $\tilde{\ell} \to \ell\tilde{\chi}^0_1$. Masses in this table are provided in GeV.

Assumption	$m_{\tilde{\ell}}$
$\tilde{\mu}_R$, $\Delta m(\tilde{\mu}_R, \tilde{\chi}^0_1) > 10$	> 94
$\tilde{e}_R$, $\Delta m(\tilde{e}_R, \tilde{\chi}^0_1) > 10$	> 94
$\tilde{e}_R$, any Δm	> 73
$\tilde{\tau}_R$, $\Delta m(\tilde{\tau}_R, \tilde{\chi}^0_1) > 7$	> 87
$\tilde{\nu}_e$, $\Delta m(\tilde{e}_R, \tilde{\chi}^0_1) > 10$	> 94
$m_{\tilde{e}_{L,R}} = m_{\tilde{\mu}_{L,R}}$, $m_{\tilde{\chi}^0_1} \approx 0$	> 700
$m_{\tilde{\chi}^0_1} >\approx 400$	no LHC limit
$m_{\tilde{\tau}_L} = m_{\tilde{\tau}_R}$, $m_{\tilde{\chi}^0_1} \approx 0$	> 480
$m_{\tilde{\chi}^0_1} >\approx 200$	no LHC limit
$m_{\tilde{\tau}_L}$, $m_{\tilde{\chi}^0_1} \approx 0$	> 410
$m_{\tilde{\chi}^0_1} >\approx 150$	no LHC limit
$m_{\tilde{\tau}_R}$, $m_{\tilde{\chi}^0_1} \approx 0$	> 330
$m_{\tilde{\chi}^0_1} >\approx 100$	no LHC limit

89.8 Exclusion limits on promptly decaying sparticle masses in RPV scenarios

The large variety of possible configurations for non-zero λ, λ' and λ'' couplings in RPV SUSY scenarios leads to a huge number of potential signatures to be investigated in the strong and electroweak sectors. The lightest supersymmetric particle can be any particle, although most of the models considered at the LHC assume that to be the lightest neutralino, and can decay promptly or displaced. Cascade decays of sparticles down to the LSP can also be prompt or displaced depending on the strength of the couplings involved, although typically such cascades are dominated by gauge couplings which are prompt. In this section, we review dedicated searches for scenarios with small non-zero RPV couplings but still large enough to allow prompt decays of the sparticles involved (see Section 89.9 for examples of dedicated signatures searches for non-prompt decays).

Prompt RPV gluino and squark decays are searched for in final states generally characterised by the presence of multiple leptons or jets and moderate or no missing transverse momentum.

Searches in multilepton final states [90, 166, 201–205] set lower gluino mass limits between 1 and 2.5 TeV for decays mediated by λ and λ' couplings, with strong dependence on the couplings involved, the neutralino mass and the lepton flavor. Multijet final states have been used to search for fully hadronic gluino decays involving λ'' couplings, by CDF [206], ATLAS [96, 207–210] and CMS [211–213]. Lower gluino mass limits range between 600 and 2000 GeV depending on neutralino mass and flavor content of the final state. ATLAS [214] also searched in events characterised by high jet multiplicity, at least one isolated light lepton and either zero or at least three b-tagged jets, reaching as high as 2.4 TeV in gluino mass. If gluinos decay via top squark into *tbd* final states through a non-zero λ''_{313} coupling, a search for same-sign/three-lepton events can be effective. ATLAS [90] sets a lower limit of 1.65 TeV for a top squark with a mass below 1.45 TeV.

RPV production of single squarks via a λ'-type coupling has been studied at HERA. In such models, a lower limit on the squark mass of the order of 275 GeV has been set for electromagnetic-strength-like couplings $\lambda' = 0.3$ [215]. At the LHC, prompt [202, 205, 216] R-parity violating squark decays have been searched for, with mass limits very model-dependent.

Dedicated searches for RPV top squarks (at production and/or in decays) have been carried out in the past decades. Production of single top squarks has been searched for at LEP, HERA, and the Tevatron. For example, an analysis from the ZEUS collaboration [217] makes an interpretation of its search result assuming top squarks to be produced via a λ' coupling and decay either to $b\tilde{\chi}^\pm_1$ or R-parity-violating to a lepton and a jet. Limits are set on λ'_{131} as a function of the top squark mass in an MSSM framework with gaugino mass unification at the GUT scale. CMS and ATLAS have performed several searches for top squarks using a variety of multilepton and/or multijet final states and Run 2 data. The λ'-mediated top squark decay $\tilde{t} \to b\ell$ has been studied by ATLAS for prompt decays [218], and by ATLAS and CMS for non-prompt decays [219–221], setting limits up to $1.4 - 1.6$ TeV in simplified models for this mode. CMS also searched for the λ'-mediated

decay $\tilde{t} \to b\ell qq$, setting lower stop mass limits of 890 GeV (e) or 1000 GeV (μ) [222]. The fully hadronic R-parity violating top squark decays $\tilde{t} \to bs$, $\tilde{t} \to ds$, and $\tilde{t} \to bd$, involving λ'', have been searched for by ATLAS [202, 208, 223–225], and CMS [226, 227]. Other recent searches target top squarks decaying through cascades into several $b-$ and light-quarks, for example as in [228]. The most recent results set lower top squark mass limits up to 1.35 TeV in top-squark mass [214] if decays include top- and b-quarks [214] lower top squark mass limits are up to 1.35 TeV in top-squark mass. Constraints on masses up to 670 GeV are found if the top squarks decays include top- and light-quarks [229].

Various searches for multi-lepton and lepton plus jets events are interpreted in a model with RPV decays of charginos and neutralinos (including the LSP) involving a non-zero λ [166,201,205] or λ' [202,210,230,231] coupling. Neutralino decays involving non-zero λ'' lead to fully hadronic final states, and searches for multi-jet events and jet-pair resonances are used to set limits, typically on the production of colored particles like top squarks or gluinos, which are assumed to be the primary produced sparticles in these interpretations, as discussed earlier. For instance, the ATLAS search [214] in events with one lepton and high jet multiplicity excludes up to 320 (365) GeV in higgsino (wino) masses. If top quarks arise in the decay of the neutralino, lepton-enriched final state events are also relevant, see for example preliminary results in [144]. The multilepton search in [232] set limits on the production of charginos and neutralinos for a minimal SUSY model with an approximate $B-L$ symmetry. In this case, charginos and neutralinos with masses between 100 GeV and 1.1 TeV are excluded depending on the assumed decay BR into a lepton plus a W, Z or H boson. Finally, recent results from ATLAS [144] set the first experimental constraints on bilinear RPV models (bRPV) with degenerate higgsino masses exploiting same-sign/three-lepton signatures, excluding masses smaller than 440 GeV.

Limits also exist on sleptons in RPV models, both from LEP and the Tevatron experiments. From LEP, lower limits on $\tilde{\mu}_{\rm R}$ and $\tilde{e}_{\rm R}$ masses in such models are 97 GeV, and the limits on the stau mass are very close: 96 GeV [233]. CMS has searched for resonant smuon production in a modified CMSSM scenario [234], putting limits on λ'_{211} as a function of $m_0, m_{1/2}$. Production of pairs of sneutrinos in R-parity violating models has been searched for at LEP [233]. Assuming fully leptonic decays via λ-type couplings, lower mass limits between 85 and 100 GeV are set. At the Tevatron [235, 236] and at the LHC [234, 237–239], searches have focused on scenarios with resonant production of a sneutrino decaying to $e\mu$, $\mu\tau$ and $e\tau$ final states. Limits have been set on sneutrino masses as a function of the value of relevant RPV couplings. As an example, the LHC experiments exclude a resonant tau sneutrino with a mass below 3.9 TeV for $\lambda_{312} = \lambda_{321} > 0.07$ and $\lambda'_{311} > 0.11$ [240].

Formulating a general assessment of the existing bounds on RPV SUSY models is becoming increasingly important in order to evaluate loopholes and potential new search directions. A classification of all potential RPV signatures at the LHC for small couplings has been recently published [241] to evaluate the coverage of the most general RPV-MSSM setup, without making any assumptions about the sparticle spectrum details. Small RPV couplings imply that sparticles are pair-produced at the LHC as in the RPC-MSSM case. Figure 89.10 shows a summary of the 95% C.L. limits on sparticle masses in RPV models for two types of λ couplings, compared to the direct production mass bound when the sparticle under consideration is the LSP. This is done to quantify the impact of possible assumptions made on the nature, mass and coupling choices for the LSP which in turn might lead to different leptons, jets and top-quark multiplicities. As underlined in [241], changes in exclusion limits on sparticle masses are at most around 20%.

Finally, RPV signatures are often similar to signatures of Stealth SUSY [242–244]. In these scenarios, squarks can decay to a quark and a chargino (neutralino), which can subsequently decay to a singlino $\tilde{S}$ and a $W^{\pm}$ (photon), with the $\tilde{S}$ decaying to two gluons and a soft gravitino $\tilde{G}$. Dedicated CMS searches [245, 246] exclude squark masses up to 1.85 TeV in the photon channel and up to 550 GeV in the charged lepton channel. Gluino masses up to 2.1 TeV are excluded in the di-photon channel [246]. Limits have also been placed on top squarks in stealth SUSY scenarios, where the top squark decays to a top quark, a gluon and a $\tilde{S}$, and the $\tilde{S}$ subsequently decays to a $\tilde{G}$ and two gluons. In such a scenario, top squark masses up to 870 GeV have been excluded by CMS [229].

89.9 Exclusion limits on long-lived sparticles

Long-lived sparticles arise in many different SUSY models. In particular in co-annihilation scenarios, where the NLSP and LSP are nearly mass-degenerate, this is rather common in order to obtain the correct Dark Matter relic density. Prominent examples are scenarios featuring stau co-annihilation, or models of SUSY breaking, e.g. minimal anomaly-mediated SUSY breaking (AMSB), in which the appropriate Dark Matter density is obtained by co-annihilation of the LSP with an almost degenerate long-lived wino. R-parity violating SUSY models might also lead to non-prompt decays. Searches for events with a displaced hadronic vertex, with or without a matched lepton, are for instance interpreted in a model with RPV neutralino decays involving a non-zero λ' coupling [231]. However, in general, other sparticles can also be long-lived and it is desirable to establish a comprehensive search program for these special long-lived cases, which lead to distinct experimental search signatures. Past experiments have performed dedicated searches for long-lived SUSY signatures, but given the absence of any experimental evidence for SUSY so far, more effort and focus has gone into such searches at the LHC recently. Signatures interpreted in terms of SUSY models include disappearing tracks, identification of tracks with atypical properties or unusual ionization, small and localized deposits of energy inside of the calorimeters without associated tracks, or stopped particles that decay out of time with collisions. Some examples are reported below with interpretations provided for gluinos, squarks and electroweak SUSY particles in a variety of SUSY models.

If the decay of gluinos is suppressed, for example if squark masses are high, gluinos may live longer than typical hadronization times. It is expected that such gluinos will hadronize to long-living strongly interacting particles known as R-hadrons. In particular, if the suppression of the gluino decay is strong, as in the case that the squark masses are much higher than the TeV scale, these R-hadrons can be (semi-)stable in collider timescales. Searches for such R-hadrons exploit the typical signature of stable charged massive particles in the detector. R-hadrons decaying in the detector are searched for using dE/dx measurements and searches for displaced vertices. As shown in the left plot of Fig. 89.11, the ATLAS experiment excludes semi-stable gluino R-hadrons with masses below $1.9 - 2.3$ TeV for all lifetimes in a simplified model where such gluinos always form R-hadrons, and decay into jets and a light neutralino, by combining a number of analyses [208, 247–250]. A combination of CMS searches for long-lived particles, as shown in Fig. 89.12, reaches similar limits [251–255].

Alternatively, since such R-hadrons are strongly interacting, they may be stopped in the calorimeter or in other material, and decay later into energetic jets. These decays are searched for by identifying the jets [256–258] or muons [258] outside the time window associated with bunch-bunch collisions. As shown in Fig. 89.12, the CMS collaboration sets limits on such stopped R-hadrons over 13 orders of magnitude in gluino lifetime, up to masses of 1390 GeV [258]. Recent results from ATLAS [259] sets constraint on the mass of gluino R-hadrons using large out-of-time energy deposits in the calorimeters. Also in this case, masses of up to 1.4 TeV are excluded for gluino lifetimes of $10^{-5} - 10^{3}$ s.

Top squarks can also be long-lived and hadronize to a R-hadron, for example in the scenario where the top squark is the next-to-lightest SUSY particle, with a small mass difference to the LSP. Searches for massive stable charged particles are sensitive to such top squarks. Tevatron limits are approximately $m_{\tilde{t}} > 300$ GeV [260, 261]. ATLAS sets a limit of 1340 GeV on such top squarks [249], the CMS limits are comparable [253]. Intermediate lifetimes of top squarks decaying through RPV coupling into a quark and a lepton are also targeted by ATLAS and CMS. Limits on top squarks decaying into a quark and a muon

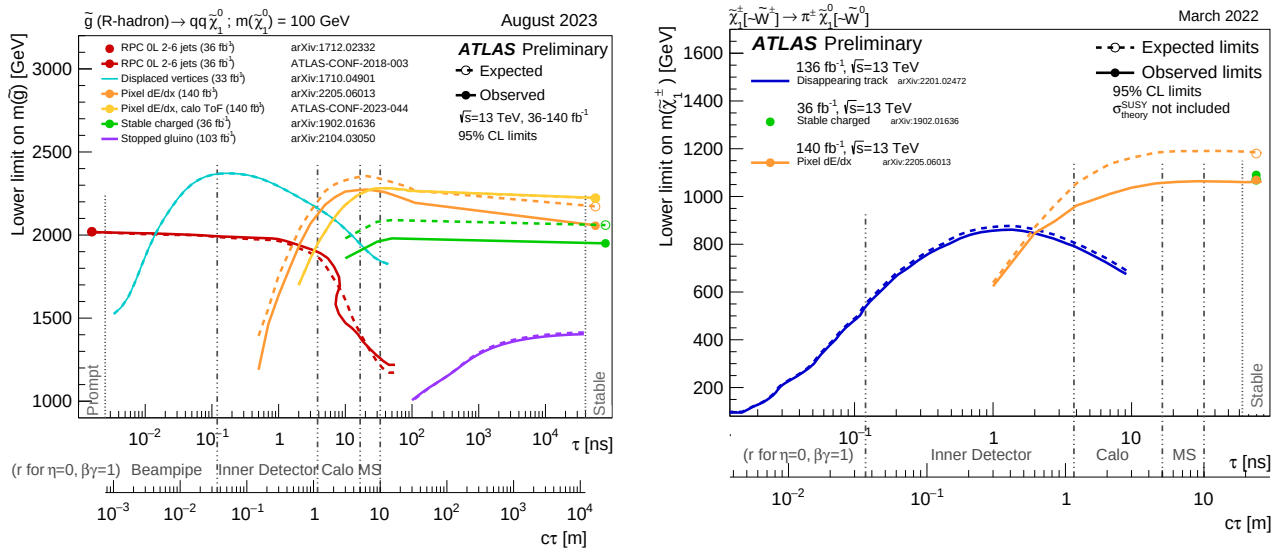

Figure 89.11: Limits at 95% C.L. on the gluino mass in R-hadron models (left), and on the chargino mass in a model where the wino-like chargino is almost degenerate with the LSP (right), as a function of gluino or chargino lifetime, as obtained by ATLAS.

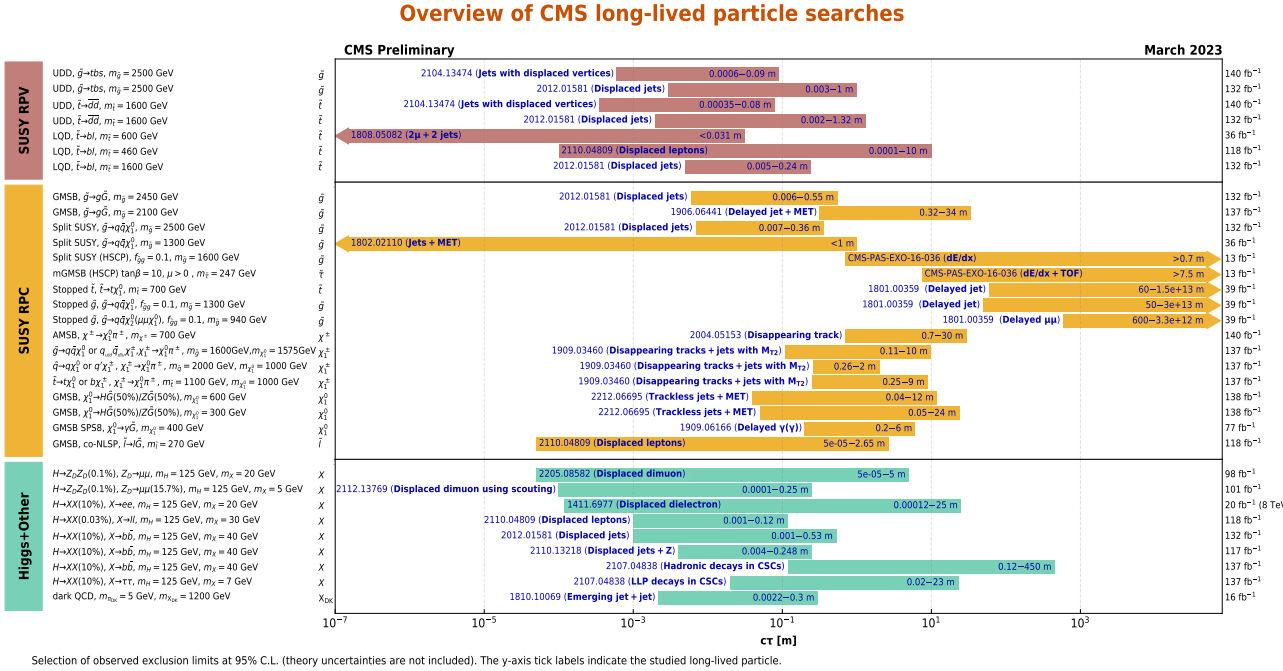

Selection of observed exclusion limits at 95% C.L. (theory uncertainties are not included). The y-axis tick labels indicate the studied long-lived particle.

Figure 89.12: Excluded regions, at 95% C.L., in the lifetimes of long-lived particles in several models, as obtained by CMS.

are set by ATLAS [262] using events that pass a muon or missing-transverse-momentum trigger and contain a displaced muon track and a displaced vertex. Masses up to 1.7 TeV are excluded for a lifetime of 0.1 ns, and masses below 1.3 TeV are excluded for lifetimes between 0.01 ns and 30 ns. CMS [263] utilizes events with two leptons with transverse impact parameter values between 0.01 and 10 cm not required to form a common vertex to exclude top squarks with masses between 100 and at least 460 GeV for $0.01 < c\tau_0 < 1000$ cm, where $c\tau_0$ is the proper decay length.

In addition to colored sparticles, sparticles like charginos may also be long-lived, especially in scenarios with compressed mass spectra. Charginos decaying in the detectors away from the primary vertex could lead to signatures such as kinked-tracks, or apparently disappearing tracks, since, for example, the pion in $\tilde{\chi}_1^{\pm} \rightarrow \pi^{\pm}\tilde{\chi}_1^0$ might be too soft to be reconstructed. At the LHC, searches have been performed for such disappearing tracks, and interpreted within anomaly-mediated SUSY breaking models [264–267]. The right plot of Fig. 89.11 shows constraints for different ATLAS searches on the chargino mass-vs-lifetime plane for an AMSB model ($\tan\beta = 5$, $\mu > 0$) in which a wino-like $\tilde{\chi}^{\pm}$ decays to a soft pion and an almost mass-degenerated wino-like $\tilde{\chi}_1^0$ [249, 250, 265–268]. The disappearing track search [267] provides constraints also for higgsino-like models. Results from [268] exploiting anomalously large specific ionisation losses dE/dx are extrapolated to the stable regime. For a similar AMSB-like model, CMS excludes $c\tau$ values between 0.15 and 18 m for a chargino mass of 505 GeV [264], see Fig. 89.12. Their most recent results [269] expand and improve the constraints on masses of charginos as well as of colored sparticles by making use of electron and muon plus disappearing track signatures, measurements of the dE/dx ionization energy loss of candidate tracks, and by re-analyzing the fully hadronic signatures using ML techniques.

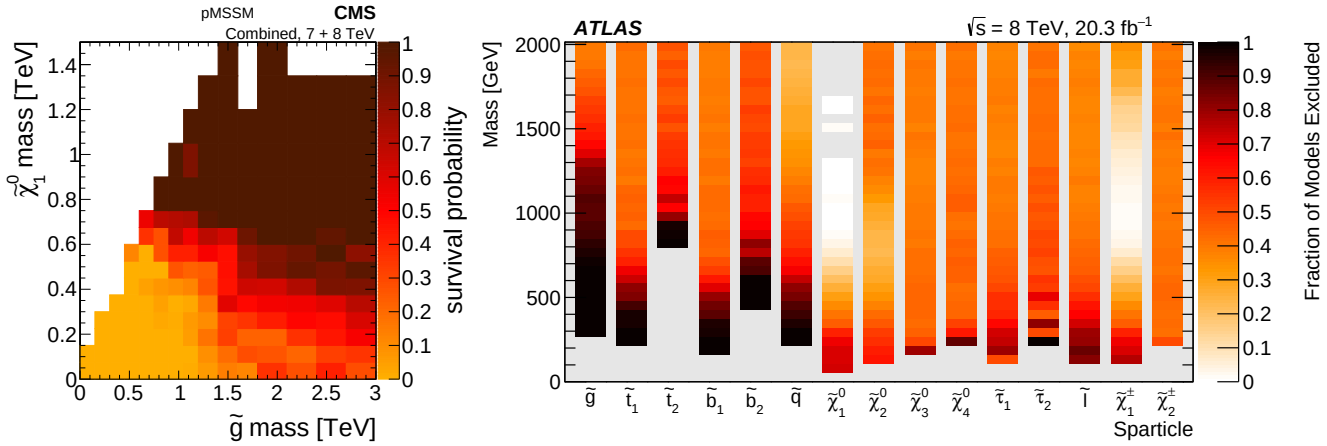

Figure 89.13: The plot on the left shows the survival probability of a pMSSM parameter space model in the gluino-neutralino mass plane after the application of the relevant CMS search results. The plot on the right shows a graphical representation of the ATLAS exclusion power in a pMSSM model. Each vertical bar is a one-dimensional projection of the fraction of models points excluded for each sparticle by ATLAS analyses. The experimental results are obtained from data taken at $\sqrt{s} = 7$ and 8 TeV.

Charginos with a lifetime longer than the time needed to pass through the detector appear as charged stable massive particles. Limits have been derived by the LEP experiments [270], by D0 at the Tevatron [261], and by the LHC experiments [249, 271], and such charginos with mass below 1090 GeV are excluded.

In gauge mediation models, NLSP neutralino decays need not be prompt, and experiments have searched for late decays with photons in the final state. CDF has searched for delayed $\tilde{\chi}_1^0 \to \gamma\tilde{G}$ decays using the timing of photon signals in the calorimeter [272]. CMS has used the same technique at the LHC [273]. Results are given as exclusion contours in the neutralino mass versus lifetime plane, and for example in a GMSB model with a neutralino mass of 300 GeV, $c\tau$ values between 10 and 2000 cm are excluded [273]. D0 has looked at the direction of showers in the electromagnetic calorimeter with a similar goal [274], and ATLAS has searched for photon candidates that do not point back to the primary vertex, as well as for delayed photons [275].

Charged slepton decays may be kinematically suppressed, for example in the scenario of a NLSP slepton with a very small mass difference to the LSP. Such a slepton may appear to be a stable charged massive particle. Interpretation of searches at LEP for such signatures within GMSB models with a stau NLSP or slepton co-NLSP exclude masses up to 99 GeV [270]. Searches for stable charged particles at the Tevatron [260, 261] and at the LHC [249, 253] are also interpreted in terms of limits on stable charged sleptons. The limits obtained at the LHC exclude stable staus with masses below 430 GeV when produced directly in pairs, and below 660 GeV when staus are produced both directly and indirectly in the decay of other particles in a GMSB model. Recent results from ATLAS and CMS set constraints on long-lived charged slepton with intermediate lifetimes. ATLAS searches for charged leptons with large impact parameters and exclude selectron, smuon and stau masses up to 720 GeV, 680 GeV, and 340 GeV, respectively, in case of lifetimes of 0.1 ns. They also exclude smuons with lifetimes down to 1 ps for a smuon mass of 100 GeV, and smuon masses up to 520 GeV are excluded for a proper lifetime of 10 ps [276]. CMS [193] targets long-lived stau with $c\tau$ of about 0.1 mm excluding masses between 115 and 220 GeV for the case that the LSP is nearly massless.

89.10 Global interpretations

Apart from the interpretation of direct searches for sparticle production at colliders in terms of limits on masses of individual SUSY particles, model-dependent interpretations of allowed SUSY parameter space are derived from global SUSY fits. Typically these fits combine the results from collider experiments with indirect constraints on SUSY as obtained from low-energy experiments, flavor physics, high-precision electroweak results, and astrophysical data.

In the pre-LHC era these fits were mainly dominated by indirect constraints. Even for very constrained models like the CMSSM, the allowed parameter space, in terms of squark and gluino masses, ranged from several hundreds of GeV to a few TeV. Furthermore, these global fits indicated that squarks and gluino masses in the range of 500 to 1000 GeV were the preferred region of parameter space, although values as high as a few TeV were allowed with lower probabilities [277–284].

With ATLAS and CMS now probing mass scales around 1 TeV and beyond, the importance of the direct searches for global analyses of allowed SUSY parameter space has increased. For example, imposing the new experimental limits on constrained supergravity models pushes the most likely values of first generation squark and gluino masses significantly beyond 2 TeV, typically resulting in overall values of fit quality much worse than those in the pre-LHC era [155–157, 185, 285–292]. The measured value of m_h pushes the sparticle masses upwards. Although these constrained models are not yet ruled out, the extended experimental limits impose very tight constraints on the allowed parameter space.

For this reason, the emphasis of global SUSY fits has shifted towards less-constrained SUSY models. Interpretations in the pMSSM [183–187, 271, 285, 293] as well as in simplified models, have been useful to generalize SUSY searches, for example to redesign experimental analyses in order to increase their sensitivity for compressed spectra, where the mass of the LSP is much closer to squark and gluino masses than predicted by the CMSSM. As shown in Table 89.1, for neutralino masses above $0.5 - 1$ TeV the current set of ATLAS and CMS searches, interpreted in simplified models, cannot exclude the existence of squarks or gluinos with masses only marginally above the neutralino mass. However, as these exclusion limits are defined in the context of simplified models, they are only valid for the assumptions in which these models are defined.

Fig. 89.13 shows graphically the LHC exclusion power in the pMSSM based on searches performed at $\sqrt{s} = 7$ and 8 TeV as reported by ATLAS [183] and CMS [184]. The plot on the left shows the survival probability in the gluino-neutralino mass plane, which is a measure of the parameter space that remains after inclusion of the relevant CMS search results. As can be seen, gluino masses below about 1.2 TeV are almost fully excluded. This result agrees well with the typical exclusion obtained at 8 TeV in simplified models for gluino production. However, as shown in the right plot of Fig. 89.13, when a similar analysis for other sparticles is performed it becomes apparent that exclusions on the pMSSM parameter can be significantly less stringent than simplified model limits might suggest. This is especially apparent for the electroweak sector, where even at rather low masses several of the pMSSM test points still survive the constraint of ATLAS searches at $\sqrt{s} = 7$ and 8 TeV. This again indicates that care

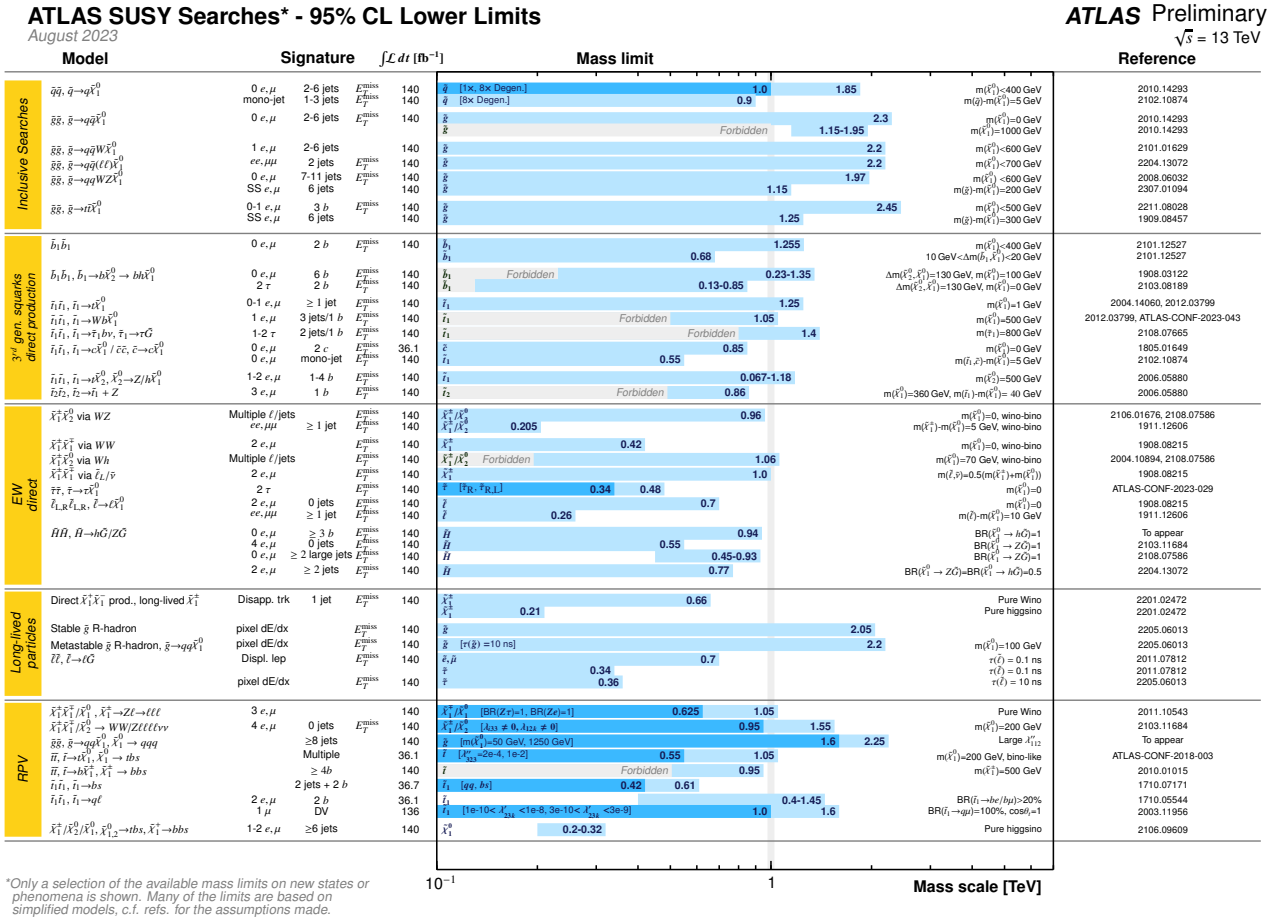

Figure 89.14: Overview of the current landscape of SUSY searches at the LHC (updated on August 2023). The plot shows exclusion mass limits of ATLAS for different searches and interpretation assumptions. The corresponding results of the CMS experiment are similar.

must be taken when interpreting results from the LHC searches and there are still several scenarios where sparticles below the 1 TeV scale are not excluded, even when considering the most recent results at $\sqrt{s} = 13$ TeV. Interpretations in the pMSSM of searches performed on the full Run 2 dataset are in preparation and will offer further insights on the validity of constraints obtained with simplified models and, thus, guidance towards the future LHC runs and beyond.

Furthermore, the discovery of a Higgs boson with a mass around 125 GeV has triggered many studies regarding the compatibility of SUSY parameter space with this new particle (see for example [294, 295]). Much of it is still work in progress and it will be interesting to see how the interplay between the results from direct SUSY searches and more precise measurements of the properties of the Higgs boson will unfold in the future.

89.11 Summary and Outlook

The absence of any observation of new phenomena at the first run of the LHC at $\sqrt{s} = 7/8$ TeV, and after the second run at $\sqrt{s} = 13$ TeV, places significant constraints on SUSY parameter space. An overview of the current landscape of SUSY searches and limits at the LHC is shown in Figure 89.14, where a summary of results from the ATLAS experiment [296] (CMS results are similar [297]), is reported for illustration purposes. Inclusive searches probe production of gluinos at about 2.45 TeV, first and second generation squarks in the range of about 1 to 1.9 TeV, third generation squarks at scales around 600 GeV to 1.2 TeV, electroweak gauginos at scales around $400 - 1100$ GeV, and sleptons around 700 GeV. However, depending on the assumptions made on the underlying SUSY spectrum these limits can also weaken considerably.

With the LHC having reached almost its maximum energy of about $\sqrt{s} = 14$ TeV and analyses explored the full Run 2 dataset, future sensitivity improvements will have to originate from more data, the improvement of experimental analysis techniques and the focus on special signatures like the ones arising in long-lived sparticle decays. Therefore, it is expected that the current landscape of SUSY searches and corresponding exclusion limits at the LHC, especially for strongly produced sparticles in RPC scenarios, will not change as rapidly anymore as it did in the past, when the LHC underwent several successive increases of collision energy.

The interpretation of results at the LHC has moved away from constrained models like the CMSSM towards a large set of simplified models, or the pMSSM. Quoted limits in simplified models are only valid under the explicit assumptions made in these models. The addition of more comprehensive interpretations in the pMSSM complement those and therefore enable an even more refined understanding of the probed SUSY parameter space.

In this context, the limit range of $1.5 - 2.45$ TeV on generic colored SUSY particles only holds for light neutralinos, in the R-parity conserving MSSM. Limits on third generation squarks and electroweak gauginos also only hold for light neutralinos, and under specific assumptions for decay modes and slepton masses. Constraints in R-parity violating SUSY models strongly depend also on the assumed non-zero couplings.

The next LHC runs, with $\sqrt{s}$ between 13 and 14 TeV and significantly larger integrated luminosities (notably the High-Luminosity LHC), will provide a large data sample for future SUSY searches. As mentioned above, the improvement in sensitivity will largely have to come from a larger data set, and evolution of trigger and analysis techniques, since there will be no significant energy increase at the LHC anymore. Although the sensi-

tivity for colored sparticles will increase somewhat as well, the expanded data set will be particularly beneficial for electroweak gaugino searches, and for the more difficult final states presented by compressed particle spectra, stealth SUSY, long-lived sparticles, or R-parity violating scenarios.

90. Axions and Other Similar Particles

Revised August 2023 by L. J Rosenberg (U. Washington), G. Rybka (U. Washington) and B. Safdi (UC Berkeley).

90.1 Introduction

In this section, we list coupling-strength and mass limits for light neutral scalar or pseudoscalar bosons that couple weakly to normal matter and radiation. Such bosons may arise from the spontaneous breaking of a global U(1) symmetry, resulting in a massless Nambu-Goldstone (NG) boson. If there is a small explicit symmetry breaking, either already in the Lagrangian or due to quantum effects such as anomalies, the boson acquires a mass and is called a pseudo-NG boson. Typical examples are axions (a) [1–4] and majorons [5,6], associated, respectively, with a spontaneously broken Peccei-Quinn PQ and lepton-number symmetry. Axions may also arise in extra dimension constructions as the zero-modes of higher-dimensional gauge fields compactified on internal manifolds; in this case, the absence of a local contributions to the axion mass is due to the higher-dimensional gauge symmetry [7,8].

A common feature of these light bosons ϕ is that their coupling to Standard-Model particles is suppressed by the energy scale that characterizes the symmetry breaking, *i.e.*, the decay constant f. For example, in models where the axion arises as a Goldstone boson, the interaction Lagrangian at energy scales below f is

$$\mathcal{L} = f^{-1} J^\mu \partial_\mu \phi \,, \tag{90.1}$$

where J^μ is the Noether current of the spontaneously broken global symmetry. If f is very large, these new particles interact very weakly. Detecting them would provide a window to physics far beyond what can be probed at accelerators.

Axions are of particular interest because the PQ mechanism is a compelling scheme to preserve CP-symmetry in QCD. Moreover, the cold dark matter (CDM) of the Universe may well consist of axions and they are searched for in dedicated experiments with a realistic chance of discovery.

Originally it was assumed that the PQ scale f_a was related to the electroweak symmetry-breaking scale $v_{\rm EW} = (\sqrt{2}G_{\rm F})^{-1/2} = 246.22$ GeV. However, the associated "standard" and "variant" axions were quickly excluded—we refer to the Listings for detailed limits. Here we focus on "invisible axions" with $f_a \gg v_{\rm EW}$ as the main possibility.

Axions have a characteristic two-photon vertex, inherited from their mixing with π^0 and η. This coupling allows for the main search strategy based on axion-photon conversion in external magnetic fields [9], an effect that also can be of astrophysical interest. While for axions the product "$a\gamma\gamma$ interaction strength × mass" is essentially fixed by the corresponding π^0 properties, one may consider a more general class of axion-like particles (ALPs) where the two parameters (coupling and mass) are independent. A number of experiments explore this more general ALP parameter space. ALPs populating the latter are predicted to arise generically, in addition to the axion, in low-energy effective field theories emerging from string theory [7,8,10–16]. The latter may contain also very light Abelian vector bosons under which the Standard-Model particles are not charged: so-called hidden-sector photons, dark photons or paraphotons. They share a number of phenomenological features with the axion and ALPs, notably the possibility of hidden photon-to-photon conversion and of hidden photon dark matter [17–19]. Their physics cases and the current constraints are compiled in Refs. [20–23].

90.2 Theory

90.2.1 *Peccei-Quinn mechanism and axions*

The QCD Lagrangian includes a CP-violating term $\mathcal{L}_\Theta = -\bar{\Theta}\,(\alpha_s/8\pi)\,G^{\mu\nu a}\tilde{G}^a_{\mu\nu}$, where $-\pi \le \bar{\Theta} \le +\pi$ is the effective Θ parameter after diagonalizing quark masses, $G^a_{\mu\nu}$ is the color field strength tensor, and $\tilde{G}^{a,\mu\nu} \equiv \epsilon^{\mu\nu\lambda\rho}G^a_{\lambda\rho}/2$, with $\varepsilon^{0123} = 1$, its dual. This term induces an electric dipole moment (EDM) of the neutron of strength $d_n = C_{\rm EDM}\, e\, \bar{\Theta}$. The coefficient $C_{\rm EDM}$ is calculated using QCD sum rules as $C_{\rm EDM} = 2.4(1.0) \times 10^{-16}\,$cm [24], while lattice QCD computations find $C_{\rm EDM} = 1.48(14)(31) \times 10^{-16}\,$cm [25] including statistical and systematic uncertainties. Experimental upper bounds on the latter, $|d_n| < 1.8 \times 10^{-26}\, e\,$cm [26,27], imply $|\bar{\Theta}| \lesssim 10^{-10}$ even though $\bar{\Theta} = \mathcal{O}(1)$ is otherwise completely satisfactory. Note that the proton has a similar EDM as the neutron, but it is less strongly constrained at present; this could change in the future [28]. The proton EDM may be written as $d_p = C^p_{\rm EDM}\, e\, \bar{\Theta}$, with $C^p_{\rm EDM} = -3.8(11)(8)$ [25]. The opposite signs of the neutron and proton EDMs may be understood from the opposite signs of their magnetic moments. The spontaneously broken global PQ symmetry $\mathrm{U}(1)_{\rm PQ}$ was introduced to solve the "strong CP problem" [1,2] of small Θ , the axion being the pseudo-NG boson of $\mathrm{U}(1)_{\rm PQ}$ [3,4]. This symmetry is broken due to the axion's anomalous triangle coupling to gluons,

$$\mathcal{L} = \left(\frac{a}{f_a} - \bar{\Theta}\right) \frac{\alpha_s}{8\pi}\, G^{\mu\nu a}\tilde{G}^a_{\mu\nu} \,, \tag{90.2}$$

where a is the axion field and f_a the axion decay constant. Color anomaly factors have been absorbed in the normalization of f_a which is defined by this Lagrangian. Thus normalized, f_a is the quantity that enters all low-energy phenomena [29]. Non-perturbative topological fluctuations of the gluon fields in QCD induce a potential for a whose minimum is at $a = \bar{\Theta}\, f_a$, thereby canceling the $\bar{\Theta}$ term in the QCD Lagrangian and thus restoring CP symmetry.

The resulting axion mass, in units of the PQ scale f_a, is identical to the square root of the topological susceptibility in QCD, $m_a f_a = \sqrt{\chi}$. The latter can be evaluated further [30,31], exploiting the chiral limit (masses of up and down quarks much smaller than the scale of QCD), yielding $m_a f_a = \sqrt{\chi} \approx f_\pi m_\pi$, where $m_\pi \approx 135$ MeV and $f_\pi \approx 92$ MeV . In more detail one finds, by including $\mathcal{O}(\alpha)$ QED corrections and next-to-next-to-leading order (NNLO) corrections in chiral perturbation theory [32],

$$m_a = 5.691(51)\, \left(\frac{10^9\ \mathrm{GeV}}{f_a}\right) \mathrm{meV} \,. \tag{90.3}$$

A direct calculation of the topological susceptibility via QCD lattice simulations finds almost the same central value, albeit with an about five times larger error bar [33].

The QCD axion acquires a variety couplings to low-energy Standard Model observables, as we discuss in detail in this review. The most model-independent couplings are those of the axion to the neutron and proton EDM operators. While the axion removes the static neutron and proton EDMs, displacements of the axion field a from its vacuum expectation value induce field-dependent EDMs, which are characterized through the operator

$$\mathcal{L}_{aN\gamma} = -\frac{i}{2} g_{aN\gamma}\, a\, \overline{\Psi}_N \sigma_{\mu\nu}\gamma_5 \Psi_N F^{\mu\nu} \,, \tag{90.4}$$

with $N = n, p$ for neutrons or protons, respectively. The coupling $g_{an\gamma}$ is related to $C_{\rm EDM}$ by $g_{an\gamma} = eC_{\rm EDM}/f_a$ and similarly for $g_{ap\gamma}$. Direct probes of the axion-EDM operators are difficult, though by studying the thermal production of axions in the early universe one can broadly constrain, using Planck and Baryon Acoustic Oscillation (BAO) data, $m_a \lesssim 0.3$ eV [34]. In the presence of an oscillatory relic axion DM field, this operator induces an oscillating neutron EDM; this effect forms the basis of the CASPEr experiment [35,36] that is discussed more later in this review. Non-linearly realized discrete-symmetries may be used to suppress the QCD axion mass below the prediction in Eq. (90.3), in which case a variety of cosmological and terrestrial constraints on the operator in Eq. (90.4) are also relevant [37–44]

Axions with $f_a \gg v_{\rm EW}$ evade almost all current experimental limits. One generic class of models invokes "hadronic axions" where new heavy quarks carry $\mathrm{U}(1)_{\rm PQ}$ charges, leaving ordinary quarks and leptons without tree-level axion couplings. The archetype is the KSVZ model [45,46], where in addition the heavy new quarks are electrically neutral. Another generic class of axion models requires at least two Higgs doublets and ordinary quarks and leptons carry PQ charges, the archetype being the DFSZ model [47,48]; in this case the quarks and leptons may

have tree-level axion couplings. All of these models contain at least one electroweak singlet scalar that acquires a vacuum expectation value and thereby breaks the PQ symmetry. The KSVZ and DFSZ models are frequently used as benchmark examples, but other models exist where both heavy quarks and Higgs doublets carry PQ charges (see [49] for an extensive review). In supersymmetric models, the axion is part of a supermultiplet and thus inevitably accompanied by a spin-0 saxion and a spin-1/2 axino, which both also have couplings suppressed by f_a and are expected to have large masses due to supersymmetry breaking [50]. In extra-dimension constructions the axion emerges from a higher-dimensional gauge field; the other components of the gauge field, however, tend to have masses proportional to the Kaluza-Klein mass scale of the extra dimensions.

90.2.2 *Model-dependent axion couplings*

Although the generic axion interactions scale approximately with f_π/f_a from the corresponding π^0 couplings, there are non-negligible model-dependent factors and uncertainties. The axion's two-photon interaction plays a key role for many searches,

$$\mathcal{L}_{a\gamma\gamma} = -\frac{g_{a\gamma\gamma}}{4}\, a\, F_{\mu\nu}\tilde{F}^{\mu\nu} = g_{a\gamma\gamma}\, a\, \mathbf{E}\cdot\mathbf{B}\,, \tag{90.5}$$

where F is the electromagnetic field-strength tensor and $\tilde{F}^{\mu\nu} \equiv \epsilon^{\mu\nu\lambda\rho}F_{\lambda\rho}/2$, with $\varepsilon^{0123} = 1$, its dual. The coupling constant is [51]

$$g_{a\gamma\gamma} = \frac{\alpha}{2\pi f_a}\left(\frac{E}{N} - 1.92(4)\right) = \left(0.203(3)\frac{E}{N} - 0.39(1)\right)\frac{m_a}{\mathrm{GeV}^2}\,, \tag{90.6}$$

where E and N are the electromagnetic and color anomalies of the axial current associated with the axion. In grand unified models, and notably for DFSZ [47, 48], $E/N = 8/3$, whereas for KSVZ [45, 46] $E/N = 0$ if the electric charge of the new heavy quark is taken to vanish. In general, a broad range of E/N values is possible [49, 52–54], as indicated by the diagonal yellow band in Fig. 90.1, whose width is roughly determined by the boundary values $E/N = 44/3$ and $E/N = 5/3$, respectively. However, this band still does not exhaust all the possibilities. In fact, there exist classes of QCD axion models whose photon couplings populate the entire still-allowed region outside the yellow band in Fig. 90.1 [55–60], motivating axion search efforts over a wide range of masses and couplings.

The two-photon decay width is

$$\Gamma_{a\to\gamma\gamma} = \frac{g_{a\gamma\gamma}^2 m_a^3}{64\,\pi} \approx 1.1\times10^{-24}\ \mathrm{s}^{-1}\left(\frac{m_a}{\mathrm{eV}}\right)^5. \tag{90.7}$$

The second expression uses Eq. (90.6) with $E/N = 0$. Axions decay faster than the age of the Universe if $m_a \gtrsim 20$ eV.

The interaction with fermions f has derivative form and is invariant under a shift $a \to a + a_0$ as behooves a NG boson,

$$\mathcal{L}_{aff} = \frac{C_f}{2f_a}\,\partial_\mu a\,\bar{\Psi}_f\gamma^\mu\gamma_5\Psi_f\,. \tag{90.8}$$

Here, Ψ_f is the fermion field, m_f its mass, and C_f a model-dependent coefficient. The dimensionless combination $g_{aff} \equiv C_f m_f/f_a$ plays the role of a Yukawa coupling and $\alpha_{aff} \equiv g_{aff}^2/4\pi$ of a "fine-structure constant." The often-used pseudoscalar form $\mathcal{L}_{aff} = -\mathrm{i}\,(C_f m_f/f_a)\,a\,\bar{\Psi}_f\gamma_5\Psi_f$ need not be equivalent to the appropriate derivative structure, for example when two NG bosons are attached to one fermion line as in axion emission by nucleon bremsstrahlung [169–171].

In hadronic axion models, C_e vanishes at tree level, but is then generated radiatively at one loop [172, 173],

$$C_e \simeq \frac{3\alpha^2}{4\pi^2}\left[\frac{E}{N}\log\left(\frac{f_a}{m_e}\right) - 1.92\log\left(\frac{\Lambda_\chi}{m_e}\right)\right], \tag{90.9}$$

where $\Lambda_\chi \simeq 1$ GeV is the chiral symmetry breaking scale. In the DFSZ model [47,48], the tree-level coupling coefficient to electrons is [172]

$$C_e = \frac{\sin^2\beta}{3}\,, \tag{90.10}$$

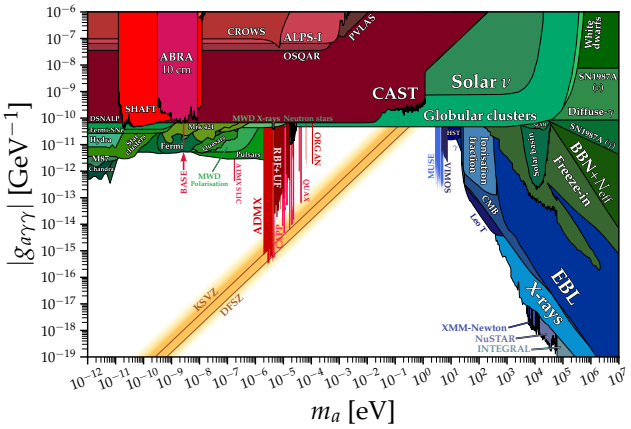

Figure 90.1: Exclusion plot for the ALP-photon coupling. Figure courtesy of Ciaran O'Hare [61], contains exclusions from refs. [62–168]. Constraints in red are from terrestrial experiments. ABRA 10 cm, SHAFT, BASE, ADMX SLIC, ADMX, RBF+UF, CAPP, QUAX, and ORGAN search for axion DM and assume the axion in 100% DM; CROWS. ALPS-I, OSQAR, PVLAS are light-shining-through-walls experiments that are purely terrestrial, while CAST searches for axions produced in the Sun with no DM assumption. Those shown in green are astrophysical but make no assumption about axions being DM. See text for details regarding the orange band expectation for the QCD axion and assumptions for blue high mass axion astrophysical limits.

where $\tan\beta$ is the ratio of the vacuum expectation values of the two Higgs doublets giving masses to the up- and down-type quarks, respectively: $\tan\beta = v_u/v_d$. As a cautionary note, many of the original axion references, such as [172], defined $\tan\beta = v_d/v_u$, but the choice $\tan\beta = v_u/v_d$ adopted here and in more modern axion works is a reflection of the choice taken in the two-Higgs-doublet literature [174]. The resulting prediction for the axion-electron coupling, as a function of the axion mass, for the KSVZ axion ($E/N = 0$), hadronic axions, with $5/3 \le E/N \le 44/3$, and the DFSZ axion is displayed in Fig. 90.2. For the DFSZ range we have taken into account the constraint $0.28 \lesssim \tan\beta \lesssim 140$ [175] arising from the requirement of perturbative unitarity of the Yukawa couplings of Standard Model fermions.

For nucleons, $C_{p,n}$ have been determined as [51]

$$\begin{aligned} C_p &= -0.47(3) + 0.88(3)C_u - 0.39(2)C_d - 0.038(5)C_s \\ &\quad - 0.012(5)C_c - 0.009(2)C_b - 0.0035(4)C_t\,, \\ C_n &= -0.02(3) + 0.88(3)C_d - 0.39(2)C_u - 0.038(5)C_s \\ &\quad - 0.012(5)C_c - 0.009(2)C_b - 0.0035(4)C_t\,, \end{aligned} \tag{90.11}$$

in terms of the corresponding model-dependent quark couplings C_q, $q = u, d, s, c, b, t$. For hadronic axions, the latter vanish at tree-level, which means that C_n is expected to be much smaller than C_p. In the DFSZ model, $C_u = C_c = C_t = \frac{1}{3}\cos^2\beta$ and $C_d = C_s = C_b = \frac{1}{3}\sin^2\beta$, and C_p and C_n, as functions of β,

$$\begin{aligned} C_p &= -0.435\sin^2\beta + (-0.182 \pm 0.025)\,, \\ C_n &= 0.414\sin^2\beta + (-0.160 \pm 0.025)\,. \end{aligned} \tag{90.12}$$

The resulting prediction for the axion-neutron coupling, as a function of the axion mass, for the KSVZ axion and the DFSZ axion is displayed in Fig. 90.3. Note, however, that these couplings receive in-medium corrections, which may be important when considering compact stars [176].

The axion-pion interaction is given by the Lagrangian [173,177]

$$\mathcal{L}_{a\pi} = \frac{C_{a\pi}}{2f_\pi f_a}\,\partial_\mu a\left(\pi^0\pi^+\partial_\mu\pi^- + \pi^0\pi^-\partial_\mu\pi^+ - 2\pi^+\pi^-\partial_\mu\pi^0\right), \tag{90.13}$$

where $C_{a\pi} = 2(C_p - C_n)/(3g_A)$ and g_A is the nucleon axial charge $g_A = 1.2723(23)$. Additionally, there are axion-pion-nucleon interactions of the form

$$\mathcal{L}_{a\pi N} = \frac{C_{a\pi N}}{2f_\pi f_a}\partial_\mu a \left(i\pi^+\bar{p}\gamma^\mu n - i\pi^-\bar{n}\gamma^\mu p\right) , \qquad (90.14)$$

where $C_{a\pi N} = (C_{ap} - C_{an})/(\sqrt{2}g_A)$.

90.3 Laboratory Searches

90.3.1 *Light shining through walls*

Searching for "invisible axions" is extremely challenging due to their extraordinarily feeble coupling to normal matter and radiation. Currently, the most promising approaches rely on the axion-two-photon interaction, allowing for axion-photon conversion in external electric or magnetic fields [9]. For the Coulomb field of a charged particle, the conversion can be viewed as a scattering process, $\gamma + Ze \leftrightarrow Ze + a$, called Primakoff effect [178]. In the other extreme of a macroscopic field, usually a large-scale B-field, the momentum transfer is small, the interaction is coherent over a large distance, and the conversion can be viewed as an axion-photon oscillation phenomenon in analogy to neutrino flavor oscillations [179].

Photons propagating through a transverse magnetic field, with incident $\mathbf{E}_\gamma$ and magnetic field $\mathbf{B}$ parallel, may convert into axions. For $m_a^2 L/2\omega \ll 2\pi$, where L is the length of the B field region and ω the photon energy, the resultant axion beam is coherent with the incident photon beam and the conversion probability is $\Pi \sim (1/4)(g_{a\gamma\gamma}BL)^2$. One such realization uses a laser beam propagating down the bore of a superconducting dipole magnet (like, say, the bending magnets in high-energy accelerators). If another magnet is in line with the first, but shielded by an optical barrier, then photons may be regenerated from the pure axion beam [180, 181]. The overall probability is $P(\gamma \to A \to \gamma) = \Pi^2$.

The first such Light-Shining-through-Walls (LSW) experiment was performed by the BFRT (Brookhaven-Fermilab-Rochester-Trieste) collaboration. It utilized two magnets of length $L = 4.4$ m and $B = 3.7$ T and found $|g_{a\gamma\gamma}| < 6.7 \times 10^{-7}$ GeV^{-1} at 95% CL for $m_a < 1$ meV [182, 183]. More recently, several such experiments were performed (see Listings) [98, 101, 184–188]. The current best limit, $|g_{a\gamma\gamma}| < 3.5 \times 10^{-8}$ GeV^{-1} at 95% CL for $m_a \lesssim 0.3$ meV (see Fig. 90.1), has been achieved by the OSQAR (Optical Search for QED Vacuum Birefringence, Axions, and Photon Regeneration) experiment, which exploited two 9 T LHC dipole magnets and an 18.5 W continuous wave laser emitting at the wavelength of 532 nm [101]. The ALPS I (Any Light Particle Search I) experiment achieved a similar sensitivity [98], see Fig. 90.1. Some of these experiments have also reported limits for scalar bosons where the photon $\mathbf{E}_\gamma$ must be chosen perpendicular to the magnetic field $\mathbf{B}$.

The concept of resonantly enhanced photon regeneration may open unexplored regions of coupling strength [189–191]. In this scheme, both the production and detection magnets are within Fabry-Perot optical cavities and actively locked in frequency. The $\gamma \to a \to \gamma$ rate is enhanced by a factor $\mathcal{F}\mathcal{F}'/\pi^2$ relative to a single-pass experiment, where $\mathcal{F}$ and $\mathcal{F}'$ are the finesses of the two cavities. The resonant enhancement could be of order $10^{(10-12)}$, improving the $g_{a\gamma\gamma}$ sensitivity by $10^{(2.5-3)}$. The experiment ALPS II (Any Light Particle Search II) is based on this concept and aims at an improvement of the current laboratory bound on $g_{a\gamma\gamma}$ by a factor $\sim 10^3$ [192]. ALPS II began operations in 2023.

Resonantly enhanced photon regeneration has already been exploited in experiments searching for "radiowaves shining through a shielding" [193–196]. For $m_a \lesssim 10^{-5}$ eV, the upper bound on $g_{a\gamma\gamma}$ established by the CROWS (CERN Resonant Weakly Interacting sub-eV Particle Search) experiment [100] is slightly less stringent than the one set by OSQAR, see Fig. 90.1.

90.3.2 *Photon polarization*

An alternative to regenerating the lost photons is to use the beam itself to detect conversion: the polarization of light propagating through a transverse B field undergoes dichroism and birefringence [197]. Dichroism: The $E_\parallel$ component, but not $E_\perp$, is depleted by axion production, causing a small rotation of linearly polarized light. For $m_a^2 L/2\omega \ll 2\pi$, the effect is independent of m_a. For heavier axions, it oscillates and diminishes as m_a increases, and it vanishes for $m_a > \omega$. Birefringence: This effect occurs because there is mixing of virtual axions in the $E_\parallel$ state, but not for $E_\perp$. Hence, linearly polarized light will develop elliptical polarization. Higher-order QED also induces vacuum magnetic birefringence (VMB). A search for these effects was performed in the same dipole magnets of the BFRT experiment mentioned before [198]. The dichroic rotation gave a stronger limit than the ellipticity rotation: $|g_{a\gamma\gamma}| < 3.6 \times 10^{-7}$ GeV^{-1} at 95% CL, for $m_a < 5 \times 10^{-4}$ eV. The ellipticity limits are better at higher masses, as they fall off smoothly and do not terminate at m_a.

90.3.3 *Long-range forces*

New bosons would mediate new long-range forces, which are severely constrained by "fifth force" experiments [199]. Those looking for new mass-spin couplings provide significant constraints on pseudoscalar bosons [200–205], see for example in Fig. 90.3 the limit on the axion-neutron coupling [206] from torsion balance tests of the gravitational inverse square law [207]. Presently, the most restrictive limits are obtained from combining long-range force measurements with stellar cooling arguments [208, 209]. For the moment, any of these limits are far from realistic values expected for the QCD axion. Still, these efforts provide constraints on more general low-mass bosons.

In Ref. [210], a method was proposed that can extend the search for axion-mediated spin-dependent forces by several orders of magnitude. By combining techniques used in nuclear magnetic resonance and short-distance tests of gravity, this method appears to be sensitive to the QCD axion in the μeV – meV mass range, independent of the cosmic axion abundance, if axions have a CP-violating interaction with nuclei as large as the current experimental bound on the electric dipole moment of the neutron allows. (Note that the CP-violation already present in the Standard Model is sufficient for generating an axion-mediated force, though in this case the signal appears too small to be detectable for the QCD axion in the foreseeable future [210].) The ARIADNE (Axion Resonant InterAction DetectioN Experiment) is under development and employs this approach to search for axion-mediated spin-dependent short-range interactions between a hyper-polarized 3-He sample and an unpolarized tungsten source mass [211]. The method relies on superconducting magnetic shielding to screen the sample from ordinary magnetic field noise. Experimental tests to demonstrate the requirements of ARIADNE, including characterization of the magnetic field backgrounds, are under way [212, 213].

90.4 Axions from Astrophysical Sources

90.4.1 *Stellar energy-loss limits*

Axions are produced in hot astrophysical plasmas, and can thus transport energy out of stars. The coupling strength of these particles with normal matter and radiation is bounded by the constraint that stellar lifetimes or energy-loss rates are not in conflict with observation [214, 215].

We begin this discussion with our Sun and concentrate first on the axion-photon coupling. In the Sun axions are produced by the Primakoff process $\gamma + Ze \to Ze + a$. Integrating this process over a standard solar model yields the axion luminosity [216]

$$L_a = g_{10}^2 \times 1.85 \times 10^{-3}\, L_\odot , \qquad (90.15)$$

where $g_{10} = |g_{a\gamma\gamma}| \times 10^{10}$ GeV. The maximum of the spectrum is at 3.0 keV, the average at 4.2 keV, and the number flux at Earth is $g_{10}^2 \times 3.75 \times 10^{11}$ cm^{-2} s^{-1}. The solar photon luminosity is fixed, so energy losses due to the Primakoff process require enhanced nuclear energy production and thus enhanced neutrino fluxes. The all-flavor measurements by SNO (Sudbury Neutrino Observatory), together with a standard solar model, imply $L_a \lesssim 0.10\, L_\odot$, corresponding to $g_{10} \lesssim 7$ [217], mildly superseding a similar limit from helioseismology (sound speed, surface helium and convective radius) [218]. In Ref. [147], this limit was improved to $g_{10} < 4.1$ (at $3\,\sigma$), see Fig. 90.1, exploiting a new statistical analysis that combined helioseismology and solar neutrino observations, including

theoretical and observational errors, and accounting for tensions between input parameters of solar models, in particular the solar element abundances. Going beyond the axion-photon coupling, Ref. [217] considered also a non-zero axion-electron coupling and obtained the bound on the latter displayed in Fig. 90.2.

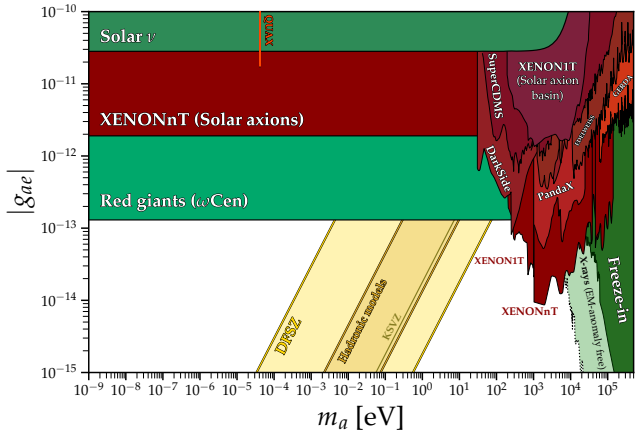

Figure 90.2: Exclusion plot for ALP-electron coupling as described in the text. Figure courtesy of Ciaran O'Hare [61], contains data from refs. [168, 217, 219–228]. The hadronic QCD axion-electron coupling arises at one loop and is given in Eq. (90.9); varying E/N between 5/3 and 44/3 gives the indicated hadronic axion band. The KSVZ axion has $E/N = 0$, while the DFSZ axion-electron coupling has the tree-level coupling given in Eq. (90.10) that depends on the unknown but bounded value of $\tan\beta$ (see text for details).

A more restrictive limit derives from globular-cluster (GC) stars that allow for detailed tests of stellar-evolution theory. The stars on the horizontal branch (HB) in the color-magnitude diagram have reached helium burning with a core-averaged energy release of about 80 erg g^{-1} s^{-1}, compared to Primakoff axion losses of g_{10}^2 30 erg g^{-1} s^{-1}. The accelerated consumption of helium reduces the HB lifetime by about $80/(80 + 30\,g_{10}^2)$. In contrast, the red giant (RG) branch stars are not strongly affected by Primakoff losses, since unlike for the HB stars the plasma frequency in the RG stellar cores is below the temperature. Thus, Primakoff production reduces the R-parameter, which is the number of observed HB branch stars to RG branch stars in a GC. Measurements of the R-parameter in a large sample of 39 Galactic GCs

give a weak indication of non-standard losses which may be accounted by Primakoff-like axion emission, if the photon coupling is in the range $|g_{a\gamma\gamma}| = (2.9 \pm 1.8) \times 10^{-11}$ GeV^{-1} [122,229]. Still, the upper bound found in this analysis,

$$|g_{a\gamma\gamma}| < 6.6 \times 10^{-11}\,\text{GeV}^{-1}\ (95\%\,\text{CL}), \tag{90.16}$$

represents one of the strongest limits on $g_{a\gamma\gamma}$ for a wide mass range. More recently, the R_2-parameter has emerged as a potentially more sensitive probe of axions; the R_2-parameter is defined as the ratio of the asymptotic giant branch (AGB) stars to the HB stars in a GC. AGB stars have more efficient Primakoff production than HB stars, meaning that R_2 is expected to decrease for increasing $|g_{a\gamma\gamma}|$. Ref. [123] used an R_2 measurement based off of 48 GCs as observed by the Hubble Space Telescope [230] to constrain

$$|g_{a\gamma\gamma}| < 4.7 \times 10^{-11}\,\text{GeV}^{-1}\ (95\%\,\text{CL})\,. \tag{90.17}$$

The constraint above on $g_{a\gamma\gamma}$ may be translated to $f_a > 4.8 \times 10^7$ GeV $(m_a < 0.12$ eV) , using $E/N = 0$ as in the KSVZ model, or to $f_a > 1.8 \times 10^7$ GeV $(m_a < 0.32$ eV) , for the DFSZ axion model, with $E/N = 8/3$, see Fig. 90.1.

If axions couple directly to electrons, the dominant emission processes are atomic axio-recombination and axio-deexcitation, axio-bremsstrahlung in electron-ion or electron-electron collisions, and Compton scattering [231]. Stars in the RG branch of the color-magnitude diagram of GCs are particularly sensitive to these processes: they would lead to an extension of the latter to larger brightness. In fact, the tip of the RG branch (TRGB) – the brightest point of the RG branch – provides the currently most sensitive method to test the axion coupling to electrons. The strongest bounds on it are derived from analyses of the TRGB in several GCs [232] and in the Galactic GC ω Centauri [226]. The two analyses lead to very similar results,

$$|g_{aee}| < 1.48{\times}10^{-13}\ (95\%\ \text{CL}) \text{ and } |g_{aee}| < 1.3{\times}10^{-13}\ (95\%\ \text{CL}), \tag{90.18}$$

respectively, see Fig. 90.2. Reference [232] finds also a small hint for extra cooling, corresponding to $|g_{aee}| = 0.60^{+0..32}_{-0.58} \times 10^{-13}$, while Ref. [226] does not find any evidence for exotic cooling.

Bremsstrahlung is also efficient in white dwarfs (WDs), where the Primakoff and Compton processes are suppressed by the large plasma frequency. A comparison of the predicted and observed luminosity function of WDs can be used to put limits on $|g_{aee}|$ [233, 234]. An analysis based on detailed WD cooling treatment and data on the WD luminosity function (WDLF) of the Galactic disk found that electron couplings above $|g_{aee}| \gtrsim 3 \times 10^{-13}$ are disfavoured [235]. Lower couplings cannot be discarded from the current knowledge of the WDLF of the Galactic disk [235–237]. These probes may be improved by the Rubin Observatory Large Synoptic Survey Telescope (LSST), which is expected to increase the sample of WDs in the Galactic halo to hundreds of thousands [238]. For pulsationally unstable WDs (ZZ Ceti stars), the period decrease $\dot{P}/P$ is a measure of the cooling speed. The corresponding observations of a handful pulsating WDs imply additional cooling that can be interpreted in terms of axion energy losses [239–243], though with axion-electron coupling values likely incompatible with other constraints [244].

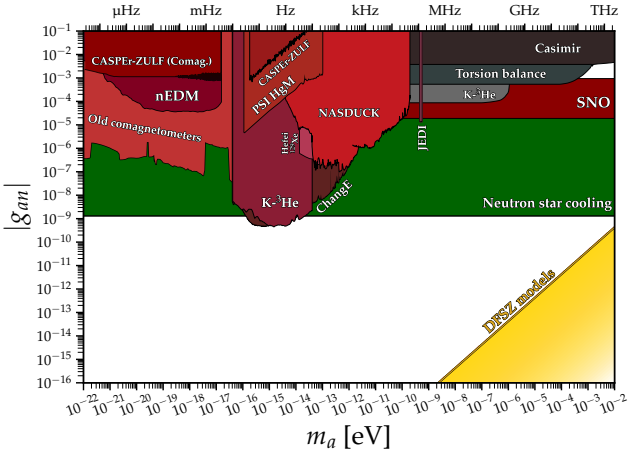

Figure 90.3: Exclusion plot for ALP-neutron coupling as described in the text. Figure courtesy of Ciaran O'Hare [61], includes data from refs. [40, 42, 206, 245–255]. The hadronic axion model prediction is given in Eq. (90.11) with vanishing quark couplings, while the DFSZ model prediction depends on $\tan\beta$ as is found in Eq. (90.12), giving the shaded yellow region above. Note that for a fine-tuned value of $\tan\beta$ g_{an} can be taken to zero. On the other hand, the neutron star cooling constraints [254] also probe the axion-proton coupling g_{ap} at a comparable level (not shown), and both g_{an} and g_{ap} cannot simultaneously be taken to zero in the DFSZ model.

Analogous constraints derive from neutron stars (NS) cooling. Broadly speaking, there are two classes of NS cooling searches for axions. One approach uses the proto-NS formed after SN 1987A to constrain the axion luminosity produced during the first seconds of the proto-NS when the neutrino luminosity is measured with terrestrial experiments. The second class of NS cooling constraints consider older NSs, typically much older than ∼100 yr, and constrains the axion luminosity using the surface temperature as measured with photons versus the age of NS as measured

through *e.g.* kinematic considerations. We begin with a discussion of the limits from SN 1987A.

Numerical simulations reveal that the energy-loss rate due to axions in a nuclear medium at the density 3×10^{14} g cm^{-3} and temperature 30 MeV should not exceed about 1×10^{19} erg g^{-1} s^{-1} to be consistent with the neutrino signal observed from SN 1987A [256]. The energy-loss rate from nucleon bremsstrahlung, $N + N \to N + N + a$, is $(C_N/2f_a)^2 (T^4/\pi^2 m_N)\, F$. Here F is a numerical factor that represents an integral over the dynamical spin-density structure function because axions couple to the nucleon spin. For realistic conditions, even after considerable effort, one is limited to a heuristic estimate leading to $F \approx 1$ [215]. The SN 1987A limits are of particular interest for hadronic axions where the bounds on $|g_{aee}|$ are moot. Using a proton fraction of 0.3, $g_{ann} = 0$, $F = 1$, and $T = 30$ MeV, one finds $f_a > 4 \times 10^8$ GeV and $m_a < 16$ meV [215]. A more detailed numerical calculation [257] with state of the art SN models, again assuming $g_{ann} = 0$, found that a coupling larger than $|g_{app}| \gtrsim 6 \times 10^{-10}$, would shorten significantly the timescale of the neutrino emission. This result is, not surprisingly, rather close to the estimate in Ref. [215]. Improving the calculation of axion emission via nucleon-nucleon bremsstrahlung beyond the basic one-pion exchange approximation appears to loosen the bound [258, 259]. The latter analysis finds a reduction of the axion emissivity by an order of magnitude if one takes into account the non-vanishing mass of the exchanged pion, the contribution from two-pion exchange, effective in-medium nucleon masses and multiple nucleon scattering, leading to the result [259]

$$g_{ann}^2 + 0.61\, g_{app}^2 + 0.53\, g_{ann}\, g_{app} < 8.26 \times 10^{-19}\,, \qquad (90.19)$$

which is consistent with the original estimate in [215]. This analysis, however, still neglects another very efficient mechanism for axion production in a SN: the pion production process, $\pi^- + p \to a + n$, also induced by the axion coupling to nucleons. Pion production was recognized long ago as being competitive with nucleon bremsstrahlung [260–262]. However, only recently it was shown that the pion abundance in the early stages of a SN is much larger than previously expected [263]. It was shown in Ref. [264] that pion induced processes dominate over bremsstrahlung and so strengthen the bound on the axion-nucleon coupling. On the other hand, given the modeling uncertainties and the sparse data from SN 1987A, the constraint on the axion-nucleon couplings from SN 1987A should be considered more as indicative than as a sharp bound [257]. Furthermore, note that if axions interact sufficiently strongly they are trapped. Only about three orders of magnitude in g_{aNN}, where $N = n, p$, or m_a are excluded. For even larger couplings, the axion flux would have been negligible, yet it would have triggered additional events in the detectors, excluding a further range [265].

Further bounds on the axion-nucleon coupling can be derived from observations of the cooling of older NSs. Recently, strong constraints were obtained by modeling the cooling of the "Magnificent Seven" (M7) NSs in the presence of axions [254]. Axion emission would accelerate NS cooling. Thus, if the age and temperature of a NS are independently known, then by modeling axion-induced cooling in conjunction with the standard NS cooling mechanisms, in particular cooling via neutrino emission from the bulk of the NS and thermal emission from the NS surface, one is able to constrain the axion's coupling strength. Ref. [254] used a sample of four of the M7 along with PSR J0659 to constrain $m_a < 16$ meV for the KSVZ QCD axion at 95% CL and $m_a \lesssim 5$ meV ($m_a \lesssim 30$ meV) in the DFSZ scenario for asymptotically large (small) $\tan\beta$. For axions that couple exclusively to neutrons (protons) Ref. [254] constrains $|g_{ann}| < 1.3 \times 10^{-9}$ ($|g_{app}| < 1.5 \times 10^{-9}$), as illustrated in Fig. 90.3. The five NSs used in that work are unique in that their ages, all in the range $0.1 - 1$ Myr, are known by kinematic measurements (*e.g.*, tracing back to the SN remnant), while their surface temperatures are measured in the X-ray band. Beyond statistical uncertainties on these measurements, there are a number of confounding systematic uncertainties that must be accounted for in NS cooling analyses, including uncertainties related to the core-surface temperature relation, which involves the chemical composition of the NS envelope. The NS equation of state and the superfluid critical temperatures of the dense nuclear matter are also sources of uncertainty. Note that axions are predominantly produced by nuclear bremsstrahlung [266, 267] except for temperatures near the superfluid critical temperature, when Cooper pair breaking and formation (PBF) processes may efficiently produce axions [268, 269]. Given the large densities it is crucial to account for medium dependent couplings when computing the axion luminosities [270].

The young NS in the supernova remnant Cassiopeia A (Cas A) was previously though to strongly constrain axions, at a level similar to the NS cooling bound described above, due to PBF axion production [271]. This is because it was observed that Cas A was cooling rapidly, which may be explained by neutrino cooling with neutron superfluidity and proton superconductivity [272, 273]. However, it is possible that the excessive cooling of Cas A is at least in part instrumental in origin [274]. Fully accounting for uncertainties on both the NS properties and the data, constraints from young NSs such as Cas A and the NS in the supernova remnant HESS J1731-347 [275] appear to be subdominant compared to the limits from SN 1987A and the M7 [254].

Finally, let us note that if $m_a \sim$ meV, SNe would lose a large fraction of their energy as axions. This would lead to a diffuse SN axion background in the Universe with an energy density comparable to the extra-galactic background light [276]. However, there is no apparent way of detecting it or the axion burst from the next nearby SN. On the other hand, neutrino detectors such as IceCube, Super-Kamiokande or a future mega-ton water Cherenkov detector will probe exactly the mass region of interest by measuring the neutrino pulse duration of the next Galactic SN [257].

90.4.2 *Searches for solar axions and ALPs*

Instead of using stellar energy losses to derive axion limits, one can also search directly for these fluxes, notably from the Sun. The main focus has been on ALPs with a two-photon vertex. They are produced by the Primakoff process with a flux given by Eq. (90.15) and an average energy of 4.2 keV, and can be detected at Earth with the reverse process in a macroscopic B-field ("axion helioscope") [9]. In order to extend the sensitivity in mass towards larger values, one can endow the photon with an effective mass in a gas, $\omega_{\rm plas}$, and tune the mass to match the axion's dispersion relation ($\omega_{\rm plas} = m_a$) [277].

An early implementation of these ideas used a conventional dipole magnet, with a conversion volume of variable-pressure gas with a xenon proportional chamber as x-ray detector [278]. The conversion magnet was fixed in orientation and collected data for about 1000 s/day. Axions were excluded for $|g_{a\gamma\gamma}| < 3.6 \times 10^{-9}$ GeV^{-1} for $m_a < 0.03$ eV, and $|g_{a\gamma\gamma}| < 7.7 \times 10^{-9}$ GeV^{-1} for $0.03 < m_a < 0.11$ eV at 95% CL.

Later, the Tokyo axion helioscope used a superconducting magnet on a tracking mount, viewing the Sun continuously. They reported $|g_{a\gamma\gamma}| < 6 \times 10^{-10}$ GeV^{-1} for $m_a < 0.3$ eV [279,280]. This experiment was recommissioned and a similar limit for masses around 1 eV was reported [281].

The most recent helioscope CAST (CERN Axion Solar Telescope) uses a decommissioned LHC dipole magnet on a tracking mount. The hardware includes grazing-incidence x-ray optics with solid-state x-ray detectors, as well as x-ray Micromegas position-sensitive gaseous detectors. Exploiting an IAXO (see below) pathfinder system, CAST has established the limit

$$|g_{a\gamma\gamma}| < 6.6 \times 10^{-11}\ \text{GeV}^{-1} \quad (95\%\ \text{CL}), \qquad (90.20)$$

for $m_a < 0.02$ eV [99]. To cover larger masses, the magnet bores are filled with a gas at varying pressure. The runs with ^{4}He cover masses up to about 0.4 eV [282], providing the high-mass component of the CAST limits shown in Fig. 90.1. To cover yet larger masses, ^{3}He was used to achieve a larger pressure at cryogenic temperatures. Limits up to 1.17 eV allowed CAST to "cross the axion line" for the KSVZ model [283–285], see Fig. 90.1.

Sensitivity to significantly smaller values of $g_{a\gamma\gamma}$ can be achieved with a next-generation axion helioscope with a much larger magnetic-field cross section. Realistic design options for this "International Axion Observatory" (IAXO) have been studied in some detail [286] and its physics potential has been reviewed

recently [287]. Such a next-generation axion helioscope may also push the sensitivity in the product of couplings to photons and to electrons, $g_{a\gamma\gamma}g_{aee}$, into a range beyond stellar energy-loss limits and test the hypothesis that WD, RG, and HB cooling is dominated by axion emission [288, 289]. As a first step towards IAXO, an intermediate experimental stage called BabyIAXO is currently under preparation at DESY [290].

Direct detection experiments searching for dark matter (DM) consisting of weakly interacting massive particles have also the capability to search for solar axions and ALPs. For low masses, $m_a \lesssim 100\,\mathrm{eV}$, the XENONnT experiment [291] has provided the most stringent bound among those experiments on the axion-electron coupling constant,

$$|g_{aee}| < 1.9 \times 10^{-12} \quad (90\%\ \mathrm{CL}), \tag{90.21}$$

see Fig. 90.2, by exploiting the axio-electric effect in liquid xenon. Slightly less stringent limits were set by PandaX-II [292] and by LUX [293]. However, this technique has not reached the sensitivity of energy-loss considerations in stars.

90.4.3 *Conversion of astrophysical axion fluxes*

Large-scale B fields exist in astrophysics that can induce axion-photon oscillations. In practical cases, the strength of B is much smaller than in the laboratory, whereas the conversion region L is much larger. Therefore, while the product BL can be large, realistic sensitivities are usually restricted to very low-mass particles, far away from the "QCD axion band" in a plot like Fig. 90.1.

One example of this is SN 1987A, which would have emitted a burst of ALPs due to the Primakoff production in its core. They would have partially converted into γ-rays in the Galactic B-field. The lack of a gamma-ray signal in the GRS instrument of the SMM satellite in coincidence with the observation of the neutrinos emitted from SN 1987A therefore provides a strong bound on their coupling to photons [294, 295]. This bound has been revisited and the underlying physics has been brought to the current state-of-the-art, as far as modeling of the supernova and the Milky-Way magnetic field are concerned, resulting in the limit [151, 152] $|g_{a\gamma\gamma}| < 5.2 \times 10^{-12}\ \mathrm{GeV}^{-1}$ for $m_a \lesssim 5 \times 10^{-10}$ eV.

Reference [119] reports no evidence of a γ-ray burst in observations of extragalactic SNe with the Fermi Large Area Telescope (LAT). Under the assumption that at least one SN was contained within the LAT field of view, the authors derive an upper bound on the axion photon coupling which is about a factor of 5 weaker than the one from SN 1987A, see Fig. 90.1.

The cumulative emission of ALPs from all past core-collapse SNe would lead to a diffuse gamma-ray flux peaked at energies $\sim 50 - 100\,\mathrm{MeV}$ which can convert in the Galactic magnetic field into photons. Using Fermi-LAT measurements of the diffuse γ-ray flux, Ref. [296] obtains a conservative bound on the photon coupling, $|g_{a\gamma\gamma}| < 5 \times 10^{-10}\ \mathrm{GeV}^{-1}$, for $m_a \lesssim 10^{-11}$ eV, see see Fig. 90.1, which can be decreased by nearly three orders of magnitude, if an ALP-nucleon coupling of maximal phenomenologically allowed strength, $|g_{aNN}| \sim 10^{-9}$, is allowed.

Hot, young stars, such as Wolf-Rayet stars, efficiently produce ALPs with energies $\sim 10 - 100\,\mathrm{keV}$ via the Primakoff effect. Large numbers of those stars are hosted by the Galactic Quintuplet and Westerlund 1 super star clusters (SSCs). The non-observation of hard X-rays originating from axion-photon conversion in the Galactic magnetic field in archival NuSTAR (Nuclear Spectroscopic Telescope Array) data from these SSCs leads to a bound on the axion-photon coupling [159], $|g_{a\gamma\gamma}| < 3.6 \times 10^{-12}\,\mathrm{GeV}^{-1}$, for $m_a \lesssim 5 \times 10^{-11}\,\mathrm{eV}$, see Fig. 90.1. A somewhat weaker bound in the same mass range was established exploiting NuSTAR data on Betelgeuse [105].

A hard X-ray excess in data from the nearby M7 isolated NSs [297] may be explained by ALPs produced in the cores of those stars and converted in the surrounding magnetic fields, with $|g_{aNN}g_{a\gamma\gamma}| \in (2 \times 10^{-21}, 10^{-18})\,\mathrm{GeV}^{-1}$, for $m_a \lesssim 10^{-5}\,\mathrm{eV}$ [298]. The non-observation of an X-ray excess from the magnetic WD RE J0317-853 [299] by Chandra yields the constraint $|g_{aee}g_{a\gamma\gamma}| \lesssim 1.3 \times 10^{-25}\,\mathrm{GeV}^{-1}$, for $m_a \ll 10^{-5}\,\mathrm{eV}$ [128], which provides a non-trivial constraint on the ratio g_{aee}/g_{aNN} for axion models explaining the M7 X-ray excess.

In addition to being produced in NS cores, axions may also be produced in NS magnetospheres. In particular, it has recently been shown that axions could be copiously produced in the polar-cap regions of NS magnetospheres due to time-varying, un-screened electric fields [145]. Those axions could then convert to photons in the outer regions of the NS magnetosphere, leading to observable, broadband radio flux. The absence of such radio flux sets competitive constraints on ALPs, as indicated by the "pulsars" constraint in Fig. 90.1.

90.4.4 *Conversion of astrophysical photon fluxes*

Magnetically induced oscillations between photons and ALPs can modify the photon fluxes from distant sources in various ways, featuring (i) frequency-dependent dimming, (ii) modified polarization, and (iii) avoiding absorption by propagation in the form of axions. For example, dimming of SNe Ia could influence the interpretation in terms of cosmic acceleration [300], although it has become clear that photon-ALP conversion could only be a subdominant effect [301].

Polarization measurements are particularly powerful probes of photon-to-axion conversion since only photons polarized parallel to astrophysical magnetic fields may convert into axions, meaning that in the presence of large-scale ordered magnetic fields axions tend to leave distinct polarization signatures in passing radiation. Searches for linear polarization from radio galaxies (see, *e.g.*, Ref. [302]) and quasars [303] may approach in sensitivity $|g_{a\gamma\gamma}| \sim \text{few} \times 10^{-13}\ \mathrm{GeV}^{-1}$, albeit with uncertainties related to the underlying modeling assumptions. Recently, robust limits at the level $|g_{a\gamma\gamma}| \leq 5.4 \times 10^{-12}\ \mathrm{GeV}^{-1}$ at 95% CL have been derived from optical polarization measurements of nearby magnetic WDs [129] (see also [304]), see Fig. 90.1. The magnetic fields of magnetic WDs may be well-measured through the Zeeman splitting of bound-bound transitions in the WD atmospheres.

Remarkably, it appears that the Universe could be too transparent to TeV γ-rays that should be absorbed by pair production on the extra-galactic background light [109, 305–308]. The situation is not conclusive at present [309–312], but the possible role of photon-ALP oscillations in TeV γ-ray astronomy is tantalizing [313–315]. On the other hand, much of this parameter space is excluded by the previously-discussed WD polarization probes. Fortunately, the region in ALP parameter space, $g_{a\gamma\gamma} \sim 10^{-12} - 10^{-10}\ \mathrm{GeV}^{-1}$ for $m_a \lesssim 10^{-7}$ eV [316], required to explain the anomalous TeV transparency of the Universe, could be conceivably probed by the next generation of laboratory experiments (ALPS II) and helioscopes (IAXO) mentioned above.

This parameter region can also be probed by searching for an irregular behavior of the gamma ray spectrum of distant active galactic nuclei (AGN), expected to arise from photon-ALP mixing in a limited energy range. In this type of studies, the uncertainty in the magnetic field around the source needs to be taken into account. This typically leads to a range of limits on the ALP-photon coupling that depend on the modeling assumptions. The H.E.S.S. collaboration has set a limit of $|g_{a\gamma\gamma}| \lesssim 2.1 \times 10^{-11}\ \mathrm{GeV}^{-1}$, for $1.5 \times 10^{-8}\ \mathrm{eV} \lesssim m_a \lesssim 6.0 \times 10^{-8}$ eV, from the non-observation of an irregular behavior of the spectrum of the AGN PKS 2155-304 [317]. The Fermi-LAT collaboration has put an even more stringent limit on the ALP-photon coupling [118] from observations of the gamma ray spectrum of NGC 1275, the central galaxy of the Perseus cluster, see Fig. 90.1. A similar analysis has been carried out in Ref. [318], using Fermi-LAT data of PKS 2155-304, and in Ref. [131], using ARGO-YBJ and Fermi-LAT data of Mrk 421, see Fig. 90.1. However, these constraints were obtained under certain theoretical assumptions about magnetic fields surrounding the sources, not confirmed yet by direct astronomical observations in these particular directions; this introduces large systematic uncertainties in the reported constraints [319].

Evidence for spectral irregularities has been reported in Galactic sources, such as pulsars and supernova remnants, and has been interpreted as hints for ALPs [334, 335] (see also discussion in Ref. [336] and references therein). However, the inferred ALP parameters, $|g_{a\gamma\gamma}| \sim 10^{-10}\,\mathrm{GeV}^{-1}$, $m_a \sim$ neV, are in tension with the CAST helioscope bounds. Reference [336] updated the analysis of the pulsar signal region including astrophysical nuisance parameters and correctly deriving confidence intervals on ALP

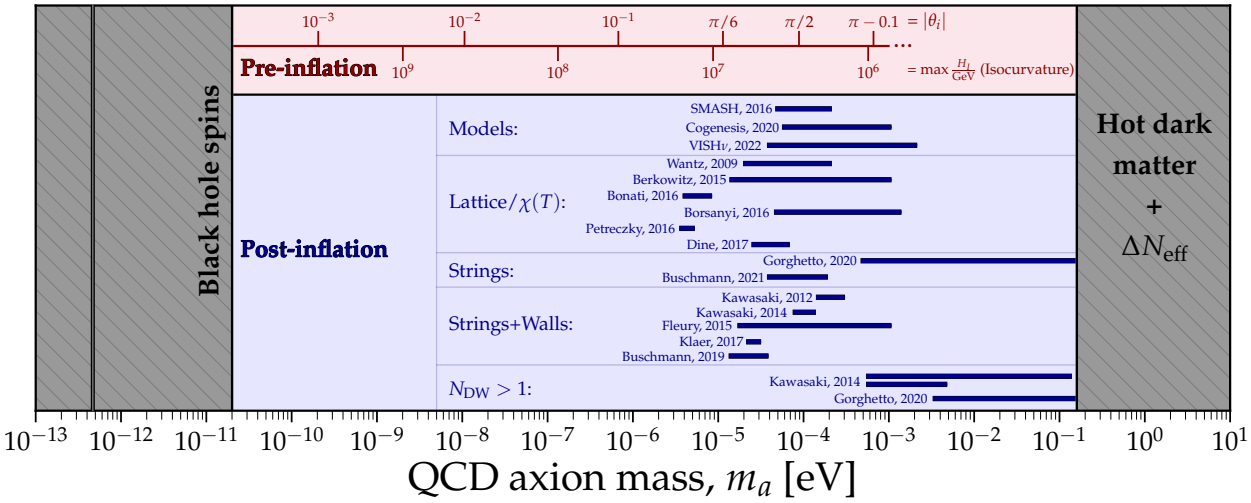

Figure 90.4: QCD axion mass predictions for obtaining the correct DM abundance assuming the PQ symmetry is and is not restored after inflation and, in the case the PQ symmetry is restored after inflation, depending on the domain wall number N. Figure courtesy of Ciaran O'Hare [61], includes data from refs. [18,33,320–333]. The lower-end of the possible mass range is bounded by BH superradiance constraints and the theoretical requirement that f_a be below the Planck scale, while the upper end is bounded by the somewhat model-dependent NS cooling constraints (not shown), which exclude QCD axion masses above roughly ∼15-30 meV, depending on the UV completion. At even higher masses there are strong constraints from the production of DM in the early universe, which behaves as hot DM and contributes to $\Delta N_{\rm eff}$.

parameters by means of Monte Carlo simulations. The tension with the CAST bounds can be evaded if environmental effects in matter, which would suppress the ALP production in dense astrophysical plasmas like the solar interior, are invoked. If this explanation is correct, the claimed ALP signal would be in reach of the next-generation LSW experiment ALPS II. Other ways to make the CAST bound compatible with photon-ALP conversions in the low-density Galactic medium are invoking photon-ALP-dark photon oscillations [337] or the existence of a number of 'hidden' ALPs [338].

At smaller masses, $m_a \lesssim 10^{-12}\,\text{eV}$, galaxy clusters become highly efficient at interconverting ALPs and photons at X-ray energies. Constraints on spectral irregularities in the spectra of luminous X-ray sources (Hydra A, M87, NGC 1275, NGC 3862, Seyfert galaxy 2E3140; taken by Chandra and XMM-Newton) located in or behind galaxy clusters then lead to stringent upper limits on the ALP-photon coupling [110–112, 339–341], (for the limits exploiting spectra from Hydra and M87 from Refs. [110] and [111], respectively, see Fig. 90.1). Reference [112] recently performed the most sensitive x-ray searches for ALPs to date by employing Chandra's High-Energy Transmission Gratings that allow for an unsurpassed spectral resolution. New observations of the AGN NGC 1275 then led to the bound $|g_{a\gamma\gamma}| < 8\times10^{-13}\ \text{GeV}^{-1}$ at 99.7% C.L. for ultra-light ALPs, as illustrated in Fig. 90.1. On the other hand, magnetic field modeling uncertainties in the clusters may not be fully accounted for in these analyses [319].

90.4.5 *Finite density effects for the QCD axion*

If the QCD axion sector has a discrete, $\mathbb{Z}_{\mathcal{N}}$, shift symmetry, its potential is much shallower, and its mass, in units of its decay constant, $m_a f_a \simeq (3\pi)^{-1/4}\,\mathcal{N}^{3/4}\,2^{-\mathcal{N}/2}\,m_\pi f_\pi$, is smaller than the one of the canonical QCD axion by an exponential factor $\propto 2^{-\mathcal{N}/2}$ [57, 58]. This opens up the parameter space over which one should search for a QCD axion towards the left of the yellow canonical QCD axion band in Fig. 90.1, Fig. 90.2, and Fig. 90.3. Novel bounds apply to this exceptionally light QCD axion due to finite density effects [342–344]. In fact, in dense stellar media, the minimum of the axion potential may be shifted to π. This has a number of phenomenological consequences that span from the modification of nuclear processes in stars due to $\theta = \mathcal{O}(\pi)$ to modifications in the orbital decay of binary systems (and subsequently in the emitted gravitational waves). Recently strong constraints have been set using the modification of the WD mass-radius relation due to such axions [345].

In fact, $\theta \sim 1$ in the solar core would lead to an increased proton-neutron mass difference, which would prohibit the neutrino line corresponding to the ^{7}Be-^{7}Li mass difference observed by Borexino [346].

Moreover, the fact that the position of the minimum of the axion potential depends on the nuclear density of the medium may also source a long-range force between dense stars [342]. This new long-range force sourced by the axion can be constrained by the measurement of the orbital decay of double pulsar or NS-pulsar binaries [342]. The gravitational wave signal of NS-NS mergers or black hole (BH) - NS mergers would also be modified by these axionic long-range forces [342,343]. There is also a corresponding bound [344] exploiting the gravitational waves observation from the binary NS inspiral GW170817 detected by LIGO (Laser Interferometer Gravitational-Wave Observatory) and Virgo [347].

90.4.6 *Superradiance of black holes*

Light bosonic fields such as axions or ALPs can affect the dynamics and gravitational wave emission of rapidly rotating astrophysical BHs through the superradiance mechanism. When the boson's Compton wavelength is of order of the size of the BH's ergoregion, they form gravitational bound states around the BH. Their occupation number grows exponentially by extracting energy and angular momentum from the black hole, forming a coherent axion or ALP bound state emitting gravitational waves. When accretion cannot replenish the spin of the BH, superradiance dominates the BH spin evolution; this is true for both supermassive and stellar mass BHs. The existence of destabilizing light bosonic fields thus leads to exclusion regions in the mass versus spin plot of rotating BHs. Stellar BH spin measurements exploiting well-studied binaries and two independent techniques exclude a mass range – up to self-interaction caveats discussed below – $6\times10^{-13}\,\text{eV} < m_a < 2\times10^{-11}\,\text{eV}$ at $2\,\sigma$, which for the axion excludes $3\times10^{17}\,\text{GeV} < f_a < 1\times10^{19}\,\text{GeV}$ [12, 348, 349], see Fig. 90.4. These bounds apply when gravitational interactions dominate over the axion self-interaction, which is largely true for the QCD axion in this mass range. On the other hand, Mehta *et al.* [350, 351] considered superradiance bounds for string theory ALPs with a quartic self-coupling (of either sign) given by $\lambda = m_a^2/f_a^2$, using the bosenova model of Ref. [349], and found that for $m_a \sim 10^{-12}$ eV the superradiant cloud, and thus the constraints, are destroyed for $f_a \lesssim 10^{11} - 10^{12}$ GeV, depending precisely on the mass and the source.

Baryakhtar *et al.* [352] used a more advanced model for the ef-

fect of self-interactions on superradiant evolution, and a different (frequentist) statistical methodology, leading to more conservative bounds from stellar mass BHs (region near 10^{-12} eV). In particular, Baryakhtar *et al.* [352] found that QCD axions are only excluded for $m_a \lesssim 6\times10^{-12}\ M_\odot$ instead of the $2\times10^{-11}\ M_\odot$, as claimed in [350,351]. Baryakhtar *et al.* [352] also vetoed supermassive BHs (SMBHs) with spins measured at low significance, and thus found no ALP bounds in the SMBH region (near 10^{-18} eV); Mehta *et al.* [350, 351, 353], in constrast, included SMBHs in a (quasi-)Bayesian analysis with a flat prior on the spin and found non-trivial constraints . In summary, it appears likely that the lower end of the QCD axion mass range is excluded by superradiance, with the requirement $m_a \gtrsim 10^{-11}$ eV, but the exact location of this limit is still debated. It is also too early to claim that ultralight ALP parameter space is excluded by SMBHs, though this may change with future work.

Long lasting, monochromatic gravitational wave signals, which can be distinguished from ordinary astrophysical sources by their clustering in a narrow frequency range, are expected to be produced by axions or ALPs annihilating to gravitons. Gravitational waves could also be sourced by axions/ALPs transitioning between energy levels of the effective gravitational atom. Accordingly, the gravitational wave detector Advanced LIGO should be sensitive to the axion in the $m_a \lesssim 10^{-10}\,\text{eV}$ region. LIGO measurements of BH spins in binary merger events could also provide statistical evidence for the presence of an axion [354, 355]. Similar signatures could arise for supermassive and intermediate mass BHs for particles with masses $\lesssim 10^{-15}\,\text{eV}$. Gravitational waves from such sources could be detected at lower-frequency observatories such as LISA (Laser Interferometer Space Antenna). First attempts to use LIGO/Virgo data to search for monochromatic signatures of axion superradiance were recently made in [356, 357].

90.5 Cosmic Axions

90.5.1 *Cosmic axion populations*

There are two distinct populations of cosmic relic axion populations: a non-thermal one behaving as CDM, and a thermal one comprising a HDM component, in analogy to massive neutrinos. For $m_a \lesssim 0.01\,\text{eV}$, thermal axions are dominantly produced by processes involving quarks and gluons [358, 359], while, for larger masses, the dominant thermalization process is $\pi + \pi \leftrightarrow \pi + a$ [173, 360, 361]. A number of evaluations exploiting cosmological precision data have found restrictive constraints on a possible HDM fraction that translate into an upper bound on the axion mass, $m_a \lesssim 1$ eV, if a LO axion-pion chiral effective field theory (EFT) analysis of the axion-pion thermalization rate is used [362–365]. Recently, it was found that the NLO contribution exceeds the LO contributions for masses below $m_a \lesssim 1.2\,(0.12/C_{a\pi})\,\text{eV}$ [366]. Therefore, in order to assess the reach in sensitivity of future cosmological data sets, one has to improve the EFT description or to compute axion-pion scattering via lattice QCD techniques. Alternatively, recently Ref. [367] used pion-pion scattering data to overcome the EFT description issues and found the constraint $m_a \lesssim 0.24$ eV, see Fig. 90.4.

For $m_a \gtrsim 10$ eV, axions may decay faster than the age of the Universe (see Eq. (90.7)), depending on the decay constant, which would remove the cosmic axion population while injecting photons. If the axions were in thermal equilibrium in the early Universe, which depends on the inflationary reheat temperature and assumptions about the pre-BBN cosmology [368, 369], this excess radiation provides additional limits on the axion- or ALP-photon coupling up to very large masses [368, 369]. Such photons could contribute to the extragalactic background light (EBL), could ionize primordial hydrogen and thus contribute to the optical depth after recombination, or could spoil the agreement of big bang nucleosynthesis (BBN) with observations. The corresponding up-to-date bounds from Refs. [166, 167] are displayed in Fig. 90.1. It has recently been shown that there is an *irreducible axion background* [168] that arises from axion freeze-in before BBN; decays of that axion population provide strong constraints on axions with masses above roughly 100 eV (see Fig. 90.1). For high enough decay constants, high-mass axions ($m_a \gtrsim 10$ eV) can account for the DM abundance through the misalignment mechanism, described in more detail below, though additional entropy dilution or fine-tuning is needed to avoid overproducing the DM abundance [370] (see also [371] for heavy axion production through lepton-flavor-violating decays). The decay of such high-mass axions to photon pairs could leave narrow spectral features in *e.g.* optical or X-ray backgrounds [126, 138–140, 161, 163, 372, 373] (see Fig. 90.1).

The main cosmological interest in axions at present derives from their possible role as CDM. In addition to thermal processes, axions are abundantly produced by the misalignment (MIS) mechanism [374–376]. The axion DM abundance crucially depends on the cosmological history. Let us first consider the so called *pre-inflationary PQ symmetry breaking scenario*, in which the PQ symmetry is broken before and during inflation and not restored afterwards. After the breakdown of the PQ symmetry, the axion field relaxes somewhere in the bottom of the "wine-bottle-bottom" potential. Near the QCD epoch, topological fluctuations of the gluon fields such as instantons explicitly break the PQ symmetry. This tilting of the "wine-bottle-bottom" drives the axion field toward the CP-conserving minimum, thereby exciting coherent oscillations of the axion field that ultimately represent a condensate of CDM. The fractional cosmic mass density in this homogeneous field mode, created by the MIS mechanism, is [33, 377–379],

$$\begin{aligned}\Omega_a^{\rm MIS}h^2 &\approx 0.12\,\left(\frac{f_a}{9\times10^{11}\ \text{GeV}}\right)^{1.165} F\,\Theta_{\rm i}^2\\ &\approx 0.12\,\left(\frac{6\ \mu\text{eV}}{m_a}\right)^{1.165} F\,\Theta_{\rm i}^2\,,\end{aligned} \tag{90.22}$$

where h is the present-day Hubble expansion parameter in units of 100 km s^{-1} Mpc^{-1}, and $-\pi \le \Theta_{\rm i} \le \pi$ is the initial "misalignment angle" relative to the CP-conserving position attained in the causally connected region which evolved into today's observable Universe. $F = F(\Theta_{\rm i}, f_a)$ is a factor accounting for anharmonicities in the axion potential. For $F\Theta_{\rm i}^2 = \mathcal{O}(1)$, m_a should be above $\sim 6\,\mu$eV in order that the cosmic axion density does not exceed the observed CDM density, $\Omega_{\rm CDM}h^2 = 0.12$. However, much smaller axion masses (much higher PQ scales) are still possible if entropy is diluted for example by the late decay of a scalar condensate (see for example [380] and references therein) or the initial value $\Theta_{\rm i}$ just happens to be small enough in today's observable Universe ("anthropic axion window" [381]). In the latter cosmological scenario, however, quantum fluctuations of the axion field during inflation are expected to lead to isocurvature density fluctuations which get imprinted to the temperature fluctuations of the CMB [382,383]. Their non-observation puts severe constraints on the Hubble expansion rate H_I during inflation [384–389], which read, in the simplest cosmological inflationary scenario,

$$H_I \lesssim 5.7\times10^8\ \text{GeV}\left(\frac{5\,\text{neV}}{m_a}\right)^{0.4175}\,, \tag{90.23}$$

if axions represent all of DM. In Ref. [390] an alternative to the MIS mechanism was proposed: the so-called kinetic MIS mechanism. In this case, the axion field is assumed to have an initial velocity which may be generated, e.g., by a hypothesized explicit breaking of the axion shift symmetry in the early universe. The amount of QCD axion dark matter generated by the kinetic MIS mechanism can fit the observed dark matter abundance for any $f_a \lesssim 1.5\times10^{11}$ GeV, down to the minimum value allowed by the SN 1987A constraint.

In the above prediction of the fractional cosmic mass density in axions, the exponent, 1.165, arises from the non-trivial temperature dependence of the topological susceptibility $\chi(T) = m_A^2(T)f_A^2$ at temperatures slighty above the QCD quark-hadron phase transition. Lattice QCD calculations of this exponent [33, 323, 325, 391–393], but also Ref. [324], found it to be remarkably close to the prediction of the dilute instanton gas approximation [394] which was previously exploited. Therefore, the state-of-the-art prediction of the axion mass relevant for DM for a fixed initial misalignment angle $\Theta_{\rm i}$ differs from the previous prediction by just a factor of order one.

In the *post-inflationary PQ symmetry breaking scenario*, on the other hand, $\Theta_{\rm i}$ will take on different values in different patches of

the present Universe. The average contribution is [33, 377–379]

$$\Omega_a^{\rm MIS} h^2 \approx 0.12 \left(\frac{30\ \mu{\rm eV}}{m_a}\right)^{1.165} . \quad (90.24)$$

The decay of cosmic strings and domain walls gives rise to a further population of CDM axions, whose abundance suffers from significant uncertainties [321, 327–329, 378, 379, 395–403] which arise from the difficulty in understanding the energy loss process of topological defects and the generated axion spectrum in a quantitative way. In fact, in the present state-of-the-art it is still possible that the CDM contribution from the decay of topological defects is subdominant [327] or overwhelmingly large [328] in comparison to the one from the MIS mechanism. Correspondingly, the plausible range of axion masses providing all of CDM in scenarios with postinflationary PQ symmetry breaking is still rather large, namely [327, 328]

$$m_a \approx 26\ \mu{\rm eV} - 0.5\ {\rm meV}, \quad (90.25)$$

for models with short-lived (requiring unit color anomaly $N = 1$) domain walls, such as the KSVZ model. On the other hand, the most recent adaptive mesh refinement axion string simulations, which are able to evolve over larger dynamic ranges than static lattice simulations, suggest the mass range $m_a \approx 40 - 180$ μeV [321]. For models with long-lived ($N > 1$) domain walls, such as an accidental DFSZ model [404], where the PQ symmetry is broken by higher dimensional Planck suppressed operators, the mass is predicted to be significantly higher [287, 329, 404–406],

$$m_a \approx (0.58 - 130)\,{\rm meV} . \quad (90.26)$$

However, the upper part of the predicted range is in conflict with stellar energy-loss limits on the axion. The pre- and post-inflationary mass predictions are summarized in Fig. 90.4.

In this post-inflationary PQ symmetry breakdown scenario, the spatial axion density variations are large at the QCD transition, and they are not erased by free streaming. Gravitationally bound "axion miniclusters" form before and around matter-radiation equality [407–409]. A significant fraction of CDM axions can reside in these bound objects [400, 410]. Remarkably, the minicluster fraction can be bounded by gravitational lensing [411–413], although more simulations are required to understand whether miniclusters are dense enough and survive in sufficient quantities for lensing bounds to apply.

The non-thermal production mechanisms attributed to axions are generic to light bosonic weakly interacting particles such as ALPs [18]. The relic abundance is set by the epoch when the axion mass becomes significant, $3H(t) \approx m_a(t)$, and ALP field oscillations begin. For ALPs to contribute to the DM density this epoch must precede that of matter radiation equality. For a temperature independent ALP mass this leads to the bound:

$$m_a \gtrsim 7 \times 10^{-28}\,{\rm eV} \left(\frac{\Omega_m\, h^2}{0.15}\right)^{1/2} \left(\frac{1+z_{\rm eq}}{3.4\times 10^3}\right)^{3/2} . \quad (90.27)$$

ALPs lighter than this bound are allowed if their cosmic energy density is small, but they are quite distinct from other forms of DM [414]. Ignoring anharmonicities in the ALP potential, and taking the ALP mass to be temperature independent, the relic density in DM ALPs due to the MIS mechanism is given by

$$\Omega_{\rm ALP}^{\rm MIS} h^2 = 0.12 \left(\frac{m_a}{4.7\times 10^{-19}\,{\rm eV}}\right)^{1/2} \left(\frac{f_a}{10^{16}\,{\rm GeV}}\right)^2 \times \left(\frac{\Omega_m h^2}{0.15}\right)^{3/4} \left(\frac{1+z_{\rm eq}}{3.4\times 10^3}\right)^{-3/4} \Theta_{\rm i}^2 . \quad (90.28)$$

An ALP decay constant near the GUT scale gives the correct relic abundance for *ultralight ALPs* (ULAs) with $m_{\rm ULA} \approx 10^{-19}$ eV [415, 416]. ULAs encompass the entire Earth in a single Compton wavelength, and for large occupation numbers are modelled as a coherent classical field. The coherence time is determined by the mass and virial velocity in the Milky Way, $\tau_{\rm coh} \sim 1/m_{\rm ULA} v_{\rm vir}^2$, with the detailed properties described by a stochastic model with an approximately Rayleigh Jeans distribution [417]. Natural models for ULAs can be found in string and M-theory compactifications [7, 8, 10–15], in field theory with accidental symmetries [418, 419], or new hidden strongly coupled sectors [420, 421].

In addition to the gravitational potential energy, the ULA field also carries gradient energy. On scales where the gradient energy is non-negligible, ULAs acquire an effective pressure and do not behave as CDM. The gradient energy opposes gravitational collapse, leading to a Jeans scale below which perturbations are stable [422]. The Jeans scale suppresses linear cosmological structure formation relative to CDM [423–425]. The Jeans scale at matter-radiation equality in the case that ULAs make up all of CDM is:

$$k_{\rm J,eq} = 8.7\,{\rm Mpc}^{-1} \left(\frac{1+z_{\rm eq}}{3.4\times 10^3}\right)^{-1/4} \left(\frac{h^2\Omega_{\rm ALP}^{\rm MIS}}{0.12}\right)^{1/4} \times \left(\frac{m_{\rm ULA}}{10^{-22}\,{\rm eV}}\right)^{1/2} . \quad (90.29)$$

On non-linear scales the gradient energy leads to the existence of a class of pseudo-solitons known as oscillatons, or axion stars [426]. Axion stars are expected to form in all cosmological scenarios, and for all types of ALPs, including the QCD axion [427–429]. Some axion stars may explode into radio photons, heating the interstellar medium [104].

Cosmological and astrophysical observations are consistent with the CDM model, and departures from it are only allowed on the scales of the smallest observed DM structures with $M \sim 10^{6-8} M_\odot$. The CMB power spectrum and galaxy autocorrelation power spectrum limit the ULA mass to $m_{\rm ULA} \gtrsim \mathcal{O}({\rm few}) \times 10^{-24}$ eV from linear theory of structure formation [414, 430]. Analytic models [431] and N-body simulations [432] for non-linear structures show that halo formation is suppressed in ULA models relative to CDM. This leads to constraints on the ULA mass of $m_{\rm ULA} > 10^{-22}\,{\rm eV}$ from observations of high-z galaxies [432–434], and $m_{\rm ULA} > 2\times 10^{-20}\,{\rm eV}$ from the Lyman-alpha forest flux power spectrum [435]. Including the effects of anharmonicities on structure formation with ALPs can weaken these bounds if the misalignment angle $\Theta_{\rm i} \approx \pi$ [436]. A comprehensive study of Milky Way satellites by the DES collaboration resulted in the bound $m_{\rm ULA} > 2.9\times 10^{-21}\,{\rm eV}$ [437].

Cosmological simulations that treat gradient energy in the ULA field beyond the N-body approximation have just recently become available [427, 438–440], and show, among other things, evidence for the formation of axion stars in the centres of ULA halos (various consequences of axion stars are considered in Refs. [441]). These central axion stars have been conjectured to play a role in the apparently cored density profiles of dwarf spheroidal galaxies, and other central galactic regions [127,427,442–446]. However, the relationship between the halo mass and the axion star mass [447] leads to problems with this scenario in some galaxies [448–450]. It should be emphasised that many of the conclusions about the role of ULA axion stars in galactic dynamics are based on use of simulation results that do not contain baryons and feedback could be important [451–453].

Inside DM halos the axion gradient energy causes coherence on the de Broglie wavelength and fluctuations on the coherence time [427,454]. These fluctuations can be thought of as short-lived quasiparticles and lead to relaxation processes that can be described statistically [416, 455] (this relaxation processes also leads to the gravitational condensation of axion stars [428]). The typical relaxation time is:

$$t \sim 10^{10}\ {\rm years} \left(\frac{m_{\rm ULA}}{10^{-22}\ {\rm eV}}\right)^3 \left(\frac{v}{100\ {\rm km\ s^{-1}}}\right)^2 \left(\frac{r}{5\ {\rm kpc}}\right)^4 , \quad (90.30)$$

where v and r are the velocity and radius of the orbit in the host DM halo.

Relaxation processes such as these are not observed in galaxies, though there are some circumstances where they may be desirable [416]. An absence of observed relaxation can be used to set

limits on the ULA mass. An absence of Milky Way disk thickening excludes $m_{\rm ULA} > 0.6 \times 10^{-22}$ eV [456], while stellar streams give the stronger bound $m_{\rm ULA} > 1.5 \times 10^{-22}$ eV [457]. The survival of the old star cluster in Eridanus II [458] excludes the range of masses 10^{-21} eV $\lesssim m_{\rm ULA} \lesssim 10^{-19}$ eV [459]. Recently Ref. [460] finds that ULA DM is excluded for $m_{\rm ULA} \lesssim 3 \times 10^{-19}$ eV at 99% CL because such DM would kinematically heat the stars in the Segue I and Segue II ultra-faint dwarf galaxies to a level inconsistent with their observed dynamics.

Finally, one should note that the beyond-CDM physics of ULAs (Jeans scale, relaxation, axion star formation) of course also applies to the QCD axion on smaller length scales. This is of particular interest inside axion miniclusters [407, 408, 428, 429].

90.5.2 *Electron recoil searches*

In a DM direct detection experiment, a DM ALP featuring a coupling to the electron can be absorbed by the target material, leading to a mono-energetic electronic recoil signal peaked at m_a. This mechanism allowed the EDELWEISS [461], PandaX [221], SuperCDMS [222] and XENON1T [462] collaborations to put the bounds on the axion-electron coupling displayed in Fig. 90.2 in the keV mass range. As discussed in the last sub-section, additionally dynamics beyond the standard misalignment mechanism are needed to explain the axion DM abundance for keV-scale axion masses (*e.g.*, [370, 371]). Moreover, such models are subject to stringent constraints from axion decays to photons [370].

90.5.3 *Telescope searches*

The two-photon decay is extremely slow for axions with masses in the CDM regime, but could be detectable for eV masses. The signature would be a quasi-monochromatic emission line from galaxies and galaxy clusters. The expected optical line intensity for DFSZ axions is similar to the continuum night emission. A search for optical line emission in two Abell clusters using spectra from the VIMOS (Visible Multi-Object Spectrograph) integral field unit at the Very Large Telescope (VLT) excludes axions and ALPs with a two photon coupling bigger than $\sim 5 \times 10^{-12}\,\mathrm{GeV}^{-1}$ in the mass range between 4.5 and 5.5 eV [163], see Fig. 90.1. Spectral data on the dwarf spheroidal galaxy Leo T from the Multi Unit Spectroscopic Explorer (MUSE) at the VLT improve these constraints by more than an order of magnitude for ALP masses between 2.7 and 5.3 eV [162], see Fig. 90.1.

Very low-mass axions in halos produce a weak quasi-monochromatic radio line. Virial velocities in undisrupted dwarf galaxies are very low, and the axion decay line would therefore be extremely narrow. A search with the Haystack radio telescope on three nearby dwarf galaxies gave a limit $|g_{a\gamma\gamma}| < 1.0 \times 10^{-9}$ GeV^{-1} at 96% CL for $298 < m_a < 363\,\mu$eV [161]. However, this combination of m_a and $g_{a\gamma\gamma}$ does not exclude plausible axion models.

A monochromatic signal is also produced in the conversion of DM axions in the background of slowly varying galactic B-fields [463]. The signal is, however, sensitive to magnetic field power on the scale of the axion mass [464]. Present and future radio telescopes appear to be able to probe ALP DM in the mass range $0.1 - 100$ μeV for couplings $g_{a\gamma\gamma} \gtrsim 10^{-13}$ GeV^{-1} [464] – unfortunately not reaching down to the benchmark QCD axion sensitivity.

Resonant conversion of QCD axion or ALP DM in NS magnetospheres may give a detectable signal from individual NSs and populations of NSs for axion masses in the μeV range [465, 466]. Recent analyses of radio data in the frequency range 1-40 GHz from several NSs have found no evidence for a narrow peak predicted from this mechanism and therefore put bounds on the axion-photon coupling around $10^{-11}\,\mathrm{GeV}^{-2}$ for $m_a \sim 10$ μeV [133–136], see Fig. 90.1. However, these limits may still suffer from uncertainties because the line intensity is difficult to predict in detail in the complicated environments of NSs [135, 467–470]. Still, next-generation radio telescopes such as the Square Kilometer Array (SKA) may reach sensitivity to QCD axion-strength couplings [136]. Stimulated ALP decays in high radiation environments may be detectable, by *e.g.* the future SKA, down to $g_{a\gamma\gamma} \gtrsim 10^{-11}\,\mathrm{GeV}^{-1}$, for masses between μeV and 0.1 meV [471]. Furthermore, in condensed ALP dark matter structures such as ALP stars, a parametric instability may lead to an exponential enhancement of the photon flux from ALP-photon conversion by a factor $\sim \exp\left[|g_{a\gamma\gamma}| \int ds \rho_a^{1/2}(s)\right]$, where the integral is along any photon trajectory through the ALP overdensity [472, 473].

Photon propagation on an ULA DM background can induce birefringence that can be compared with upper limits from the CMB [106, 141, 474] and may also be probed with other sources such as pulsars [475].

90.5.4 *Microwave cavity experiments*

Over a large part of the plausible m_a range for CDM, Galactic halo axions may be detected by their resonant conversion into a quasi-monochromatic microwave signal in a high-Q electromagnetic cavity permeated by a strong, static B field [9, 476, 477]. The cavity frequency is tunable, and the signal is maximized when the cavity resonant frequency is the total axion energy, rest mass plus kinetic energy, of $\nu = (m_a/2\pi)\,[1 + \mathcal{O}(10^{-6})]$, the width above the rest mass representing the axions' virial distribution in the galaxy near Earth. The frequency spectrum may also contain finer structure from axions more recently fallen into the galactic potential and not yet completely virialized [478, 479] or otherwise incompletely thermalized.

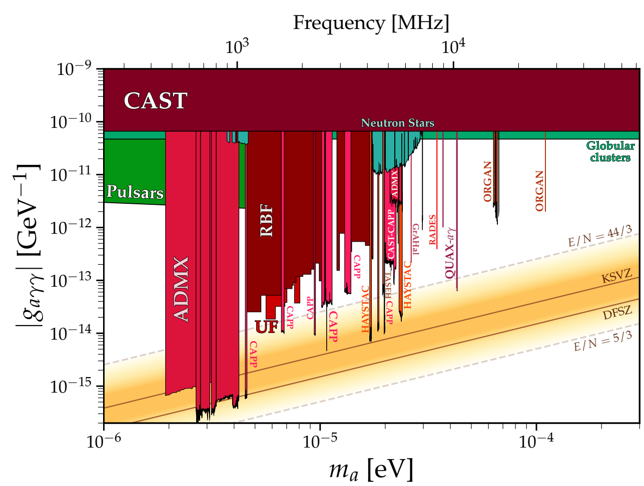

Figure 90.5: Exclusion plot for ALP-photon coupling with closeup on the parameter space of RF cavity experiments as described in the text. This is a zoom-in of Fig. 90.1 that highlights regions probed by axion DM direct detection experiments. In particular, note that all of the terrestrial experiments shaded in red, except that of CAST, assume that the axion is 100% of the local DM. Figure courtesy of Ciaran O'Hare [61], including data from Refs. [43, 64–68, 76, 78, 81–84, 86, 87, 91, 93, 99, 122, 123, 145, 216, 480–484]

The feasibility of this technique was established in early experiments (RBF (Rochester-Brookhaven-Florida) and UF (University of Florida)) of relatively small sensitive volume, $\mathcal{O}$(1 liter), with HFET-based microwave amplifiers, setting limits in the range $4.5 < m_a < 16.3$ μeV [91, 95, 482], but lacking by 2–3 orders of magnitude the sensitivity required to detect realistic axions, see Fig. 90.5.

Later, the first generation of ADMX ($B \sim 8$ T, $V \sim 200$ liters) achieved sensitivity to KSVZ axions, assuming they saturate the local DM density and are well virialized, over the mass range 1.9–3.3 μeV [485]. Should halo axions have a significant narrow component not yet virialized, ADMX was sensitive to DFSZ axions over the entire mass range [486]. The corresponding 90% CL exclusion regions shown in Fig. 90.5 assume a local CDM density of 7.5×10^{-25} g cm^{-3} (450 MeV cm^{-3}).

Somewhat later, the ADMX experiment commissioned an upgrade [64] that replaced the microwave HFET amplifiers by near-quantum-limited low-noise dc SQUID microwave amplifiers [487] and, more recently, with Josephson parametric amplifiers (related

to the earlier dc SQUID amplifiers), also with noise near-quantum-limited [481]. With its large volume and low noise, ADMX has achieved an unprecedented axion DM sensitivity in the mass range between 2.7 and 4.2 μeV [66–68, 480], down to the DFSZ benchmark axion-photon coupling over much of the range, see Fig. 90.5. This apparatus is also sensitive to certain other hypothetical light bosons, such as hidden photons or chameleons, over a limited parameter space [18, 488, 489].

ADMX continues to scan at DFSZ sensitivity, and has since been joined by an array of haloscopes. One of the CAPP experiments has also achieved DFSZ sensitivity over a small range of frequencies near 4.55 μeV [76]. A number of other experiments from the CAPP group have operated at higher frequencies, many with KSVZ or near KSVZ sensitivity. [72–74, 74, 75] The HAYSTAC experiment also operates at or near KSVZ sensitivity and was the first to demonstrate near-quantum limited noise using a Josephson parametric amplifier [82,490], and demonstrated 'state-squeezing' to increase scan speed by nearly a factor of 2. [83, 84] Other haloscopes operating at or near KSVZ over narrow bands include TASEH [93] and QUAX-aγ [90]. The ORGAN experiment is the highest frequency haloscope, operating with a small cavity and sensitive to axion-like-particle masses up to 67.1 μeV, though not yet with sensitivity to the KSVZ model. [86, 87] There are also a number of other haloscopes sensitive to axion-like-particles with couplings above those predicted by KSVZ. [65, 81, 88, 89, 483] Fig. 90.5 shows the exclusions on axion-photon coupling from these haloscopes to date.

90.5.5 *New concepts for axion DM direct detection*

Other new concepts for searching for axion DM are also being investigated. "Plasma haloscopes" are under development by the ALPHA consortium [491]. This concept uses a metamaterial consisting of a parallel-wire array, thereby inducing an effective photon mass which is tunable by adjusting wire separation, and sensitive to axion masses 35–400 μeV. Another detector concept exploits the fact that a magnetized mirror would radiate photons in the background of axion DM, which could be collected like in a dish antenna [492]. The proposed MADMAX experiment will place a stack of dielectric layers in a magnetic field in order to resonantly enhance the photon signal, aiming a sensitivity to probe the mass range $40\,\mu\text{eV} \lesssim m_a \lesssim 200\,\mu\text{eV}$ [493, 494]. Optical dielectric haloscopes with single photon signal detection have been proposed to search for axions in the 50 meV – 10 eV mass range [495]. Other semi-resonant or nonresonant axion haloscope ideas to read high mass axions that are based around similar principles but novel configurations include BREAD [496] and CADEx [497].

Absorption of axions on molecular transitions can be sensitive to the axion pseudoscalar coupling g_{aNN} to nucleons or the pseudoscalar coupling g_{aee} to electrons in the 0.5 – 20 eV range [498]. It has also been pointed out that the coupling induced by an axion field between photonic modes [96, 499] or atomic states [500] separated by an energy equal to the axion mass may be leveraged for axion detection, though the implementation may be challenging. Certain magnetic topological insulators are conjectured to contain axion-polaritons, quasiparticles composed of magnons and the electric field, with magnetically tunable mass in the meV to eV range [501–503]. Axion dark matter leads to resonant photon emission from such materials, which can be detected [504, 505].

In the intermediate mass region, $\text{neV} \lesssim m_a \lesssim 0.1\,\mu\text{eV}$, one may exploit a cooled LC circuit and precision magnetometry to search for the oscillating electric current induced by DM axions in a strong magnetic field [506, 507]. A number of small-scale pathfinder experiments have implemented this approach: ABRACADABRA [62,63] used a nonresonant configuration in a toroidal magnet for a broadband search, ADMX-SLIC [70] used a resonant configuration in a solenoid magnet for a narrowband search, SHAFT [92] used a nonresonant configuration in a toroidal magnet enhanced with a ferromagnetic core, BASE [80] used antiprotons in a Penning trap as the LC circuit, and DANCE [508] used a laser interferometer. The exclusion limits from these experiments are shown in Fig. 90.1; none are yet sensitive to the QCD axion. Future work in this direction is expected to have much more competitive limits [509, 510].

The oscillating Galactic DM axion field induces oscillating nuclear electric dipole moments (EDMs) [35],

$$d_N(t) = g_{aN\gamma}\sqrt{2\rho_{a\text{DM}}}\cos(m_a\,t)/m_a\,, \tag{90.31}$$

where $g_{aN\gamma}$ is the coupling of the axion to the nucleon EDM operator, defined in Eq. (90.4). An analysis of the ratio of spin-precession frequencies of stored ultracold neutrons and ^{199}Hg atoms measured by neutron EDM experiments for an axion-induced oscillating neutron EDM revealed no signal consistent with axion DM, excluding a sizeable region of parameter space in the mass region $10^{-24}\,\text{eV} \le m_a \le 10^{-17}\,\text{eV}$ [40], which surpass the limits on anomalous energy loss of SN 1987A by more than seven orders of magnitude and are competitive with the ones from the requirement of successful BBN established in [38].[1] In fact, the oscillating dark matter axion field could increase the neutron-proton mass difference at neutron freeze-out and thus result in the underproduction of ^{4}He during BBN. The oscillating EDMs cause also the precession of nuclear spins in a nucleon spin polarized sample in the presence of an electric field. The resulting transverse magnetization can be searched for by exploiting magnetic-resonance (MR) techniques, which are most sensitive in the range of low oscillation frequencies corresponding to sub-neV axion masses. The aim of the corresponding Cosmic Axion Spin Precession Experiment (CASPEr) [36] is to probe axion DM in the anthropic window, $f_a \gtrsim 10^{15}\,\text{GeV}$ ($m_a \lesssim$neV), motivated from Grand Unification [511–514]. There are two interactions probed through MR: the electric dipole coupling as searched for by CASPEr-electric (with first result presented in [39]) and an interaction between the axion field gradient and the nuclear spin, which is aimed for by CASPEr-Gradient. In the meantime, the latter has been explored through comagnetometry between a variety of nuclei: H-^{12}C in CASPEr-ZULF [246,247], Xe-Rb in NASDUCK [515], and K-^{3}He [251, 252]. The exclusions from these searches are shown in Fig. 90.3. Sub-μeV ALP masses can also be probed by using the storage ring EDM method proposed in Ref. [516] which exploits a combination of B and E-fields to produce a resonance between the $g-2$ spin precession frequency and the DM ALP field oscillation frequency. This method, however, does not reach the sensitivity to probe the QCD axion prediction for $g_{aN\gamma}$. An eventually non-zero axion electron coupling g_{aee} will lead to an electron spin precession about the axion DM wind [517, 518]. The QUAX a-e experiment exploits MR inside a magnetized material [519]. Because of the higher Larmor frequency of the electron, it is sensitive in the classic window. Its first run established the bound in the mass range 42.4 to 43.2 μeV [227], slightly better than the solar ν bound, shown in Fig. 90.2.

90.6 Conclusions

There is a strengthening physics case for very weakly coupled light particles beyond the Standard Model. The elegant solution of the strong CP problem proposed by Peccei and Quinn yields a particularly strong motivation for the axion. In many theoretically appealing ultraviolet completions of the Standard Model axions and ALPs occur automatically. Moreover, they are natural CDM candidates. Perhaps the first hints of their existence have already been seen in the anomalous excessive cooling of stars and the anomalous transparency of the Universe for very high energy gamma rays. Interestingly, a significant portion of previously unexplored, but phenomenologically very interesting and theoretically very well motivated axion and ALP parameter space can be explored in the foreseeable future by a number of terrestrial experiments searching for axion/ALP DM, for solar axions/ALPs, and for light apparently shining through a wall.

90.7 Acknowledgements

It is a pleasure to thank Masha Baryakhtar, Francesca Calore, Luca Di Luzio, Andrew Geraci, Maurizio Giannotti, Igor Irastorza, David J.E. Marsh, Alessandro Mirizzi, Ciaran O'Hare, Georg Raffelt, Ken'ichi Saikawa, Yannis Semertzidis, Guenter

[1] These limits are still to the left of the canonical QCD axion line. However, as already mention in non-minimal models where the QCD axion is a mediator between strongly interacting hidden sectors enjoying a discrete, $\mathbb{Z}_{\mathcal{N}}$, shift symmetry, the QCD axion line can be shifted to the left in discrete steps, without any fine tuning [57, 58, 421].

Sigl, Sergey Troitsky, and Lindley Winslow for discussions, suggestions, and comments on this review. Particular thanks to Ciaran O'Hare for maintaining a publicly accessible collection of axion plots and providing updates to accommodate this review [61].

91. Searches for Quark and Lepton Compositeness

Revised October 2023 by K. Hikasa (Tohoku U.), M. Tanabashi (Nagoya U.; KMI, Nagoya U.), K. Terashi (ICEPP, Tokyo U.) and N. Varelas (U. of Illinois at Chicago).

91.1 Limits on contact interactions

If quarks and leptons are made of constituents, then at the scale of constituent binding energies (compositeness scale) there should appear new interactions among them. At energies much below the compositeness scale (Λ), these interactions are suppressed by inverse powers of Λ. The dominant effect of the compositeness of fermion ψ should come from the lowest dimensional interactions with four fermions (contact terms), whose most general flavor-diagonal color-singlet chirally invariant form reads [1, 2]

$$\mathcal{L} = \mathcal{L}_{LL} + \mathcal{L}_{RR} + \mathcal{L}_{LR} + \mathcal{L}_{RL},$$

with

$$\mathcal{L}_{LL} = \frac{g^2_{\rm contact}}{2\Lambda^2} \sum_{i,j} \eta^{ij}_{LL} (\bar{\psi}^i_L \gamma_\mu \psi^i_L)(\bar{\psi}^j_L \gamma^\mu \psi^j_L),$$

$$\mathcal{L}_{RR} = \frac{g^2_{\rm contact}}{2\Lambda^2} \sum_{i,j} \eta^{ij}_{RR} (\bar{\psi}^i_R \gamma_\mu \psi^i_R)(\bar{\psi}^j_R \gamma^\mu \psi^j_R),$$

$$\mathcal{L}_{LR} = \frac{g^2_{\rm contact}}{2\Lambda^2} \sum_{i,j} \eta^{ij}_{LR} (\bar{\psi}^i_L \gamma_\mu \psi^i_L)(\bar{\psi}^j_R \gamma^\mu \psi^j_R),$$

$$\mathcal{L}_{RL} = \frac{g^2_{\rm contact}}{2\Lambda^2} \sum_{i,j} \eta^{ij}_{RL} (\bar{\psi}^i_R \gamma_\mu \psi^i_R)(\bar{\psi}^j_L \gamma^\mu \psi^j_L), \qquad (91.1)$$

where i, j are the indices of fermion species. Color and other indices are suppressed in Eq. (91.1). Chiral invariance provides a natural explanation why quark and lepton masses are much smaller than their inverse size (inverse radius) Λ. Note $\eta^{ij}_{\alpha\beta} = \eta^{ji}_{\beta\alpha}$, thus $\mathcal{L}_{LR}$ and $\mathcal{L}_{RL}$ are identical. Therefore, in order to specify the contact interaction among the same fermion species $i = j$, it is enough to use η_{LL}, η_{RR} and η_{LR}. We will suppress the indices of fermion species hereafter. We may determine the scale Λ unambiguously by using the above form of the effective interactions; the conventional method [1] is to fix its scale by setting $g^2_{\rm contact}/4\pi = g^2_{\rm contact}(\Lambda)/4\pi = 1$ for the new strong interaction coupling and by setting the largest magnitude of the coefficients $\eta_{\alpha\beta}$ to be unity. In the following, we denote

$$\Lambda = \Lambda^\pm_{LL}\,, \Lambda^\pm_{RR}\,, \Lambda^\pm_{VV}\,, \Lambda^\pm_{AA}\,, \Lambda^\pm_{V-A}\,, \qquad (91.2)$$

for $(\eta_{LL}, \eta_{RR}, \eta_{LR}) = (\pm1, 0, 0)$, $(0, \pm1, 0)$, $(\pm1, \pm1, \pm1)$, $(\pm1, \pm1, \mp1)$, $(0, 0, \pm1)$. Such interactions can arise by interchanging constituents (when the fermions have common constituents), and/or by exchanging the binding quanta (whenever binding quanta couple to constituents of both particles).

Fermion scattering amplitude induced from the contact interaction in Eq. (91.1) interferes with the Standard Model (SM) amplitude destructively or constructively [2]. The sign of interference depends on the sign of $\eta_{\alpha\beta}$ ($\alpha, \beta = L, R$). For instance, in the parton level $qq \to qq$ scattering cross section in the $\Lambda^\pm_{LL}$ model, the contact interaction amplitude and the SM gluon exchange amplitude interfere destructively for $\eta_{LL} = +1$, while they interfere constructively for $\eta_{LL} = -1$. In models of quark compositeness, the quark scattering cross sections induced from the contact interactions receive sizable QCD radiative corrections. The exact next-to-leading order (NLO) QCD corrections to the quark scatterings cross sections induced by the contact interactions are given in [3].

Over the last three decades experiments at the CERN Sp$\bar{\rm p}$S [4, 5], the Fermilab Tevatron [6, 7], and the CERN LHC [8–12] have searched for quark contact interactions, characterized by the four-fermion effective Lagrangian in Eq. (91.1), using jet final states. These searches have been performed primarily by studying the angular distribution of the two highest transverse momentum, $p_{\rm T}$, jets (dijets), and the inclusive jet $p_{\rm T}$ spectrum. The variable $\chi = \exp(|(y_1 - y_2)|)$ is used to measure the dijet angular distribution, where y_1 and y_2 are the rapidities of the two jets with the highest transverse momenta. For collinear massless parton scattering, χ is related to the polar scattering angle θ^* in the partonic center-of-mass frame by $\chi = (1+|\cos\theta^*|)/(1-|\cos\theta^*|)$. The choice of χ is motivated by the fact that the angular distribution for Rutherford scattering, which is proportional to $1/(1-\cos\theta^*)^2$, is independent of χ. In perturbative QCD the χ distributions are relatively uniform and only mildly modified by higher-order QCD or electroweak corrections. Signatures of quark contact interactions exhibit more isotropic angular distribution than QCD and can be identified as an excess at low values of χ. In the inclusive jet cross section measurement, quark contact interaction effects are searched for as deviations from the predictions of perturbative QCD in the tails of the high-$p_{\rm T}$ jet spectrum [11].

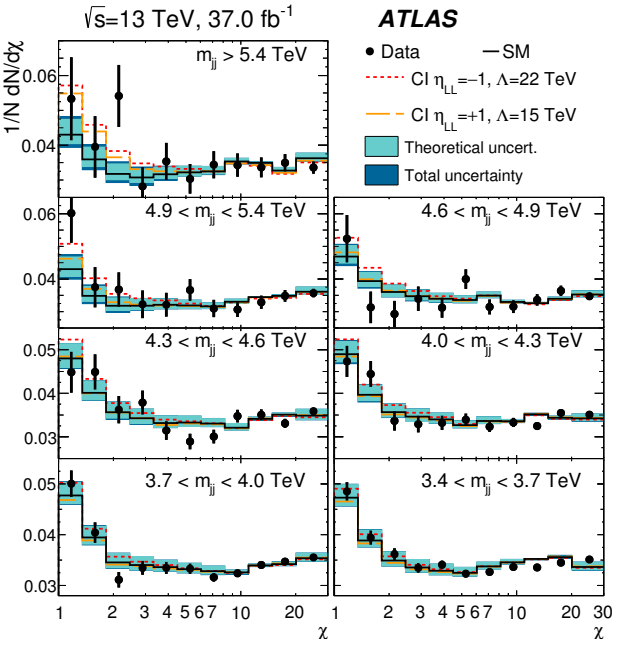

Figure 91.1: Normalized dijet angular distributions in several dijet mass (m_{jj}) ranges. The data distributions are compared to PYTHIA8 predictions with NLO and electroweak corrections applied (solid line) and with the predictions including a contact interaction (CI) term in which only left-handed quarks participate of compositeness scale $\Lambda^+_{LL} = 15$ TeV (dashed line) and $\Lambda^-_{LL} = 22$ TeV (dotted line). The theoretical uncertainties and the total theoretical and experimental uncertainties in the predictions are displayed as shaded bands around the SM prediction. Figure adopted from [9].

Recent results from the LHC, using data collected at proton-proton center-of-mass energy of $\sqrt{s} = 13$ TeV, extend previous limits on quark contact interactions. Figure 91.1 shows the normalized dijet angular distributions for several dijet mass ranges measured in ATLAS [9] at $\sqrt{s} = 13$ TeV. The data distributions are compared with SM predictions, estimated using PYTHIA8 [13] with GEANT4-based [14] ATLAS detector simulation and corrected to NLO QCD calculation provided by NLO Jet++ [15] including electroweak corrections [16]. Predictions including a contact interaction term in which only left-handed quarks participate at compositeness scale $\Lambda^+_{LL} = 15$ TeV ($\Lambda^-_{LL} = 22$ TeV) with destructive (constructive) interference are also shown. Over a wide range of χ and dijet mass the data are well described by the SM predictions. Using the dijet angular distributions measured at high dijet masses and $\sqrt{s} = 13$ TeV, the ATLAS [9] and CMS [12] Collaborations have set 95% confidence level (C.L.) lower limits on the contact interaction scale Λ, ranging from 9.2 to 29.5 TeV for different quark contact interaction models that correspond to various combinations of (η_{LL}, η_{RR}, η_{LR}), as summarized in Figure 91.2. The contact interaction scale limits extracted using the dijet angular distributions include the exact NLO QCD corrections to dijet production induced by contact interactions [3]. In proton-

proton collisions, the $\Lambda^{\pm}_{LL}$ and $\Lambda^{\pm}_{RR}$ contact interaction models result in identical tree-level cross sections and NLO QCD corrections and yield the same exclusion limits. For $\Lambda^{\pm}_{VV}$ and $\Lambda^{\pm}_{AA}$, the contact interaction predictions are identical at tree level, but exhibit different NLO QCD corrections and yield different exclusion limits.

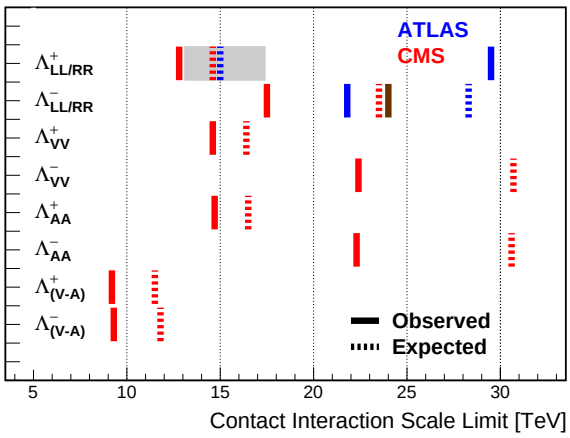

Figure 91.2: Observed (solid lines) and expected (dashed lines) 95% C.L. lower limits on the contact interaction scale Λ for different contact interaction models from ATLAS [9] and CMS [12] using the dijet angular distributions. The contact interaction models used for the dijet angular distributions include the exact NLO QCD corrections to dijet production. The shaded band for the $\Lambda^{+}_{LL/RR}$ model indicates the range of contact interaction scale that was not excluded in ATLAS [9], due to an observed excess in the data that produced a weaker limit. The observed 95% C.L. lower limit on the Λ^{-}_{LL} from CMS [17] is shown as the second solid line in brown.

If leptons (l) and quarks (q) are composite with common constituents, the interaction of these constituents will manifest itself in the form of a $llqq$-type four-fermion contact interaction Lagrangian at energies below the compositeness scale Λ. The $llqq$ terms in the contact interaction Lagrangian can be expressed as

$$\mathcal{L}_{LL} = \frac{g^2_{\rm contact}}{\Lambda^2} \sum_{i,j} \eta^{ij}_{LL} (\bar{q}^i_L \gamma_\mu q^i_L)(\bar{l}^j_L \gamma^\mu l^j_L),$$

$$\mathcal{L}_{RR} = \frac{g^2_{\rm contact}}{\Lambda^2} \sum_{i,j} \eta^{ij}_{RR} (\bar{q}^i_R \gamma_\mu q^i_R)(\bar{l}^j_R \gamma^\mu l^j_R),$$

$$\mathcal{L}_{LR} = \frac{g^2_{\rm contact}}{\Lambda^2} \sum_{i,j} \eta^{ij}_{LR} (\bar{q}^i_L \gamma_\mu q^i_L)(\bar{l}^j_R \gamma^\mu l^j_R),$$

$$\mathcal{L}_{RL} = \frac{g^2_{\rm contact}}{\Lambda^2} \sum_{i,j} \eta^{ij}_{RL} (\bar{q}^i_R \gamma_\mu q^i_R)(\bar{l}^j_L \gamma^\mu l^j_L). \qquad (91.3)$$

Searches on quark-lepton compositeness have been reported from experiments at LEP [18–21], HERA [22, 23], the Tevatron [24, 25], and recently from the ATLAS [26, 27] and CMS [28, 29] experiments at the LHC. The most stringent searches for $llqq$ contact interactions are performed by the LHC experiments using high-mass oppositely-charged lepton pairs produced through the $q\bar{q} \to l^+l^-$ Drell-Yan process. The contact interaction amplitude of the $u\bar{u} \to l^+l^-$ process ($l = e$ or μ) interferes with the corresponding SM amplitude constructively (destructively) for $\eta^{ul}_{\alpha\beta} = -1$ ($\eta^{ul}_{\alpha\beta} = +1$). The ATLAS Collaboration, using a 139 fb^{-1} dataset at $\sqrt{s} = 13$ TeV, has extracted limits on the $llqq$ contact interaction for the right-right ($\eta_{RR} = \pm 1$, $\eta_{LL} = \eta_{LR} = \eta_{RL} = 0$), left-left ($\eta_{LL} = \pm 1$, $\eta_{RR} = \eta_{LR} = \eta_{RL} = 0$), and left-right ($\eta_{LR} = \eta_{RL} = \pm 1$, $\eta_{RR} = \eta_{LL} = 0$) models. In Ref. [27], ATLAS used a background estimate directly obtained from data. Combining the dielectron and dimuon channels, the 95% C.L. lower limits on the $llqq$ contact interaction scale Λ are 36 TeV (27 TeV) for the right-right model, 36 TeV (26 TeV) for the left-left model, and 33 TeV (29 TeV) for the left-right model, each with constructive (destructive) interference [27]. The CMS Collaboration, using a 140 fb^{-1} dataset at 13 TeV, has set 95% C.L. exclusion limits on the $llqq$ contact interaction scale that range from $\Lambda_{LL} > 23.9$ TeV for the destructive interference to $\Lambda_{RR} > 36.4$ TeV for the constructive interference, for the left-left and the right-right models, respectively [29].

Note that the contact interactions arising from the compositeness of quarks and leptons in Eq. (91.1) can also be regarded as a part of more general dimension-six operators in the context of low-energy standard-model effective field theory (SMEFT). For a complete list of SM gauge-invariant dimension-six operators, see [30, 31]. A computation of the one-loop anomalous dimension matrix for SMEFT operators are found in Refs. [32–34]. See also Refs. [35–37] for recent reviews. Ref. [17] sets limits on the Wilson coefficients of the contact interaction operators in the SMEFT framework, using the CMS data of the inclusive jet production cross sections together with the deep inelastic scattering data from HERA and the CMS $t\bar{t}$ cross section data. The results are translated into a 95% C.L. exclusion limit on the quark compositeness $\Lambda^{-}_{LL} > 24$ TeV, which is shown as the second solid line in brown in Figure 91.2. In models where the SM fermions get their masses though the mixing with the composite states, the top-quark is expected to show compositeness properties [38] resulting in the $t\bar{t}t\bar{t}$ contact interaction operators in the SMEFT context. An enhancement of the four-top-quark production cross section is expected at hadron colliders in these models [39]. The ATLAS Collaboration has extracted 95% C.L. observed (expected) limits on the $t\bar{t}t\bar{t}$ contact interaction operator $|C_{4t}|/\Lambda^2 < 1.9$ TeV^{-2} (1.6 TeV^{-2}) using their 36.1 fb^{-1} data at $\sqrt{s} = 13$ TeV [40]. Consistent SMEFT reinterpretations of top-quark data, and high energy non-resonant dijet and dilepton data are provided, e.g., in Refs. [41, 42].

Interactions of hypothetical dark matter candidate particles with SM particles through mediators can also be described as contact interactions at low energy. See *"Searches for WIMPs and Other Particles"* in this volume for limits on the interactions involving dark matter candidate particles.

91.2 Limits on excited fermions

Another typical consequence of compositeness is the appearance of excited leptons and quarks (l^* and q^*). Phenomenologically, an excited lepton is defined to be a heavy lepton which shares a leptonic quantum number with one of the existing leptons (an excited quark is defined similarly). For example, an excited electron e^* is characterized by a nonzero transition-magnetic coupling with electrons. The smallness of the lepton mass and the success of QED prediction for $g-2$ suggest chirality conservation, *i.e.,* an excited lepton should not couple to both left- and right-handed components of the corresponding lepton [43–45].

Excited leptons may be classified by $SU(2) \times U(1)$ quantum numbers. Typical examples are:

1. Sequential type

$$\begin{pmatrix} \nu^* \\ l^* \end{pmatrix}_L, \qquad [\nu^*_R], \qquad l^*_R.$$

   ν^*_R is necessary if we assume ν^* has a Dirac mass.

2. Mirror type

$$[\nu^*_L], \qquad l^*_L, \qquad \begin{pmatrix} \nu^* \\ l^* \end{pmatrix}_R.$$

3. Homodoublet type

$$\begin{pmatrix} \nu^* \\ l^* \end{pmatrix}_L, \qquad \begin{pmatrix} \nu^* \\ l^* \end{pmatrix}_R.$$

Similar classification can be made for excited quarks.

Excited fermions can be pair produced via their minimal gauge couplings. The couplings of excited leptons with Z are given by

$$\frac{e}{2\sin\theta_W\cos\theta_W}\left[(-1+2\sin^2\theta_W)\bar{l}^*\gamma^\mu l^* Z_\mu + \bar{\nu}^*\gamma^\mu\nu^* Z_\mu\right]$$

in the homodoublet model. The corresponding couplings of excited quarks can be easily obtained. Although form factor effects can be present for the gauge couplings at $q^2 \neq 0$, they are usually neglected.

Excited fermions may also be produced via the contact interactions with ordinary quarks and leptons [46]

$$\mathcal{L} = \frac{g^2_{\rm contact}}{\Lambda^2}\left[\eta'_{LL}(\bar{\psi}_L\gamma_\mu\psi_L)(\bar{\psi}^*_L\gamma^\mu\psi^*_L) + (\eta''_{LL}(\bar{\psi}_L\gamma_\mu\psi_L)(\bar{\psi}^*_L\gamma^\mu\psi_L) + \text{h.c.}) + \cdots\right]. \quad (91.4)$$

Again, the coefficient is conventionally taken $g^2_{\rm contact} = 4\pi$. It is widely assumed $\eta'_{LL} = \eta''_{LL} = 1$, $\eta'_{LR} = \eta''_{LR} = \eta'_{RL} = \eta''_{RL} = \eta'_{RR} = \eta''_{RR} = 0$ in experimental analyses for simplicity.

In addition, transition-magnetic type couplings with a gauge boson are expected. These couplings can be generally parameterized as follows:

$$\begin{aligned}\mathcal{L} =& \frac{\lambda^{(\psi^*)}_\gamma e}{2m_{\psi^*}}\bar{\psi}^*\sigma^{\mu\nu}(\eta_L\frac{1-\gamma_5}{2}+\eta_R\frac{1+\gamma_5}{2})\psi F_{\mu\nu} \\ &+ \frac{\lambda^{(\psi^*)}_Z e}{2m_{\psi^*}}\bar{\psi}^*\sigma^{\mu\nu}(\eta_L\frac{1-\gamma_5}{2}+\eta_R\frac{1+\gamma_5}{2})\psi Z_{\mu\nu} \\ &+ \frac{\lambda^{(l^*)}_W g}{2m_{l^*}}\bar{l}^*\sigma^{\mu\nu}\frac{1-\gamma_5}{2}\nu W_{\mu\nu} \\ &+ \frac{\lambda^{(\nu^*)}_W g}{2m_{\nu^*}}\bar{\nu}^*\sigma^{\mu\nu}(\eta_L\frac{1-\gamma_5}{2}+\eta_R\frac{1+\gamma_5}{2})l W^\dagger_{\mu\nu} \\ &+ \text{h.c.}, \end{aligned} \quad (91.5)$$

where $g = e/\sin\theta_W$, $\psi = \nu$ or l, $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the photon field strength, $Z_{\mu\nu} = \partial_\mu Z_\nu - \partial_\nu Z_\mu$, *etc.*. The normalization of the coupling is chosen such that

$$\max(|\eta_L|, |\eta_R|) = 1.$$

Chirality conservation requires

$$\eta_L\eta_R = 0. \quad (91.6)$$

These couplings in Eq. (91.5) can arise from $SU(2)\times U(1)$-invariant higher-dimensional interactions. A well-studied model is the interaction of homodoublet type l^* with the Lagrangian (see [47, 48])

$$\mathcal{L} = \frac{1}{2\Lambda}\bar{L}^*\sigma^{\mu\nu}(gf\frac{\tau^a}{2}W^a_{\mu\nu} + g'f'YB_{\mu\nu})\frac{1-\gamma_5}{2}L + \text{h.c.}, \quad (91.7)$$

where L denotes the lepton doublet (ν, l), Λ is the compositeness scale, g, g' are $SU(2)$ and $U(1)_Y$ gauge couplings, and $W^a_{\mu\nu}$ and $B_{\mu\nu}$ are the field strengths for $SU(2)$ and $U(1)_Y$ gauge fields. These couplings satisfy the relation

$$\lambda_W = -\sqrt{2}\sin^2\theta_W(\lambda_Z\cot\theta_W + \lambda_\gamma), \quad (91.8)$$

with $\lambda_{W,Z,\gamma}$ being defined in Eq. (91.5) with $\lambda_{W,Z,\gamma} = \lambda^{(\ell^*)}_{W,Z,\gamma}$ or $\lambda_{W,Z,\gamma} = \lambda^{(\nu^*)}_{W,Z,\gamma}$. Here $(\eta_L, \eta_R) = (1, 0)$ is assumed. It should be noted that the electromagnetic radiative decay of l^* (ν^*) is forbidden if $f = -f'$ ($f = f'$).

Additional coupling with gluons is possible for excited quarks:

$$\mathcal{L} = \frac{1}{2\Lambda}\bar{Q}^*\sigma^{\mu\nu}\left(g_s f_s\frac{\lambda^a}{2}G^a_{\mu\nu} + gf\frac{\tau^a}{2}W^a_{\mu\nu} + g'f'YB_{\mu\nu}\right) \times \frac{1-\gamma_5}{2}Q + \text{h.c.}, \quad (91.9)$$

where Q denotes a quark doublet, g_s is the QCD gauge coupling, and $G^a_{\mu\nu}$ the gluon field strength.

If leptons are made of color triplet and antitriplet constituents, we may expect their color-octet partners. Transitions between the octet leptons (l_8) and the ordinary lepton (l) may take place via the dimension-five interactions

$$\mathcal{L} = \frac{1}{2\Lambda}\sum_l\left\{\bar{l}^\alpha_8 g_S F^\alpha_{\mu\nu}\sigma^{\mu\nu}(\eta_L l_L + \eta_R l_R) + \text{h.c.}\right\} \quad (91.10)$$

where the summation is over charged leptons and neutrinos. The leptonic chiral invariance implies $\eta_L\eta_R = 0$ as before.

Searches for the excited quarks and leptons have been performed over the last decades in experiments at the LEP [49–52], HERA [53, 54], Tevatron [55, 56], and LHC [57–89]. Most stringent constraints, which are described below at 95% confidence level, come from the LHC experiments.

The signature of excited quarks q^* at hadron colliders is characterized by a narrow resonant peak in the reconstructed invariant mass distribution of the q^* decay products. The decays via the transition-magnetic type operator in Eq. (91.9) are considered for excited quarks in LHC searches, and the final states to search for are dijet (qg) [57, 58, 70–73] or a jet in association with a photon ($q\gamma$) [59,60,74,75,89] or a weak gauge boson (qW, qZ) [76,77]. All analyses consider only spin-1/2 excited states of first generation quarks (u^*, d^*) with degenerate masses, expected to be predominantly produced in proton-proton collisions except for the excited b quark searches described below. Only the minimal gauge interactions and the transition-magnetic couplings with the form given in Eq. (91.9) are considered in the production process, and hence the contact interactions in Eq. (91.4) are not considered. The compositeness scale Λ is taken to be the same as the excited quark mass m_{q^*}. The transition-magnetic coupling coefficients f_s, f and f' are assumed to be equal to 1 (denoted by f).

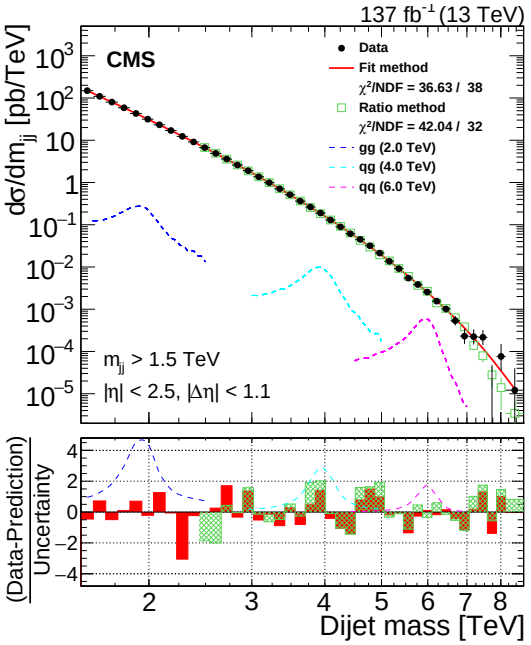

Figure 91.3: Dijet mass distribution measured by CMS using wide jets reconstructed from two highest transverse momentum jets by adding nearby jets within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 1.1$. The data distribution is compared to a fit representing a smooth background spectrum (solid curve) and the background prediction obtained from the $\Delta\eta_{\rm jj}$ control regions (open squares), denoted as Ratio method, at $m_{\rm jj} > 2.4$ TeV. The excited quark signal with mass of 4.0 TeV (labeled as qg) is shown together with other benchmark signals. Shown at the bottom panel is the difference between the data and the fitted parametrization from the fit method or the data and the background prediction from the Ratio method, divided by the statistical uncertainty of the data. Figure adopted from [73].

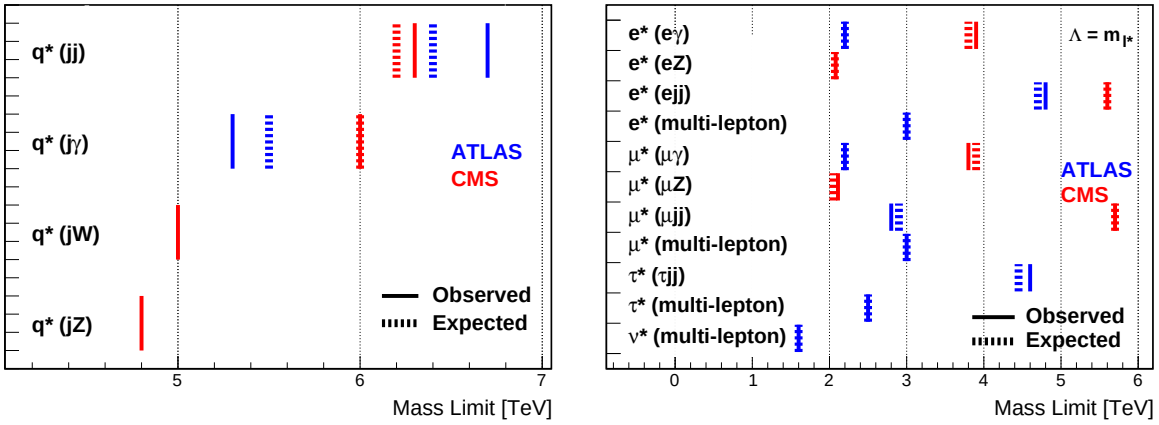

Figure 91.4: 95% C.L. lower mass limits for the excited quarks (left) and excited leptons (right) at ATLAS [58, 60, 66–68, 88] and CMS [73, 75, 77, 80–82, 89] experiments. Shown are the most stringent limits for each final state (denoted in parentheses) of the excited fermions from both experiments. Only first generation quarks (u, d) with transition-magnetic type interactions with $f_s = f = f' = 1$ are considered for the excited quarks. The excited lepton limits are given for the production via contact interactions with $\Lambda = m_{l^*}$.

With proton-proton collision data recorded at $\sqrt{s} = 13$ TeV at the LHC, the excited quark masses are excluded in dijet resonance searches up to 6.7 TeV in ATLAS using 139 fb^{-1} [58] and 6.3 TeV in CMS using 137 fb^{-1} [73]. Figure 91.3 shows the dijet mass (m_{jj}) distribution measured in CMS [73] by using the two highest p_T jets reconstructed with the anti-k_T algorithm [90] of a distance parameter of 0.4, and by combining nearby jets within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 1.1$ around the leading two jets. The measured dijet mass spectrum is compared to a fit with smoothly falling background shape (solid curve) at $m_{jj} > 1.5$ TeV and the background prediction obtained from $\Delta\eta_{jj}$ control regions (open squares), denoted as Ratio method, at $m_{jj} > 2.4$ TeV to look for a narrow resonance. Here $\Delta\eta_{jj}$ is the pseudorapidity separation between the two jets. An excited quark signal with mass of 4.0 TeV is shown in the figure (denoted by qg) as one of the benchmark signals considered in the analysis.

The photon + jet resonance searches, targeting excited quarks decaying into a quark and a photon ($q^* \to q + \gamma$), have excluded q^* masses up to 5.3 TeV in ATLAS [60] and 6.0 TeV in CMS [89] using collision data at $\sqrt{s} = 13$ TeV. The W/Z boson + jet final states are examined to look for the $q^* \to q + W$ and $q + Z$ signal in CMS [77], exploiting jet substructure technique designed to provide sensitivity for highly-boosted hadronically decaying W and Z bosons. The lower mass limit of 5.0 (4.8) TeV is obtained from the W + jet (Z + jet) search using dataset recorded at $\sqrt{s} = 13$ TeV.

The excited b quarks (b^*) are also considered in the present searches at the LHC. Assuming the similar production processes to the first-generation excited quarks, the b^* has been searched for in final states containing at least one jet identified as originating from a b quark (b-tagging). The searches using two jets including at least one b-tagged jet have been performed at 8 and 13 TeV [58, 61, 62, 71, 85], resulting in b^* lower mass limits of 3.2 TeV in ATLAS using 139 fb^{-1} at $\sqrt{s} = 13$ TeV [58] and 4.0 TeV in CMS using 138 fb^{-1} at $\sqrt{s} = 13$ TeV [85]. The CMS Collaboration also performed a search for $b^* \to b + \gamma$ in events with a b-tagged jet in association with a photon using data at $\sqrt{s} = 13$ TeV [89], and excluded b^* masses up to 2.2 TeV. For the same coupling strength, the observed lower mass bounds on the excited bottom quarks extends to 3.8 TeV, when the production mode from contact interactions Eq. (91.4) is also considered. Excited b quarks with charged-current decay into a W-boson and a top quark ($b^* \to t + W$) were looked for in both ATLAS and CMS using the full 8 TeV data [63, 78] and in CMS using the full 13 TeV data [86, 87]. For the left(right)-handed couplings, CMS excluded the masses below 2.6(2.8) TeV in the fully hadronic final states [86] and 3.0(3.2) TeV in the lepton+jets final states [87].

The excited top quarks (t^*) have also been searched for at the LHC. The CMS Collaboration performed the search for pair-produced t^* quarks with the assumption of the t^* quark decay into a top quark and a gluon, in events with a charged lepton, missing transverse momentum and multiple jets including b-tagged jets at $\sqrt{s} = 8$ TeV [84] and 13 TeV [83]. With 35.9 fb^{-1} data at 13 TeV, CMS excluded the t^* masses below 1.2 TeV for spin 3/2 t^* quarks [83].

Searches for excited leptons l^* are also performed at the LHC using proton-proton collision data recorded at $\sqrt{s} = 7$ and 8 TeV [65–69, 79, 80] as well as at 13 TeV [81]. Considering single l^* production in contact interactions (Eq. (91.4)) and electromagnetic radiative decay to a SM lepton and a photon ($l^* \to l + \gamma$ where $l = e, \mu$), the excited electron and muon masses are excluded for $\Lambda = m_{l^*}$ up to 3.9 and 3.8 TeV, respectively, using 35.9 fb^{-1} at $\sqrt{s} = 13$ TeV in CMS [81] and 2.2 TeV using 13 fb^{-1} at $\sqrt{s} = 8$ TeV in ATLAS [66].

With the full 20.3 fb^{-1} data at $\sqrt{s} = 8$ TeV, the inclusive search on multi-lepton signatures with 3 or more charged leptons in ATLAS [67] further constrains the excited charged leptons and neutrinos. Considering both the transition-magnetic (Eq. (91.7)) and contact interaction (Eq. (91.4)) processes, the lower mass limits for the e^*, μ^*, τ^* and ν^* (for every excited neutrino flavor) are obtained to be 3.0, 3.0, 2.5 and 1.6 TeV, respectively, for $\Lambda = m_{e^*}$, m_{μ^*}, m_{τ^*} and m_{ν^*}. The rate of pair-produced excited leptons is independent of Λ for the minimal gauge interaction processes, and it allows to improve search sensitivity with multi-lepton signatures at high Λ, especially for excited neutrinos because the predominant $\nu_l^* \to l + W$ decays result in a higher acceptance for ≥ 3 charged lepton final states.

Both ATLAS and CMS Collaborations performed searches for singly produced excited leptons. The single excited leptons, both produced and decaying in contact interaction processes (Eq. (91.4)), were searched for in CMS with 77.4 fb^{-1} at 13 TeV [82] and in ATLAS with 20.3 fb^{-1} at 8 TeV [68] and 139 fb^{-1} at 13 TeV [88] using the final states with two leptons and two jets ($q\bar{q} \to ll^* \to llq\bar{q}$). The CMS search [82] considered both excited electrons and excited muons, using the invariant mass of the combination of the two leptons and two jets as a discriminating variable to separate signal from background. The ATLAS search considered excited muons [68] and excited τ leptons [88]. The single excited electrons, produced in contact interactions and decayed either in contact interaction or charged-current processes, were considered in ATLAS using 36.1 fb^{-1} at 13 TeV [69] in the final states with two electrons and two jets ($q\bar{q} \to ee^* \to eeq\bar{q}$) or an electron, missing transverse momentum and a hadronically decaying W-boson candidate ($q\bar{q} \to ee^* \to e\nu W$). The excited electron (muon) mass was excluded up to 5.6 (5.7) TeV in CMS [82] at $\Lambda = m_{e^*}$ ($\Lambda = m_{\mu^*}$), which is the best limit to date on the ex-

cited electrons (muons). The excited τ lepton mass was excluded up to 4.6 TeV in ATLAS [88] at $\Lambda = m_{\tau^*}$.

The CMS Collaboration also performed an excited lepton search in the final states containing a Z boson [80], probing the excited leptons produced in contact interactions and decayed in neutral-current processes ($l^* \to l + Z$) with $f = f' = 1$ or $f = -f' = 1$. The leptonic and hadronic decays of Z bosons have been considered in the search, and the most stringent limits are obtained from the hadronic Z decay to be 2.08 (2.34) TeV and 2.11 (2.37) TeV for the e^* and μ^*, respectively, with $f = f' = 1$ ($f = -f' = 1$) at $\Lambda = m_{l^*}$.

Figure 91.4 summarizes the most stringent 95% C.L. lower mass limits for excited quarks and leptons obtained from the LHC experiments.

92. Dynamical Electroweak Symmetry Breaking: Implications of the H^0

Revised August 2023 by K.M. Black (Wisconsin U.), R. Sekhar Chivukula (UC San Diego) and A. Lister (U. of British Columbia).

92.1 Introduction and Phenomenology

In theories of dynamical electroweak symmetry breaking, the electroweak interactions are broken to electromagnetism by the vacuum expectation value of a composite operator, typically a fermion bilinear. In these theories, the longitudinal components of the massive weak bosons are identified with composite Nambu-Goldstone bosons arising from dynamical symmetry breaking in a strongly-coupled extension of the standard model. Viable theories of dynamical electroweak symmetry breaking must also explain (or at least accommodate) the presence of an additional composite scalar state to be identified with the H^0 scalar boson [1,2] – a state unlike any other observed previously.

Theories of dynamical electroweak symmetry breaking can be classified by the nature of the composite singlet state to be associated with the H^0 and the corresponding dimensional scales f, the analog of the pion decay-constant in QCD, and Λ, the scale of the underlying strong dynamics.[1] Of particular importance is the ratio v/f, where $v^2 = 1/(\sqrt{2}G_F) \approx (246\,\text{GeV})^2$, since this ratio measures the expected size of the deviations of the couplings of a composite Higgs boson from those expected in the standard model. The basic possibilities, and the additional states that they predict, are described below.

92.1.1 *Technicolor, $v/f \simeq 1$, $\Lambda \simeq 1$ TeV*

Technicolor models [7–9] provided the first examples of theories of dynamical electroweak symmetry breaking. These theories incorporate a new asymptotically free gauge theory ("technicolor") and additional massless fermions ("technifermions" transforming under a vectorial representation of the gauge group). The global chiral symmetry of the fermions is spontaneously broken by the formation of a technifermion condensate, just as the approximate chiral symmetry in QCD is broken down to isospin by the formation of a quark condensate. The $\text{SU}(2)_W \times \text{U}(1)_Y$ interactions are embedded in the global technifermion chiral symmetries in such a way that the only unbroken gauge symmetry after chiral symmetry breaking is $\text{U}(1)_{em}$.[2] The theories naturally provide the Nambu-Goldstone bosons "eaten" by the W and Z bosons. There would also typically be additional heavy states (e.g. vector mesons, analogous to the ρ and ω mesons in QCD) with TeV masses [13,14], and the WW and ZZ scattering amplitudes would be expected to be strong at energies of order 1 TeV.

There are various possibilities for the scalar H^0 in technicolor models. First, the H^0 could be identified as a singlet scalar resonance, analogous to the σ particle expected in pion-scattering in QCD [15, 16]. Alternatively, the H^0 could be identified as a dilaton, a (pseudo-)Goldstone boson of scale invariance in theories of "walking technicolor" [17–21].[3] Finally, the H^0 could be identified as an additional isosinglet state if the chiral symmetry breaking pattern of the technicolor theory provides for such a state.[4] In all of these cases, however, one expects large deviations in the couplings of this particle from those of the standard model Higgs boson. Since the couplings observed for the H^0 approximate those of the Higgs boson to the 10% level, models of this kind are very highly constrained.

[1] In a strongly interacting theory "Naive Dimensional Analysis" [3, 4] implies that, in the absence of fine-tuning, $\Lambda \simeq g^* f$ where $g^* \simeq 4\pi$ is the typical size of a strong coupling in the low-energy theory [5, 6]. This estimate is modified in the presence of multiple flavors or colors [7] .

[2] For a review of technicolor models, see [10–12].

[3] If both the electroweak symmetry and the approximate scale symmetry are broken only by electroweak doublet condensate(s), then the decay-constants for scale and electroweak symmetry breaking may be approximately equal – differing only by terms formally proportional to the amount of explicit scale-symmetry breaking.

[4] In this case, however, the coupling strength of the singlet state to WW and ZZ pairs would be comparable to the couplings to gluon and photon pairs, and these would all arise from loop-level couplings in the underlying technicolor theory [22].

92.1.2 *The Higgs doublet as a pseudo-Nambu-Goldstone Boson, $v/f < 1$, $\Lambda > 1$ TeV*

In technicolor models, the symmetry-breaking properties of the underlying strong dynamics necessarily breaks the electroweak gauge symmetries. An alternative possibility is that the underlying strong dynamics itself does not break the electroweak interactions, and that the entire quartet of bosons in the Higgs doublet (including the state associated with the H^0) are composite (pseudo-) Nambu-Goldstone particles [23–25]. In this case, the underlying dynamics can occur at energies exceeding 1 TeV and additional interactions with the top-quark mass generating sector (and possibly with additional weakly-coupled gauge bosons) cause the vacuum energy to be minimized when the composite Higgs doublet gains a vacuum expectation value [26, 27]. In these theories, the couplings of the remaining singlet scalar state would naturally be equal to that of the standard model Higgs boson up to corrections of order $(v/f)^2$ and, therefore, constraints on the size of deviations of the H^0 couplings from that of the standard model Higgs [28] give rise to lower bounds on the scales f and Λ.[5]

The electroweak gauge interactions, as well as the interactions responsible for the top-quark mass, explicitly break the chiral symmetries of the composite Higgs model and lead generically to sizable corrections to the mass-squared of the Higgs-doublet – the so-called "Little Hierarchy Problem" [29]. "Little Higgs" theories [30–33] are examples of composite Higgs models in which the (collective) symmetry-breaking structure is selected so as to suppress these contributions to the Higgs mass-squared.

Composite Higgs models typically require a larger global symmetry of the underlying theory, and hence additional relatively light (compared to Λ) scalar particles, extra electroweak vector bosons (e.g. an additional $\text{SU}(2)\times\text{U}(1)$ gauge group), and vector-like partners of the top-quark of charge $+2/3$ and possibly also $+5/3$ [34]. In addition to these states, one would expect the underlying dynamics to yield additional scalar and vector resonances with masses of order Λ. If the theory respects a custodial symmetry [35], the couplings of these additional states to the electroweak and Higgs boson will be related – and, for example, one might expect a charged vector resonance to have similar branching ratios to WZ and WH. Different composite Higgs models utilize different mechanisms for arranging for the hierarchy of scales $v < f$ and arranging for a scalar Higgs self-coupling small enough to produce an H^0 of mass of order 125 GeV, for a review see [36] . If the additional states in these models carry color, they can provide additional contributions to Higgs production via gluon fusion [37]. The extent to which Higgs production at the LHC conforms with standard model predictions provides additional constraints (typically lower bounds on the masses of the additional colored states of order 0.7 TeV) on these models.

In addition, if the larger symmetry of the underlying composite Higgs theory does not commute with the standard model gauge group, then the additional states found in those models – especially those related to the top-quark, which tend to have the largest couplings to the electroweak sector – may be *colorless*. For example, in twin Higgs models [38], the top-partners carry no standard model charges. The phenomenology of the additional states in twin Higgs theories is rather different, since lacking color the production of these particles at the LHC will be suppressed – and, their decays may occur only via the electroweak symmetry breaking sector, leading to their being long-lived.

92.1.3 *Top-Condensate, Top-Color, Top-Seesaw and related theories, $v/f < 1$, $\Lambda > 1$ TeV*

A final alternative is to consider a strongly interacting theory with a high (compared to a TeV) underlying dynamical scale that *would* naturally break the electroweak interactions, but whose

[5] In these models v/f is an adjustable parameter, and in the limit $v/f \to 1$ they reduce, essentially, to the technicolor models discussed in the previous subsection. Our discussion here is consistent with that given there, since we expect corrections to the SM Higgs couplings to be large for $v/f \simeq 1$. Current measurements constrain the couplings of the H^0 to equal those predicted for the Higgs in the standard model to about the 10% level [28], suggesting that f must have values of order a TeV or higher and, therefore, a dynamical scale Λ of at least several TeV.

strength is adjusted ("fine-tuned") to produce electroweak symmetry breaking at 1 TeV. This alternative is possible if the electroweak (quantum) phase transition is continuous (second order) in the strength of the strong dynamics [39]. If the fine-tuning can be achieved, the underlying strong interactions will produce a light composite Higgs bound state with couplings equal to that of the standard model Higgs boson up to corrections of order $(1\ \text{TeV}/\Lambda)^2$. As in theories in which electroweak symmetry breaking occurs through vacuum alignment, therefore, constraints on the size of deviations of the H^0 couplings from that of the standard model Higgs give rise to lower bounds on the scale Λ. Formally, in the limit $\Lambda \to \infty$ (a limit which requires arbitrarily fine adjustment of the strength of the high-energy interactions), these theories are equivalent to a theory with a fundamental Higgs boson – and the fine adjustment of the coupling strength is a manifestation of the hierarchy problem of theories with a fundamental scalar particle.

In many of these theories the top-quark itself interacts strongly (at high energies), potentially through an extended color gauge sector [40, 40–44]. In these theories, top-quark condensation (or the condensation of an admixture of the top with additional vector-like quarks) is responsible for electroweak symmetry breaking, and the H^0 is identified with a bound state involving the third generation of quarks. These theories typically include an extra set of massive color-octet vector bosons (top-gluons), and an extra $U(1)$ interaction (giving rise to a top-color Z') which couple preferentially to the third generation and whose masses define the scale Λ of the underlying physics.

92.1.4 *Flavor*

In addition to the electroweak symmetry breaking dynamics described above, which gives rise to the masses of the W and Z particles, additional interactions must be introduced to produce the masses of the standard model fermions. Two general avenues have been suggested for these new interactions. In "extended technicolor" (ETC) theories [45, 46], the gauge interactions in the underlying strongly interacting theory are extended to incorporate flavor. This extended gauge symmetry is broken down (possibly sequentially, at several different mass scales) to the residual strong interaction responsible for electroweak symmetry breaking. The massive gauge-bosons corresponding to the broken symmetries then mediate interactions between mass operators for the quarks/leptons and the corresponding bilinears of the strongly-interacting fermions, giving rise to the masses of the ordinary fermions after electroweak symmetry breaking.

In the case of "partial compositeness" [47], the additional flavor-dependent interactions arise from mixing between the ordinary quarks and leptons and massive composite fermions in the strongly-interacting underlying theory. Theories incorporating partial compositeness include additional vector-like partners of the ordinary quarks and leptons, typically with masses of order a TeV or less.

In both cases, the effects of flavor interactions on the electroweak properties of the ordinary quarks and leptons are likely to be most pronounced in the third generation of fermions.[6] The additional particles present in these theories, especially the additional scalars, often couple more strongly to heavier fermions.

Moreover, since the flavor interactions must give rise to quark mixing, we expect that a generic theory of this kind could give rise to large flavor-changing neutral-currents [46]. In ETC theories, these constraints are typically somewhat relaxed if the theory incorporates approximate generational flavor symmetries [48], the theory has a slowly running coupling constant or "walks" [17–21], or if $\Lambda > 1$ TeV [49]. In theories of partial compositeness, the masses of the ordinary fermions depend on the scaling-dimension of the operators corresponding to the composite fermions with which they mix. This leads to a new mechanism for generating the mass-hierarchy of the observed quarks and leptons that, potentially, ameliorates flavor-changing neutral current problems and can provide new contributions to the composite Higgs potential which allow for $v/f < 1$ [50–54].

Alternatively, one can assume that the underlying flavor dynamics respect flavor symmetries ("minimal" [55, 56] or "next-to-minimal" [57] flavor violation) that suppress flavor-changing neutral currents in the two light generations. Additional considerations apply when extending these arguments to potential explanation of neutrino masses (see, for example, [58, 59]).

92.1.5 *Theoretical Considerations*

Since the underlying high-energy dynamics in these theories are strongly coupled, there are no reliable calculation techniques that can be applied to analyze their properties. Instead, most phenomenological studies depend on the construction of a "low-energy" effective theory describing additional scalar, fermion, or vector boson degrees of freedom, which incorporates the relevant symmetries and, when available, dynamical principles. In some cases, motivated by the AdS/CFT correspondence [60], the strongly-interacting theories described above have been investigated by analyzing a dual compactified five-dimensional gauge theory. In these cases, the AdS/CFT "dictionary" is used to map the features of the underlying strongly coupled high-energy dynamics onto the low-energy weakly coupled dual theory [61].

More recently, progress has been made in investigating strongly-coupled models using lattice gauge theory [62–65]. These calculations offer the prospect of establishing which strongly coupled theories of electroweak symmetry breaking have a particle with properties consistent with those observed for the H^0 – and for establishing concrete predictions for these theories at the LHC [66].

92.1.6 *Summary*

The theoretical ideas and models reviewed here motivate searches for a wide variety of new states. Heavy vector bound states decaying to dibosons and additional scalar states appear naturally in both technicolor (92.1.1) and composite higgs models (92.1.2). Composite Higgs models based on collective symmetry breaking naturally include W', Z', and vector-like quark states (especially for the third-generation, and potentially including charge +5/3 custodial top-partner quarks). Vector-like states are also natural for any theory including partial compositeness in order to address the flavor problem (92.1.4). Top-condensate and related models (92.1.3) predict the existence of colorons which preferentially couple to third-generation quarks. Finally, the new states discussed here also occur in extra-dimensional models [61], which is understandable given that many strongly-coupled theories can be viewed as compactified five-dimensional gauge theories via duality (92.1.5). We turn now to a review the status of experimental searches related to dynamical electroweak symmetry breaking.

92.2 Experimental Searches

As discussed above, the extent to which the couplings of the H^0 conform to the expectations for a standard model Higgs boson constrains the viability of each of these models. Measurements of the H^0 couplings, and their interpretation in terms of effective field theory, are summarized in the H^0 review in this volume. In what follows, we will focus on searches for the additional particles that might be expected to accompany the singlet scalar: extra scalars, fermions, and vector bosons. In some cases, detailed model-specific searches have been made for the particles described above (though generally not yet taking account of the demonstrated existence of the H^0 boson).

In most cases, however, generic searches (e.g. for extra W' or Z' particles, extra scalars in the context of multi-Higgs models, or for fourth-generation quarks) are quoted that can be used – when appropriately translated – to derive bounds on a specific model of interest.

The mass scale of the new particles implied by the interpretations of the low mass of H^0 discussed above, and existing studies from the Tevatron and lower-energy colliders, suggests that only the Large Hadron Collider has any real sensitivity. A number of analyses already carried out by ATLAS and CMS use relevant final states and might have been expected to observe a deviation from standard model expectations – in no case so far has any such deviation been reported. The detailed implications of these

[6] Indeed, from this point of view, the vector-like partners of the top-quark in top-seesaw and little Higgs models can be viewed as incorporating partial compositeness to explain the origin of the top quark's large mass.

searches in various model frameworks are described below.

Except where otherwise noted, all limits in this section are quoted at a confidence level of 95%. The searches at $\sqrt{s} = 8$ TeV (Run 1) are based on 20.3 fb^{-1} of data recorded by ATLAS, and an integrated luminosity of 19.7 fb^{-1} analyzed by CMS. The datasets collected at $\sqrt{s} = 13$ TeV during Run 2 of the LHC since 2015 are based on analyses with varied integrated luminosities ranging from ∼2-140 fb^{-1}.

92.2.1 *Searches for Z' or W' Bosons*

Massive vector bosons or particles with similar decay channels would be expected to arise in Little Higgs theories, in theories of Technicolor, or models involving a dilaton, adjusted to produce a light Higgs boson, consistent with the observed H^0. These particles would be expected to decay to pairs of vector bosons, or to third generation quarks, or to leptons. The generic searches for W' and Z' vector bosons listed below can, therefore, be used to constrain models incorporating a composite Higgs-like boson.

A general review of searches for Z' and W' bosons is also included in this volume [67, 68]. In the context of the dynamical electroweak symmetry breaking models, we emphasize their decays to third generation fermions by including a detailed overview, while also briefly summarizing the other searches.

$Z' \to \ell\ell$:

ATLAS [69] and CMS [70] have both searched for Z' production with $Z' \to ee$ or $\mu\mu$. No deviation from the standard model prediction was seen in the dielectron and dimuon invariant mass spectra, by either the ATLAS or the CMS analysis, and lower limits on possible Z' boson masses were set. A $Z'_{\rm SSM}$ with couplings equal to the standard model Z' (a "sequential standard model" Z') and a mass below 5.1 TeV was excluded by ATLAS, while CMS set a lower mass limit of 5.15 TeV. The experiments also place limits on the parameters of extra dimension models and in the case of ATLAS on the parameters of a minimal walking technicolor model [17–21], consistent with a 125 GeV Higgs boson [71]. For a general review of searches in these channels see the PDG review of Z prime in this volume [67].

In addition, both experiments have also searched for Z' decaying to a ditau final state [72, 73]. An excess in $\tau^+\tau^-$ could have interesting implications for models in which lepton universality is not a requirement and enhanced couplings to the third generation are allowed. This analysis led to lower limits on the mass of a $Z'_{\rm SSM}$ of 2.4 and 2.1 TeV from ATLAS and CMS respectively.

$Z' \to q\bar{q}$:

The ability to relatively cleanly select $t\bar{t}$ pairs at the LHC together with the existence of enhanced couplings to the third generation in many models makes it worthwhile to search for new particles decaying in this channel. Both ATLAS [74] and CMS [75] have carried out searches for new particles decaying into $t\bar{t}$.

Both ATLAS and CMS searched for $t\bar{t}$ in the all hadronic mode [76] [77] in both the resolved and boosted regions. No evidence of resonance production were seen and limits were produced for various models including the Z' boson in topcolor-assisted technicolor which excludes masses less than 3.1 to 3.6 TeV (ATLAS) depending on the details of the model and 3.3, 5.25, and 6.65 TeV for widths of 1, 10 and 30 percent relative to the mass of the resonance .

ATLAS also presented results on the lepton plus jets final state, where the top quark pair decays as $t\bar{t} \to WbWb$ with one W boson decaying leptonically and the other hadronically; CMS used final states where both, one or neither W decays leptonically and then combined the results. The $t\bar{t}$ invariant mass spectrum was analyzed for any excess, and no evidence for any resonance was seen. ATLAS excluded a narrow ($\Gamma/m = 1.2\%$) leptophobic topcolor Z' boson with masses between 0.7 and 2.1 TeV and with $\Gamma/m = 3\%$ between 0.7 and 3.2 TeV. CMS set limits on leptophobic Z' bosons for three different assumed widths $\Gamma/m = 1.0\%$, $\Gamma/m = 10.0\%$, and $\Gamma/m = 30.0\%$ of 3.9 TeV to 4.0 TeV and exclude RS KK gluons up to 3.3 TeV.

Both ATLAS [78] and CMS [79] have also searched for resonances decaying into $q\bar{q}$, qg or gg using the dijet invariant mass spectrum. Excited quarks are excluded up to masses of 6.7 TeV and model-independent upper limits on cross sections with a Gaussian signal shape were set. CMS excluded string resonances with masses below 7.9 TeV, scalar diquarks below 7.5 TeV, axigluons and colorons below 6.6 TeV, excited quarks below 6.3 TeV, color-octet scalars below 3.7 TeV, W' bosons below 3.6 TeV, Z' bosons with SM-like couplings below 2.9 TeV and between 3.1 TeV and 3.3 TeV, Randall–Sundrum Gravitons below 2.6 TeV.

$W' \to \ell\nu$:

Both LHC experiments have also searched for massive charged vector bosons. In this section we include a summary of the results, with emphasis on final states with third generation fermions, while the details on other decays are discussed in the mini-review of W' [68]. ATLAS searched for a heavy W' decaying to $e\nu$ or $\mu\nu$ and found no excess over the standard model expectation. A sequential standard model (SSM) W' boson (assuming zero branching ratio to WZ) with mass less than 7 TeV was excluded [80] using the 139 fb^{-1} dataset at $\sqrt{s} = 13$ TeV. Model independent cross-section limits as a function of mass were also set. Based on a similar dataset, the CMS experiment excluded a SSM W' boson with mass up to 5.7 TeV [81] and presented upper limits on the production of generic W' bosons decaying into this final state using a model-independent approach.

CMS [82] has carried out a complementary search in the $\tau\nu$ final state. As noted above, such searches place limits on models with enhanced couplings to the third generation. No excess was observed and limits between 2.0 and 2.7 TeV were set on the mass of a W' decaying preferentially to the third generation; a W' with universal fermion couplings was also excluded for masses less than 2.7 TeV.

$W' \to t\bar{b}$:

Heavy new gauge bosons can couple to left-handed fermions like the SM W boson or to right-handed fermions. W' bosons that couple only to right-handed fermions (W'_R) may not have leptonic decay modes, depending on the mass of the right-handed neutrino. For these W' bosons, the tb ($t\bar{b} + \bar{t}b$) decay mode is especially important because in many models the W' boson is expected to have enhanced couplings to the third generation of quarks relative to those in the first and second generations. It is also the hadronic decay mode with the best signal-to-background. ATLAS and CMS have performed searches for W' bosons via the $W' \to tb$ decay channel in the lepton+jets and all-hadronic final state.

The CMS lepton+jets search [83–86], $W' \to tb \to Wbb \to \ell\nu bb$, proceeded via selecting events with an isolated lepton (electron or muon), and at least two jets, one of which is identified to originate from a b-quark. The mass of the W' boson (M_{tb}) was reconstructed using the four-momentum vectors of the final state objects ($bb\ell\nu$). The distribution of M_{tb} is used as the search discriminant. A search [86] using 35.9 fb^{-1} of data, collected at $\sqrt{s}$ = 13 TeV, led to an exclusion of W'_R bosons with masses below 3.4 TeV (3.6 TeV) if $M_{W'_R} >> M_{\nu_R}$ ($M_{W'_R} < M_{\nu_R}$), where M_{ν_R} is the mass of the right-handed neutrino.

The CMS search for $W' \to tb$ decays using the all-hadronic final state focused on W' masses above 1 TeV [85, 87]. In this region, the top quark gets a large Lorentz boost and hence the three hadronic products from its decay merge into a single large-radius jet. Deep neural network(DNN) algorithms are used to identify the jet initiated by the bottom quark. Techniques including DNN, which rely on substructure information of the jets [88] are employed to identify boosted all hadronic W boson and top quark [87] decays. The W' candidate mass was computed from back-to-back boosted top-tagged jet and a low mass b-tagged jet. From this all-hadronic search, W' bosons were excluded for masses up to 3.4 TeV [87].

ATLAS has searched for W'_R bosons in the $t\bar{b}$ final state both for lepton+jets [89] and all-hadronic [90] decays of the top. No significant deviations from the standard model were seen in either analysis and limits were set on the $W' \to t\bar{b}$ cross section times branching ratio and W' bosons with with both purely right and purely left-handed coupling and limits are set between 0.5 and 6 TeV for different values of the coupling strength.

In addition, the above studies also provided upper limits on the W' effective couplings to right- and left-handed fermions.

In Fig. 92.1 (bottom) the upper limits on W' couplings normalized to the SM W boson couplings derived by ATLAS [90] are shown. The top panel of Fig. 92.1 shows the upper limits for arbitrary combinations of left- and right-handed couplings of the W' boson to fermions set using a model independent approach by CMS [86].

92.2.2 *Searches for Resonances decaying to Vector Bosons and/or Higgs Bosons*

Both ATLAS and CMS have used the data collected at $\sqrt{s} =$ 13 TeV to search for resonances decaying to pairs of bosons. Overall no significant excesses were seen in the full datasets that were analyzed and the results are interpreted in models with heavy vector triplets (HVT) [92], models with strong gravity and extra spatial dimensions, and model independent limits as a function of mass are set. For a full review of models including extra spatial dimensions and the interpretation of many of these results in that context please see the review of extra dimensions in this volume [61].

Utilizing data collected at $\sqrt{s} = 13$ TeV, ATLAS [93] and CMS [94], have both looked for a resonant state decaying into VV (with $V = W$ or Z) , VH (with H representing the SM Higgs boson), and HH. ATLAS has searched in the $qqqq$, $\nu\nu qq$, $l\nu qq$, $llqq$, $l\nu l\nu$, $ll\nu\nu$, $l\nu ll$, $llll$, $qqbb$ $\nu\nu bb$, $l\nu bb$, and $llbb$ final states and combined the results . While CMS analyzed the $qqqq$, $\nu\nu qq$, $l\nu qq$, $llqq$, $ll\nu\nu$, $\nu\nu bb$, $l\nu bb$, $llbb$, $bbbb$, $\tau\tau bb$, and $qq\tau\tau$ final states.

The combined limits are expressed both as limits on the cross-section as a function resonance mass as well as constraints on the coupling of the heavy boson triplet to quarks, leptons, and the Higgs boson.

$X \to WZ$:

ATLAS searched for new heavy resonances decaying into WZ in the channels $WZ \to qqqq$ [95] , $l\nu qq$ [96], and $l\nu ll$ [97]. In the fully leptonic channel , the invariant mass of the W Z pair is obtained by considering all possible four lepton permutations in each event. The dominant background is Standard Model continuum WZ production, ZZ production where one lepton is not identified or falls outside the detector acceptance, and top quark plus vector boson production. No resonant production is seen in data and lower limits on the mass of a HVT decaying into WZ are set at 2260 (2460) GeV assuming a coupling constant of $g_V = 1$ ($g_V = 3$). In the $WZ \to l\nu qq$ mode, ATLAS searches in both the cases that the quarks are observed as individual jets (resolved) and where they merge into one jet in the detector (boosted) which probe the low and high p_T regime of the Z boson. No significant excess is seen in either channel and combined lower mass limits are placed at 2900 (3000) GeV for $g_V = 1$ ($g_V = 3$) in the HVT model. In the all hadronic decay mode, ATLAS searched for two high p_T hadronically decaying vector bosons looking for a resonant structure. No excess is seen and limits are placed exclude 1200-3000 (1200-3300) GeV for $g_V = 1$ ($g_V = 3$) in the HVT model.

CMS searched for new heavy resonances in the ZV final state using the semi-leptonic decay channels excluding W' masses up to 1800 GEV in HVT two models with $g_V = 1$ and 3 and in the ZZ channel excludes gravitons up to 1200 GeV. The CMS collaboration searched for $VV \to qqqq$ [98] in the large R dijet search. The W and Z boson are identified through the mass of the large R jet and substructure variables. No excess is seen and limits are set for charged HVT bosons with masses lower than 3200 (3800) GeV for $g_V = 1$ ($g_V = 3$). Cross-section limits as function of mass are reported for the charged spin-1 resonance interpretation and are placed at 44.4 fb at 1.4 TeV to 0.7 pb at 4 TeV. In the $\nu\nu qq$ final state [99], the CMS collaboration searched for a charged spin 1 resonance decaying into a VZ final state with a Z boson decaying into a pair of neutrinos and the other boson decaying into two collimated quarks reconstructed as a large R-jet. The transverse mass of the VZ candidate is reconstructed and utilized to search for evidence of resonant VZ production. No excess is seen and lower mass limits are placed on the charged resonance at 3100 (3400) GeV for $g_V = 1$ ($g_V = 3$) . In the $2l2q$ final state, the CMS collaboration searched for a heavy resonance decaying into ZV [100] looking for events with one large R-jet consistent with the hadronic decay of a vector boson and a Z boson reconstructed in the charged lepton decay channel (e or μ). Limits are set for a HVT W' with a lower mass of 2270 (2330) for $g_V = 1$ ($g_V = 3$) .

$X \to WW$:

ATLAS searched for a new heavy resonance decaying into WW in the channels $WW \to qqqq$ [95] , $l\nu qq$ [96], and $l\nu\nu$ [101]. In the case where both Ws decay leptonically, ATLAS utilized the transverse mass of the two lepton and two neutrino final state and searched for an excess in this distribution between 200 GeV and 5 TeV. No excess is seen and a HVT is excluded for masses below 1300 GeV. Vector boson fusion is also considered and cross-section limits as a function of mass are placed ranging from 1.3 pb to 0.006 pb at 200 GeV to 3 TeV, respectively. In the $l\nu qq$ mode , ATLAS completed a companion analysis to the $WZ \to$ analysis discussed above and places lower mass limits of 2850 (3150) GeV for $g_V = 1$ ($g_V = 3$) in the HVT model. ATLAS also interprets the all hadronic mode analysis in the hypothesis that $WW \to qqqq$ and places limits on a HVT boson decaying into WW in the all hadronic mode between 1200 and 2200 (1200 and 2800) GeV for $g_V = 1$ ($g_V = 3$).

The CMS collaboration searched for $VV \to qqqq$ [98] in the large R dijet search. The W and Z boson are identified through the mass of the large R jet and substructure variables. No excess is seen and limits are set for charged HVT bosons with masses lower than 2700 (2800) GeV for $g_V = 1$ ($g_V = 3$). Cross-section limits as function of mass are reported for the uncharged spin-1 resonance interpretation and are placed at 41.6 fb at 1.4 TeV to 0.6 pb at 4 TeV.

$X \to VH$:

ATLAS searched for a new heavy resonance decaying into WH and ZH in the $qqbb$ (WH and ZH) [102], $l\nu bb$ (WH), $\nu\nu bb$ (ZH), $llbb$(ZH) [103] modes. In the all hadronic mode, ATLAS searched for boosted VH production looking for two large R jets where the larger invariant mass large R jet is interpreted as the Higgs boson decay products while the lesser invariant mass jet is taken to be the hadronically decaying vector boson requiring b-tagging on the Higgs boson subjets. The invariant mass is reconstructed and a search is performed for resonant production of ZH. None is found and limits from 1100 to 2500 (1300 to 3800 GeV) are placed for $g_V = 1$ ($g_V = 3$). ATLAS also searched for XH where the W or Z boson decays into $\nu\nu$, $l\nu$, and ll . The analysis searched for both resolved and merged (boosted) b-jets from the decay of the Higgs boson and defines the signal regions based on the number of reconstructed charged leptons (0,1,or 2). In the dilepton channel the invariant mass is explicitly reconstructed of the entire diboson system, the single lepton channel reconstructs the diboson final state constraining the lepton and missing transverse momentum utilizing the known W boson mass, while the 0 charged lepton channel reconstructs the transverse mass of the diboson system. No excess is seen in any channel and limits on the production of a HVT are placed at 2800 GeV (2930) GeV for $g_V = 1$ ($g_V = 3$).

The CMS Collaboration searched for a heavy resonance decaying into VH [104] searching for a resonances decaying into a Higgs boson and a hadronically decaying W or Z boson. The search identifies events with two large-R jets using substructure variables and requires one large-R jets is tagged with a pair of b-hadrons clustered in a single jet. The invariant mass of the VH bosons is reconstructed and evidence for resonance production is sought. No excess is seen and limits are placed. With $g_V = 1$ (3) a narrow W' resonance with $m_{W'} < 2470(3150)$ GeV and $m_{Z'} < 1150(1190)$.

The CMS collaboration searched for a heavy resonance decaying into a pair of boosted Higgs boson with $HH \to b\bar{b}WW^*$ in the single and dilepton channel [105]. Events are categorized according to lepton flavor and multiplicity, along with discriminators that characterize the compatibility with having jets arising from the decay of boosted Higgs and W bosons. The reconstructed Higgs and diHiggs mass distributions are fit and used as the final discriminators. No significant deviations in the 12 sub-categories are seen and 95% confidence limits on spin-0 bosons are set from 24.5 fb at 0.8 TeV to 0.78 fb at 4.5 TeV and spin-2 bosons from 16.7 fb at 0.8 TeV to 0.67 fb at 4.5 TeV. A similar search in the

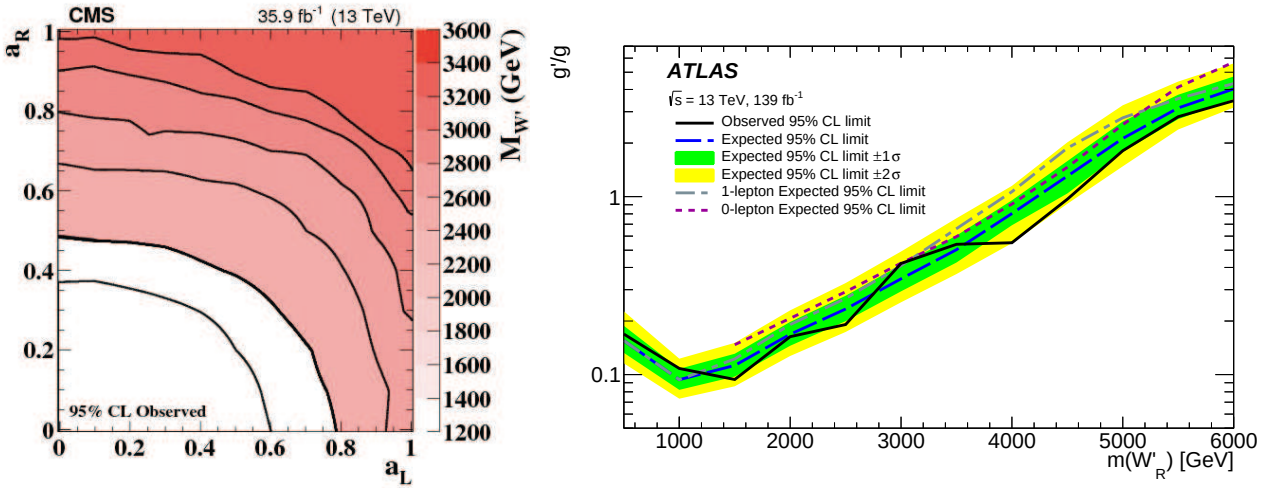

Figure 92.1: Left panel: Observed limits on the W' boson mass as function of the left-handed ($a_{\rm L}$) and right-handed ($a_{\rm R}$) couplings. Black lines represent contours of equal W' boson mass [86]. Right panel: Observed and expected regions, on the g′/g vs mass of the W' boson plane, that are excluded at 95% CL, for right-handed W' bosons [91] showing the exclusion of the values of a hypothetical right-handed coupling of a heavy W particle.

four b-quark final state is used to set limits range 9.74 to 0.29 fb and 4.94 to 0.19 fb in the spin-0 bosons and spin-2 gravitons (respectively) interpretation with masses of 1-3 TeV [106].

$X \to H\gamma$ or $V\gamma$:

Both CMS and ATLAS search for heavy resonances decaying into either a vector boson and a photon or a Higgs boson or a photon. These searched are motivated generically by the fact that new heavy gauge bosons are generically predicted to decay to either a Higgs boson or a vector boson and a photon by one loop decays [107]. ATLAS searched for for a heavy resonances decaying into a Higgs boson and a photon and sets limits from 0.7 to 4 TeV from 11.6 fb to 0.11 fb [108]. ATLAS searched for a heavy resonance decaying into XH where $XH \to qqbb$ [109] and sets limits from 1 to 4 TeV. CMS searched for a heavy resonance decaying into a W boson and a photon [110] setting limits for narrow resonances range between 0.17 fb at 6.0 TeV and 55 fb at 0.7 TeV.

Summary of Searches with Diboson Final States:

Both ATLAS [93] and CMS [94] provide plots summarizing the various searched results and limits combining. The results are shown in the context of HVT models and models of strong gravity with extra spatial dimensions. No excess is seen in any search and limits on the 4.3 (4.5) TeV (ATLAS) and (CMS). Inclusion of decays directly to fermions increase these limits to 5.3 (5.5) TeV and 5.0 (5.2) TeV from the ATLAS and CMS combinations, respectively. Both collaborations also place varying limits on the coupling strength as a function of HVT boson mass as well.

Searches for Triboson Resonances:

The CMS collaboration presents the first search for massive triboson resonances in both the semi-leptonic [111] and fully hadronic final state [112]. Three boson final states can be produced via the decay of Kaluza-Klein (KK) states decaying via $W_{KK} \to WR$ with $R \to WW$ where R is a scalar radion. The search utilizes novel deep neural networks to perform optimal separation between signal and background and searched for evidence of resonance structure in the triboson invariant mass-spectrum. No excesses above SM backgrounds are seen and W_{KK} and radion masses are excluded up to $M_{W_{KK}} = 3.4$ TeV and $M_R = 1$ TeV and up to $M_{W_{KK}} = 3.6$ TeV and $M_R = 0.35$ TeV . $M_{W_{KK}}$ below 3 TeV are excluded for $0.6 < \frac{M_R}{M_{W_{KK}}} < 0.7$ in the semi-leptonic final state and up to $M_{W_{KK}} = 3.0$ TeV and $M_R = 200$ GeV and up to $M_{W_{KK}} = 1.5$ TeV and $M_R = 1.5$ TeV in the fully hadronic final state.

92.2.3 *Vector-like third generation quarks*

Vector-like quarks (VLQ) have non-chiral couplings to W bosons, i.e. their left- and right-handed components couple in the same way. They therefore have vectorial couplings to W bosons. Vector-like quarks arise in Little Higgs theories, top-coloron-models, and theories of a composite Higgs boson with partial compositeness. In the following, the notation T quark refers to a vector-like quark with charge 2/3 and the notation B quark refers to a vector-like quark with charge $-1/3$, the same charges as the SM top and b quarks respectively. The exotic vector-like quarks $X_{5/3}$ and $Y_{-4/3}$ have charges 5/3, and $-4/3$ respectively. Vector-like quarks couple with SM quarks with Yukawa interactions and may exist as SU(2) singlets (T, and B), doublets $[(X_{5/3}, T)$,(T, B),$(B, Y_{-4/3})]$, or triplets $[(X_{5/3}, T, B)$, $(T, B, Y_{-4/3})]$. At the LHC, VLQs can be pair produced via the dominant gluon-gluon fusion process. VLQs can also be produced singly by their electroweak effective couplings to a weak boson and a standard model quark. The single production rate is expected to dominate over the rate of pair production at large VLQ masses. T quarks can decay to bW, tZ, or tH^0. Weak isospin singlets are expected to decay to all three final states with (asymptotic) branching fractions of 50%, 25%, 25%, respectively. Weak isospin doublets are expected to decay exclusively to tZ and to tH^0 [113] with equal branching ratios. Analogously, B quarks can decay to tW, bZ, or bH^0. The $Y_{-4/3}$ and $X_{5/3}$ quarks decay exclusively to bW and to tW. While these are taken as the benchmark scenarios, other representations and decays to exotic new particles are possible [114–116], and hence the final results are interpreted for many allowed branching fraction combinations.

Given the multiple decay modes of the VLQs, the final state signatures of both pair produced and the singly produced VLQs are fairly rich with leptons, jets, b-jets, and missing energy. Depending on the mass of the VLQ, the top quarks and $W/Z/H^0$ bosons may be Lorentz boosted and identified using jet substructure techniques. Thus the searches are performed using lepton+jets signatures, multi-lepton and all-hadronic decays. In addition, T or B quarks with their antiparticles can result in events with same-sign leptons, for example if the decay $T \to tH \to bWW^+W^-$ is present, followed by leptonic decays of two same-sign W bosons. In the following subsections, while we describe the searches for each of the decay modes of the VLQs, the same analysis can be re-interpreted to obtain the sensitivity to a combination with varied branching fractions to the different decay modes.

In the following sections, the results obtained for T (B) quarks assuming 100% branching ratio to Wb (Wt) are also applicable to heavy vector-like $Y_{-4/3}$ ($X_{5/3}$) with charge 4/3 (5/3).

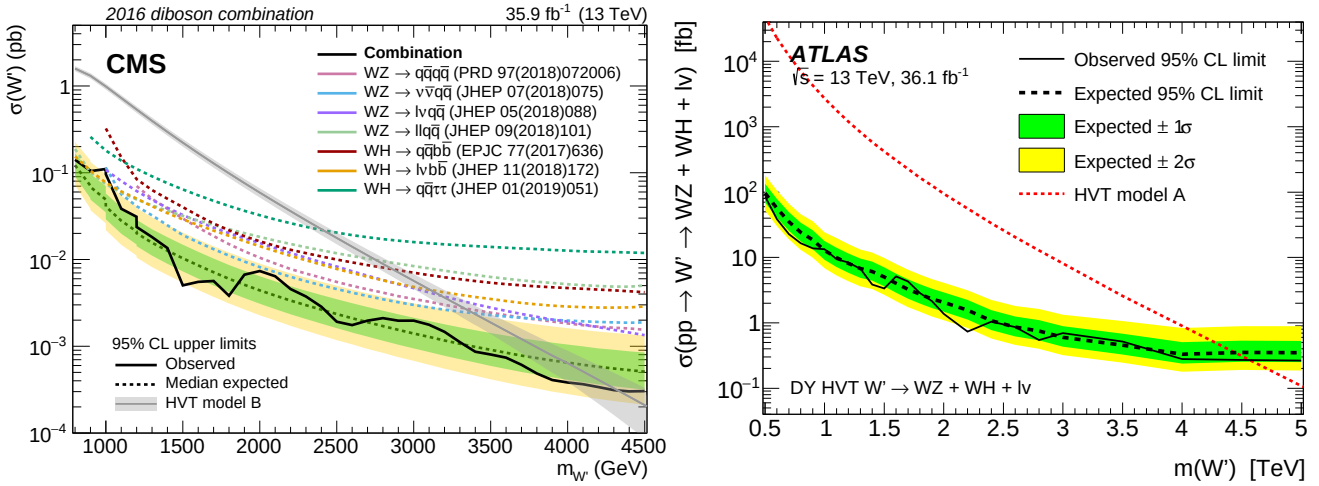

Figure 92.2: Left panel:Observed limits from W' to diboson from CMS [94]. Right panel: Observed limits from W' to diboson decays from ATLAS [93].

92.2.3.1 *Searches for* $\boldsymbol{T}$ *quarks that decay to* $\boldsymbol{W}$, $\boldsymbol{Z}$ *and* $\boldsymbol{H^0}$ *bosons*

$T/Y \to bW$:

CMS has searched for pair production of heavy T quarks that decay exclusively to bW [117–119]. The analysis selected events with exactly one charged lepton, assuming that the W boson from the second T quark decays hadronically. Under this hypothesis, a 2-constraint kinematic fit can be performed to reconstruct the mass of the T quark as a narrow mass peak with a mass resolution of around 7%. In Refs. [118] and [119], the two-dimensional distribution of reconstructed mass vs S_T was used to test for the signal, where S_T is the scalar sum of the missing p_T and the transverse momenta of the lepton and the leading four jets. This analysis, when combined with the search in the fully hadronic final state [120] excluded new quarks that decay 100% to bW for masses below 0.89 TeV [119]. At times the hadronically-decaying W boson is produced with a large Lorentz boost, leading to the W decay products merged into a large-radius jet. Algorithms such as jet pruning [121] were used to remove contributions from soft, wide angle radiation, from large-radius jets, leading to better discrimination between jets from multijet events and those arising from decays of the heavy particles. If the mass of the boosted jet was compatible with the W boson mass, then the W boson candidate jet and its subjets were used in the kinematic reconstruction of the T quark. No excess over standard model backgrounds was observed. Upper limits on the production cross section as a function of the mass of T quarks were measured. By comparing them with the predicted cross section for vector like quark pair production, the strong pair production of T quarks was excluded for masses below 1.30 TeV (1.28 TeV expected) [117].

Another "cut-based" search for pair produced T quarks in the all-hadronic final state targeting the Wb decay mode [122], relies on mass reconstruction of two highest p_T Wb combinations using boosted W boson candidates with $p_T > 200$ GeV and b-tagged jets. H_T is used as the signal discriminator, with selected events divided into nine categories based on the multiplicity of W and b-jets in the event. From this search T quarks with pure Wb decays are excluded for masses below 1.04 TeV (1.07 TeV expected).

An analogous search has been carried out by ATLAS [123, 124] for the pair production of heavy T quarks. It used the lepton+jets final state with an isolated electron or muon and at least four jets, including a b-jet, and required reconstruction of the T quark mass. Given that the mass range for the T quark being explored was from a 0.4 TeV to a couple of TeV, the W boson from the T quark may fall in two categories: those with a high boost leading to merged decay products, and others where the two jets from the W boson were resolved. In addition, the selection was optimized to require large angular separation between the high p_T W bosons and the b-jets.

The $T \to Wb$ candidates were constructed from both the leptonically and hadronically decaying W bosons by pairing them with the two highest p_T b-tagged jets in the event. The pairing of b-jets with W bosons which minimizes the difference between the masses of leptonically decaying T ($m_{lep}(T)$) and the hadronic T ($m_{had}(T)$) was chosen. Finally, $m_{lep}(T)$ was used as the discriminating variable in a signal region defined by high S'_T (here S'_T is defined as the scalar sum of the missing p_T, the p_T of the lepton and jets), and the opening angle between the lepton and the neutrino ($\Delta R(e,\nu)$). With the 36.1 fb^{-1} data collected during Run 2 at $\sqrt{s} = 13$ TeV, assuming 100% branching ratio to the Wb decay, the observed lower limit on the T mass was 1.35 TeV, and in the SU(2) singlet scenario, the lower mass limit was obtained to be 1.17 TeV [123].

A targeted search for a T quark, produced singly in association with a light flavor quark and a b quark and decaying into bW, was carried out by CMS at $\sqrt{s}$=13 TeV and a dataset corresponding to 2.3 fb^{-1} [125]. The analysis used lepton+jets events, with at least one b-tagged jet with large transverse momentum, and a jet in the forward η region. Selected events were required to have $S''_T > 500$ GeV, where S''_T is defined as the scalar sum of the transverse momenta of the lepton, the leading central jet, and the missing transverse momentum. The invariant mass of the T candidate was used as the discriminating variable and was reconstructed using the four-vectors of the leptonically decaying W boson and the leading central jet. No excess over the standard model prediction was observed. As the VLQ width is proportional to the square of the coupling, upper limits were set on the production cross section assuming a narrow width VLQ with coupling greater than 0.5. For Y/T quarks with a coupling of 0.5 and a 100% branching fraction for the decay to bW the excluded masses were in the range from 0.85 to 1.40 TeV [125]. A similar search [126, 127] was performed by ATLAS for a singly produced T or $Y_{-4/3}$ quark decaying to Wb using a dataset corresponding to 36.1 fb^{-1}. The search was performed using lepton+jets events with a high p_T b-tagged jet, and at least one forward jet. The reconstructed mass of the $T/Y_{-4/3}$ quark, was used as the discriminating variable and showed no excess above the expectation from SM. Interference effects with the SM background are included in the study. This search led to 95% CL upper limits on the mixing angle $|sin(\theta_L)|$ (C_L^{Wb}) in the range of 0.18–0.35 (0.25–0.49) for singlet T quark mass between 0.8–1.2 TeV. This search also provided limits as a function of the $Y_{-4/3}$ quark mass, on the coupling of the $Y_{-4/3}$ quark to bW, and the mixing parameter $|sin\theta_R|$ (C_R^{Wb}) for a (B,$Y_{-4/3}$) doublet model [126]. For VLQ masses between 0.08–1.8 TeV, the limits on $|sin(\theta_R)|$ (C_R^{Wb}) are in the range 0.17–0.55 (0.24–0.77), and for for $Y_{-4/3}$ quark mass between 0.9–1.25 TeV, the limits on $|sin\theta_R|$ are around 0.18–0.19 and below the constraints from electroweak precision observables.

For $Y_{-4/3}$ quark in the triplets (T,B,$Y_{-4/3}$), limits on $|sin(\theta_L)|$ (C_L^{Wb}) are between 0.16–0.39 (0.31–0.78) for masses between 0.8 GeV–1.6 TeV [126].

$T \to tH^0$:

ATLAS has performed a search for $T\overline{T}$ production with $T \to tH^0$ [124, 128]. Given the dominant decay mode $H^0 \to b\bar{b}$, these events are characterized by a large number of jets, many of which are b-jets. Thus the event selection required one isolated electron or muon and high jet multiplicity (including b-tagged jets). The sample is categorized by the jet multiplicity (5 and $\geq$6 jets in the 1-lepton channel; 6 and $\geq$7 jets in the 0-lepton channel), b tag multiplicity (2, 3 and $\geq$4) and mass-tagged jet multiplicity (0, 1 and $\geq$2). The distributions of $m_{\rm eff}$, defined as the scalar sum of the lepton and jet p_T and the missing p_T, for each category were used as the discriminant for the final signal and background separation. No excess of events was found. Weak isospin doublet T quarks were excluded below 1.16 TeV.

A search by ATLAS for pair produced VLQs with an all-hadronic final state signature yields an exclusion of pure decays $T \to tH^0$ upto a T quark mass of 2.3 TeV [129].

The CMS search for $T\overline{T}$ production, with $T \to tH^0$ decays has been performed in lepton+jets, multilepton and all-hadronic final states. The lepton+jets analysis [130] emphasizes the presence of a large number of b-tagged jets, and combines it with other kinematic variables in a Boosted Decision Tree (BDT) to enhance signal to background discrimination. The multilepton analysis [130] was optimized for the presence of b-jets and the large hadronic activity. For $\mathcal{B}(T \to tH^0) = 1$, the combined lepton+jets and multilepton analyses led to a lower limit on T quark masses of 0.71 TeV. A search for $T \to tH^0$ in all-hadronic decays [131], optimized for a high mass T quark, and based on identifying boosted top quark jets has been carried out by CMS. This search aimed to resolve subjets within the jets arising from boosted top quark decays, including b tagging of the subjets. A likelihood discriminator was defined based on the distributions of H_T and the invariant mass of the two b-jets in the events for signal and background. No excess above background expectations was observed. Assuming 100% branching ratio for $T \to tH^0$, this analysis led to a lower limit of 0.75 TeV on the mass of the T quark.

Searches for T quarks at $\sqrt{s}$=13 TeV, based on a 2.6 fb^{-1} dataset [132] have been performed by CMS using the lepton+jets final state. This search has been optimized for high mass T quarks by exploiting techniques to identify W or Higgs bosons decaying hadronically with large transverse momenta. The boosted W channel excluded T quarks decaying only to bW with masses below 0.91 TeV, and the boosted tH channel excluded T quarks decaying only to tH for masses below 0.89 TeV.

A CMS search for $T \to tH^0$ with $H^0 \to \gamma\gamma$ decays has been performed [133] in pair production of T quarks. To identify the Higgs boson produced in the decay of the heavy T quark, and the subsequent $H^0 \to \gamma\gamma$ decay, the analysis focused on identification of two photons in events with one or more high p_T lepton+jets or events with no leptons and large hadronic activity. A search for a resonance in the invariant mass distribution of the two photons in events with large hadronic activity defined by the H_T variable showed no excess above the prediction from standard model processes. The analysis resulted in exclusion of T quark masses below 0.54 TeV.

A search for electroweak single production of T quarks decaying to tH^0 using boosted topologies in fully hadronic [134] and lepton+jets [135] in the final states has been performed by CMS. The electroweak couplings of the T quarks to the SM third generation quarks are highly model dependent, and hence these couplings determine the rates of the single T quark production. In both analyses, T quark invariant mass was reconstructed using the boosted Higgs boson jet and the top quark. Higgs boson jets were identified using jet substructure techniques and subjet b tagging. For the lepton+jets analysis, the top quark was reconstructed from the leptonically decaying W and the b jet, while in the all-hadronic analysis the top quark jet was tagged using substructure analysis. There was no excess of events observed above background. Exclusion limits on the product of the production cross section and the branching fraction ($\sigma(pp \to Tqt/b) \times \mathcal{B}(T \to tH^0)$ were derived for the T quark masses in the range 0.70-1.8 TeV. From the lepton+jets analysis, for a mass of 1.0 TeV, values of ($\sigma(pp \to Tqt/b) \times \mathcal{B}(T \to tH^0)$ greater than 0.8 and 0.7 pb were excluded assuming left- and right-handed coupling of the T quark to standard model fermions, respectively [135]. For the all-hadronic analysis, upper limits between 0.31 and 0.93 pb were obtained on ($\sigma(pp \to Tqt/b) \times \mathcal{B}(T \to tH^0)$ for T quark masses in the range 1.0-1.8 TeV [134]. ATLAS performs a similar search [136] for single production of vector-like T quarks decaying into a Higgs Boson and a top quark and places limits between 1 and 1.7 TeV depending on the coupling

$T \to tZ$:

Both ATLAS and CMS search for T quarks that decay exclusively into tZ in pp collisions at $\sqrt{s} = 13$ TeV. No excesses were found in either search.

ATLAS performes a search [137] optimized for pair production of vector-like top quarks decaying into tZ where the Z boson subsequently decays into neutrino pairs, utilizing 139 fb^{-1} of data. The search selected events with one lepton, multiple jets, and significant missing transverse momentum. No significant excesses were found and lower limits on the mass of a vector like top quark were placed, excluding masses below 1.59 TeV (weak-isospin doublet) and 1.47 TeV (pure tZ mode).

Another search by ATLAS for pair produced T decaying to tZ has been carried out by reconstructing the high transverse momentum Z boson from a pair of opposite-sign same-flavor leptons, using events with two or three charged leptons [138]. The final analysis is based on three final state signatures. In the trilepton events, at least one b-tagged jet is required and H_T, formed from all hadronic jets and charged leptons, is used as the discriminating variable. In events with two leptons, at least 2 b-jets are requested and events with zero or one high p_T top-tagged jet, use H_T as the discriminator. The second dilepton analysis with two top-tagged high p_T jets focuses on hadronically decaying heavy resonances and the invariant mass of the Z boson and the highest p_T b-tagged jet is found to be a good discriminating variable. No excess was observed over the background expectations. Limits were placed at a heavy vector like top of 1.6 TeV.

ATLAS has subsequently carried out a search [139] for singly produced T quarks decaying to tZ where the Z boson decays into neutrino pairs. The search is carried out using 36.1 fb^{-1} of data in events with two different final state signatures: one with jets and significant missing p_T (0L) and the other with a single lepton, jets and missing p_T (1L). Events are divided into signal and dedicated W+jets and $t\bar{t}$ background control regions. The sensitivity to the T quark signal is extracted using distributions of missing p_T for the 1L and the distribution of T quark transverse mass constructed from missing p_T and the high p_T large-radius top-tagged jet, for 0L analysis. There is no excess found over the expected background and lower limits on the production of T singlets are obtained as a function of the left- and right-handed couplings $c_{L,W}$ and $c_{R,W}$ to top quarks and W bosons, where c_W above 0.7 is excluded for T quark mass of 1.4 TeV. The limits on c_W are also recasted into expected and observed 95% CL upper limits for the mixing angle (θ_L) of a singlet T with the top quark.

CMS searched [140] for single production of T quarks decaying into tZ with the Z boson decaying to pairs of charged leptons (electrons and muons) and the top quark decaying hadronically using 35.9 fb^{-1} of data. Limits were placed on T quarks with masses between 0.7 and 1.7 TeV excluding the product of cross section and branching fraction above values of 0.27 to 0.04 pb. Additionally, limits on the product of cross section and branching fractions for a Z' boson decaying into tZ were set between 0.13 and 0.06 pb for Z' boson masses in the range from 1.5 to 2.5 TeV.

Similar searches by ATLAS for singly produced T decaying to Zt have been performed in final state signatures with two or three charged leptons [141]. The analysis relies on tagging b-jets and high p_T large-radius jets originating from top-quarks. Additional selections are devised to reduce the contributions from pair production of T quarks. For events with dilepton analysis, the discriminating variable is the mass of the T quark formed using the invariant mass of the Z boson candidate and the highest p_T top-

tagged jet, while for the trilepton analysis, the variable S_T is used to search for an excess of data over the expected SM background. No excess above the SM expectations is observed. The two final states (dilepton and trileptons) are combined to obtain the final results. For the coupling parameter κ_T between 0.1–1.6, the 95% CL upper limits on the production cross section times branching fraction into Zt is between 0.16–0.18 (0.03–0.05) pb at T quark mass of 0.7 (2) TeV.

The search by the ATLAS experiment for VLQ pair production optimized to search for $T \to tZ$ decays [142] in a dataset with 139 fb^{-1} of luminosity has been performed in final states with either two leptons or three or more leptons. A multi-class boosted object tagger based on DNN techniques for large-radius jets is used to categorize events according to the number of high p_T boosted H^0, Z/W, and top quark jets. The discriminant in the signal to evaluate the sensitivity depends on the number of leptons in the event. For the two lepton analysis, the discriminant is the mass of the T quark which is constructed from b and Z candidates, while for the three or more lepton analysis, H_T computed using the p_T of the jets and leptons is used as the discriminant. This analysis excludes T quark masses up to 1.27 GeV (1.46 GeV), for the singlet (doublet) configuration [142].

Combination of $T \to tZ/tH^0$:

The search performed by the ATLAS experiment for electroweak single production of T quark decaying to tH^0 and tZ uses a dataset corresponding to 139 fb^{-1} of integrated luminosity, and events with a single lepton with multiple jets and b-jets in the final state [143]. The single production channel for VLQs probes κ, the universal coupling constant, which also controls the production cross section and the resonance width of the VLQ. The analysis uses techniques to tag boosted jets, and categorizes events by numbers of jets and b-jets. The event discriminant is the "effective mass" (meff) observable, defined as the scalar sum of the p_T of all central jets, p_T of leptons and the missing p_T in the event. No significant excess is observed. Limits on the mass of T quark and universal coupling strength (κ) are obtained. For singlet T quarks, values of κ above 0.5 are excluded for all masses below 1.8 TeV. For T quark mass of 1.6 TeV, κ above 0.41 is excluded [143].

A CMS search published in 2020 concentrates on the electroweak production of the T quark with $T \to tH^0$, and $T \to tZ$ decays, where subsequently both H^0 and Z Bosons decay hadronically, leading to fully hadronic final states [144]. The search focuses on evidence of T quarks produced in association with a b quark ($qg \to T\bar{b}q'$) or a top quark ($qg \to T\bar{t}q$). The production cross sections are model dependent, as the electroweak production depends on the strength of the T quark coupling, TbW (TtZ), for the charged-current (neutral-current) process, at the production vertex. The searches are split into two domains depending on the mass of the T quark and consider a wide range of widths of the T quark from a few percent to about 30% of the T quark mass. The event selection relies primarily on the large number of jets and on efficient identification of jets from b-quarks, in addition to double-b jet decays of the H^0 and Z bosons. The final sensitivity is derived by the search for a resonant peak in the tH^0/Z invariant mass spectrum. For low mass T quark searches, three independent regions based on the b-tagged jet requirements are examined. For T quark masses above 1 TeV, which result in highly Lorentz-boosted top quarks and H^0 or Z boson, large-area jets are used to form the T quark. This search reports upper limits at 95% confidence level on $\sigma B(T \to tH)$ and $\sigma B(T \to tZ)$ between 2 pb and 20 fb for T masses between 0.6 to 2.6 TeV in the Tbq and Ttq production channels. The analysis also reports combined results for $T \to tH$ and $T \to tZ$ associated production with a bottom quark and provides constraints on T quarks in the T singlet model for masses below 1.00 TeV. For an expected fractional width of 30%, the expected sensitivity extends to 1.28 TeV, comparable to the most stringent results.

Combination of $T \to bW/tZ/tH^0$:

Most of the analyses described above target an individual decay mode of the T quark, with 100% branching ratio to either bW, tZ or tH^0 and are optimized accordingly. However, they have varied sensitivity to all three decay modes and the results can be interpreted as a function of branching ratios to each of the three decay modes, assuming the total adds up to unity ($\mathcal{B}(tH) + \mathcal{B}(tZ) + \mathcal{B}(Wb) = 1$).

Combinations of analyses have been performed by both ATLAS and CMS. The limits set by ATLAS searches in $W(\ell\nu)b + X, H(bb)b + X, Z(\nu\overline{\nu}), Z(\ell\ell)t/b + X$, dileptons with same-sign charge, trileptons, all-hadronic final states have been combined and the results obtained for various sets of branching fractions for T quark decays to bW, tH^0 and tZ are shown in Fig. 92.3 (left). In the combined analysis, ATLAS sets lower T quarks mass limit of 1.31 TeV for all possible values of the branching fractions to the three decay modes [123,145,146]. In Fig. 92.3, exclusion is shown in the plane of $\mathcal{B}(T \to Ht)$ versus $\mathcal{B}(T \to Wb)$, for different values of the T quark mass. The default branching ratio values for the weak-isospin singlet and doublet cases are also shown in Fig. 92.3 as yellow circle and star symbols respectively. Assuming a weak isospin (T,B) doublet and $|V_{Tb}| << |V_{tB}|$, T quark mass below 1.37 TeV is excluded.

A CMS analysis for pair production of T combines three channels with lepton final states: single lepton, two leptons with the same sign of the electric charge (SS), or at least three leptons (trilepton) [147]. For various combinations of branching fractions for T quark decays to bW, tH^0 and tZ, the combined results exclude T quarks with masses below 1.14–1.3 TeV and are shown in Figure 92.3 (right). Single lepton events are classified into 16 signal categories and 6 background control regions based on multiplicity of b-tagged, high p_T H^0 and W-tagged jets. The discriminating variables are H_T for H^0-tagged events and the minimum invariant mass constructed from the lepton and the b jet, min[M_{lb}], for zero H^0-tagged events. For the same-sign dilepton and trilepton analyses, the non-prompt backgrounds due to misidentified jets and leptons are derived from data control regions. In the trilepton analysis the S_T variable is used as the signal discriminator binned in four categories based on the lepton flavor combinations (eee, $ee\mu$, $e\mu\mu$, $\mu\mu\mu$). The single lepton analysis is most sensitive for $tHbW$ and $WbWb$ decay modes, within the SS dilepton analysis $tHtH$ and $tHtZ$ have the best efficiency and for trileptons the $tZtZ$ and $tHtZ$ decays modes have the highest efficiency. CMS excludes singlet (doublet) T quark masses below 1.2 (1.28) TeV. Masses below 800 GeV were excluded in previous searches. For T quark masses in the range 0.8–1.8 TeV, cross sections smaller than 30.4–9.4 fb (21.2–6.1 fb) are excluded for the singlet (doublet) scenario.

Another inclusive search for pair produced T in the all-hadronic final state [122] has been performed by CMS using the boosted event shape tagger (BEST NN) neural network technique to classify jets in six categories W, Z, H^0, t, b, and light. This search does not focus on a given VLQ mode, but on various combinations of the boson and quark jets in the final state. Anti-k_T jets with a distance parameter of 0.8 are used. The BEST NN algorithm simultaneously classifies jets according to heavy object type. For each of the six particle hypotheses, it boosts each jet constituent into corresponding frame along the jet momentum direction, and calculates event shape and angular variables in the boosted frame, with the expectation that when boosting to the correct rest frame, jet constituents will be isotropic and show the expected N-prong structure of the decaying object in its rest frame. A neural network is trained using the event shape and angular variables in the boosted frame to classify jets according to one of those six possibilities (W, Z, H, t, b, or light). The analysis bins the events into 126 categories depending on the number of W, Z, H, t, b, or light jets in the final state with a maximum of four such objects. For each category H_T^{AK8}, the scalar sum of p_T of all AK8 jets, is used as the signal discriminator. A scan over a combination of various branching fractions is also performed. This search excludes T quark masses in the range 0.74–1.37 TeV for the tH decay mode in the NN analysis.

An inclusive search for VLQs has been carried out by CMS targeted at heavy T quarks decaying to any combination of bW, tZ, or tH^0 as described in [130]. Selected events have at least one isolated charged lepton. Events were categorized according to number and flavor of the leptons, the number of jets, and the

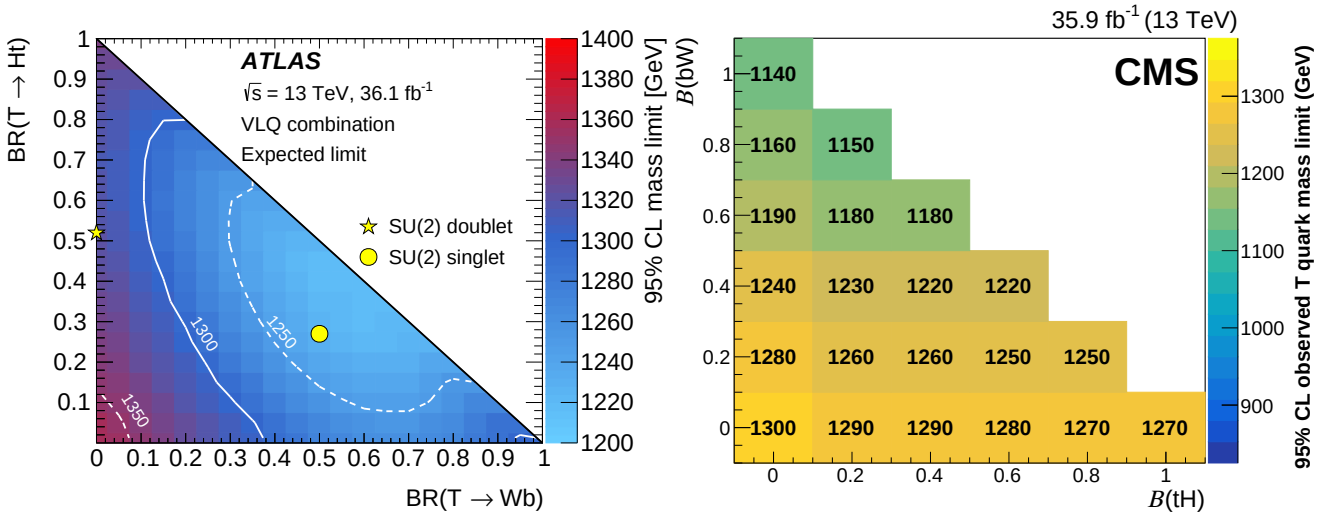

Figure 92.3: Left panel: observed limits on the mass of the T quark in the plane of $\mathcal{B}(T \to tH^0)$ versus $\mathcal{B}(T \to bW)$ from a combination [145] of all ATLAS searches for TT production. The markers indicate the default branching ratios for the SU(2) singlet and doublet scenarios. Right panel: the observed lower limits on the T quark mass (in GeV), from CMS searches after combining all lepton channels [147], for various branching fraction scenarios. $\mathcal{B}(T \to Wb) + \mathcal{B}(T \to tZ) + \mathcal{B}(T \to tH^0) = 1$ is assumed.

presence of hadronic vector boson and top quark decays that are merged into a single jet. The use of jet substructure to identify hadronic decays significantly increases the acceptance for high T quark masses. No excess above standard model backgrounds was observed. Limits on the pair production cross section of the new quarks are set, combining all event categories, for all combinations of branching fractions into the three final states. For T quarks that exclusively decay to $bW/tZ/tH^0$, masses below 0.70/0.78/0.71 TeV are excluded.

92.2.3.2 *Searches for* $\boldsymbol{B}$ *quarks that decay to* $\boldsymbol{W}$, $\boldsymbol{Z}$ *and* $\boldsymbol{H^0}$ *bosons*

ATLAS and CMS have performed searches for pair production of heavy B quarks which subsequently decay to Wt, bZ or bH^0. The searches have been carried out in final states with single leptons, dileptons (with same charge or opposite charge), multileptons, as well as in fully hadronic final states.

$B \to bH^0$:

A search for B pair-produced events has been performed by the CMS experiment [123] using 137 fb^{-1} of data where the B decays into a $b/\bar{b}$ quark and either a H^0 or a Z boson. This search concentrates on final states with fully hadronic signatures, and utilizes different jet multiplicity categories to account for two resolved jets or merged single jets from H^0 or Z boson to $b\bar{b}$ decays, depending on the p_T of the H^0 or Z bosons. Nine final state categories are used, depending on the number of observed jets and the reconstructed event mode. No significant excess over expected background is observed. For the case $\mathcal{B}(B \to bH) = 100\%(50\%)$, VLQs with masses below 1.57 (1.45) TeV are ruled out.

Using 36.1 fb^{-1} of data, ATLAS has performed a search for pair produced VLQs with all-hadronic final state signature [148]. While this analysis provides exclusion limits for all third generation VLQs, it provides the strongest results for the $B \to bH^0$ decay mode and excludes decays with $\mathcal{B}(\mathcal{B} \to [\mathcal{H}') = \infty.\imath$ scenario for B masses upto 1.01 TeV. The limits are also cast in a two-dimensional plane of branching ratio values of $B \to bH^0$ vs. $B \to Wb$. This analysis required the presence of high p_T jets and multiple b tags. It used a multi-class DNN to classify jets arising from W, Z, H^0 bosons and top-quarks. In addition, the matrix element method was used to compute the likelihood for the event to arise from a particular VLQ final state and to construct the final discriminator. To increase the sensitivity of the analysis, processes with the same number of top quarks, W/Z bosons, and H^0 Higgs bosons are combined into a single hypothesis.

ATLAS has performed a search for single production of a vector-like B quark decaying to a b-quark and a H^0 boson, with $H^0 \to b\bar{b}$ decay, using a dataset corresponding to an integrated luminosity of 139 fb^{-1} [149]. The all hadronic final state signature relies on identification of at least 3 b-jets, with an additional soft forward jet from the spectator quark. Large area jets are used to identify boosted H^0 decays. This analysis results in excluding the single production of a VLQ (B, Y) doublet with relative width larger than 5% between masses of 1.0 TeV and 2.0 TeV [150]. The CMS experiment has searched for a single vector-like quark decaying into tH or tZ in the all hadronic final state with 138 fb^{-1} of data in the all hadronic channel reconstring both the boson invariant mass and the tH or tZ invariant mass and searching for a resonance. No signficant excess is found and cross-section limits are placed between 600 GeV and 1200 GeV between 600 and 68 fb [151].

$B \to Wt$:

A search for $B \to tW$ in B pair produced events has been performed by ATLAS [123] using lepton+jets events with one hadronically decaying W and one leptonically decaying W utilizing 36.1 fb^{-1} of data at $\sqrt{s} = 13$ TeV. The search was optimized for T production decaying into Wb. Since the analysis was optimized for $T \to Wb$ rather than Wt decays the analysis does not reconstruct the full B mass. As discussed earlier, the hadronically and leptonically decaying heavy quarks were required to have similar reconstructed masses (within 300 GeV). The interpretation of the $T \to Wb$ in the context of $B \to tW$ production led to the exclusion of heavy B like VLQs for masses less than 1.25 TeV and 1.08 TeV, assuming a 100% branching fraction to tW or SU(2) singlet B scenario, respectively.

A similar search by CMS [152], using 19.8 fb^{-1} of $\sqrt{s} = 8$ TeV data, selected events with one lepton and four or more jets, with at least one b-tagged jet, significant missing p_T, and further categorized them based on the number of jets tagged as arising from the decay of boosted W, Z or H^0 bosons. The S_T distributions of the events in different categories showed no excess of events above the expected background and yielded a lower limit on the B quark mass of 0.73 TeV for $BR(B \to Wt) = 1$.

CMS [132] also searched for pair production of both TT and BB with collisions from 2.5 fb^{-1} of $\sqrt{s} = 13$ TeV data. The analysis seaarched for events with one high p_T lepton , multiple jets, and highly boosted W or Higgs bosons decaying hadronically. The analysis focused on pair production and selects events with either a boosted W or Higgs candidate and then proceeds to search for anomalous production in excess of standard model production. Seeing no significant excesses CMS then proceeded to set limits in many different interpretations. The strongest was from the $B \to Wt$ interpretation leading to excluding heavy vector-like B quarks with mass less than 0.73 TeV.

The all-hadronic inclusive analysis [122] performed by CMS using the BEST NN technique to classify $W/Z/H^0/t/b$/light jets also gives exclusion limits on B quark production for various combinations of branching fractions for decays to tW, bZ, bH^0. By considering categories based on various combinations of the boson and quark jets in the final state it excludes B quarks with masses up to 1230 GeV, for B decays to tW with a 100% branching fraction.

Electroweak production of single heavy B+b production has been studied by CMS in the decay to tW with the lepton+jets final state [153]. Single lepton events with hadronic jets, including a forward jet, and missing p_T are selected and divided into 10 different categories based on lepton flavor (e/μ), top-tagged, W-tagged, and 0/1/2 b-tagged jets. The B quark mass m_{reco} is fully reconstructed from lepton, jets, and missing p_T, where the neutrino four-momentum is computed using the missing p_T and the W mass constraint. For events within the top-tagged category, the high p_T top-tagged hadronic jet and the leptonically decaying W boson are used to compute m_{reco}. The m_{reco} distribution are used as the signal discriminator. In the absence of an excess over the expected SM background, the exclusion limits on the production cross section for B quark masses between 0.7-2 TeV varies between 0.3 to 0.03 pb. In addition, B quarks with left-handed couplings and a relative width of 10, 20, and 30% are excluded for masses below 1.49, 1.59, and 1.66 TeV respectively.

$B \to bZ$:

As mentioned above, a search for B pair produced events, with final states with fully hadronic signature, using 137 fb^{-1} of data, has been performed by the CMS experiment [123]. In this search, the B decays into a $b/\bar{b}$ quark and either a H^0 or a Z boson. For the case $\mathcal{B}(B \to bZ) = 100\%(50\%)$, VLQs with masses below 1.39 (1.45) TeV are ruled out by this analysis.

A search by CMS [154] for the pair-production of a heavy B quark and its antiparticle has been performed, where one of the heavy B quark decays to bZ. Events with a Z boson decaying to e^+e^- or $\mu^+\mu^-$ and at least one b jet are selected. The signal from $B \to bZ$ decays is expected to appear as a local enhancement in the bZ mass distribution. No such enhancement was found and B quarks that decay 100% into bZ are excluded below 0.70 TeV. This analysis also set upper limits on the branching fraction for $B \to bZ$ decays of 30-100% in the B quark mass range 0.45-0.70 TeV. A complementary search has been carried out by ATLAS for new heavy quarks decaying into a Z boson and a b-quark [155]. Selected dilepton events contain a high transverse momentum Z boson that decays leptonically, together with two b-jets. If the dilepton events have an extra lepton in addition to those from the Z boson, then only one b-jet is required. No significant excess of events above the standard model expectation was observed, and mass limits were set depending on the assumed branching ratios, as shown in Fig. 92.4. In a weak-isospin singlet scenario, a B quark with mass lower than 0.65 TeV was excluded, while for a particular weak-isospin doublet scenario, a B quark with mass lower than 0.73 TeV was ruled out.

The search by ATLAS for $B \to bZ$ decays [142] in final states with either two leptons or three or more leptons using a multi-class boosted object tagger to categorize events according to the number of high p_T boosted H^0, Z/W, and top quark jets excludes B quark masses up to 1.20 GeV (1.32 GeV), for the singlet (doublet) configuration [142].

In addition to pair production, ATLAS has also searched for the electroweak production of single B quarks, which is accompanied by a b-jet and a light jet [155]. The dilepton selection for double B production was modified for the single B production study by requiring the presence of an additional energetic jet in the forward region. An upper limit of 200 fb was obtained for the process $\sigma(pp \to B\bar{b}q) \times B(B \to Zb)$ with a heavy B quark mass at 0.70 TeV. This search indicated that the electroweak mixing parameter X_{Bb} below 0.5 is neither expected nor observed to be excluded for any values of B quark mass.

Combination of $B \to tW/bZ/bH^0$:

ATLAS has combined the various analyses targeted for specific decay modes to obtain the most sensitive limit on the pair production of B quarks [123, 124, 145]. Various searches ($W(\ell\nu)t + X, Z(\ell\ell)t/b + X$, same sign charge dilepton events, trilepton events, and all-hadronic) are combined to obtain lower limit on the mass of the B quark [in the plane of $BR(B \to Wt)$ vs $BR(B \to bH)$]. The searches were optimized for 100% branching fractions and hence are most sensitive at large $BR(B \to Wt)$, and also at large $BR(B \to bH^0)$. For all possible values of branching ratios in the three decay modes tW, bZ, or bH^0, the lower limits on the B quark mass was found to be 1.03 TeV and shown in Fig. 92.4 (left) as a function of the B quark branching ratios.

CMS combined three channels with lepton final states: single lepton, two leptons with the same sign of the electric charge (SS), or at least three leptons (trilepton) [147]. For various combinations of branching fractions for B quark decays to tW, bH^0 and bZ, the combined results exclude b quarks with masses below 0.91–1.24 TeV and are shown in Figure 92.4 (right); the details are provided earlier in subsection 92.2.3.1. The single lepton analysis is most sensitive for $tHbW$ and $WbWb$ decay modes, within the SS dilepton analysis $tHtH$ and $tHtZ$ have the best efficiency and for trileptons the $tZtZ$ and $tHtZ$ decays modes have the highest efficiency. CMS excludes singlet (doublet) B quark masses below 1.17 (0.94) TeV. Masses below 800 GeV were excluded in previous searches. For B quark masses in the range 0.8–1.8 TeV, cross sections smaller than 40.6-–9.4 fb (101-–49.0 fb) are excluded for the singlet (doublet) scenario.

92.2.3.3 *Searches for top-partner quark* $\boldsymbol{X_{5/3}}$

Searches for a heavy top vector-like quark $X_{5/3}$, with exotic charge $\pm 5/3$, such as that proposed in Refs. [156, 157], have been performed by both ATLAS and CMS [123, 158].

The analyses assumed pair-production or single production of $X_{5/3}$ with $X_{5/3}$ decaying with 100% branching fraction to tW. Searches for $X_{5/3}$ have been performed using two final state signatures: same-sign leptons and lepton+jets.

The analysis based on searching for same-sign leptons, from the two W bosons from one of the $X_{5/3}$, has smaller backgrounds compared to the lepton+jets signature. Requiring same-sign leptons eliminates most of the standard model background processes, leaving those with smaller cross sections: $t\bar{t}W$, $t\bar{t}Z$, WWW, and same-sign WW. In addition, backgrounds from instrumental effects due to charge misidentification were considered. Assuming pair production of $X_{5/3}$, the analysis by CMS using H_T as the discriminating variable restrict the $X_{5/3}$ mass to be higher than 1.16 (1.10) TeV for a right (left) handed chirality particle [158–160]. The limits obtained by ATLAS, by classifying the signal region by number of b-jets, H_T, and missing p_T in the event, led to a lower mass limit on $X_{5/3}$ of 1.19 TeV [161, 162].

Searches for $X_{5/3}$ using leptons+jets final state signatures are based on either full or partial reconstruction of the T mass from the lepton, jets (including b-jets) and missing p_T. The CMS search [158, 163] also utilized jet substructure techniques to identify boosted $X_{5/3}$ topologies. The discriminating variable used was the mass constructed from the lepton and b-tagged jet, $M_{(\ell,b)}$, which corresponds to the visible mass of the leptonically decaying top quark. To optimize the search sensitivity, the events were further separated into categories based on lepton flavor (e, μ), the number of b-tagged jets, the number of W-tagged jets, and the number of t-tagged jets. In the absence of a signal, the CMS analysis excluded $X_{5/3}$ quark masses with right-handed (left-handed) couplings below 1.32 (1.30) TeV [163]. Combining the lepton+jets with the same-sign leptons analyses leads to a slight improvement and excludes $X_{5/3}$ quark masses with right-handed (left-handed) couplings below 1.33 (1.30) TeV.

The ATLAS lepton+jets search for $X_{5/3}$ utilized events with high p_T W bosons and b-jets. The search described earlier for T pair production, with $T \to Wb$ decays, can be reinterpreted as a search for $X \to tW$. This analysis excluded $X_{5/3}$ with masses below 1.25 TeV [123].

The single $X_{5/3}$ production cross section depends on the coupling constant λ of the tWX vertex. ATLAS has performed an analysis of same-sign dileptons which includes both the single and pair production. This analysis led to a lower limit on the mass of the $X_{5/3}$ of 0.75 TeV for both values of $\lambda = 0.5$ and 1.0 [164].

Single heavy $X_{5/3}$+t production has been studied by CMS in

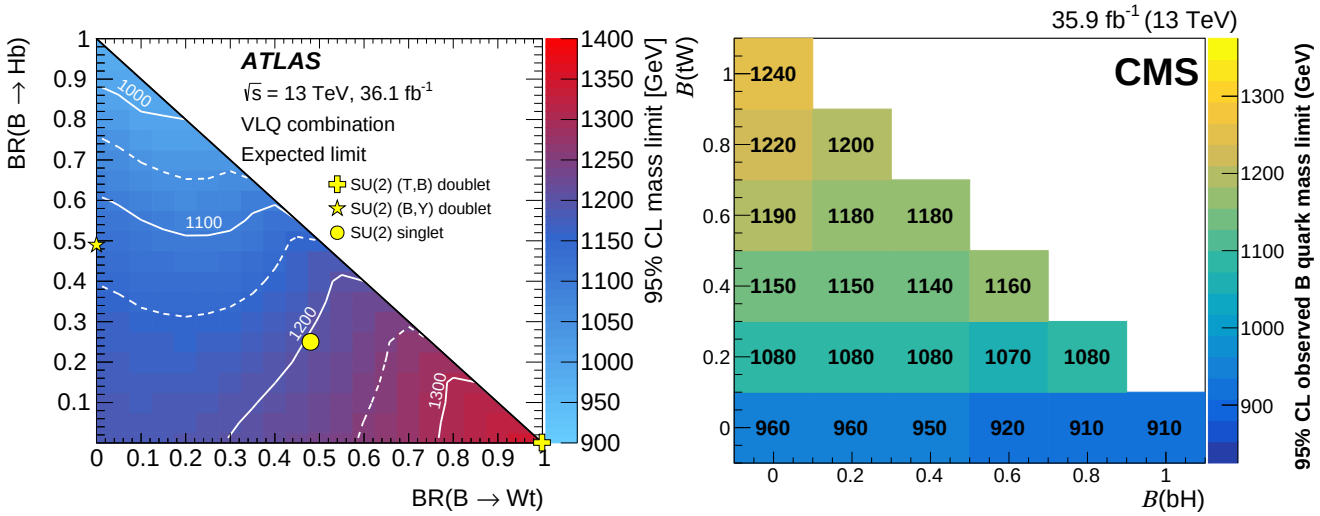

Figure 92.4: Observed limits on the mass of the B quark in the plane of $BR(B \to bH^0)$ versus $BR(B \to tW)$ from ATLAS searches [145] on the left panel, and CMS searches [147] on the right panel, for BB production. $\mathcal{B}(\mathcal{B} \to \mathcal{H}\rfloor)+\mathcal{B}(\mathcal{B} \to \lfloor\mathcal{Z})+\mathcal{B}(\mathcal{B} \to \mathcal{W}\sqcup) = 1$ is assumed. The yellow markers indicate the branching ratios for the SU(2) singlet and doublet scenarios.

the decay to tW with the lepton+jets final state [153]. The description of the analysis is provided earlier in the discussion of $B \to WtX$ decays, where the reconstructed mass of $X_{5/3}$, m_{reco} distribution is used as the signal discriminator. In the absence of an excess over the expected SM background, the exclusion limits on the production cross section for $X_{5/3}$ quark masses between 0.7–2 TeV varies between 0.3 to 0.03 pb, depending on the width of $X_{5/3}$ between 1–10%. In addition, $X_{5/3}$ quarks with left-handed couplings and a relative width of 10, 20, and 30% are excluded for masses below 0.92, 1.3, and 1.45 TeV respectively.

92.2.4 *Heavy resonances decaying to VLQ*

CMS has performed search for VLQ production in the decay of massive resonances such as Z' and W' bosons.

$Z' \to tT$: Specifically searches are presented by CMS in Refs. [165] and [166] for massive spin-1 Z' resonances decaying to a top quark and a heavy VLQ top quark partner T. The results of this search for a heavy spin-1 resonance are interpreted in the context of two different models. In the $G^\star$ model which predicts ten VLQs ($T,\ B, \tilde{T}, \tilde{B}, T_{5/3}, T_{2/3}, T', B', B_{-1/3}, B_{-4/3}$) with the mass relationship $M(T_{5/3}) = M(T_{2/3}) = M(T)\cos(\phi_L)$. For the benchmark scenario [167], $\cos(\phi_L)$=0.84 and the branching fractions $T \to tH^0, tZ, Wb$ are 0.25, 0.25 and 0.5 respectively. The ρ^0 model predicts a multiplet of four new VLQs $T, B, X_{2/3}, X_{5/3}$, and in the benchmark scenario [168], the branching fractions $T \to tH^0, tZ, Wb$ are 0.5, 0.5 and 0 respectively.

Two of the three decays of the $Z' \to tT$ with $T \to tH^0, tZ, Wb$ are characterized by the presence of two top quark decays and a boson (H^0/Z). A search [166] by CMS, optimized for $T \to tH/Zt$ decays was carried out in the lepton+jets final state using a dataset corresponding to an integrated luminosity of 35.9 fb^{-1}. Jet substructure techniques are used to identify (or tag) the high p_T large-radius jets originating from H^0, Z bosons and merged top quarks. The mass of the Z' boson is used as the signal discriminator and constructed using H^0 or Z-tagged dijet, the hadronic and leptonic top quark four vectors. For the leptonic top quark reconstruction ($t \to b\ell\nu_\ell$), the neutrino four vector is obtained from the event missing p_T using the W boson mass constraint. While the high p_T hadronic top quark jets from decays of massive Z' bosons are mostly merged and identified by top tagging techniques, those from T decays maybe resolved. The reconstructed Z' candidate events are classified into six different categories requiring the presence of either a H^0-tagged jet with 2 b-tagged subjets or one b-tagged subjet or a Z-tagged boson, each with either zero or one top-tagged jet. This search does not observe any significant deviation in data over the expectation from standard model backgrounds. Within the context of the $G^\star$ model, for a T mass of 1.2 (1.5) TeV, this search excludes $G^\star$ [167] resonances with masses between 1.5–2.3 (2.0–2.4) TeV.

The search in the all-hadronic final state is based on a 2.6 fb^{-1} dataset [165], and optimized for $T \to Wb$ decays. Jet substructure techniques are deployed for tagging jets from high p_T W boson and top quarks. Events are categorized into two groups based on the presence of b-tagged subjets in the top-tagged jet. The multijet background estimation is challenging and determined using side-bands defined by inverting the b-tagging requirement. Upper limits on the cross section for $Z' \to tT$ are obtained in the range of 0.13–10 pb.

$W' \to Tb/Bt$: W' bosons are predicted to decay to VLQ third generation partners T, B quarks within composite Higgs and warped extra dimensional models [169]. In the benchmark scenarios of this framework, W' decays to Tb or Bt are equally distributed and the subsequent VLQ decays $T \to tH$ and $B \to bH^0$ each are assumed to have a branching fraction of 0.5. The search for $W' \to Tb/bH^0 \to tbH^0$ is performed using a sample of 35.9 fb^{-1} by CMS [170] in the final state with all-hadronic decays of both the Higgs boson ($H^0 \to b\bar{b}$) and the top quark. Both the H^0 boson and the top quark are expected to be boosted in the decay of a heavy W', and hence jet substructure techniques, including subjet b-tagging and double b-tagging are deployed to identify the H^0-tagged and the top-tagged jets. The three particle mass m_{tbH^0}, is used as the signal discriminant to observe the W' resonance. There is no excess observed in data above the expected SM background. This search excludes W' production cross section above 0.01–0.43 pb for masses between 1.5–4.0 TeV.

92.2.5 *Colorons and Colored Scalars*

These particles are associated with top-condensate and top-seesaw models, which involve an enlarged color gauge group. The new particles decay to dijets, $t\bar{t}$, and $b\bar{b}$.

Direct searches for colorons, color-octect scalars and other heavy objects decaying to $q\bar{q}$, qg, qq, or gg have been performed using LHC data from pp collisions at $\sqrt{s}$ =7, 8 and 13 TeV. Based on the analysis of dijet events from a data sample corresponding to a luminosity of 19.6 fb^{-1}, at $\sqrt{s} = 8$ TeV, the CMS experiment excluded pair production of colorons with mass between 1.20−3.60 and 3.90 − 4.08 TeV [171]. Analyses of inclusive 8- and 10-jet final states with low missing transverse momentum by CMS [172], set limits in several benchmark models. Colorons (axigluons) with masses between 0.6 and 0.75 (up to 1.15) TeV were excluded, and gluinos in R-parity violating supersymmetric scenarios were ruled out from 0.6 up to 1.1 TeV.

A search for pair-produced colorons based on an integrated luminosity of 5.0 fb^{-1} at $\sqrt{s} = 7$ TeV by CMS excluded colorons with masses between 0.25 TeV and 0.74 TeV, assuming colorons decay 100% into $q\bar{q}$ [174]. This analysis was based on events with

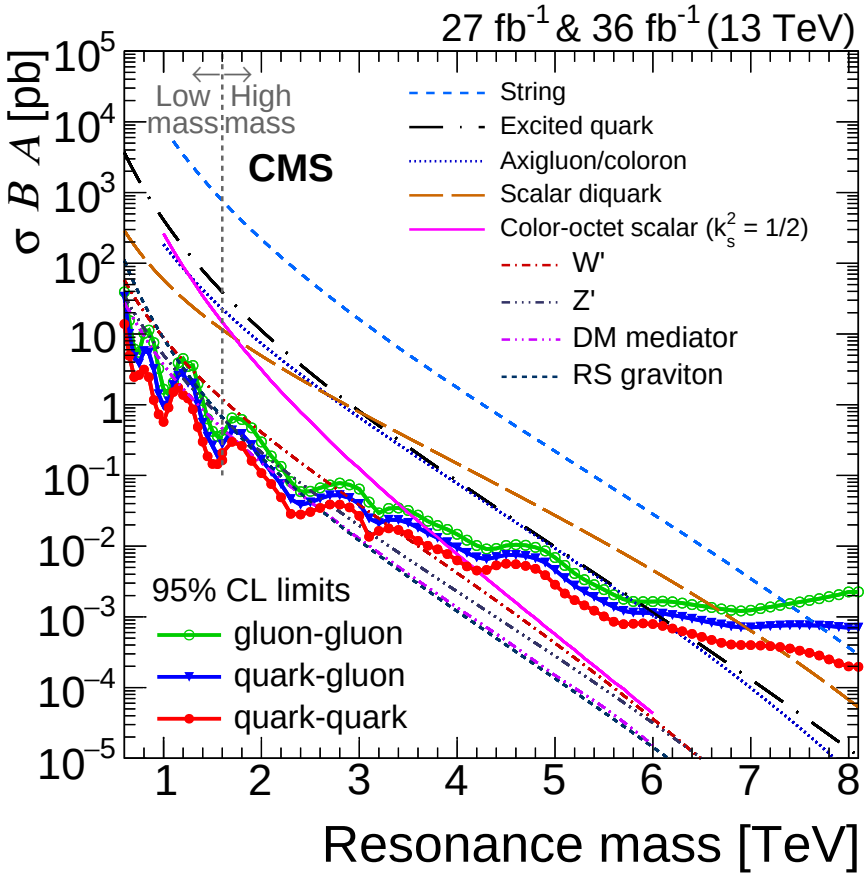

Figure 92.5: Observed 95% C.L. limits on $\sigma \times B \times A$ for string resonances, excited quarks, axigluons, colorons, E6 diquarks, s8 resonances, W' and Z' bosons, and Randall–Sundrum Gravitons g_{KK} from [173].

at least four jets and two dijet combinations with similar dijet mass. Color-octet scalars (s8) with masses between 1.20−2.79 TeV were excluded by CMS [171], and below 2.7 TeV by ATLAS [175].

These studies have now been extended to take advantage of the increased center-of-mass energy during Run 2 of the LHC. Using 35.9 fb^{-1} of data collected at $\sqrt{s}$ =13 TeV, searches for narrow resonances have been performed by CMS. An analysis of the dijet invariant mass spectrum formed using wide jets [173, 176, 177], separated by $\Delta\eta_{jj} \leq 1.3$, led to limits on new particles decaying to parton pairs (qq, qg, gg). Specific exclusions on the masses of colorons and color-octet scalars were obtained and are shown in Fig. 92.5. Exclusions have been obtained for axigluons and colorons below 6.1 TeV, and color-octet scalars below 3.4 TeV.

Additional searches for dijet resonances have been performed by both ATLAS [178–180] and CMS [181, 182], though they have not been interpreted in the context of coloron production.

92.3 Conclusions

As the above analyses have demonstrated, there is already substantial sensitivity to possible new particles predicted to accompany the H^0 in dynamical frameworks of electroweak symmetry breaking. No significant hints of any deviations from the standard model have been observed, and limits typically at the scale of a few hundred GeV to a few TeV are set.

Given the need to better understand the H^0 and to determine in detail how it behaves, such analyses continue to be a major theme of Run 3 of the LHC, and we look forward to increased sensitivity as a result of the higher luminosity at the increased center of mass energy of collisions.

93. Grand Unified Theories

Revised August 2023 by A. Hebecker (Heidelberg U.), J. Hisano (Nagoya U.; KMI, Nagoya U.) and N. Nagata (UTokyo).

93.1 The standard model

The Standard Model (SM) may be defined as the renormalizable field theory with gauge group $G_{SM} = SU(3)_C \times SU(2)_L \times U(1)_Y$, with 3 generations of fermions in the representation

$$(\mathbf{3},\mathbf{2})_{1/3} + (\overline{\mathbf{3}},\mathbf{1})_{-4/3} + (\overline{\mathbf{3}},\mathbf{1})_{2/3} + (\mathbf{1},\mathbf{2})_{-1} + (\mathbf{1},\mathbf{1})_{2}\ , \quad (93.1)$$

and a scalar Higgs doublet H transforming as $(\mathbf{1},\mathbf{2})_1$. Here and below we use boldface numbers to specify the dimension of representations of non-Abelian groups (in this case fundamental and antifundamental) and lower indices for $U(1)$ charges. The fields of Eq. (93.1) should also be familiar as $[Q, u^c, d^c, L, e^c]$, with $Q = (u, d)$ and $L = (\nu, e)$ being the quark and lepton $SU(2)$-doublets and u^c, d^c, e^c charge conjugate $SU(2)$-singlets.[1] Especially after the discovery of the Higgs, this model is remarkably complete and consistent with almost all experimental data.

A notable exception are neutrino masses, which are known to be non-zero but are absent in the SM even after the Higgs acquires its vacuum expectation value (VEV). The minimalist attitude is to allow for the dimension-five operator $(HL)^2$ [1], which induces (Majorana) neutrino masses. In the seesaw mechanism [2–4] this operator is generated by integrating out heavy singlet fermions (right-handed (r.h.) neutrinos). Alternatively, neutrinos can have Dirac masses if light singlet neutrinos are added to the SM spectrum.

Conceptual problems of the SM include the absence of a Dark Matter candidate, of a mechanism for generating the baryon asymmetry of the Universe, and of any reason for the observed smallness of the θ parameter of QCD (θ_{QCD}). In addition, the apparently rather complex group-theoretic data of Eq. (93.1) remains unexplained. Together with the abundance of seemingly arbitrary coupling constants, this disfavors the SM as a candidate fundamental theory, even before quantum gravity problems arise at energies near the Planck mass M_P.

To be precise, there are 19 SM parameters which have to be fitted to data: Three gauge couplings[2] g_3, g_2 and g_1, 13 parameters associated with the Yukawa couplings (9 charged fermion masses, three mixing angles and one CP phase in the CKM matrix.), the Higgs mass and quartic coupling, and θ_{QCD}. In addition, Majorana neutrinos introduce 3 more masses and 6 mixing angles and phases. As we will see, the paradigm of grand unification addresses mainly the group theoretic data of Eq. (93.1) and the values of the three gauge couplings. In many concrete realizations, it then impacts also the other mentioned issues of the SM, such as the family structure and fermion mass hierarchy.

More specifically, after precision measurements of the Weinberg angle θ_W in the LEP experiments, supersymmetric GUTs (SUSY GUTs) have become the leading candidates in the search for 'Physics beyond the SM'. Supersymmetry (SUSY) is a symmetry between bosons and fermions which requires the addition of superpartners to the SM spectrum. If SUSY is motivated as a solution to the gauge hierarchy problem (i.e. to the naturalness or fine-tuning problem of the electroweak scale) [5], superpartners have to be present near the weak scale. Assuming a minimal Higgs sector, SUSY GUTs [6] then lead to the prediction of θ_W, in good agreement with subsequent observations [7]. However, the non-discovery of new particles at the LHC puts into question the presence of new physics at the TeV scale in general and in particular of low-scale supersymmetry. Still, SUSY may be present just outside the presently explored energy domain.

The measured Higgs mass (125 GeV) is in principle consistent with this picture, assuming superpartners in the region of roughly 10 TeV. Such heavy superpartners then induce radiative corrections raising the Higgs mass above the Z boson mass m_Z [8, 9]. However, from the vantage point of the hierarchy problem, heavy superpartners are problematic: They also contribute to SUSY-breaking Higgs mass parameters and thereby to the Higgs potential, tending to raise the Z mass. As a result, the incarnation of SUSY in terms of the minimal supersymmetric SM (MSSM) is becoming questionable. Turning the logic around, one may say that compared to expectations based on the MSSM with superpartner masses below about 1 TeV, the measured Higgs mass value of 125 GeV is somewhat too high [10]. Independently, the LHC has disfavored light colored superpartners (which does not imply that *all* superpartners are heavy). These facts represent new hints for future work on SUSY GUTs or on GUTs without TeV-scale supersymmetry.

93.2 Basic group theory and charge quantization

93.2.1 $SU(4)_C \times SU(2)_L \times SU(2)_R$

Historically, the first attempt at unification was the Pati-Salam model with gauge group $G_{PS} = SU(4)_C \times SU(2)_L \times SU(2)_R$ [11]. It unifies SM fermions in the sense that one generation (plus an extra SM singlet) now comes from the $(\mathbf{4},\mathbf{2},\mathbf{1}) + (\overline{\mathbf{4}},\mathbf{1},\mathbf{2})$ of G_{PS}. This is easy to verify from the breaking pattern $SU(4)_C \to SU(3)_C \times U(1)_{B-L}$ together with the identification of SM hypercharge as a linear combination between $B - L$ (baryon minus lepton number) and the T_3 generator of $SU(2)_R$. This model explains charge quantization, that is, why all electric charges are integer multiples of some smallest charge in the SM. Concretely, the $\mathbf{4}$ and $\overline{\mathbf{4}}$ of $SU(4)_C$ identify lepton number as the 4th colour and the tracelessness of the diagonal generator implies that quark charges are expressed in terms of $1/N_c$ fractions of lepton charges. However, G_{PS} is not simple (containing three simple factors), and thus it does not predict gauge coupling unification.

93.2.2 $SU(5)$

Since G_{SM} has rank four (two for $SU(3)_C$ and one for $SU(2)_L$ and $U(1)_Y$, respectively), the rank-four group $SU(5)$ is the minimal choice for unification in a simple group [12]. The three SM gauge coupling constants derive from a universal coupling α_G at the GUT scale M_G. Explicitly embedding G_{SM} in $SU(5)$ is straightforward, with $SU(3)_C$ and $SU(2)_L$ corresponding e.g. to the upper-left 3×3 and lower-right 2×2 blocks, respectively, in traceless 5×5 matrices for $SU(5)$ generators of the fundamental representation. The $U(1)_Y$ corresponds to matrices generated by $\mathrm{diag}(-2/3, -2/3, -2/3, 1, 1)$ and hence commutes with $SU(3)_C \times SU(2)_L \subset SU(5)$. It is then easy to derive how one SM generation precisely comes from the $\mathbf{10} + \overline{\mathbf{5}}$ of $SU(5)$ (where $\mathbf{10}$ is the antisymmetric rank-2 tensor):

$$\mathbf{10}: \begin{pmatrix} 0 & u_b^c & -u_g^c & u_r & d_r \\ -u_b^c & 0 & u_r^c & u_g & d_g \\ u_g^c & -u_r^c & 0 & u_b & d_b \\ -u_r & -u_g & -u_b & 0 & e^c \\ -d_r & -d_g & -d_b & -e^c & 0 \end{pmatrix} \quad \text{and} \quad \overline{\mathbf{5}}: \begin{pmatrix} d_r^c \\ d_g^c \\ d_b^c \\ e \\ -\nu_e \end{pmatrix}. \quad (93.2)$$

In addition to charge quantization this structure explains why the l.h. quark and lepton states fall in $SU(2)_L$ doublets while the r.h. states are singlets.

Since $SU(5)$ has 24 generators, $SU(5)$ GUTs have 12 new gauge bosons known as X bosons (or X/Y bosons) in addition to the SM. X bosons form an $SU(3)_C$-triplet and $SU(2)_L$-doublet. Their interaction connects quarks and leptons such that baryon and lepton numbers are not conserved and nucleon decay is predicted. Furthermore, $U(1)_Y$ hypercharge is automatically quantized since it is embedded in $SU(5)$.

In order to break the electroweak symmetry at the weak scale and give mass to quarks and leptons, Higgs doublets are needed. In the minimal $SU(5)$ model, they can sit in either a $\mathbf{5}_H$ or $\overline{\mathbf{5}}_H$. The three additional states are referred to as color-triplet Higgs scalars. Their couplings also violate baryon and lepton numbers, inducing nucleon decay. In order not to violently disagree with the non-observation of nucleon decay, the triplet mass must be greater than $\sim 10^{11}$ GeV [13]. Moreover, in SUSY GUTs [6], in order to cancel anomalies as well as give mass to both up and down quarks, both Higgs multiplets $\mathbf{5}_H$ and $\overline{\mathbf{5}}_H$ are required. As we shall discuss later, nucleon decay now constrains the Higgs triplets to have

[1] In our convention the electric charge is $Q = T_3 + Y/2$ and all our spinor fields are left-handed (l.h.).

[2] Equivalently, the $SU(2)_L$ and $U(1)_Y$ couplings are denoted as $g = g_2$ and $g' = \sqrt{3/5}\ g_1$. One also uses $\alpha_s = \alpha_3 = (g_3^2/4\pi)$, $\alpha_{\rm EM} = (e^2/4\pi)$ with $e = g\ \sin\theta_W$ and $\sin^2\theta_W = (g')^2/(g^2 + (g')^2)$.

mass significantly greater than M_G in the minimal SUSY $SU(5)$ GUT since integrating out the Higgs triplets generates dimension-five baryon-number-violating operators [14]. The mass splitting between doublet and triplet in the $\mathbf{5}_H$ (and $\overline{\mathbf{5}}_H$) comes from their interaction with the $SU(5)$ breaking sector.

93.2.3 $SO(10)$

While $SU(5)$ allows for the minimal GUT models, unification is not complete: Two independent representations, **10** and $\overline{\mathbf{5}}$, are required for one SM generation. A further representation, an SU(5) singlet, has to be added to serve as r.h. neutrino in the seesaw mechanism. In this case, the r.h. neutrino masses are not necessarily related to the GUT scale. By contrast, a single **16**-dimensional spinor representation of $SO(10)$ accommodates a full SM generation together with an extra singlet, potentially providing a r.h. neutrino [15]. This is most easily understood from the breaking pattern $SO(10) \to SU(5) \times U(1)_X$ and the associated branching rule[3] $\mathbf{16} = \mathbf{10}_{-1} + \overline{\mathbf{5}}_3 + \mathbf{1}_{-4}$. Here the indices refer to charges under the $U(1)_X$ subgroup, which is orthogonal to $SU(5)$ and reflects the fact that $SO(10)$ has rank five. From the above, it is easy to see that $U(1)_X$ charges can be given as $2Y - 5(B-L)$. Intriguingly, all representations of $SO(10)$ are anomaly free in four dimensions (4d). Thus, the absence of anomalies in an $SU(5)$-GUT or a SM generation can be viewed as deriving from this feature.

We now describe in more detail how one family of quarks and leptons appears in the **16**. To understand this, recall that the Γ-matrices of the 10d Clifford algebra give rise to five independent, anticommuting 'creation-annihilation' operators $\Gamma^{a\pm} = (\Gamma^{2a-1} \pm i\Gamma^{2a})/2$ with $a = 1, ..., 5$. These correspond to five fermionic harmonic oscillators or "spin" 1/2 systems. The 32-dimensional tensor product of those is reducible since the 10d rotation generators $M_{mn} = -i[\Gamma^m, \Gamma^n]/4$ $(m, n = 1, ..., 10)$ always flip an even number of "spins". This gives rise to the **16** as displayed in Table 93.1. Next, one also recalls that the natural embedding of $SU(5)$ in $SO(10)$ relies on 'pairing up' the 10 real dimensions to produce 5 complex dimensions, $\mathbb{R}^{10} \equiv \mathbb{C}^5$, similarly to the paring up of Γ^ms used above. This makes it clear how to associate one $|\pm>$ system to each complex dimension of $SU(5)$, which explains the labeling of the "spin" columns in Table 93.1: The first three and last two "spins" correspond to $SU(3)_C$ and $SU(2)_L$, respectively. In fact, an $SU(3)_C$ rotation just raises one color index and lowers another, changing colors $\{r, g, b\}$, or changes relative phases between the three spin states. Similarly, an $SU(2)_L$ rotation raises one weak index and lowers another, thereby flipping the weak isospin from up to down or vice versa, or changes the relative phase between the two spin states. In this representation $U(1)_Y$ hypercharge is simply given by $Y = -2/3(\sum \text{ color spins}) + (\sum \text{ weak spins})$. $SU(5)$ rotations corresponding to X bosons then raise (or lower) a color index, while at the same time lowering (or raising) a weak index. It is easy to see that such rotations can mix the states $\{Q,\ u^c,\ e^c\}$ and $\{d^c, L\}$ among themselves and ν^c is a singlet. Since $SO(10)$ has 45 generators, additional 21 gauge bosons are introduced including the $U(1)_X$ above. The 20 new $SO(10)$ rotations not in $SU(5)$ are then given by either raising any two spins or lowering them. With these rotations, **1** and **5** are connected with **10**. The last $SO(10)$ rotation changes phases of states with weight $2(\sum \text{ color spins}) + 2(\sum \text{ weak spins})$, which corresponds to $U(1)_X$.

$SO(10)$ has two inequivalent maximal subgroups and hence breaking patterns, $SO(10) \to SU(5) \times U(1)_X$ and $SO(10) \to SU(4)_C \times SU(2)_L \times SU(2)_R$. In the first case, one can carry on breaking to $G_{SM} \subset SU(5)$ precisely as in the minimal $SU(5)$ case above. Alternatively, one can identify $U(1)_Y$ as an appropriate linear combination of $U(1)_X$ and the $U(1)$ factor from $SU(5)$, leading to the so-called flipped $SU(5)$ [17] as an intermediate step in breaking $SO(10)$ to G_{SM}. In the second case, we have an intermediate Pati-Salam model thanks to the branching rule $\mathbf{16} = (\mathbf{4}, \mathbf{2}, \mathbf{1}) + (\overline{\mathbf{4}}, \mathbf{1}, \mathbf{2})$. Finally, $SO(10)$ can break directly to the SM at M_G. Gauge coupling unification remains intact in the case of this 'direct' breaking and for the breaking pattern $SO(10) \to SU(5) \to G_{SM}$ (with $SU(5)$ broken at M_G). In the case of intermediate-scale Pati-Salam or flipped $SU(5)$ models, gauge coupling predictions are modified. The Higgs multiplets in the minimal $SO(10)$ come from the fundamental representation, $\mathbf{10}_H = \mathbf{5}_H + \overline{\mathbf{5}}_H$. Note, only in $SO(10)$ does the representation type distinguish SM matter from Higgs fields.

[3] Useful references on group theory in the present context include [16] and refs. therein.

Table 93.1: Quantum numbers of **16**-dimensional representation of $SO(10)$.

state	Y	Color	Weak	$SU(5)$	$SO(10)$
ν^c	0	$---$	$--$	**1**	**16**
e^c	2	$---$	$++$	**10**	
u_r	1/3	$+--$	$-+$		
d_r	1/3	$+--$	$+-$		
u_g	1/3	$-+-$	$-+$		
d_g	1/3	$-+-$	$+-$		
u_b	1/3	$--+$	$-+$		
d_b	1/3	$--+$	$+-$		
u_r^c	$-4/3$	$-++$	$--$		
u_g^c	$-4/3$	$+-+$	$--$		
u_b^c	$-4/3$	$++-$	$--$		
d_r^c	2/3	$-++$	$++$	$\overline{\mathbf{5}}$	
d_g^c	2/3	$+-+$	$++$		
d_b^c	2/3	$++-$	$++$		
ν	-1	$+++$	$-+$		
e	-1	$+++$	$+-$		

93.2.4 *Beyond* $SO(10)$

Finally, larger symmetry groups can be considered. For example, the exceptional group E_6 has maximal subgroup $SO(10) \times U(1)$ [18]. Its fundamental representation branches as $\mathbf{27} = \mathbf{16}_1 + \mathbf{10}_{-2} + \mathbf{1}_4$. Another maximal subgroup is $SU(3)_C \times SU(3)_L \times SU(3)_R \subset E_6$ with branching rule $\mathbf{27} = (\mathbf{3}, \mathbf{3}, \mathbf{1}) + (\overline{\mathbf{3}}, \mathbf{1}, \overline{\mathbf{3}}) + (\mathbf{1}, \overline{\mathbf{3}}, \mathbf{3})$. Independently of any underlying E_6, the group $[SU(3)]^3$ with additional permutation symmetry Z_3 interchanging the three factors can be considered. This is known as "trinification" [19]. The $E_6 \to [SU(3)]^3$ breaking pattern has been used in phenomenological analyses of the heterotic string [20]. However, in larger symmetry groups, such as E_6, $SU(6)$, etc., there are now many more states which have not been observed and must be removed from the effective low-energy theory.

Intriguingly, the logic by which G_{SM} is a maximal subgroup of $SU(5)$, which together with $U(1)_X$ is a maximal subgroup of $SO(10)$, continues in a very elegant and systematic way up to the largest exceptional group. The resulting famous breaking chain $E_8 \to E_7 \to E_6 \to SO(10) \to SU(5) \to G_{SM}$ together with the special role played by E_8 in group and in string theory is a tantalizing hint at deeper structures. However, since all representations of E_8 and E_7 are real and can not lead to 4d chiral fermions, this is necessarily outside the 4d GUT framework.

93.3 GUT breaking and doublet-triplet splitting

In the standard, 4d field-theoretic approach to GUTs, the unified gauge group is broken spontaneously by an appropriate GUT Higgs sector. Scalar potentials (or superpotentials in SUSY GUTs) exist whose vacua spontaneously break $SU(5)$ or $SO(10)$. While these potentials are ad hoc (just like the Higgs potential in the SM), the most naive expectation is that all their dimensionful parameters are $O(M_G)$. In the simplest case of $SU(5)$, the **24** (adjoint) GUT Higgs develops a VEV along the G_{SM}-singlet direction as $\langle \Phi \rangle \propto \text{diag}(-2/3, -2/3, -2/3, 1, 1)$. In order for $SO(10)$ to break to $SU(5)$, the **16** or **126**, which have a G_{SM}-singlet with non-zero $U(1)_X$ charge, get a VEV.

The masses of doublet and triplet in the $\mathbf{5}_H$ (and $\overline{\mathbf{5}}_H$) generically split due to their coupling to the GUT Higgs. In addition, both the doublet and the triplet masses also get an equal contribution from an $SU(5)$-invariant GUT-scale mass term. Without any further structure, an extreme fine-tuning between two large effects is then necessary to keep the doublet mass at the electroweak scale. Supersymmetry plays an important role in for-

bidding large radiative correction to the doublet mass due to the non-renormalization theorem [5]. However, even in this case we have to fine tune parameters at tree level. This is the doublet-triplet splitting problem which, in the SUSY context, is clearly related to the μ-term problem of the MSSM (the smallness of the coefficient of $\mu H_u\ H_d$).

Several mechanisms for natural doublet-triplet splitting have been suggested under the assumption of supersymmetry, such as the sliding singlet [21], missing partner [22], missing VEV [23], and pseudo-Nambu-Goldstone boson mechanisms [24]. Particular examples of the missing partner mechanism for $SU(5)$ [25], the missing VEV mechanism for $SO(10)$ [26, 27] and the pseudo-Nambu-Goldstone boson mechanism for $SU(6)$ [28] have been shown to be consistent with gauge coupling unification and nucleon decay. From the GUT-scale perspective, one is satisfied if the triplets are naturally heavy and the doublets are massless. In other words, one wants to ensure that the fundamental superpotential term $\mu H_u\ H_d$ is absent ($\mu \simeq 0$) while the corresponding term for the Higgs triplets is large. We note however that implementing this by a global symmetry is problematic, see e.g. [29–31].

Once a model with vanishing fundamental μ term has been realized, an *effective* μ term of order the SUSY breaking scale can then be induced by, for example, higher-mass-dimension terms in the Kahler potential [32]. For a review of the μ problem and some suggested solutions in SUSY GUTs and string theory, see [30, 33–35] and references therein.

In general, GUT-breaking sectors successfully resolving the doublet-triplet splitting problem, dynamically stabilizing all GUT-scale VEVs and allowing for realistic neutrino masses and Yukawa couplings (including the GUT-symmetry violation in the latter) require a number of ingredients. However, for validity of the effective theory, introduction of higher or many representations is limited, otherwise a Landau pole may appear below the Planck scale. In addition, GUTs are only effective theories below the Planck scale in the 4d field-theoretic approach. Since M_G is close to this scale, the effects of higher-dimension operators are not obviously negligible. In particular, operators including the GUT-breaking Higgs may affect low-energy predictions, such as quark and lepton masses.

Thus, especially in the context of GUT breaking and doublet-triplet splitting, models beyond 4d field theory appear attractive. While this is mainly the subject of the next section, some advantages can already be noted: In models with extra dimensions, in particular string constructions, GUT breaking may occur due to boundary conditions in the compactified dimensions [36–39]. No complicated GUT breaking sector is then required. Moreover, boundary conditions can give mass only to the triplet, leaving the doublet massless. This is similar to the 'missing partner mechanism' since the effective mass term does not 'pair up' the triplets from $\mathbf{5}_H$ and $\overline{\mathbf{5}}_H$ but rather each of them with further fields which are automatically present in the higher-dimensional theory. This can eliminate dimension-five nucleon decay (cf. Sec. 93.6).

93.4 String-theoretic and higher-dimensional unified models

As noted earlier, the GUT scale is dangerously close to the scale of quantum gravity. It may hence be necessary to discuss unified models of particle physics in the latter, more ambitious context. Among the models of quantum gravity, superstring or M-theory stands out as the best-studied and technically most developed proposal, possessing in particular a high level of internal, mathematical consistency. For our purposes, it is sufficient to know that five 10d and one 11d low-energy effective supergravity theories arise in this setting (cf. [40] and refs. therein).

Grand unification is realized most naturally in the context of the two 'heterotic' theories with gauge groups $\mathrm{E}_8\times\mathrm{E}_8$ and $SO(32)$, respectively [38, 41] (see [42] for some of the more recent results). Justified in part by the intriguing breaking path $\mathrm{E}_8 \to \cdots \to G_{SM}$ mentioned above, the focus has historically largely been on $\mathrm{E}_8\times\mathrm{E}_8$. To describe particle physics, solutions of the 10d theory with geometry $\mathbb{R}^{1,3} \times M_6$ are considered, where M_6 is a Calabi-Yau (CY) 3-fold (with 6 real dimensions) [38]. The background solution involves expectation values of higher-dimensional components of the $\mathrm{E}_8\times\mathrm{E}_8$ gauge fields. This includes both Wilson lines [36] and non-vanishing field-strength and leads, in general, to a reduced gauge symmetry and to chirality in the resulting 4d effective theory. The 4d fermions arise from 10d gauginos.

Given an appropriate embedding[4] of G_{SM} in $\mathrm{E}_8\times\mathrm{E}_8$, gauge coupling unification is automatic at leading order. Corrections arise mainly through (string)-loop effects and are similar to the familiar field-theory thresholds of 4d GUTs[5] [43]. Thus, one may say that coupling unification is a generic prediction in spite of the complete absence[6] of a 4d GUT at any energy scale. This absence is both an advantage and a weakness. On the up side, GUT breaking and doublet-triplet splitting [45] are more naturally realized and dimension-five nucleon decay is relatively easy to avoid. On the down side, there is no reason to expect full GUT representations in the matter sector and flavor model building is much less tied to the GUT structure than in 4d.

Let us pause to explain the beautiful idea behind the advertised solution of the doublet-triplet splitting problem: One starts with a simply connected CY X and mods out the action of a discrete group G (say $\mathbb{Z}_2$). In the absence of fixed points, X/G is smooth and has a non-contractible 1-cycle. Furthermore, let G also act on the gauge bundle, according to an embedding $G \to \mathrm{E}_8$. Now the parallel transport around the 1-cycle is tied to a gauge rotation (one says a non-trivial Wilson-line is present). Moreover, this Wilson line can not be continuously turned off since, e.g. in the case of $\mathbb{Z}_2$, its square is the unit element of the group. The induced 'Wilson-line breaking', which comes on top of the breaking by non-zero field strengths, may remove certain sub-representations (e.g. the triplet of $SU(5) \to G_{SM}$) while keeping others exactly massless. A simpler and, due to fixed points, singular version of this will appear below in the context of orbifold GUTs.

One technical problem of heterotic constructions is the dependence on the numerous size and shape parameters of M_6 (the so-called moduli), the stabilization of which is poorly understood (see [46] for recent developments). Another is the sheer mathematical complexity of the analysis, involving in particular the study of (non-Abelian) gauge-bundles on CY spaces [47] (see however [48]).

An interesting aspect of heterotic string constructions is represented by orbifold models [37]. Here the internal space is given by a six-torus, modded out by a discrete symmetry group (e.g. $T^6/\mathbb{Z}_n$). More recent progress is reported in [49, 50], including in particular the systematic exploration of the phenomenological advantages of so-called 'non-prime' (referring to n) orbifolds. The symmetry breaking to G_{SM} as well as the survival of Higgs doublets without triplet partners is ensured by the appropriate embedding of the discrete orbifold group in $\mathrm{E}_8\times\mathrm{E}_8$. String theory on such spaces, which are locally flat but include singularities, is much more calculable than in the CY case. The orbifold geometries can be viewed as singular limits of CYs.

An even simpler approach to unified models, which includes many of the advantages of full-fledged string constructions, is provided by Orbifold GUTs [39]. These are (mostly) 5d or 6d SUSY field theories with unified gauge group (e.g. $SU(5)$ or $SO(10)$), broken in the process of compactifying to 4d. To give a particularly simple example, consider $SU(5)$ on $\mathbb{R}^{1,3} \times S^1/(\mathbb{Z}_2 \times \mathbb{Z}_2')$. Here the compact space is an interval of length $\pi R/2$ and the embedding of $\mathbb{Z}_2'$ in the hypercharge direction of $SU(5)$ realizes the breaking to G_{SM}. Concretely, 5d X bosons are given Dirichlet BCs at one endpoint of the interval and thus have no Kaluza-Klein (KK) zero mode. Their lightest modes have mass $\sim 1/R$, making the KK-scale the effective GUT scale. As an implication, the boundary theory has no $SU(5)$ invariance. Nevertheless, since the $SU(5)$-symmetric 5d bulk dominates 4d gauge couplings, unifica-

[4] All embeddings of G_{SM} in one E_8 factor which are consistent with a breaking-pattern $\mathrm{E}_8 \to SU(5) \to G_{SM}$ are suitable (cf. for example the natural breaking chain from E_8 to G_{SM} through maximal subgroups mentioned at the end of Sect. 93.3). Other embeddings can change the ratios between the three resulting G_{SM} couplings at the GUT scale by group-theoretic factors. Crucially, due to the single 10d gauge coupling, no continuous tuning is possible.

[5] Field-theory thresholds of 4d GUTs are discussed in 93.5.

[6] See however [44].

tion remains a prediction. Many other features but also problems of 4d GUTs can be circumvented, especially doublet-triplet splitting is easily realized.

With the advent of the string-theory 'flux landscape' [51], which is best understood in 10d type-IIB supergravity, the focus in string model building has shifted to this framework. While type II string theories have no gauge group in 10d, brane-stacks support gauge dynamics. A particularly appealing setting (see e.g. [52]) is provided by type IIB models with D7 branes (defining 8d submanifolds). However, in the $SO(10)$ context the **16** is not available and, for $SU(5)$, the top-Yukawa coupling vanishes at leading order [53]. As a crucial insight, this can be overcome on the non-perturbative branch of type IIB, also known as F-theory [54,55]. This setting allows for more general branes, thus avoiding constraints of the Dp-brane framework. GUT breaking can be realized using hypercharge flux (the VEV of the $\mathrm{U}(1)_Y$ field strength), an option not available in heterotic models. The whole framework combines the advantages of the heterotic or higher-dimensional unification approach with the more recent progress in understanding moduli stabilization. It thus represents at this moment the most active and promising branch of theory-driven GUT model building (see e.g. [56] and refs. therein).

As a result of the flux-breaking, a characteristic 'type IIB' or 'F-theoretic' tree-level correction to gauge unification arises [57]. The fact that this correction can be rather significant numerically is occasionally held against the framework of F-theory GUTs. However, at a parametric level, this correction nevertheless behaves like a 4d threshold, i.e., it provides $\mathcal{O}(1)$ additive contributions to the inverse 4d gauge couplings $\alpha_i^{-1}(M_G)$.

A final important issue in string GUTs is the so-called string-scale/GUT-scale problem [58]. It arises since, in heterotic compactifications, the Planck scale and the high-scale value of the gauge coupling unambiguously fix the string-scale to about 10^{18} GeV. As the compactification radius R is raised above the string length, the GUT scale (identified with $1/R$) goes down and the string coupling goes up. Within the domain of perturbative string theory, a gap of about a factor ~ 20 remains between the lowest GUT scale achievable in this way and the phenomenological goal of 2×10^{16} GeV. The situation can be improved by venturing into the non-perturbative regime [58], by considering 'anisotropic' geometries with hierarchically different radii R [58,59] or by including GUT scale threshold corrections [60,61].

In F-theory GUTs, the situation is dramatically improved since the gauge theory lives only in four out of the six compact dimensions. This allows for models with a 'decoupling limit', where the GUT scale is parametrically below the Planck scale [55]. However, moduli stabilization may not be without problems in such constructions, in part due to a tension between the required large volume and the desirable low SUSY breaking scale.

93.5 Gauge coupling unification

The quantitative unification of the three SM gauge couplings at the energy scale M_G is one of the cornerstones of the GUT paradigm. It is obviously of direct phenomenological relevance. Gauge coupling unification is well understood in the framework of effective field theory (EFT) [62]. In the simplest case, the relevant EFT at energies $\mu \gg M_G$ has a unified gauge symmetry (say $SU(5)$ for definiteness) and a single running gauge coupling $\alpha_G(\mu)$. At energies $\mu \ll M_G$, states with mass $\sim M_G$ (such as X bosons, GUT Higgs, color-triplet Higgs) have to be integrated out. The EFT now has three independent couplings and SM (or SUSY SM) matter content. One-loop renormalization group equations readily allow for an extrapolation to the weak scale,

$$\alpha_i^{-1}(m_Z) = \alpha_G^{-1}(M_G) + \frac{b_i}{2\pi}\log\left(\frac{M_G}{m_Z}\right) + \delta_i\,, \qquad (93.3)$$

$(i=1,2,3)$. Here we defined δ_i to absorb all sub-leading effects, such as threshold corrections at or near the weak scale (e.g. from superpartners and the additional Higgs bosons in the case of the MSSM) and at the GUT scale, and also higher-order corrections. We will discuss them momentarily.

It is apparent from Eq. (93.3) that the three low-scale couplings can be very different. This is due to the large energy range $m_Z \ll \mu \ll M_G$ and the non-universal β-function coefficients ($b_i^{\rm SM} = \{41/10, -19/6, -7\}$ or $b_i^{\rm MSSM} = \{33/5, 1, -3\}$). Incomplete GUT multiplets, such as gauge and Higgs bosons in the SM and also their superpartners and the additional Higgs bosons in the MSSM, contribute to the differences between the β functions. Inverting the argument, one expects that extrapolating the measured couplings to the high scale, we find quantitative unification at $\mu \sim M_G$. While this fails in the SM, it works intriguingly well in the MSSM (cf. Fig. 93.1).

The three equations contained in Eq. (93.3) can be used to determine the three 'unknowns' $\alpha_3(m_Z)$, $\alpha_G(M_G)$ and M_G, assuming that all other parameters entering the equations are given. Focusing on the SUSY case and using the $\overline{\rm MS}$ coupling constants $\alpha_{\rm EM}^{-1}(m_Z)$ and $\sin^2\theta_W(m_Z)$ from [64],

$$\alpha_{\rm EM}^{-1}(m_Z) = 127.951 \pm 0.009\,, \qquad (93.4)$$

$$\sin^2\theta_W(m_Z) = 0.23122 \pm 0.00004\,, \qquad (93.5)$$

as input, one determines $\alpha_{1,2}^{-1}(m_Z)$, which then gives

$$\alpha_G^{-1}(M_G) \simeq 24.3 \qquad \text{and} \qquad M_G \simeq 2\times 10^{16}\ \text{GeV}\,. \qquad (93.6)$$

Here we have set $\delta_i = 0$ for simplicity. Crucially, one in addition obtains a prediction for the low-energy observable α_3,

$$\alpha_3^{-1}(m_Z) = -\frac{5}{7}\alpha_1^{-1}(m_Z) + \frac{12}{7}\alpha_2^{-1}(m_Z) + \Delta_3\,, \qquad (93.7)$$

where

$$\Delta_3 = \frac{5}{7}\delta_1 - \frac{12}{7}\delta_2 + \delta_3\,. \qquad (93.8)$$

Here we followed the elegant formulation in Ref. [65] of the classical analyses of [7]. Of course, it is a matter of convention which of the three low-energy gauge coupling parameters one 'predicts' and indeed, early works on the subject discussed the prediction of $\sin^2\theta_W$ in terms of $\alpha_{\rm EM}$ and α_3 [66,67].

Remarkably, the leading order result (i.e. Eq. (93.7) with $\delta_i = 0$) is in excellent agreement with experiments [64]:

$$\alpha_3^{\rm LO}(m_Z) = 0.117 \qquad \text{vs.} \qquad \alpha_3^{\rm EXP}(m_Z) = 0.1179 \pm 0.0009\,. \qquad (93.9)$$

However, this near perfection is to some extent accidental. To see this, we now discuss the various contributions to the δ_i (and hence to Δ_3).

The two-loop running correction from the gauge sector $\Delta_3^{(2)}$ and the low-scale threshold correction $\Delta_3^{(l)}$ from superpartners can be summarized as [65]

$$\Delta_3^{(2)} \simeq -0.82 \qquad \text{and} \qquad \Delta_3^{(l)} \simeq \frac{19}{28\pi}\log\left(\frac{m_{\rm SUSY}}{m_Z}\right)\,. \qquad (93.10)$$

The relevant scale $m_{\rm SUSY}$ can be estimated as [68]

$$m_{\rm SUSY} \;\to\; m_H^{3/19} m_{\widetilde{H}}^{12/19} m_{\widetilde{W}}^{4/19} \times \left(\frac{m_{\widetilde{W}}}{m_{\widetilde{g}}}\right)^{28/19} \left(\frac{m_{\widetilde{l}}}{m_{\widetilde{q}}}\right)^{3/19}\,, \qquad (93.11)$$

where m_H stands for the masses of non-SM Higgs states and superpartner masses are given in self-evident notation. Detailed analyses including the above effects are best done using appropriate software packages, such as SOFTSUSY [63] (or alternatively SuSpect [69] or SPheno [70]). See also [63] for references to the underlying theoretical two-loop analyses.

To get a very rough feeling for these effects, let us assume that all superpartners are degenerate at $m_{\rm SUSY} = 1$ TeV, except for heavier gluinos: $m_{\widetilde{W}}/m_{\widetilde{g}} \simeq 1/3$. This gives $\Delta_3^{(l)} \simeq -0.35 + 0.22\ln(m_{\rm SUSY}/m_Z) \simeq 0.18$. The resulting prediction of $\alpha_3(m_Z) \simeq 0.126$ significantly upsets the perfect one-loop agreement found earlier. Before discussing this issue further, it is useful to introduce yet another important type of correction, the high or GUT scale thresholds.

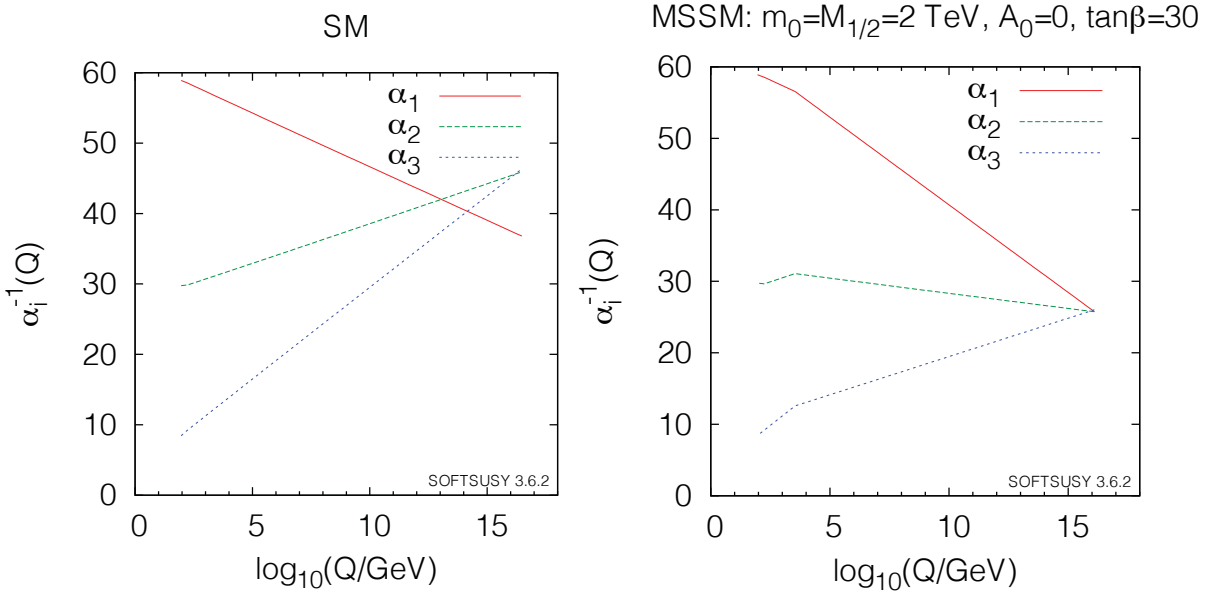

Figure 93.1: Running couplings in SM and MSSM using two-loop RG evolution. The SUSY threshold at 2 TeV is clearly visible on the MSSM side. (We thank Ben Allanach for providing the plots created using SOFTSUSY [63].)

To discuss high scale thresholds, let us set all other corrections to zero for the moment and write down a version of Eq. (93.3) that captures the running near and above the GUT scale more correctly. The threshold correction at one-loop level can be evaluated accurately by the simple step-function approximation for the β functions in the $\overline{\rm DR}$ scheme[7] [74],

$$\alpha_i^{-1}(m_Z) = \alpha_G^{-1}(\mu) + \frac{1}{2\pi}\left[b_i \ln\frac{\mu}{m_Z} + b_i^C \ln\frac{\mu}{M_C} + b_i^X \ln\frac{\mu}{M_X} + b_i^\Phi \ln\frac{\mu}{M_\Phi}\right] . \tag{93.12}$$

Here we started the running at some scale $\mu \gg M_G$, including the contribution of the minimal set of states relevant for the transition from the high-scale $SU(5)$ model to the MSSM. These are the color-triplet Higgs multiplets with mass M_C, massive vector multiplets of X-bosons with mass M_X (including GUT Higgs degrees of freedom), and the remaining GUT-Higgs fields and superpartners with mass M_Φ. The coefficients $b_i^{C,X,\Phi}$ can be found in Ref. [75]. Crucially, the b_i in Eq. (93.12) conspire to make the running GUT-universal at high scales, such that the resulting prediction for α_3 does not depend on the value of μ.

To relate this to our previous discussion, we can, for example, define $M_G \equiv M_X$ and then choose $\mu = M_G$ in Eq. (93.12). This gives the high-scale threshold corrections

$$\delta_i^{(h)} = \frac{1}{2\pi}\left[b_i^C \ln\frac{M_G}{M_C} + b_i^\Phi \ln\frac{M_G}{M_\Phi}\right] , \tag{93.13}$$

and a corresponding correction $\Delta_3^{(h)}$. To get some intuition for the magnitude, one can furthermore assume $M_\Phi = M_G$, finding (with $b_i^C = \{2/5, 0, 1\}$)

$$\Delta_3^{(h)} = \frac{9}{14\pi}\ln\left(\frac{M_G}{M_C}\right) . \tag{93.14}$$

To obtain the desired effect of $-\Delta_3^{(2)} - \Delta_3^{(l)} \simeq +0.64$, the triplet Higgs would have to be by about a factor 20 lighter than the GUT scale. While this is ruled out by nucleon decay in the minimal model [76] as will be discussed Sec. 93.6, it is also clear that threshold corrections of this order of magnitude can, in general, be realized with a certain amount of GUT-scale model building, e.g. in specific $SU(5)$ [25] or $SO(10)$ [26,27] constructions. Corrections can also be much larger or of different sign if, as is required in many fully realistic 4d GUT models, many additional (and in particular higher) representations are introduced. Thus, there is considerable model building freedom. Nevertheless, a significant constraint from getting the right GUT threshold corrections while keeping the triplet Higgs heavy remains.

The above analysis implicitly assumes universal soft SUSY breaking masses at the GUT scale, which directly affect the spectrum of SUSY particles at the weak scale. In the simplest case we have a universal gaugino mass $M_{1/2}$, a universal mass for squarks and sleptons m_{16} and a universal Higgs mass m_{10}, as motivated by $SO(10)$. In some cases, threshold corrections to gauge coupling unification can be exchanged for threshold corrections to soft SUSY parameters (see [77] and refs. therein). For example, if gaugino masses were not unified at M_G and, in particular, gluinos were lighter than winos at the weak scale (cf. Eq. (93.11)), then it is possible that, due to weak scale threshold corrections, a much smaller or even slightly negative threshold correction at the GUT scale would be consistent with gauge coupling unification [78].

It is also noteworthy that perfect unification can be realized without significant GUT-scale corrections, simply by slightly raising the (universal) SUSY breaking scale. In this case the dark matter abundance produced by thermal processes in the early Universe (if the lightest neutralino is the dark matter particle) is too high. However, even if the gaugino mass in the MSSM is about 1 TeV to explain the dark matter abundance, if the Higgsino and the non-SM Higgs boson masses are about 10-100 TeV, the effective SUSY scale can be raised [79]. This setup is realized in split SUSY [80] or the pure gravity mediation model [81] based on anomaly mediation [82]. Since the squarks and sleptons are much heavier than the gaugino masses in those setups, a gauge hierarchy problem is reintroduced. The facts that no superpartners have so far been seen at the LHC and that the observed Higgs mass favors heavier stop masses than about 1 TeV force one to accept a certain amount of fine-tuning anyway.

For non-SUSY GUTs or GUTs with a very high SUSY breaking scale to fit the data, new light states in incomplete GUT multiplets or multiple GUT breaking scales are required. For example, non-SUSY models $SO(10) \to SU(4)_C \times SU(2)_L \times SU(2)_R \to$ SM, with the second breaking scale of order an intermediate scale, determined by light neutrino masses using the see-saw mechanism, can fit the low-energy data for gauge couplings [83] and at the

[7] The $\overline{\rm DR}$ scheme is frequently used in a supersymmetric regularization [71]. The renormalization transformation of the gauge coupling constants from $\overline{\rm MS}$ to $\overline{\rm DR}$ scheme is given in Ref. [72]. For an alternative treatment using holomorphic gauge couplings and NSVZ β-functions see e.g. [73].

same time survive nucleon decay bounds [84]. Alternatively, one can appeal to string-theoretic corrections discussed in Sec. 93.4 to compensate for a high SUSY breaking scale. This has, for example, been concretely analyzed in the context of F-theory GUTs in [85]. Similarly, one may even wonder whether particularly large GUT threshold corrections could be sufficient to ensure non-SUSY precision unification. Notice here that the gauge coupling unification predicts just one parameter. When introducing new states, typically one can fit the data by choice of their masses. This is not the case in SUSY GUTs with low-scale SUSY breaking scale where the masses are constrained by fine-tuning.

In 5d or 6d orbifold GUTs, certain "GUT scale" threshold corrections come from the Kaluza-Klein modes between the compactification scale, $M_c \sim 1/R$, and the effective cutoff scale M_*. In string theory, this cutoff scale is the string scale. Gauge coupling unification at two loops then constrains the values of M_c and M_*.[8] Often, one finds M_c to be lower than the 4d GUT scale. Since the X-bosons, responsible for nucleon decay, get mass at the compactification scale, this has significant consequences for nucleon decay.

Finally, it has been shown that non-supersymmetric GUTs in warped 5d orbifolds can be consistent with gauge coupling unification. This assumes (in 4d language) that the r.h. top quark and the Higgs doublets are composite-like objects with a compositeness scale in the TeV range [87].

93.6 Nucleon decay

Quarks and leptons are indistinguishable in any 4d GUT, and both the baryon (B) and lepton number (L) are not conserved. This leads to baryon-number-violating nucleon decay. In addition to baryon-number violation, lepton-number violation is also required for nucleon decay since, in the SM, leptons are the only free fermions which are lighter than nucleons. The lowest-dimension operators relevant for nucleon decay are (B+L) violating dimension-six four-fermion-terms in the SM, and all baryon-violating operators with dimension less than seven preserve (B–L) [1, 88].

In $SU(5)$ GUTs, the dimension-six operators are induced by X boson exchange. These operators are suppressed by $(1/M_X^2)$ (M_X is the X boson mass), and the nucleon lifetime is given by $\tau_N \propto M_X^4/(\alpha_G^2\, m_p^5)$ (m_p is proton mass). The dominant decay mode of the proton (and the baryon-violating decay mode of the neutron), via X boson exchange, is $p \to e^+\,\pi^0$ ($n \to e^+\,\pi^-$). In any simple gauge symmetry, with one universal GUT coupling α_G and scale M_X, the nucleon lifetime from gauge boson exchange is calculable. Hence, the GUT scale may be directly observed via the extremely rare decay of the nucleon. The present experimental bounds on the modes come from Super-Kamiokande. With 450 kton-years of data they find $\tau_p/\mathrm{Br}(p \to e^+\pi^0) > 2.4 \times 10^{34}$ years at 90% CL [89]. In addition, Hyper-Kamiokande [90] is planned to reach to $\tau_p/\mathrm{Br}(p \to e^+\pi^0) \sim 10^{35}$ years. The reader may consult [91] for other planned experiments and some historical context. The hadronic matrix elements for baryon-number-violating operators are evaluated with lattice QCD simulations [92]. In SUSY $SU(5)$ GUTs, the lower bound on the X boson mass from null results in nucleon decay searches is approaching 10^{16} GeV [93], which is close to the GUT scale suggested by gauge coupling unification. On the other hand, the prediction for nucleon decay in non-SUSY GUTs is hard to quantify. The reason is that gauge couplings do not unify with just the SM particle content. Once extra states or large thresholds are included to ensure precision unification, a certain range of unification scales is allowed.

In SUSY GUTs there are additional sources for baryon and/or lepton-number violation – dimension-four and five operators [14]. These arise since, in the SUSY SM, quarks and leptons have scalar partners (squarks and sleptons). Although our notation does not change, when discussing SUSY models our fields are chiral superfields and both fermionic and bosonic matter is implicitly represented by those. In this language, baryon- and/or lepton-number-violating dimension-four and five operators are given as so-called F terms of products of chiral superfields, which contain two fermionic components and the rest scalars or products of scalars. Within the context of $SU(5)$ the dimension-four and five operators have the form

$$(\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}}) \supset (u^c\ d^c\ d^c) + (Q\ L\ d^c) + (e^c\ L\ L),$$

$$(\mathbf{10}\ \mathbf{10}\ \mathbf{10}\ \bar{\mathbf{5}}) \supset (Q\ Q\ Q\ L) + (u^c\ u^c\ d^c\ e^c) + B\text{- and } L\text{-conserving terms},$$

respectively.

The dimension-four operators in $(\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}})$ violate either baryon number or lepton number. The nucleon lifetime is extremely short if both types of dimension-four operators are present in the SUSY SM since squark or slepton exchange induces the dangerous dimension-six SM operators. Even in the case that they violate baryon number or lepton number only but not both, they are constrained by various phenomena [94]. For example, the primordial baryon number in the Universe is washed out unless the dimensionless coupling constants are less than 10^{-7}. Both types of operators can be eliminated by requiring R parity, which distinguishes Higgs from ordinary matter multiplets. R parity [95] or its cousin, matter parity [6, 96], act as $F \to -F$, $H \to H$ with $F = \{\mathbf{10}, \bar{\mathbf{5}}\}$, $H = \{\bar{\mathbf{5}}_H, \mathbf{5}_H\}$ in $SU(5)$.[9] In $SU(5)$, the Higgs multiplet $\bar{\mathbf{5}}_H$ and the matter multiplets $\bar{\mathbf{5}}$ have identical gauge quantum numbers. In E_6, Higgs and matter multiplets could be unified within the fundamental **27** representation. Only in $SO(10)$ are Higgs and matter multiplets distinguished by their gauge quantum numbers. The Z_4 center of $SO(10)$ distinguishes **10**s from **16**s and can be associated with R parity [97].

The baryon-number violating dimension-five operators have a dimensionful coupling. They are generated by integrating out the color-triplet Higgs with GUT-scale mass in SUSY GUTs such that the coefficient is suppressed by $1/M_G$. Note that both triplet Higgsinos (due to their fermionic nature) and Higgs scalars (due to their mass-enhanced trilinear coupling with matter) contribute to the operators. The dimension-five operators include squarks and/or sleptons. To allow for nucleon decay, these must be converted to light quarks or leptons by exchange of a gaugino or Higgsino in the SUSY SM. The nucleon lifetime is proportional to $M_G^2\, m_{\mathrm{SUSY}}^2/m_p^5$, where m_{SUSY} is the SUSY breaking scale. Thus, dimension-five operators may predict a shorter nucleon lifetime than dimension-six operators. Unless accidental cancellations are present, the dominant decay modes from dimension-five operators include a K meson, such as $p \to K^+\ \bar{\nu}$ ($n \to K^0\ \bar{\nu}$). This is due to a simple symmetry argument: The operators are given as $(Q_i\ Q_j\ Q_k\ L_l)$ and $(u_i^c\ u_j^c\ d_k^c\ e_l^c)$, where $i, j, k, l\,(= 1, 2, 3)$ are family indices and color and weak indices are implicit. They must be invariant under $SU(3)_C$ and $SU(2)_L$ so that their color and weak doublet indices must be anti-symmetrized. Since these operators are given by bosonic superfields, they must be totally symmetric under interchange of all indices. Thus, the first operator vanishes for $i = j = k$ and the second vanishes for $i = j$. Hence a second or third generation member exists in the dominant modes of nucleon decay unless these modes are accidentally suppressed [96].

The Super-Kamiokande bounds on the proton lifetime severely constrain the dimension-five operators. With 306 kton-years of data they find $\tau_p/\mathrm{Br}(p \to K^+\bar{\nu}) > 6.61 \times 10^{33}$ years at 90% CL [98]. In the minimal SUSY $SU(5)$, $\tau_p/\mathrm{Br}(p \to K^+\bar{\nu})$ is smaller than about 10^{31} years if the triplet Higgs mass is 10^{16} GeV and $m_{\mathrm{SUSY}} = 1$ TeV [99]. The triplet Higgs mass bound from nucleon decay is then in conflict with gauge coupling unification so that this model is considered to be ruled out [76].

Since nucleon decay induced by the triplet Higgs is a severe problem in SUSY GUTs, various proposals for its suppression have been made. First, some accidental symmetry or accidental structure in non-minimal Higgs sectors in $SU(5)$ or $SO(10)$ theories may suppress the dimension-five operators [22, 26, 27, 100].

[8] It is interesting to note that a ratio $M_*/M_c \sim 100$, needed for gauge coupling unification to work in orbifold GUTs, is typically the maximum value for this ratio consistent with perturbativity [86].

[9] This forbids the dimension-four operator $(\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}})$, but allows the Yukawa couplings for quark and lepton masses of the form $(\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}}_H)$ and $(\mathbf{10}\ \mathbf{10}\ \mathbf{5}_H)$. It also forbids the dimension-three, lepton-number-violating operator $(\bar{\mathbf{5}}\ \mathbf{5}_H) \supset (L\ H_u)$ as well as the dimension-five, baryon-number-violating operator $(\mathbf{10}\ \mathbf{10}\ \mathbf{10}\ \bar{\mathbf{5}}_H) \supset (Q\ Q\ Q\ H_d) + \cdots$.

Symmetries to suppress the dimension-five operators are typically broken by the VEVs responsible for the color-triplet Higgs masses. Consequently, the dimension-five operators are generically generated via the triplet Higgs exchange in SUSY $SU(5)$ GUTs, as mentioned above. In other words, the nucleon decay is suppressed if the Higgs triplets in $\bar{\mathbf{5}}_H$ and $\mathbf{5}_H$ do not have a common mass term but, instead, their mass terms involve partners from other $SU(5)$ multiplets. Second, the SUSY breaking scale may be around $\mathcal{O}$(10–100) TeV in order to explain the observed Higgs boson mass at the LHC. In this case, nucleon decay is automatically suppressed [80,101,102]. Third, accidental cancellations among diagrams due to a fine-tuned structure of squark and slepton flavor mixing might suppress nucleon decay [103]. Last, we have also implicitly assumed a hierarchical structure for Yukawa matrices in the analysis. It is however possible to fine-tune a hierarchical structure for quarks and leptons which baffles the family structure so that the nucleon decay is suppressed [104]. The upper bound on the proton lifetime from some of these theories is approximately a factor of 10 above the experimental bounds. Future experiments with larger neutrino detectors, such as JUNO [105], Hyper-Kamiokande [90], DUNE [106] and Theia [107], are planned and will have higher sensitivities to nucleon decay.

Are there ways to avoid the stringent predictions for proton decay discussed above? Orbifold GUTs and string theories, see Sec. 93.4, contain grand unified symmetries realized in higher dimensions. In the process of compactification and GUT symmetry breaking, the triplet Higgs states may be removed (projected out of the massless sector of the theory). In such models, the nucleon decay due to dimension-five operators can be severely suppressed or eliminated completely. However, nucleon decay due to dimension-six operators may be enhanced, since the gauge-bosons mediating proton decay obtain mass at the compactification scale, M_c, which is typically less than the 4d GUT scale (cf. Sec. 93.5). Alternatively, the same projections which eliminate the triplet Higgs may rearrange the quark and lepton states such that the massless states of one family come from different higher-dimensional GUT multiplets. This can suppress or completely eliminate even dimension-six proton decay. Thus, enhancement or suppression of dimension-six proton decay is model-dependent. In some complete 5d orbifold GUT models [65, 108] the lifetime for the decay $\tau_p/\mathrm{Br}(p \to e^+\pi^0)$ can be near the bound of 1×10^{34} years with, however, large model-dependence and/or theoretical uncertainties. In other cases, the modes $p \to K^+\bar{\nu}$ and $p \to K^0\mu^+$ may be dominant [65]. Thus, interestingly, the observation of nucleon decay may distinguish string or higher-dimensional GUTs from 4d ones.

In orbifold GUTs or string theory, new discrete symmetries consistent with SUSY GUTs can forbid all dimension-three and four baryon- and lepton-number-violating operators. Even the μ term and dimension-five baryon- and lepton-number-violating operators can be forbidden to all orders in perturbation theory [35]. The μ term and dimension-five baryon- and lepton-number-violating operators may then be generated, albeit sufficiently suppressed, via non-perturbative effects. The simplest example of this is a Z_4^R symmetry which is the unique discrete R symmetry consistent with $SO(10)$ [35]. Even though it forbids the dimension-five proton decay operator to the desired level, it allows the required dimension-five neutrino mass term. In this case, proton decay is dominated by dimension-six operators, leading to decays such as $p \to e^+\pi^0$.

93.7 Yukawa coupling unification

In the SM, masses and mixings for quarks and leptons come from the Yukawa couplings with the Higgs doublet, but the values of these couplings remain a mystery. GUTs provide at least a partial understanding since each generation is embedded in unified multiplet(s). Specifically, since quarks and leptons are two sides of the same coin, the GUT symmetry relates the Yukawa couplings (and hence the masses) of quarks and leptons.

In $SU(5)$, there are two types of independent renormalizable Yukawa interactions given by λ_{ij} $(\mathbf{10}_i\ \mathbf{10}_j\ \mathbf{5}_H)$ + λ'_{ij} $(\mathbf{10}_i\ \bar{\mathbf{5}}_j\ \bar{\mathbf{5}}_H)$. These contain the SM interactions $\lambda_{ij}\ (Q_i\ u^c_j\ H_u) + \lambda'_{ij}\ (Q_i\ d^c_j\ H_d + e^c_i\ L_j\ H_d)$. Here $i, j\ (=1,2,3)$ are, as before, family indices. Hence, at the GUT scale we have tree-level relations between Yukawa coupling constants for charged lepton and down quark masses, such as $\lambda_b = \lambda_\tau$ in which $\lambda_{b/\tau}$ are the bottom quark /τ lepton Yukawa coupling constants [109,110]. In $SO(10)$, there is only one type of independent renormalizable Yukawa interaction given by λ_{ij} $(\mathbf{16}_i\ \mathbf{16}_j\ \mathbf{10}_H)$, leading to relations among all Yukawa coupling constants and quark and lepton masses within one generation [111,112] (such as $\lambda_t = \lambda_b = \lambda_\tau$, with λ_t the top quark Yukawa coupling constant).

In addition to gauge coupling unification, the ratio of bottom quark and τ lepton mass has been a central target in the study of GUTs since it was found that this ratio was almost consistent with observations after including the QCD correction [109]. Today the quark masses and the gauge coupling constants are known precisely such that, as discussed below, the ratio of bottom quark and τ lepton mass has become a target of precision analyses in the GUT context.

93.7.1 *The third generation, b–τ or t–b–τ unification*

Third generation Yukawa couplings are larger than those of the first two generations. Hence, the fermion mass relations predicted from renormalizable GUT interactions which we introduced above are expected to be more reliable. In order to compare them with data, we have to include the radiative correction to these relations from the RG evolution between GUT and fermion mass scale, from integrating out heavy particles at the GUT scale, and from weak scale thresholds.

Since testing Yukawa coupling unification is only possible in models with successful gauge coupling unification, we here focus on SUSY GUTs. In the MSSM, top and bottom quark and τ lepton masses are related to the Yukawa coupling constants at the scale m_Z as

$$m_t(m_Z) = \lambda_t(m_Z)\ v_u(1 + \delta m_t/m_t),$$
$$m_{b/\tau}(m_Z) = \lambda_{b/\tau}(m_Z)\ v_d(1 + \delta m_{b/\tau}/m_{b/\tau}),$$

where $\langle H_u^0\rangle \equiv v_u = \sin\beta\ v/\sqrt{2}$, $\langle H_d^0\rangle \equiv v_d = \cos\beta\ v/\sqrt{2}$, $v_u/v_d \equiv \tan\beta$ and $v \sim 246$ GeV is fixed by the Fermi constant, G_μ. Here, $\delta m_f/m_f$ $(f = t, b, \tau)$ represents the threshold correction due to integrating out SUSY partners. For the bottom quark mass, it is found [113] that the dominant corrections come from the gluino-sbottom and from the Higgsino-stop loops,

$$\left(\frac{\delta m_b}{m_b}\right)_{g3} \sim \frac{g_3^2}{6\pi^2}\frac{m_{\tilde{g}}\mu}{m^2_{\mathrm{SUSY}}}\tan\beta \qquad \text{and}$$
$$\left(\frac{\delta m_b}{m_b}\right)_{\lambda_t} \sim \frac{\lambda_t^2}{16\pi^2}\frac{A_t\mu}{m^2_{\mathrm{SUSY}}}\tan\beta\,, \tag{93.16}$$

where $m_{\tilde{g}}$, μ, and A_t stand for gluino and Higgsino masses and trilinear stop coupling, respectively. Note that Eq. (93.16) only illustrates the structure of the corrections – non-trivial functional dependences on several soft parameters $\sim m_{\mathrm{SUSY}}$ have been suppressed. For the full one-loop correction to the bottom quark mass see, for example, Ref. [114].

Note also that the corrections do not go to zero as SUSY particles become much heavier than m_Z. They may change the bottom quark mass at the $\mathcal{O}(10)$% level for $\tan\beta = \mathcal{O}(10)$. The total effect is sensitive to the relative phase between gluino and Higgsino masses since $A_t \sim -m_{\tilde{g}}$ due to the infrared fixed point nature of the RG equation for A_t [115] in settings where SUSY breaking terms come from Planck scale dynamics, such as gravity mediation. The τ lepton mass also receives a similar correction, though only at the few % level. The top quark mass correction, not being proportional to $\tan\beta$, is at most 10% [116].

Including one loop threshold corrections at m_Z and additional RG running, one finds the top, bottom and τ pole masses. In SUSY GUTs, b–τ unification has two possible solutions with $\tan\beta \sim 1$ or $\mathcal{O}(10)$. The small $\tan\beta$ solution may be realized in the MSSM if superpartner masses are $\mathcal{O}(10)$ TeV, as suggested by the observed Higgs mass [101]. The large $\tan\beta$ limit such as $\tan\beta \sim$ 40–50 overlaps the $SO(10)$ symmetry relation [116, 117]. When $\tan\beta$ is large, there are significant threshold corrections to

down quark masses as mentioned above, and Yukawa unification is only consistent with low-energy data in a restricted region of SUSY parameter space, with important consequences for SUSY searches [116, 118]. More recent analyses of Yukawa unification after LHC Run-I are found in Ref. [119].

Gauge coupling unification is also successful in the scenario of split supersymmetry [80], in which squarks and sleptons have mass at a scale $\tilde{m} \gg m_Z$, while gauginos and/or Higgsinos have masses of order the weak scale. Unification of b–τ Yukawa couplings requires $\tan\beta$ to be fine-tuned close to 1 [101]. If by contrast, $\tan\beta \gtrsim 1.5$, b–τ Yukawa unification only works for $\tilde{m} \lesssim 10^4$ GeV. This is because the effective theory between the gaugino mass scale and $\tilde{m}$ includes only one Higgs doublet, as in the standard model. As a result, the large top quark Yukawa coupling tends to increase the ratio λ_b/λ_τ due to the vertex correction, which is absent in supersymmetric theories, as one runs down in energy below $\tilde{m}$. This is opposite to what happens in the MSSM where the large top quark Yukawa coupling lowers the ratio λ_b/λ_τ [110].

93.7.2 *Beyond leading order: three-family models*

Simple Yukawa unification is not possible for the first two generations. Indeed, the simplest implementation of $SU(5)$ implies $\lambda_s = \lambda_\mu$, $\lambda_d = \lambda_e$ and hence $\lambda_s/\lambda_d = \lambda_\mu/\lambda_e$. This is an RG-invariant relation which extrapolates to $m_s/m_d = m_\mu/m_e$ at the weak scale, in serious disagreement with data ($m_s/m_d \sim 20$ and $m_\mu/m_e \sim 200$). An elegant solution to this problem was given by Georgi and Jarlskog [120] (for a recent analysis in the SUSY context see [121]).

More generally, we have to recall that in all of the previous discussion of Yukawa couplings, we assumed renormalizable interactions as well as the minimal matter and Higgs content. Since the GUT scale is close to the Planck scale, higher-dimension operators involving the GUT-breaking Higgs may modify the predictions, especially for lower generations. An example is provided by the operators $\mathbf{10}\ \bar{\mathbf{5}}\ \bar{\mathbf{5}}_H\ \mathbf{24}_H$ with $\mathbf{24}_H$ the GUT-breaking Higgs of $SU(5)$. We can fit parameters to the observed fermion masses with these operators, though some fine-tuning is introduced in doing so. The SM Higgs doublet may come in part from higher representations of the GUT group. For example, the **45** of $SU(5)$ includes an $SU(2)_L$ doublet with appropriate $U(1)_Y$ charge [120]. This **45** can, in turn, come from the **120** or **126** of $SO(10)$ after its breaking to $SU(5)$ [122, 123]. These fields may also have renormalizable couplings with quarks and leptons. The relations among the Yukawa coupling constants in the SM are modified if the SM Higgs doublet is a linear combination of several such doublets from different $SU(5)$ multiplets. Finally, the SM fermions may not be embedded in GUT multiplets in the minimal way. Indeed, if all quarks and leptons are embedded in **16**s of $SO(10)$, the renormalizable interactions with $\mathbf{10}_H$ cannot explain the observed CKM mixing angles. This situation improves when extra matter multiplets, such as **10**, are introduced: After $U(1)_X$, which distinguishes the $\bar{\mathbf{5}}$s coming from the **16** and the **10** of $SO(10)$, is broken (e.g. by a VEV of $\mathbf{16}_H$ or $\mathbf{126}_H$), the r.h. down quarks and l.h. leptons in the SM can be linear combinations of components in **16**s and **10**s. As a result, $\lambda \neq \lambda'$ in $SU(5)$ [124].

To construct realistic three-family models, some or all of the above effects can be used. Even so, to achieve significant predictions for fermion masses and mixing angles grand unification alone is not sufficient. Other ingredients, for example additional global family symmetries are needed (in particular, non-Abelian symmetries can strongly reduce the number of free parameters). These family symmetries constrain the set of effective higher-dimensional fermion mass operators discussed above. In addition, sequential breaking of the family symmetry can be correlated with the hierarchy of fermion masses [125]. One simple, widely known idea in this context is to ensure that each $\mathbf{10}_i$ enters Yukawa interactions together with a suppression factor ϵ^{3-i} (ϵ being a small parameter). This way one automatically generates a stronger hierarchy in up-type quark Yukawas as compared to down-type quark and lepton Yukawas and no hierarchy for neutrinos, which agrees with observations at the $\mathcal{O}(1)$-level. Three-family models exist which fit all the data, including neutrino masses and mixing [27, 126].

Finally, a particularly ambitious variant of unification is to require that the fermions of all three generations come from a single representation of a large gauge group. A somewhat weaker assumption is that the flavor group (e.g. $SU(3)$) unifies with the SM gauge group in a simple gauge group at some energy scale $M \geq M_G$. Early work on such 'flavor-unified GUTs', see e.g. [124, 127], has been reviewed in [128, 129]. For a selection of more recent papers see [130]. In such settings, Yukawa couplings are generally determined by gauge couplings together with symmetry breaking VEVs. This is reminiscent of heterotic string GUTs, where all couplings come from the 10d gauge coupling. However, while the $\mathrm{E}_8 \to SU(3)\times\mathrm{E}_6$ branching rule $\mathbf{248} = (\mathbf{8},\mathbf{1}) + (\mathbf{1},\mathbf{78}) + (\mathbf{3},\mathbf{27}) + (\bar{\mathbf{3}},\bar{\mathbf{27}})$ looks very suggestive in this context, the way in which most modern heterotic models arrive at three generations is actually more complicated.

93.8 Neutrino masses

We see from atmospheric and solar neutrino oscillation observations, along with long baseline accelerator and reactor experiments, that neutrinos have finite masses. By adding three "sterile" neutrinos ν_i^c with Yukawa couplings $\lambda_{\nu,ij}$ $(\nu_i^c\ L_j\ H_u)$ $(i,j = 1,2,3)$, one easily obtains three massive Dirac neutrinos with mass $m_\nu = \lambda_\nu\ v_u$, analogously to quark and charged lepton masses. However, in order to obtain a τ neutrino with mass of order 0.1 eV, one requires the exceedingly small coupling ratio $\lambda_{\nu_\tau}/\lambda_\tau \lesssim 10^{-10}$. By contrast, in GUTs the seesaw mechanism *naturally* explains such tiny neutrino masses as follows [2–4]: The sterile neutrinos have no SM gauge quantum numbers so that there is no symmetry other than global lepton number which forbids the Majorana mass term $\frac{1}{2}M_{ij}\ \nu_i^c\ \nu_j^c$. Note also that sterile neutrinos can be identified with the r.h. neutrinos necessarily contained in complete families of $SO(10)$ or Pati-Salam models. Since the Majorana mass term violates $U(1)_X$ in $SO(10)$, one might expect $M_{ij} \sim M_G$. The heavy sterile neutrinos can be integrated out, defining an effective low-energy theory with only three light active Majorana neutrinos with the effective dimension-five operator

$$-\mathcal{L}_{eff} = \frac{1}{2}c_{ij}\ (L_i\ H_u)\ (L_j\ H_u)\,, \tag{93.17}$$

where $c = \lambda_\nu^T\ M^{-1}\ \lambda_\nu$. This then leads to a 3×3 Majorana neutrino mass matrix $m = m_\nu^T\ M^{-1}\ m_\nu$.

The seesaw mechanism implemented by r.h. neutrinos is sometimes called the type-I seesaw model. There are variant models in which the dimension-five operator for neutrino masses is induced in different ways: In the type-II model, an $SU(2)_L$ triplet Higgs boson Σ is introduced to have couplings ΣL^2 and also ΣH_u^2 [122, 131]. In the type-III model, an $SU(2)_L$ triplet of fermions $\tilde{\Sigma}$ with a Yukawa coupling $\tilde{\Sigma}LH_u$ is introduced [132]. In these models, the dimension-five operator is induced by integrating out the triplet Higgs boson or fermions. Such models can also be implemented in GUTs by introducing Higgs bosons in the **15** or fermions in the **24** in $SU(5)$ GUTs or the **126** in $SO(10)$ GUTs. Notice that the gauge non-singlet fields in the type-II and III models have masses at the intermediate scale. Thus, gauge coupling unification is not automatic if these variant mechanisms are implemented in SUSY GUTs.

Atmospheric neutrino oscillations discovered by Super-Kamiokande [133] require neutrino masses with $\Delta m_\nu^2 \sim 2.5\times 10^{-3}$ eV^2 with maximal mixing [64], in the simplest scenario of two neutrino dominance. With hierarchical neutrino masses this implies $m_{\nu_\tau} = \sqrt{\Delta m_\nu^2} \sim 0.05$ eV. Next, we can try to relate the neutrino Yukawa coupling to the top quark Yukawa coupling, $\lambda_{\nu_\tau} = \lambda_t$ at the GUT scale, as in $SO(10)$ or $SU(4)\times SU(2)_L \times SU(2)_R$ models. This gives $M \sim 10^{14}$ GeV, which is remarkably close to the GUT scale.

Neutrinos pose a special problem for GUTs. The question is why the quark mixing angles in the CKM matrix are small while there are two large lepton mixing angles in the PMNS matrix. Global fits of neutrino masses and mixing angles can, for example, be found in Refs. [134] and [135]. For SUSY GUT models which fit quark and lepton masses, see Ref. [136, 137] for reviews. Finally, for a compilation of the range of SUSY GUT predictions for neutrino mixing, see [138].

We should also note that, both within and independently of the GUT framework, much work has been devoted to neutrino-mass and more generally flavor model building on the basis of discrete symmetries (see e.g. [137,139]). A more recent interesting twist in this context is the use of the (non-linearly realized) modular group $SL(2,\mathbb{Z})$ as a discrete flavor symmetry [140]. This group plays a key role in string theory as the group of large diffeomorphisms of the 2-torus, the latter appearing as the string worldsheet and, more relevant in the present context, as part of the compactification space of torus orbifold models (cf. also Sect. 93.4). For a selection from the recent significant activity in these directions see e.g. [141].

93.9 Selected topics

93.9.1 *Global symmetries*

As we discussed, global symmetries are frequently introduced to control higher-dimension operators in GUT models. This is particularly important in the context of nucleon decay but also plays a role in GUT-based flavor model building and cosmological applications, such as baryogenesis and inflation. However, we should note that appealing to global symmetries to suppress specific interactions may not be as straightforward as it naively seems. Indeed, there are two possibilities: On the one hand, the relevant symmetry might be gauged at a higher scale. Effects of the VEVs responsible for the spontaneous breaking are then in principle dangerous and need to be quantified. On the other hand, the symmetry might be truly only global. This must e.g. be the case for anomalous symmetries, which are then also violated by field-theoretic non-perturbative effects. The latter can in principle be exponentially small. It is, however, widely believed that global symmetries are always broken in quantum gravity (see e.g. [142]). One then needs to understand which power or functional form the Planck scale suppression of the relevant interaction has. For example, dimension-five baryon number violating operators suppressed by just one unit of the Planck or string scale are completely excluded in the supersymmetric models.

In view of the above, it is also useful to recall that in string models 4d global symmetries generally originate in higher-dimensional gauge symmetries [40, 143]. Here 'global' implies that the gauge boson has acquired a Stückelberg-mass. This is a necessity in the anomalous case (Green-Schwarz mechanism [144]) but can also happen to non-anomalous symmetries. One expects no symmetry violation beyond the well-understood non-perturbative effects. Discrete symmetries arise as subgroups of continuous gauge symmetries, such as $\mathbb{Z}_N \subset U(1)$. In particular, non-anomalous subgroups of Stückelberg-massive $U(1)$s represent unbroken discrete gauge symmetries and as such are non-perturbatively exact (see e.g. [145]). Of course, such discrete gauge symmetries may also arise as remnants of continuous gauge symmetries after conventional 4d spontaneous breaking.

93.9.2 *Anomaly constraints vs. GUT paradigm*

As emphasized at the very beginning, the fact that the SM fermions of one generation fill out the $\mathbf{10}+\overline{\mathbf{5}}$ of $SU(5)$ appears to provide overwhelming evidence for some form of GUT embedding. However, one should be aware that a counterargument can be made which is related to the issue of 'charge quantization by anomaly cancellation' (see [146,147] for some early papers and [148] for a more detailed reference list): Imagine we only knew that the low-energy gauge group were G_{SM} and the matter content included the $(\mathbf{3},\mathbf{2})_Y$, i.e. a 'quark doublet' with $U(1)$-charge Y. One can then ask which possibilities exist of adding further matter to ensure the cancellation of all triangle anomalies. It turns out that this problem has only three different, minimal[10] solutions [147]. One of those is precisely a single SM generation, with the apparent '$SU(5)$-ness' emerging accidentally. Thus, if one randomly picks models from the set of consistent gauge theories, preconditioning on G_{SM} and $(\mathbf{3},\mathbf{2})_Y$, one may easily end up with '$\mathbf{10}+\overline{\mathbf{5}}$' of an $SU(5)$ that is in no way dynamically present. This is precisely what happens in the context of non-GUT string model building [149].

[10] Adding extra vector-like sets of fields, e.g. two fermions which only transform under $U(1)$ and have charges Y and $-Y$, is considered to violate minimality.

93.9.3 *Topological defects and phase transitions*

Of the various topological defects which may exist in the broken phase of GUT models, the most famous ones are magnetic monopoles. These are typically localized classical solutions carrying magnetic charge under an unbroken $U(1)$ symmetry [150]. These magnetic monopoles with mass of order M_G/α_G can be produced during a possible GUT phase transition in the early Universe. The flux of magnetic monopoles is experimentally found to be less than $\sim 10^{-16}$ cm^{-2} s^{-1} sr^{-1} [151]. Many more are however predicted, hence the GUT monopole problem. In fact, one of the original motivations for inflation was to solve the monopole problem by exponential expansion after the GUT phase transition [152] and hence dilution of the monopole density. Other possible solutions to the monopole problem include: sweeping them away by domain walls [153], $U(1)$ electromagnetic symmetry breaking at high temperature [154] or GUT symmetry non-restoration [155]. Parenthetically, it was also shown that GUT monopoles can catalyze nucleon decay [156]. A significantly stronger bound on the monopole flux can then be obtained by considering X-ray emission from radio pulsars due to monopole capture and the subsequent nucleon decay catalysis [157].

Note that the present upper bound on the inflationary vacuum energy density is very close to the GUT scale, $V_{inf}^{1/4} = (1.88\times 10^{16}\,\text{GeV})\times(r/0.10)^{1/4}$, with the scalar-to-tensor ratio constrained to $r < 0.036$ [158], This guarantees that reheating does not lead to temperatures above M_G and hence the monopole problem is solved by inflation (unless M_G is unexpectedly low).

As already noted, topological defects other than monopoles are also common, see e.g. [159]. They can be cosmologically relevant in GUT models based on a gauge group larger than SU(5), say, SO(10), where an intermediate gauge theory may appear. The breaking of this intermediate gauge symmetry can a priori occur anywhere between the GUT and the electroweak scale. Right-handed neutrino masses favor a value near $\mathcal{O}(10^{14})$ GeV and non-SUSY coupling unification may profit from such a two-step GUT breaking scheme (cf. Sect. 93.5). Crucially for the present context, the last breaking step may occur after inflation, generating topological defects (like cosmic strings) which are not diluted. Their signature can be probed through gravitational waves [160], with the metastable string case being of particular phenomenological interest [161, 162]. Metastability arises because the nucleation of a monopole-anti-monopole pair, each of which serves as an endpoint for the string, allow the cosmic string to break. The lifetime becomes long and hence the string stable as the ratio between monopole mass and the square root of the string tension grows. This is related to the ratio of scales of the two symmetry breaking steps. It is of phenomenological interest that metastability allows the string network to evade the recent bound of $G\mu \lesssim 10^{-10}$ (or $\sqrt{\mu} \lesssim 10^{14}$ GeV) [162]. Moreover the spectrum is blue-tilted compared to the stable string case. Finally, we note that if the intermediate gauge symmetry breaking proceeds with a (strong) first order phase transition, this could also generate gravitational waves [162,163]. However, due to the relatively high energy scales involved the peak frequency tends to be high, with signals hopefully to be explored in future gravitational wave experiments.

93.9.4 *Flavor violation*

Yukawa interactions of GUT-scale particles with quarks and leptons may leave imprints on the flavor violation induced by SUSY breaking parameters [164]. To understand this, focus first on the MSSM with universal Planck-scale boundary conditions (as e.g. in gravity mediation). Working in a basis where up-quark and lepton Yukawas are diagonal, one finds that the large top-quark Yukawa coupling reduces the l.h. squark mass squareds in the third generation radiatively. It turns out that only the l.h. down-type squark mass matrix has sizable off-diagonal terms in the flavor basis after CKM-rotation. However, in GUTs the color-triplet Higgs has flavor violating interactions from the Yukawa coupling λ_{ij} $(\mathbf{10}_i\ \mathbf{10}_j\ \mathbf{5}_H)$, such that flavor-violating r.h. slepton mass terms are radiatively generated in addition [165]. In $SU(5)$ extension of the type-I seesaw model, where r.h. neutrinos are introduced as $SU(5)$ singlets with interactions λ''_{ij} $(\mathbf{1}_i\ \overline{\mathbf{5}}_j\ \mathbf{5}_H)$, the doublet and color-triplet Higgses acquire another type of Yukawa

coupling, respectively. They then radiatively generate flavor-violating l.h. slepton [166] and r.h. down squark masses [167]. These flavor-violating SUSY breaking terms induce new contributions to FCNC processes in quark and lepton sectors, such as $\mu \to e\gamma$ and K^0–$\bar{K}^0$ and B^0–$\bar{B}^0$ mixing. Note that even if the flavor-universal SUSY breaking terms are generated at M_G, the r.h. neutrino Yukawa coupling may induce sizable flavor violation in l.h. slepton masses due to the running between M_G and the right-handed-neutrino mass scale.

EDMs are also induced when both l.h. and r.h. squarks/sleptons have flavor-violating mass terms with relative phases, as discussed for $SO(10)$ in [168] or for $SU(5)$ with r.h. neutrinos in [169]. Thus, such low-energy observables constrain GUT-scale interactions.

93.9.5 *From GUT baryogenesis to leptogenesis and B/L-violating transitions*

During inflation, any conserved quantum number is extremely diluted. Thus, one expects the observed baryon asymmetry of the Universe to originate at reheating or in the subsequent cosmological evolution. In detail, the situation is slightly more involved: Both baryon number B and lepton number L are global symmetries of the SM. However, $(B+L)$ is anomalous and violated by thermal fluctuations in the early Universe, via so-called sphaleron processes. Moreover, it is violated in GUT models, as is most apparent in proton decay. By contrast, $(B-L)$ is anomaly free and preserved by both the SM as well as $SU(5)$ or $SO(10)$ gauge interactions.

Now, the old idea of GUT baryogenesis [170,171] is to generate a $(B+L)$ and hence a baryon asymmetry by the out-of-equilibrium decay of the color-triplet Higgs. However such an asymmetry, generated at GUT temperatures, is washed out by sphalerons[11]. This can be overcome [173] using lepton-number violating interaction of neutrinos to create a $(B-L)$ from the $(B+L)$ asymmetry, before sphaleron processes become sufficiently fast at $T < 10^{12}$ GeV. This $(B-L)$ asymmetry can then survive the subsequent sphaleron dominated phase. Note that this does not work in the minimal SUSY GUT setting, with the triplet Higgs above the GUT scale. The reason is that a correspondingly high reheating temperature would be required which, as explained above, is ruled out by Planck data.

However, the most widely accepted simple way out of the dilemma is to directly generate a net $(B-L)$ asymmetry dynamically in the early Universe, also using r.h. neutrinos. Indeed, we have seen that neutrino oscillations suggest a new scale of physics of order 10^{14} GeV. This scale is associated with heavy Majorana neutrinos in the seesaw mechanism. If in the early Universe, the decay of the heavy neutrinos is out of equilibrium and violates both lepton number and CP, then a net lepton number may be generated. This lepton number will then be partially converted into baryon number via electroweak processes [174]. This mechanism is called leptogenesis.

If the three heavy Majorana neutrino masses are hierarchical, the net lepton number is produced by decay of the lightest one, and it is proportional to the CP asymmetry in the decay. The CP asymmetry is bounded from above, and the lightest neutrino mass is required to be larger than 10^9 GeV in order to explain the observed baryon asymmetry [175]. This implies that the reheating temperature after inflation should be larger than 10^9 GeV so that the heavy neutrinos are thermally produced[12]. In supersymmetric models, there is a tension between leptogenesis and Big Bang Nucleosynthesis (BBN) if gravitinos decay in the BBN era. The gravitino problem gives a constraint on the reheating temperature $\lesssim 10^{6-10}$ GeV though the precise value depends on the SUSY breaking parameters [177]. Recent reviews of leptogenesis can be found in Ref. [178].

One of the important tests of leptogenesis are searches for neutrinoless double-β ($0\nu\beta\beta$) decays[13]. In a $0\nu\beta\beta$ decay, only two electrons but no (anti-)neutrinos are emitted by the decaying nucleus. This is in contrast to ordinary double-β decay. Thus, $0\nu\beta\beta$ decays are lepton-number-violating with $\Delta L = 2$. At the nucleon level, this is described by dimension-nine effective operators for $nn \to ppee$. These operators may in turn come from SM operators of with dimension less than nine, in combination with SM weak interactions. The lowest one is the dimension-five operator generating the Majorana neutrino mass terms (Eq. (93.17)). Thus, if the lepton-number violating effective interactions come from physics at energies much above the weak scale, the $0\nu\beta\beta$ decay rates are proportional to the Majorana neutrino masses. The latest experimental results are reviewed in [64]. For recent studies of the $0\nu\beta\beta$ decay including SM operators up to mass dimension nine, see [179] and refs. therein.

In addition to L-violation, one can consider $(B-L)$ and B violating phenomena. They are interesting in their own right and may also be relevant to baryogenesis. The relevant operators have higher mass dimension than the familiar dimension-six $(B+L)$-violating operators (cf. Sec. 93.6). They may be predicted in SO(10) GUTs with an intermediate scale, at which baryogenesis is realized, such as in [180]. First, one may have nucleon decays with $\Delta(B-L) = 2$, such as $n \to e^-\pi^+$. This is induced by dimension-seven effective operators in the SM, which are suppressed by the SM Higgs VEV or derivatives. Second, there are neutron-antineutron (n–$\bar{n}$) oscillations, which are induced by $\Delta B = 2$ dimension-nine effective operators in the SM. The upper bound on the mean time for n–$\bar{n}$ transitions is directly derived using free neutrons [181]. It is also constrained from the lower limit on the lifetime for neutrons bound in ^{16}O, derived by Super-Kamiokande [182]. Their results are very similar. Super-Kamiokande also searches for dinucleon decays with $\Delta B = 2$, such as $pp \to \pi^+\pi^+$ and $nn \to \pi^\pm\pi^\mp$ [183].

93.9.6 *The QCD Axion*

The axion is a hypothetical pseudoscalar particle which is capable of resolving the strong CP problem [184] and may potentially be related to GUT physics. In particular, the strength of the direct coupling of the QCD axion to photons, relative to its coupling to gluons, may be seen as a phenomenological signature of grand unification. It is quantified by the predicted anomaly ratio $E/N = 8/3$ (see [185–187]). This ratio follows from the GUT normalization of the relevant generators together with the completeness of GUT multiplets contributing to the anomaly.[14] It hence arises in axion models of both DFSZ [188] and KSVZ [189] type as long as the Peccei-Quinn symmetry commutes with the GUT group (see e.g. [190]). Specifically in the case of a DFSZ axion, extra $SU(2)$ multiplets contribute to the running of gauge couplings between Peccei-Quinn and GUT scale, potentially affecting unification. By contrast, the KSVZ axion can be implemented without such effects.

We also note that, in bottom-up approaches and in the presence of split GUT multiplets, other anomaly ratios can appear (cf. e.g. [191]). Their embedding in a UV GUT structure, possibly with explicit GUT symmetry breaking, requires case-by-case study. The ratio $E/N = 8/3$ also arises in string-theoretic GUTs [186, 192]. In this case, the axion does not come from the phase of a complex scalar but is a fundamental shift-symmetric real field, coupling through a higher-dimension operator directly to the product of the GUT field-strength and its dual.

93.10 Conclusion

Most conservatively, grand unification means that (some of) the SM gauge interactions of $U(1)_Y$, $SU(2)_L$ and $SU(3)_C$ become part of a larger, unifying gauge symmetry at a high energy scale. In most models, especially in the simplest and most appealing variants of $SU(5)$ and $SO(10)$ unification, the statement is much stronger: One expects the three gauge couplings to unify (up to small threshold corrections) at a unique scale, M_G, and the proton to be unstable due to exchange of gauge bosons of the larger

[11] To be precise, if lepton flavor numbers L_i (i = 1–3) are nonzero and $(L_i - L_j) \neq 0$ ($i \neq j$), one may obtain nonzero values for B and L even if $(B-L) = 0$ [172].

[12] This constraint may be avoided in resonant leptogenesis [176], in which the right-handed neutrinos are required to be almost degenerate in mass.

[13] Another important test of leptogenesis would be the observation of CP violation in neutrino oscillations. Strictly speaking, the CP phase in the PMNS matrix does not contribute to ϵ_1 in the seesaw model. Nevertheless, the observation of CP violation in neutrino oscillations would suggest that the seesaw mechanism is associated with a large CP violation, similarly to the quark sector.

[14] See e.g. eq. (312) of [187]

symmetry group. Supersymmetric grand unified theories provide, by far, the most predictive and economical framework allowing for perturbative unification. Many more details than could be discussed in the present article can be found in some of the classic reviews [128, 193] and the four books [194] (see also [195] for two recent overviews).

Thus, the three classical pillars of GUTs are gauge coupling unification at $M_G \sim 2 \times 10^{16}$ GeV, low-energy supersymmetry (with a large SUSY desert), and nucleon decay. The first of these may be viewed as predicting the value of the strong coupling – a prediction which has already been verified (see Fig. 93.1). Numerically, this prediction remains intact even if SUSY partner masses are somewhat above the weak scale. However, at the conceptual level a continuously increasing lower bound on the SUSY scale is nevertheless problematic for the GUT paradigm: Indeed, if the independent, gauge-hierarchy-based motivation for SUSY is completely abandoned, the SUSY scale and hence α_3 become simply free parameters and the first two pillars crumble. Thus, it is important to keep pushing bounds on proton decay which, although again not completely universal in all GUT constructions, is arguably a more generic part of the GUT paradigm than low-energy SUSY.

Whether or not Yukawa couplings unify is more model dependent. However, irrespective of possible (partial) Yukawa unification, there certainly exists a very interesting and potentially fruitful interplay between flavor model building and grand unification. Especially in the neutrino sector this is strongly influenced by the developing experimental situation.

It is probably fair to say that, due to limitations of the 4d approach, including especially remaining ambiguities (free parameters or ad hoc assumptions) in models of flavor and GUT breaking, the string theoretic approach has become more important in GUT model building. In this framework, challenges include learning how to deal with the many vacua of the 'landscape' as well as, for each vacuum, developing the tools for reliably calculating detailed, phenomenological observables. Finally, due to limitations of space, the present article has barely touched on the interesting cosmological implications of GUTs. They may become more important in the future, especially in the case that a high inflationary energy scale is established observationally.

94. Leptoquarks

Revised October 2023 by S. Rolli (DOE) and M. Tanabashi (Nagoya U.; KMI, Nagoya U.).

Leptoquarks are hypothetical particles carrying both baryon number (B) and lepton number (L). The possible quantum numbers of leptoquark states can be restricted by assuming that their direct interactions with the ordinary Standard Model (SM) fermions are dimensionless and invariant under the SM gauge group. Table 94.1 shows the list of all possible quantum numbers with this assumption [1]. The columns of $SU(3)_C$, $SU(2)_W$, and $U(1)_Y$ in Table 94.1 indicate the QCD representation, the weak isospin representation, and the weak hypercharge, respectively. The spin of a leptoquark state is taken to be 1 (vector leptoquark) or 0 (scalar leptoquark).

If we do not require leptoquark states to couple directly with SM fermions, different assignments of quantum numbers become possible [2,3].

Leptoquark states are expected to exist in various extensions of the SM. The Pati-Salam model [4] is an example predicting the existence of a leptoquark state. Leptoquark states also exist in grand unification theories based on $SU(5)$ [5], $SO(10)$ [6] which includes Pati-Salam color $SU(4)$, and larger gauge groups. The existence of leptoquarks at TeV-scale also affect the renormalization group of the standard model gauge coupling strengths and may allow for the gauge coupling unification required by the grand unification theories [7]. Scalar quarks in supersymmetric models with R-parity violation may also have leptoquark-type Yukawa couplings. The bounds on the leptoquark states can therefore be applied to constrain R-parity-violating supersymmetric models [8,9]. Scalar leptoquarks are expected to exist at the TeV scale in extended technicolor models [10, 11] where leptoquark states appear as the bound states of techni-fermions. Compositeness of quarks and leptons also provides examples of models which may have light leptoquark states [12].

Bounds on leptoquark states are obtained both directly and indirectly. Direct limits are from their production cross sections at colliders, while indirect limits are calculated from bounds on leptoquark-induced two-quark two-lepton interactions, which are obtained from low-energy experiments, or from collider experiments below threshold. The quantum number assignment of Table 94.1 allows several leptoquark states to couple to both left- and right-handed quarks simultaneously. Such leptoquark states are called non-chiral and may cause low-energy interactions

$$(\bar{u}_R q_{Li})(\bar{e}_R \ell_{Lj})\epsilon^{ij} \qquad (\bar{d}_R q_{Li})(\bar{\ell}^i_L e_R)\,. \tag{94.1}$$

Here i, j are indices for the weak isospin. These two-quark two-lepton interactions affect the $(\pi \to e\nu)/(\pi \to \mu\nu)$ ratio [13]. Non-chiral scalar leptoquarks also contribute to the anomalous magnetic moments of charged leptons [14,15]. On the other hand, the exchanges of the chiral leptoquarks produce effective two-quark two-lepton interactions

$$\begin{aligned}
&(\bar{q}^i_L\gamma^\mu q_{Li})(\bar{\ell}^j_L\gamma_\mu \ell_{Lj})\,, && (\bar{q}^i_L\gamma^\mu q_{Li})(\bar{e}_R\gamma_\mu e_R)\,, && (\bar{q}^i_L\gamma^\mu(\vec{\sigma})_i{}^j q_{Lj})\cdot(\bar{\ell}^k_L\gamma_\mu(\vec{\sigma})_k{}^l \ell_{Ll})\,,\\
&(\bar{u}_R\gamma^\mu u_R)(\bar{\ell}^j_L\gamma_\mu \ell_{Lj})\,, && (\bar{u}_R\gamma^\mu u_R)(\bar{e}_R\gamma_\mu e_R)\,, &&\\
&(\bar{d}_R\gamma^\mu d_R)(\bar{\ell}^j_L\gamma_\mu \ell_{Lj})\,, && (\bar{d}_R\gamma^\mu d_R)(\bar{e}_R\gamma_\mu e_R) &&
\end{aligned} \tag{94.2}$$

below the leptoquark mass scale. Note that labels for the generations of quarks and leptons are suppressed in (94.1) and (94.2). If a leptoquark couples to quarks (leptons) belonging to more than a single generation in the mass eigenbasis, it can induce two-quark two-lepton interactions causing flavor-changing neutral currents (lepton-family-number violations). Since indirect limits provide more stringent constraints on non-chiral or flavor-violating leptoquarks, in the searches of leptoquark states at collider experiments, it is often assumed that a leptoquark state couples only to a single generation of quarks and a single generation of leptons in a chiral interaction, for which indirect limits become much weaker. Additionally, this assumption gives strong constraints on models of leptoquarks.

Refs. [16–18] give extensive lists of the bounds on the leptoquark-induced two-quark two-lepton interactions. For the isoscalar scalar and vector leptoquarks S_0 and V_0, for example, which couple with the first- (second-) generation left-handed quark, and the first-generation left-handed lepton, the bounds $\lambda^2 < 0.07 \times (M_{\rm LQ}/1\ {\rm TeV})^2$ for S_0, and $\lambda^2 < 0.4 \times (M_{\rm LQ}/1\ {\rm TeV})^2$ for V_0 ($\lambda^2 < 0.7 \times (M_{\rm LQ}/1\ {\rm TeV})^2$ for S_0, and $\lambda^2 < 0.5 \times (M_{\rm LQ}/1\ {\rm TeV})^2$ for V_0) with λ being the leptoquark coupling strength, can be derived from the limits listed in Ref. [18]. See also Refs. [19, 20] for earlier studies. The e^+e^- collider experiments are sensitive to the indirect effects coming from t- and u-channel exchanges of leptoquarks in the $e^+e^- \to q\bar{q}$ process. The HERA experiments give bounds on the leptoquark-induced two-quark two-lepton interaction. It should also be stressed that the measurements of the high-mass Drell-Yan cross sections, $pp \to \ell\nu$ and $pp \to \ell^+\ell^-$, are also sensitive to these leptoquark-induced interactions. For detailed bounds obtained in this way, see *e.g.,* Ref. [17], and the Heavy Boson Particle Listings for "Indirect Limits for Leptoquarks" and their references.

Note that the two-quark two-lepton interactions arising from the leptoquark exchanges in Eq.(94.1) and Eq.(94.2) can also be regarded as a part of more general dimension-six operators in the context of low-energy standard-model effective field theory (SMEFT). For a complete list of SM gauge-invariant dimension-six operators, see [21, 22]. A computation of the one-loop anomalous dimension matrix for SMEFT operators are found in Refs. [23–25]. The leptoquark induced two-quark two-lepton interactions often cause lepton-flavor non-universalities in heavy quark decays. The $R(D)$, $R(D^*)$ anomaly observed in the semi-leptonic B decays [26] may be explained in models with TeV scale leptoquarks.

Collider experiments provide direct limits on the leptoquark states through limits on the pair- and single-production cross sections. The leading-order cross sections of the parton processes

$$\begin{aligned}
&q + \bar{q} \to {\rm LQ} + \overline{\rm LQ}\\
&g + g \to {\rm LQ} + \overline{\rm LQ}\\
&e + q \to {\rm LQ}
\end{aligned} \tag{94.3}$$

may be written as [27]

$$\begin{aligned}
\hat{\sigma}_{\rm LO}\Big[q\bar{q} \to {\rm LQ} + \overline{\rm LQ}\Big] &= \frac{2\alpha_s^2\pi}{27\hat{s}}\beta^3,\\
\hat{\sigma}_{\rm LO}\Big[gg \to {\rm LQ} + \overline{\rm LQ}\Big] &= \frac{\alpha_s^2\pi}{96\hat{s}}\\
&\quad\times\left[\beta(41 - 31\beta^2) + (18\beta^2 - \beta^4 - 17)\log\frac{1+\beta}{1-\beta}\right],\\
\hat{\sigma}_{\rm LO}\Big[eq \to {\rm LQ}\Big] &= \frac{\pi\lambda^2}{4}\delta(\hat{s} - M^2_{\rm LQ})
\end{aligned} \tag{94.4}$$

for a scalar leptoquark. Here $\sqrt{\hat{s}}$ is the invariant energy of the parton subprocess, and $\beta \equiv \sqrt{1 - 4M^2_{\rm LQ}/\hat{s}}$. The leptoquark Yukawa coupling is given by λ. The cross sections of the pair productions of scalar leptoquarks in pp collisions at the LHC energies have been computed in Refs. [28, 29] at the next-to-leading order in QCD. Leptoquarks are also produced singly at hadron colliders through $g + q \to {\rm LQ} + \ell$ [30], which allows extending to higher

Table 94.1: Possible leptoquarks and their quantum numbers.

Spin	$3B+L$	$SU(3)_c$	$SU(2)_W$	$U(1)_Y$	Allowed coupling
0	-2	3	1	1/3	$\bar{q}_L^c \ell_L$ or $\bar{u}_R^c e_R$
0	-2	$\bar{3}$	1	4/3	$\bar{d}_R^c e_R$
0	-2	$\bar{3}$	3	1/3	$\bar{q}_L^c \ell_L$
1	-2	$\bar{3}$	2	5/6	$\bar{q}_L^c \gamma^\mu e_R$ or $\bar{d}_R^c \gamma^\mu \ell_L$
1	-2	$\bar{3}$	2	$-1/6$	$\bar{u}_R^c \gamma^\mu \ell_L$
0	0	3	2	7/6	$\bar{q}_L e_R$ or $\bar{u}_R \ell_L$
0	0	3	2	1/6	$\bar{d}_R \ell_L$
1	0	3	1	2/3	$\bar{q}_L \gamma^\mu \ell_L$ or $\bar{d}_R \gamma^\mu e_R$
1	0	3	1	5/3	$\bar{u}_R \gamma^\mu e_R$
1	0	3	3	2/3	$\bar{q}_L \gamma^\mu \ell_L$

masses the collider reach in the leptoquark search [31], depending on the leptoquark Yukawa coupling. The next-to-leading order computations for the single production of the leptoquark states at the LHC energies have been performed in Refs. [32–35]. Since protons contain leptons inside, it is possible to target lepton-induced processes at high energy pp colliders. The single leptoquark production cross sections induced from the lepton-quark collisions at the LHC have been computed in Refs. [36,37]. Ref. [38] performed searches for the leptoquark states produced in lepton-quark collisions at the LHC.

See Ref. [17] for a comprehensive review on the leptoquark phenomenology in precision experiments and particle colliders.

Leptoquark states which couple only to left- or right-handed quarks are called chiral leptoquarks. Leptoquark states which couple only to the first (second, third) generation are referred as the first- (second-, third-) generation leptoquarks.

The LHC, Tevatron and LEP experiments have been searching for pair production of the leptoquark states, which arises from the leptoquark gauge interaction. Due to the typical decay of the leptoquark into charged and neutral leptons and quarks, the searches are carried on in signatures including high p_T charged leptons, high E_T jets and large missing transverse energy. Additionally, searches for pair produced LQs are often organized by the decay mode of the pair of LQs, via the decay parameter β, which represents the branching fraction into a charge lepton vs a neutrino: $\beta = 1$ for LQs decaying into a charged lepton with 100% branching fraction, $\beta = 0.5$ for LQs decaying into a charged lepton with 50% branching fraction. The gauge couplings of a scalar leptoquark are determined uniquely according to its quantum numbers in Table 94.1. Since all of the leptoquark states belong to color-triplet representation, the scalar leptoquark QCD-induced pair-production cross section at the Tevatron and LHC can be determined solely as a function of the leptoquark mass without making further assumptions. This is in contrast to the indirect or single-production limits, which give constraints in the leptoquark mass-coupling plane.

Older results from the Tevatron run can be found here: [39–42].

Since the previous version of this review, both ATLAS and CMS continue to update their results concerning searches for first, second, and third generation LQs and leptoquark states which couple only with the i-th generation quarks and the j-th generation leptons ($i \neq j$) without causing conflicts with severe indirect constraints. The datasets were almost all collected at center of mass energy of 13 TeV and corresponding to the latest integrated luminosity collected before the shutdown of the LHC occurring in 2019 and 2020.

It is worthy to note that organizing LQs by flavor quantum number first before organizing them by gauge quantum number is becoming more common and advantageous because it relates more closely to some of the experimental searches being performed. The traditional nomenclature for 1st, 2nd, and 3rd generation LQ encourages only looking for the diagonal elements in a flavor matrix of possibilities, which has been the traditional experimental search strategy.

Current results extend previous mass limits for scalar leptoquarks to $>$ 1435 GeV (first generation, CMS, β =1, $\sqrt{s}$ = 13 TeV) and $>$ 1270 GeV(first generation, CMS, β =0.5,$\sqrt{s}$ = 13 TeV) [43]; $>$ 1800 GeV (first generation, ATLAS, β =1, $\sqrt{s}$ = 13 TeV) [44] and $>$ 1290 GeV (first generation, ATLAS, β =0.5, $\sqrt{s} = 13$ TeV) [45]; $>$ 1530 GeV (second generation, CMS, β =1, $\sqrt{s} = 13$ TeV) and $>$ 1285 GeV (second generation, CMS, β =0.5, $\sqrt{s} = 13$ TeV) [46]; and $>$ 1700 GeV (second generation, ATLAS, β =1,$\sqrt{s}$ = 13 TeV) [44] and $>$ 1230 GeV (second generation, ATLAS, β =0.5,$\sqrt{s}$ = 13 TeV) [45]. All limits are presented at 95% C.L.

As for third generation leptoquarks, CMS results are the following: 1) assuming that all leptoquarks decay to a top quark and a τ lepton, the existence of pair produced, third-generation leptoquark up to a mass of 1120 GeV (β =1, 13 TeV) is excluded at 95% confidence level [47]; 2) assuming that all leptoquarks decay to a bottom quark and a τ lepton, the existence of pair produced, third-generation leptoquark up to a mass of 1020 GeV (β =1, 13 TeV) is excluded at 95% confidence level [48]; 3) assuming that all leptoquarks decay to a bottom quark and a τ neutrino, the existence of pair produced, third-generation leptoquark up to a mass of 1185 GeV (β =0, 13 TeV) is excluded at 95% confidence level [49]. In a recent paper [50] signatures of top quark τ lepton ν bottom and top τ ν - not previously explored in dedicated searches, were analyzed in the context of searches for scalar leptoquark of charge -1/3e coupling to a top quark plus a τ lepton (tτ) or a bottom quark plus a neutrino (bν), or a vector particle of charge +2/3e, coupling to tν or bτ. These choices are motivated by models that can explain a series of anomalies observed in the measurement of B meson decays. The data are found to be in agreement with the standard model prediction. Lower limits at 95% confidence level are set on the LQ mass in the range 0.98–1.73 TeV, depending on the LQ spin and its coupling λ to a lepton and a quark, and assuming equal couplings for the two LQ decay modes considered. These are the most stringent constraints to date on the existence of leptoquarks in this scenario.

In [51] ATLAS present the result of searches for pair production of third-generation scalar leptoquarks decaying into a top quark and a τ-lepton, using 139 fb^{-1} of data collected at 13 TeV. Scalar leptoquarks decaying exclusively into tτ are excluded up to masses of 1.43 TeV while, for a branching fraction of 50% into tτ , the lower mass limit is 1.22 TeV. In two recent papers [52] and [53] ATLAS searched for pair-produced scalar or vector leptoquarks decaying into a b-quark and a τ-lepton and single production of vector leptoquarks with electric charge of 2/3e and scalar leptoquarks with an electric charge of 4/3e. For pair production of scalar leptoquarks, masses below 1490 GeV are excluded assuming a 100% branching ratio, while for vector leptoquarks the corresponding limit is 1690 GeV (1960 GeV) in the minimal-coupling (Yang–Mills) scenario. For single vector leptoquark production two models are considered: the Yang–Mills and Minimal coupling models. In the Yang–Mills (Minimal coupling) scenario, vector leptoquarks with a mass below 1.58 (1.35) TeV are excluded for a gauge coupling of 1.0 and below 2.05 (1.99) TeV for a gauge coupling of 2.5. In the case of single scalar leptoquark production, masses below 1.28 TeV (1.53 TeV) are excluded for a Yukawa coupling of 1.0 (2.5). Additionally, a search for pair production of leptoquarks with decays into third-generation leptons and quarks. in final states with hadronically decaying τ leptons, b-jets, and missing transverse momentum was performed in [54]: depending on the branching fraction into charged leptons, leptoquarks with masses up to around 1.25 TeV can be excluded at

the 95% confidence level for the case of scalar leptoquarks and up to 1.8 TeV (1.5 TeV) for vector leptoquarks in a Yang–Mills (minimal-coupling) scenario.

It is also possible to consider leptoquark states which couple only with the i-th generation quarks and the j-th generation leptons ($i \neq j$) without causing conflicts with severe indirect constraints. Such couplings have received renewed attention because they may provide an explanation to anomalies in rare $B-meson$ decays and the anomalous magnetic moment of the muon. See Ref. [55, 56] and [57] and references therein for collider search strategies and limits on the pair production cross sections of this class of leptoquark states. In this framework, in [58] and [47] CMS presents a non-traditional search for pair production of LQs coupled to a top quark and a leptons. As no deviation from the Standard Model prediction was observed, scalar LQs decaying exclusively into top quark and lepton are excluded below 1.12−1.42 TeV depending on the lepton flavor. In [59] ATLAS conducted a search for pair production of scalar and vector leptoquarks, each decaying into first and second generation leptons and a third generation quarks. This is part of leptoquark search using ATLAS data to investigate cross- generational couplings that could provide explanations for recently observed anomalies in B meson decays. All possible decays of the pair-produced leptoquarks into quarks of the third generation and charged or neutral leptons of the first or second generation with exactly one electron or muon in the final state are investigated. No significant deviations from the Standard Model expectation are observed. Upper limits on the production cross-section are provided for different models as a function of the leptoquark mass and the branching ratio of the leptoquark into the charged or neutral lepton. Some of these models have the goal of providing an explanation for the recent B-anomalies. In such models, a vector leptoquark decays into charged and neutral leptons of the second generation with a similar branching fraction. Lower limits of 1.9 TeV and 1.7 TeV are set on the leptoquark mass for these two models.

The magnetic-dipole-type and the electric-quadrupole-type interactions of a vector leptoquark are not determined even if we fix its gauge quantum numbers as listed in the Table 94.1 [60]. The production of vector leptoquarks depends in general on additional assumptions, where the leptoquark couplings and their pair production cross sections are enhanced relative to the scalar leptoquark contributions. The most stringent limits on vector LQ production are now from CMS [61] where previous searches for squarks and gluinos have been reinterpreted to constrain models of leptoquark production. LQ masses below 1530 GeV are excluded assuming the Yang-Mills case with coupling $\kappa = 1$, or 1115 GeV in the minimal coupling case where $\kappa = 0$, placing the most stringent constraint to date from pair production of vector LQs. These results and the ones in [62] were updated in [49] where searches for phenomena beyond the standard model (BSM) were performed using events with hadronic jets and significant transverse momentum imbalance to constrain a range of BSM models including the pair production of scalar and vector leptoquarks each decaying to a neutrino and a top, bottom, or light-flavor quark.

The leptoquark pair-production cross sections in e^+e^- collisions depend on the leptoquark $SU(2) \times U(1)$ quantum numbers and Yukawa coupling with electron [63].

Searches for first generation leptoquark singly produced were performed by the HERA experiments. Since the leptoquark single-production cross section depends on its Yukawa coupling, the leptoquark mass limits from HERA are usually displayed in the mass-coupling plane. For leptoquark Yukawa coupling $\lambda = 0.1$, early ZEUS Collaboration bounds on the first-generation leptoquarks range from 248 to 290 GeV, depending on the leptoquark species [64]. The ZEUS Collaboration has recently released a new paper [65] where data corresponding to a luminosity of around 1 fb^{-1} have been used in the framework of *eeqq* contact interactions (CI) to set limits on possible high-energy contributions beyond the Standard Model to electron-quark scattering. The analysis of the *ep* data has been based on simultaneous fits of parton distribution functions including contributions of Contact Interaction (CI) couplings to *ep* scattering. Several general CI models and scenarios with heavy leptoquarks were considered. As unambiguous deviations from the SM cannot be established, limits for CI compositeness scales and LQ mass scales were set that are in the TeV range. The H1 Collaboration has a comprehensive summary of searches for first generation leptoquarks using the full data sample collected in *ep* collisions at HERA (446 pb^{-1}). No evidence of production of leptoquarks was observed in final states with a large transverse momentum electron or large missing transverse momentum. For a coupling strength $\lambda = 0.3$, first generation leptoquarks with masses up to 800 GeV are excluded at 95% C.L. [66].

At the LHC, the CMS collaboration performed searches for single production of first and second generation leptoquarks [67], which is complementary to the HERA searches in the high λ region (for coupling strength $\lambda = 1.0$, first generation leptoquarks are excluded for masses up to 1.73 TeV and second generation leptoquark are excluded up to masses of 530 GeV). CMS also recently searched for third generation LQ decaying into τ and *bottom* in [68]. Assuming unit Yukawa coupling (λ), a third generation scalar leptoquark is excluded for masses below 740 GeV. Limits are also set on λ of the hypothesized leptoquark as a function of its mass. Above $\lambda = 1.4$, the results provide the best upper limit on the mass of a third-generation scalar leptoquark decaying to a τ lepton and a bottom quark.

Searches for LQ will continue with more LHC data, particularly in light of the renewed interest in this type of particle to explain violation of lepton flavor universality and other anomalies, which point to explanations laying outside the Standard Model.

95. Magnetic Monopoles

Revised March 2024 by D. Milstead (Stockholm U.) and E.J. Weinberg (Columbia U.).

95.1 Theory of magnetic monopoles

The symmetry between electric and magnetic fields in the source-free Maxwell's equations naturally suggests that electric charges might have magnetic counterparts, known as magnetic monopoles. Although the greatest interest has been in the supermassive monopoles that are a firm prediction of all grand unified theories, one cannot exclude the possibility of lighter monopoles.

In either case, the magnetic charge is constrained by a quantization condition first found by Dirac [1]. Consider a monopole with magnetic charge Q_M and a Coulomb magnetic field

$$\mathbf{B} = \frac{Q_M}{4\pi}\frac{\hat{\mathbf{r}}}{r^2}\,. \tag{95.1}$$

Any vector potential $\mathbf{A}$ whose curl is equal to $\mathbf{B}$ must be singular along some line running from the origin to spatial infinity. This Dirac string singularity could potentially be detected through the extra phase that the wavefunction of a particle with electric charge Q_E would acquire if it moved along a loop encircling the string. For the string to be unobservable, this phase must be a multiple of 2π. Requiring that this be the case for any pair of electric and magnetic charges gives the condition that all charges be integer multiples of minimum charges $Q_E^{\rm min}$ and $Q_M^{\rm min}$ obeying

$$Q_E^{\rm min}Q_M^{\rm min} = 2\pi\,. \tag{95.2}$$

(For monopoles which also carry an electric charge, called dyons [2], the quantization conditions on their electric charges can be modified. However, the constraints on magnetic charges, as well as those on all purely electric particles, will be unchanged.)

Another way to understand this result is to note that the conserved orbital angular momentum of a point electric charge moving in the field of a magnetic monopole has an additional component, with

$$\mathbf{L} = m\mathbf{r}\times\mathbf{v} - 4\pi Q_E Q_M\hat{\mathbf{r}} \tag{95.3}$$

Requiring the radial component of $\mathbf{L}$ to be quantized in half-integer units yields Eq. 95.2.

If there are unbroken gauge symmetries in addition to the U(1) of electromagnetism, the above analysis must be modified [3, 4]. For example, a monopole could have both a U(1) magnetic charge and a color magnetic charge. The latter could combine with the color charge of a quark to give an additional contribution to the phase factor associated with a loop around the Dirac string, so that the U(1) charge could be the Dirac charge $Q_M^D \equiv 2\pi/e$, the result that would be obtained by substituting the electron charge into Eq. (95.2). On the other hand, for monopoles without color-magnetic charge, one would simply insert the quark electric charges into Eq. 95.2 and conclude that Q_M must be a multiple of $6\pi/e$.

The prediction of GUT monopoles arises from the work of 't Hooft [5] and Polyakov [6], who showed that certain spontaneously broken gauge theories have nonsingular classical solutions that lead to magnetic monopoles in the quantum theory. The simplest example occurs in a theory where the vacuum expectation value of a triplet Higgs field ϕ breaks an SU(2) gauge symmetry down to the U(1) of electromagnetism and gives a mass M_V to two of the gauge bosons. In order to have finite energy, ϕ must approach a vacuum value at infinity. However, there is a continuous family of possible vacua, since the scalar field potential determines only the magnitude v of $\langle\phi\rangle$, but not its orientation in the internal SU(2) space. In the monopole solution, the direction of ϕ in internal space is correlated with the position in physical space; *i.e.*, $\phi^a \sim v\hat{r}^a$. The stability of the solution follows from the fact that this twisting Higgs field cannot be smoothly deformed to a spatially uniform vacuum configuration. Reducing the energetic cost of the spatial variation of ϕ requires a nonzero gauge potential, which turns out to yield the magnetic field corresponding to a charge $Q_M = 4\pi/e$. Numerical solution of the classical field equations shows that the mass of this monopole is

$$M_{\rm mon} \sim \frac{4\pi M_V}{e^2}\,. \tag{95.4}$$

The essential ingredient here was the fact that the Higgs fields at spatial infinity could be arranged in a topologically nontrivial configuration. A discussion of the general conditions under which this is possible is beyond the scope of this review, so we restrict ourselves to the two phenomenologically most important cases.

The first is the standard electroweak theory, with $\mathrm{SU}(2)\times\mathrm{U}(1)$ broken to U(1). There are no topologically nontrivial configurations of the Higgs field, and hence no topologically stable monopole solutions. Although electroweak scale monopoles are thus not required, there have been claims that they might not be ruled out. For example, there have been a variety of proposals in this direction involving modifications of the Lagrangian.

The second case is when any simple Lie group is broken to a subgroup with a U(1) factor, a case that includes all grand unified theories. Here the spectrum of states must include a topologically stable monopole whose mass is determined by the mass scale of the symmetry breaking that allows nontrivial topology. For example, an SU(5) model with

$$\mathrm{SU}(5) \xrightarrow{M_X} \mathrm{SU}(3)\times\mathrm{SU}(2)\times\mathrm{U}(1) \xrightarrow{M_W} \mathrm{SU}(3)\times\mathrm{U}(1) \tag{95.5}$$

has a monopole [7] with $Q_M = 2\pi/e$ and mass

$$M_{\rm mon} \sim \frac{4\pi M_{\rm X}}{g^2}\,, \tag{95.6}$$

where g is the SU(5) gauge coupling. For a unification scale of 10^{16} GeV, these monopoles would have a mass $M_{\rm mon} \sim 10^{17}$ – 10^{18} GeV.

In theories with several stages of symmetry breaking, monopoles of different mass scales can arise. In an SO(10) theory with

$$\mathrm{SO}(10) \xrightarrow{M_1} \mathrm{SU}(4)\times\mathrm{SU}(2)\times\mathrm{SU}(2) \xrightarrow{M_2} \mathrm{SU}(3)\times\mathrm{SU}(2)\times\mathrm{U}(1) \tag{95.7}$$

there is monopole with $Q_M = 2\pi/e$ and mass $\sim 4\pi M_1/g^2$ and a much lighter monopole with $Q_M = 4\pi/e$ and mass $\sim 4\pi M_2/g^2$ [8].

The central core of a GUT monopole contains the fields of the superheavy gauge bosons that mediate baryon number violation, so one might expect that baryon number conservation could be violated in baryon–monopole scattering. The surprising feature, pointed out by Callan [9] and Rubakov [10], is that these processes are not suppressed by powers of the gauge boson mass. Instead, the cross-sections for catalysis processes such as p + monopole $\to e^+ + \pi^0$ + monopole are essentially geometric; *i.e.*, $\sigma_{\Delta B}\beta \sim 10^{-27}$ cm^2, where $\beta = v/c$. Note, however, that this catalysis is model-dependent and is not even a universal property of all GUT monopoles.

95.2 Production and Annihilation

GUT monopoles are far too massive to be produced in any foreseeable accelerator. However, they could have been produced in the early Universe as topological defects arising via the Kibble mechanism [11] in a symmetry-breaking phase transition. Estimates of the initial monopole abundance, and of the degree to which it can be reduced by monopole-antimonopole annihilation, predict a present-day monopole abundance that exceeds by many orders of magnitude the astrophysical and experimental bounds described below [12]. Cosmological inflation and other proposed solutions to this primordial monopole problem generically lead to present-day abundances exponentially smaller than could be plausibly detected, although potentially observable abundances can be obtained in scenarios with carefully tuned parameters.

If monopoles light enough to be produced at colliders exist, one would expect that these could be produced by analogs of the electromagnetic processes that produce pairs of electrically charged particles. Because of the large size of the magnetic charge, this is a strong coupling problem for which perturbation theory cannot be trusted. Indeed, the problem of obtaining reliable quantitative estimates of the production cross-sections remains an open one, on which there is no clear consensus.

95.3 Astrophysical and Cosmological Bounds

If there were no galactic magnetic field, one would expect monopoles in the galaxy to have typical velocities of the order of $10^{-3}c$, comparable to the virial velocity in the galaxy (relevant if the monopoles cluster with the galaxy) and the peculiar velocity of the galaxy with respect to the CMB rest frame (relevant if the monopoles are not bound to the galaxy). This situation is modified by the existence of a galactic magnetic field $B \sim 3\mu$G. A monopole with the Dirac charge and mass M would be accelerated by this field to a velocity

$$v_{\rm mag} \sim \begin{cases} c, & M \lesssim 10^{11}{\rm GeV}\,, \\ 10^{-3}c\left(\frac{10^{17}\,{\rm GeV}}{M}\right)^{1/2}, & M \gtrsim 10^{11}{\rm GeV}\,. \end{cases} \quad (95.8)$$

Accelerating these monopoles drains energy from the magnetic field. Parker [13] obtained an upper bound on the flux of monopoles in the galaxy by requiring that the rate of this energy loss be small compared to the time scale on which the galactic field can be regenerated. With reasonable choices for the astrophysical parameters (see Ref. [14] for details), this Parker bound is

$$F < \begin{cases} 10^{-15}\,{\rm cm}^{-2}\,{\rm sr}^{-1}\,{\rm sec}^{-1}\,, & M \lesssim 10^{17}\,{\rm GeV}\,, \\ 10^{-15}\left(\frac{M}{10^{17}\,{\rm GeV}}\right){\rm cm}^{-2}\,{\rm sr}^{-1}\,{\rm sec}^{-1}\,, & M \gtrsim 10^{17}\,{\rm GeV}\,. \end{cases} \quad (95.9)$$

Applying similar arguments to an earlier seed field that was the progenitor of the current galactic field leads to a tighter bound [15],

$$F < \left[\frac{M}{10^{17}{\rm GeV}} + (3\times 10^{-6})\right] 10^{-16}\,{\rm cm}^{-2}{\rm sr}^{-1}{\rm sec}^{-1}. \quad (95.10)$$

Considering magnetic fields in galactic clusters gives a bound [16] which, although less secure, is about three orders of magnitude lower than the Parker bound.

A flux bound can also be inferred from the total mass of monopoles in the Universe. If the monopole mass density is a fraction $\Omega_{\rm M}$ of the critical density, and the monopoles were uniformly distributed throughout the Universe, there would be a monopole flux

$$F_{\rm uniform} = 1.3{\times}10^{-16}\Omega_{\rm M}\left(\frac{10^{17}\,{\rm GeV}}{M}\right)\left(\frac{v}{10^{-3}c}\right){\rm cm}^{-2}{\rm sr}^{-1}{\rm sec}^{-1}. \quad (95.11)$$

If we assume that $\Omega_{\rm M} \sim 0.1$, this gives a stronger constraint than the Parker bound for $M \sim 10^{15}$ GeV. However, monopoles with masses $\sim 10^{17}$ GeV are not ejected by the galactic field and can be gravitationally bound to the galaxy. In this case their flux within the galaxy is increased by about five orders of magnitude for a given value of $\Omega_{\rm M}$, and the mass density bound only becomes stronger than the Parker bound for $M \sim 10^{18}$ GeV.

A much more stringent flux bound applies to GUT monopoles that catalyze baryon number violation. The essential idea is that compact astrophysical objects would capture monopoles at a rate proportional to the galactic flux. These monopoles would then catalyze proton decay, with the energy released in the decay leading to an observable increase in the luminosity of the object. A variety of bounds, based on neutron stars [17–21] , white dwarfs [22], and Jovian planets [23] have been obtained. These depend in the obvious manner on the catalysis cross section, but also on the details of the astrophysical scenarios; *e.g.*, on how much the accumulated density is reduced by monopole-antimonopole annihilation, and on whether monopoles accumulated in the progenitor star survive its collapse to a white dwarf or neutron star. The bounds obtained in this manner lie in the range

$$F\left(\frac{\sigma_{\Delta B}\beta}{10^{-27}{\rm cm}^2}\right) \sim (10^{-18} - 10^{-29}){\rm cm}^{-2}{\rm sr}^{-1}{\rm sec}^{-1}. \quad (95.12)$$

It is important to remember that not all GUT monopoles catalyze baryon number nonconservation. In particular, the intermediate mass monopoles that arise in some GUTs at later stages of symmetry-breaking are examples of theoretically motivated monopoles that are exempt from the bound of the above equation.

95.4 Searches for Magnetic Monopoles

To date there have been no confirmed observations of exotic particles possessing magnetic charge. Precision measurements of the properties of known particles have led to tight limits on the values of magnetic charge they may possess. Using the induction method (see below), the electron's magnetic charge has been found to be $Q_e^m < 10^{-24}Q_M^D$ [24]. Furthermore, measurements of the anomalous magnetic moment of the muon have been used to place a model dependent lower limit of 120 GeV on the monopole mass [1] [25]. Nevertheless, guided mainly by Dirac's argument and the predicted existence of monopoles from spontaneous symmetry breaking mechanisms, searches have been routinely made for monopoles produced at accelerators, in cosmic rays, and bound in matter [26]. Although the resultant limits from such searches are usually made under the assumption of a particle possessing only magnetic charge, most of the searches are also sensitive to dyons.

95.5 Search Techniques

Search strategies are determined by the expected interactions of monopoles as they pass through matter. These would give rise to a number of striking characteristic signatures. Since a complete description of monopole search techniques falls outside of the scope of this minireview, only the most common methods are described below. More comprehensive descriptions of search techniques can be found in Refs. [27, 28].

The induction method exploits the long-range electromagnetic interaction of the monopole with the quantum state of a superconducting ring which would lead to a monopole which passes through such a ring inducing a permanent current. The induction technique typically uses Superconducting Quantum Interference Devices (SQUID) technology for detection and is employed for searches for monopoles in cosmic rays and matter. Another approach is to exploit the electromagnetic energy loss of monopoles. Monopoles with Dirac charge would typically lose energy at a rate which is several thousand times larger than that expected from particles possessing the elementary electric charge. Consequently, scintillators, gas chambers and nuclear track detectors (NTDs) have been used in cosmic ray and collider experiments. A further approach, which has been used at colliders, is to search for particles describing a non-helical path in a uniform magnetic field.

95.5.1 *Searches for Monopoles Bound in Matter*

Monopoles have been sought in a range of bulk materials which it is assumed would have absorbed incident cosmic ray monopoles over a long exposure time of order million years. Materials which have been studied include moon rock, meteorites, manganese modules, and sea water [29, 30]. A stringent upper limit on the monopoles per nucleon ratio of $\sim 10^{-29}$ has been obtained [30].

95.5.2 *Searches in Cosmic Rays*

Direct searches for monopoles in cosmic rays refer to those experiments in which the passage of the monopole is measured by an active detector. Searches made assuming a catalysis processes in which GUT monopoles could induce nucleon decay are discussed in the next section. To interpret the results of the non-catalysis searches, the cross section for the catalysis process is typically either set to zero [31] or assigned a modest value (1mb) [32].

Although early cosmic ray searches using the induction technique [33] and NTDs [34] observed monopole candidates, none of these apparent observations have been confirmed. Recent experiments have typically employed large scale detectors. The MACRO experiment at the Gran Sasso underground laboratory comprised three different types of detector: liquid scintillator, limited stream tubes, and NTDs, which provided a total acceptance of $\sim$ 10000m^2 for an isotropic flux. As shown in Fig. 95.1, this experiment has so far provided the most extensive β-dependent flux limits for GUT monopoles with Dirac charge [32]. Also shown

[1] Where no ambiguity is likely to arise, a reference to a monopole implies a particle possessing Dirac charge.

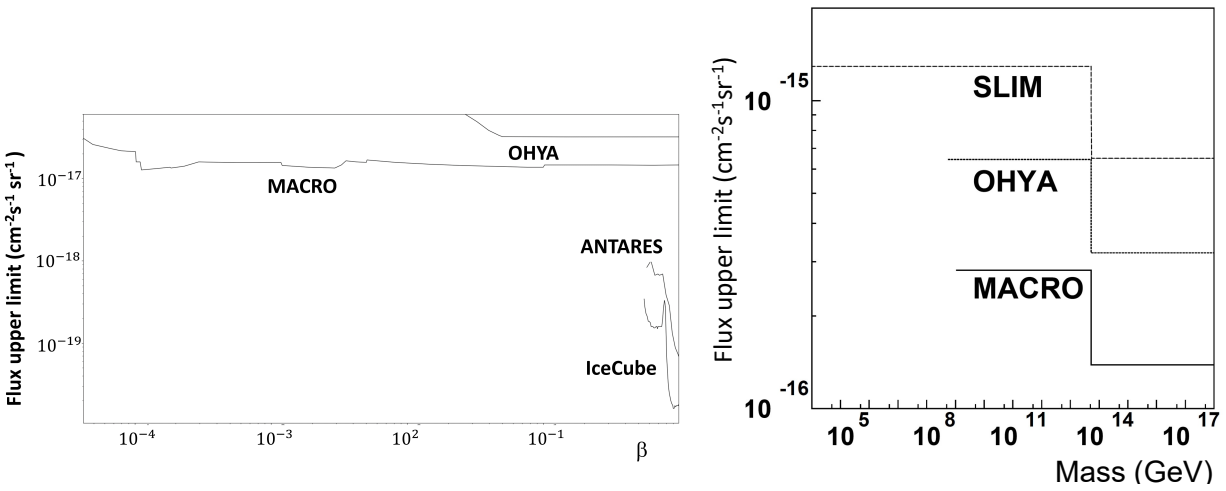

Figure 95.1: Left: upper flux limits for GUT monopoles as a function of β. Right: upper flux limits for monopoles as a function of monopole mass for $\beta > 0.05$.

are limits from an experiment at the OHYA mine in Japan [31], which used a 2000m^2 array of NTDs, and from the IceCube [35,36] and Antares [37] experiments which each employ the Cerenkov method.

In Fig. 95.1, upper flux limits are also shown as a function of monopole mass for monopole speed $\beta > 0.05$. In addition to MACRO and OYHA flux limits, results from the SLIM [38] high-altitude experiment are shown. The SLIM experiment provided a good sensitivity to intermediate mass monopoles ($10^5 \lesssim M \lesssim 10^{12}$ GeV).

In addition to the results shown in Fig. 95.1, the NoVA experiment [39] has recently set an upper limit on monopole flux of 2×10^{-14} cm^{-2}s^{-1}sr^{-1} for speeds $6 \times 10^{-4} < \beta < 10^{-3}$ for masses greater thsan 5×10^8 GeV. Stringent constraints on the flux of ultra-relativistic monopoles have been obtained at the Pierre Auger Observatory [40] which was sensitive to monopoles with γ values ranging from 10^9 to 10^{12}, leading to flux limits in the range $10^{-15} - 2.5 \times 10^{-21}$ cm^{-2}s^{-1}sr^{-1}. The RICE [41] and ANITA-II experiments [42] at the South Pole have also sought ultra-relativistic monopoles with γ values of $10^7 \lesssim \gamma \lesssim 10^{12}$ and $10^9 \lesssim \gamma \lesssim 10^{13}$, respectively, and which produced flux limits as low as 2.5×10^{-21} cm^{-2}s^{-1}sr^{-1}.

95.5.3 *Searches via the Catalysis of Nucleon-Decay*

Searches have been performed for evidence of the catalysed decay of a nucleon by a monopole, as predicted by the Callan-Rubakov mechanism. The searches are thus sensitive to the assumed value of the catalysis decay cross section. Searches have been made with the Soudan [43] and Macro [44] experiments, using tracking detectors. Searches at IMB [45], the underwater Lake Baikal experiment [46,47] and the IceCube experiment [48] which exploit the Cerenkov effect have also been made. The resulting β-dependent flux limits from these experiments typically vary between $\sim 10^{-18}$ and $\sim 10^{-14}$cm^{-2}sr^{-1}s^{-1}. A search for low energy neutrinos (assumed to be produced from induced proton decay in the sun) was made at Super-Kamiokande [49]. A model- and β-dependent of limit of $6.3 \times 10^{-24}(\frac{\beta}{10^{-3}})^2$cm^{-2}sr^{-1}s^{-1} was obtained.

95.5.4 *Searches at Colliders*

Searches have been performed at hadron-hadron, electron-positron and lepton-hadron experiments. Collider searches can be broadly classed as being direct or indirect. In a direct search, evidence of the passage of a monopole through material, such as a charged particle track, is sought. In indirect searches, virtual monopole processes are assumed to influence the production rates of certain final states.

95.5.4.1 *Direct Searches at Colliders*

Collider experiments typically express their results in terms of upper limits on a production cross section and/or monopole mass. To calculate these limits, ansatzes are used to model the kinematics of monopole-antimonopole pair production processes since perturbative field theory cannot be used to calculate the rate and kinematic properties of produced monopoles. Limits therefore suffer from a degree of model-dependence, implying that a comparison between the results of different experiments can be problematic, in particular when this concerns excluded mass regions. A conservative approach with as little model-dependence as possible is thus to present representative values of the upper cross-section limits as a function of the centre-of-mass energy of the collisions, as shown in Fig. 95.2 for recent results from high energy colliders.

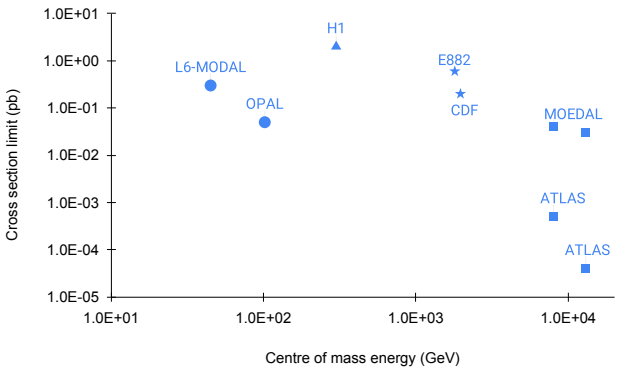

Figure 95.2: Upper limits on the production cross sections of monopoles from various collider-based experiments. Results from lepton-hadron (triangle), electron-positron (filled circle), proton-antiproton (star) and proton-proton (filled square) experiments are shown.

Searches for monopoles produced at the highest available energies in hadron-hadron collisions were made in pp collisions at the LHC by the ATLAS [50–53] and MoEDAL [54–57] experiments. ATLAS looked for highly ionising particles leaving a characteristic energy deposition profile in the tracker and calorimeter. MOEDAL used a NTD to tag highly ionising particles and the induction method to search for stopped monopoles. The charge-dependent mass limits extend up to around 4 TeV. The ATLAS experiment has considered hypotheses of monopoles with charges between $0.5Q_M^D$ and $2Q_M^D$ while MoEDAL has quoted limits for monopoles in the charge range Q_M^D to $5Q_M^D$. Models considered include monopole-pair production via photon fusion along with,

as is commonly used in hadron-hadron collisions, Drell-Yan processes [58]. MoEDAL has also looked for monopole produced via the Schwinger mechanism in the intense magnetic field created in PbPb collisions [57]. Tevatron searches have also been carried out by the CDF [59] and E882 [60] experiments. The CDF experiment used a dedicated time-of-flight system whereas the E882 experiment employed the induction technique to search for stopped monopoles in discarded detector material which had been part of the CDF and D0 detectors using periods of luminosity. Earlier searches at the Tevatron, such as [61], used NTDs and were based on comparatively modest amounts of integrated luminosity. Lower energy hadron-hadron experiments have employed a variety of search techniques including plastic track detectors [62] and searches for trapped monopoles [63].

The only LEP-2 search was made by OPAL [64] which quoted cross section limits for the production of monopoles possessing masses up to around 103 GeV. At LEP-1, searches were made with NTDs deployed around an interaction region. This allowed a range of charges to be sought for masses up to ~ 45 GeV. The L6-MODAL experiment [65] gave limits for monopoles with charges in the range $0.9Q_M^D$ and $3.6Q_M^D$, whilst an earlier search by the MODAL experiment was sensitive to monopoles with charges as low as $0.1Q_M^D$ [66]. The deployment of NTDs around the beam interaction point was also used at earlier e^+e^- colliders such as KEK [67] and PETRA [68]. Searches at e^+e^- facilities have also been made for particles following non-helical trajectories [69, 70].

There has so far been one search for monopole production in lepton-hadron scattering. Using the induction method, monopoles were sought which could have stopped in the aluminium beampipe which had been used by the H1 experiment at HERA [71]. Cross section limits were set for monopoles with charges in the range $Q_M^D - 6Q_M^D$ for masses up to around 140 GeV.

95.5.4.2 *Indirect Searches at Colliders*

It has been proposed that virtual monopoles can mediate processes which give rise to multi-photon final-states [72,73]. Photon-based searches were made by the D0 [74] and L3 [75] experiments. The D0 work led to spin-dependent lower mass limits of between 610 and 1580 GeV, while L3 reported a lower mass limit of 510 GeV. However, it should be stressed that uncertainties on the theoretical calculations which were used to derive these limits are difficult to estimate.

VOLUME II: TABLE OF CONTENTS

PARTICLE LISTINGS*

*The divider sheets give more detailed indices for each main section of the Particle Listings.

INTRODUCTION TO THE PARTICLE LISTINGS

Illustrative Key to the Particle Listings

Name of particle. "Old" name used before 1986 renaming scheme also given if different. See the section "Naming Scheme for Hadrons" for details.

$a_0(1200)$

$I^G(J^{PC}) = 1^-(0^{++})$ — Particle quantum numbers (where known).

OMITTED FROM SUMMARY TABLE — Indicates particle omitted from Particle Physics Summary Table, implying particle's existence is not confirmed.

Evidence not compelling, may be a kinematic effect.

Quantity tabulated below.

$a_0(1200)$ MASS

General comments on particle.

Top line gives our best value (and error) of quantity tabulated here, based on weighted average of measurements used. Could also be from fit, best limit, estimate, or other evaluation. See next page for details.

VALUE (MeV)	EVTS	DOCUMENT ID		TECN	CHG	COMMENT
1206± 7 OUR AVERAGE						
1210± 8±9	3000	FENNER	87	MMS	−	3.5 $\pi^- p$
1198±10		PIERCE	83	ASPK	+	2.1 $K^- p$
1216±11±9	1500	[1] MERRILL	81	HBC	0	3.2 $K^- p$
• • • We do not use the following data for averages, fits, limits, etc. • • •						
1192±16	200	LYNCH	81	HBC	±	2.7 $\pi^- p$

"Document id" for this result; full reference given below.

Measurement technique. (See abbreviations on next page.)

Footnote number linking measurement to text of footnote.

[1] Systematic error was added quadratically by us in our 1986 edition.

$a_0(1200)$ WIDTH

Number of events *above background*.

VALUE (MeV)	EVTS	DOCUMENT ID		TECN	CHG	COMMENT
41±11 OUR AVERAGE Error includes scale factor of 1.8. See the ideogram below.						
50± 8		PIERCE	83	ASPK	+	2.1 $K^- p$
70^{+30}_{-20}	200	LYNCH	81	HBC	±	2.7 $\pi^- p$
25 ± 5±7		MERRILL	81	HBC	0	3.2 $K^- p$
• • • We do not use the following data for averages, fits, limits, etc. • • •						
<60		FENNER	87	MMS	−	3.5 $\pi^- p$

Scale factor > 1 indicates possibly inconsistent data.

Reaction producing particle, or general comments.

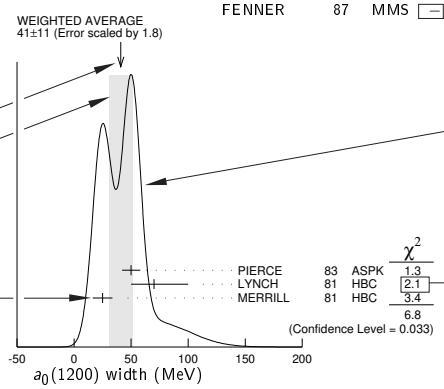
Measured value used in averages, fits, limits, etc.

Error in measured value (often statistical only; followed by systematic if separately known; the two are combined in quadrature for averaging and fitting.)

Measured value *not used* in averages, fits, limits, etc. See the Introductory Text for explanations.

"Change bar" indicates result added or changed since previous edition.

Charge(s) of particle(s) detected.



Ideogram to display possibly inconsistent data. Curve is sum of Gaussians, one for each experiment (area of Gaussian = 1/error; width of Gaussian = ±error). See Introductory Text for discussion.

Arrow points to weighted average.

Shaded pattern extends $\pm 1\sigma$ (scaled by "scale factor" S) from weighted average.

Value and error for each experiment.

Contribution of experiment to χ^2 (if no entry present, experiment not used in calculating χ^2 or scale factor because of very large error).

$a_0(1200)$ DECAY MODES

Mode	Fraction (Γ_i/Γ)	Scale factor/ Confidence level
Γ_1 3π	(65.2±1.3) %	S=1.7
Γ_2 $K\overline{K}$	(34.8±1.3) %	S=1.7
Γ_3 $\eta\pi^\pm$	< 5 $\times 10^{-4}$	CL=95%

Partial decay mode (labeled by Γ_i).

Our best value for branching fraction as determined from data averaging, fitting, evaluating, limit selection, etc. This list is basically a compact summary of results in the Branching Ratio section below.

$a_0(1200)$ BRANCHING RATIOS

Branching ratio.

$\Gamma(3\pi)/\Gamma_{total}$ — Γ_1/Γ

VALUE	DOCUMENT ID		TECN	CHG	COMMENT
0.652±0.013 OUR FIT Error includes scale factor of 1.7.					
0.643±0.010 OUR AVERAGE					
0.64 ±0.01	PIERCE	83	ASPK	+	2.1 $K^- p$
0.74 ±0.06	MERRILL	81	HBC	0	3.2 $K^- p$
• • • We do not use the following data for averages, fits, limits, etc. • • •					
0.48 ±0.15	[2] LYNCH	81	HBC	±	2.7 $\pi^- p$

Our best value (and error) of quantity tabulated, as determined from constrained fit (using *all significant* measured branching ratios for this particle).

Weighted average of measurements of this ratio only.

[2] Data has questionable background subtraction.

Footnote (referring to LYNCH 81).

$\Gamma(K\overline{K})/\Gamma_{total}$ — Γ_2/Γ

VALUE	DOCUMENT ID		TECN	CHG	COMMENT
0.348±0.013 OUR FIT Error includes scale factor of 1.7.					
0.35 ±0.05	PIERCE	83	ASPK	+	2.1 $K^- p$

Branching ratio in terms of partial decay mode(s) Γ_i above.

$\Gamma(K\overline{K})/\Gamma(3\pi)$ — Γ_2/Γ_1

VALUE	DOCUMENT ID		TECN	CHG	COMMENT
0.535±0.030 OUR FIT Error includes scale factor of 1.7.					
0.50 ±0.03	MERRILL	81	HBC	0	3.2 $K^- p$

$\Gamma(\eta(\text{neutral decay})\pi^\pm)/\Gamma_{total}$ — $0.71\Gamma_3/\Gamma$

VALUE (units 10^{-4})	CL%	DOCUMENT ID		TECN	CHG	COMMENT
<3.5	95	PIERCE	83	ASPK	+	2.1 $K^- p$

Confidence level for measured upper limit.

$a_0(1200)$ REFERENCES

References, ordered inversely by year, then author.

Partial list of author(s) in addition to first author.

FENNER	87	PRL 55 14	H. Fenner *et al.*	(SLAC)	
PIERCE	83	PL 123B 230	J.H. Pierce	(FNAL)	JP
LYNCH	81	PR D24 610	G.R. Lynch *et al.*	(CLEO Collab.)	
MERRILL	81	PRL 47 143	D.W. Merrill *et al.*	(SACL, CERN)	

"Document id" used on data entries above.

Quantum number determinations in this reference.

Journal, report, preprint, etc. (See abbreviations on next page.)

Institution(s) of author(s). (See abbreviations on next page.)

Indicator of Procedure Used to Obtain Our Result

OUR AVERAGE	From a weighted average of selected data.
OUR FIT	From a constrained or overdetermined multiparameter fit of selected data.
OUR EVALUATION	Not from a direct measurement, but evaluated from measurements of other quantities.
OUR ESTIMATE	Based on the observed range of the data. Not from a formal statistical procedure.
OUR LIMIT	For special cases where the limit is evaluated by us from measured ratios or other data. Not from a direct measurement.

Measurement Techniques (i.e., Detectors and Methods of Analysis)

A1	A1 Collaboration at MAMI
A2MM	A2 spectrometer at the Mainz Microtron, MAMI
ABRA	ABRACADABRA QCD axion dark matter search
ACCM	ACCMOR Collaboration
ADMX	Axion Dark Matter Experiment
AEMS	Argonne effective mass spectrometer
ALCE	ALICE detector at CERN LHC
ALEP	ALEPH – CERN LEP detector
ALPS	Photon regeneration experiment
AMND	AMANDA South Pole neutrino detector
AMY	AMY detector at KEK-TRISTAN
ANAI	Direct DM detection exp. with NaI at Canfranc Underground Lab, Spain
ANIC	ANTARES and IceCube combined analysis
ANIT	Antarctic Impulsive Transient Antenna balloon mission
ANTR	ANTARES underwater neutrino telescope in the Western Mediterranean Sea
APEX	FNAL APEX Collab.
ARG	ARGUS detector at DORIS
ARGD	Fit to semicircular amplitude path on Argand diagram
ASP	Anomalous single-photon detector
ASPK	Automatic spark chambers
ASTE	ASTERIX detector at LEAR
ASTR	Astronomy
ATLS	ATLAS detector at CERN LHC
AUGE	Pierre Auger Observatory
AURG	Resonant-mass gravitational wave AURIGA detector
B787	BNL experiment 787 detector
B791	BNL experiment 791 detector
B845	BNL experiment 845 detector
B852	BNL E-852
B865	BNL E865 detector
B871	BNL experiment 871 detector
B949	BNL E949 detector at AGS
BABR	BaBar Collab.
BAIK	Lake Baikal neutrino telescope
BAKS	Baksan underground scintillation telescope
BC	Bubble chamber
BDMP	Beam dump
BEAT	CERN BEATRICE Collab.
BEBC	Big European bubble chamber at CERN
BEL2	Belle II Collab.
BELL	Belle Collab.
BES	BES Beijing Spectrometer at Beijing Electron-Positron Collider
BES2	BES Beijing Spectrometer at Beijing Electron-Positron Collider
BES3	BES Beijing Spectrometer at Beijing Electron-Positron Collider
BEST	Baksan Experiment on Sterile Transitions
BIS2	BIS-2 spectrometer at Serpukhov
BKEI	BENKEI spectrometer system at KEK Proton Synchroton
BOLO	Bolometer, a cryogenic thermal detector
BONA	Bonanza nonmagnetic detector at DORIS
BORX	BOREXINO
BPWA	Barrelet-zero partial-wave analysis
BRAS	BRASS: Broadband Radiometric Axion/ALPs Search Setup
C100	COSINE-100 experiment in South Korea
CALO	Calorimeter
CAPP	CAPP18T haloscope detector
CASK	CULTASK: CAPPs Ultra Low Temperature Axion Search in Korea
CASP	Cosmic Axion Spin Precession Experiments
CAST	CAST experiment at CERN
CBAL	Crystal Ball detector at SLAC-SPEAR or DORIS
CBAR	Crystal Barrel detector at CERN-LEAR
CBOX	Crystal Box at LAMPF
CBTP	CBELSA/TAPS Collaboration
CC	Cloud chamber
CCFR	Columbia-Chicago-Fermilab-Rochester detector
CCM	Coherent CAPTAIN-Mills 10-ton liquid Ar detector at Los Alamos
CDEX	China Dark Matter Experiment
CDF	Collider detector at Fermilab
CDF2	CDF-II Collab.
CDHS	CDHS neutrino detector at CERN
CDM2	CDMS II, Cryogenic Dark Matter Search at Soudan Underground Lab.
CDMS	CDMS Collaboration
CELL	CELLO detector at DESY
CGNT	CoGeNT dark matter search experiment
CHER	Cherenkov detector
CHM2	CHARM-II neutrino detector (glass) at CERN
CHOZ	Nuclear Power Station near Chooz, France
CHRM	CHARM neutrino detector (marble) at CERN
CHRS	CHORUS Collaboration – CERNS SPS
CIB	Cosmic Infrared Background
CIBS	CERN-IHEP boson spectrometer
CLAS	Jefferson CLAS Collab.
CLE2	CLEO II detector at CESR
CLE3	CLEO III detector at CESR
CLEC	CLEO-c detector at CESR
CLEO	Cornell magnetic detector at CESR
CMB	Cosmic Microwave Background
CMD	Cryogenic magnetic detector at VEPP-2M, Novosibirsk
CMD2	Cryogenic magnetic detector 2 at VEPP-2M, Novosibirsk
CMD3	Cryogenic magnetic detector 3 at VEPP-2000, Novosibirsk
CMS	CMS detector at CERN LHC
CNTR	Counters
COHR	COHERENT experiment at the SNS, Oak Ridge
COMB	Combined analysis of data from independent experiments.
COMP	COMPASS experiment at the CERN SPS
CONN	CONNIE: Coherent Neutrino-Nucleus Interaction Experiment
COSM	Cosmology and astrophysics
COSY	COSY-TOF Collaboration
COUP	COUPP (the Chicagoland Observatory for Underground Particle Physics) Collab.
CPLR	CPLEAR Collaboration
CRBT	Crystal Ball and TAPS detector at MAMI
CRES	CRESST cryogenic detector
CRYB	Crystal Ball at BNL
CRYM	Crystal Ball detector at Mainz Microtron MAMI
CSB2	Columbia U. - Stony Brook BGO calorimeter inserted in NaI array
CSME	COSME Collaboration
CUOR	CUORICINO experiment at Gran Sasso Laboratory.
CUSB	Columbia U. - Stony Brook segmented NaI detector at CESR
D0	D0 detector at Fermilab Tevatron Collider
DAMA	DAMA, dark matter detector at Gran Sasso National Lab.
DAMP	The DArk Matter Particle Explorer, DAMPE, detector
DANC	DANCE axion search experiment
DASP	DESY double-arm spectrometer
DAYA	Daya Bay Collaboration
DBC	Deuterium bubble chamber
DCHZ	Double Chooz Collaboration
DEAP	DEAP-3600 DM search with argon at SNOLAB
DISP	Graviton mass measurement based on dispersion measure
DLCO	DELCO detector at SLAC-SPEAR or SLAC-PEP
DLPH	DELPHI detector at LEP
DM1	Magnetic detector no. 1 at Orsay DCI collider
DM2	Magnetic detector no. 2 at Orsay DCI collider
DMIC	DAMIC Dark Matter in CCD experiment at Fermilab
DMTP	Dark Matter Time Projection Chamber (DMTPC) directional detection experiment
DONU	DONUT Collab.
DORR	DOSUE-RR Collab., dark photon dark matter search
DPWA	Energy-dependent partial-wave analysis
DRFT	Directional dark matter detector at Boulby Underground Science Facility
DS50	DarkSide-50 Liquid Argon TPC at Gran Sasso National Laboratory
E137	SLAC E137 beam-dump experiment
E621	Fermilab E621 detector
E653	Fermilab E653 detector
E665	Fermilab E665 detector
E687	Fermilab E687 detector

E691 Fermilab E691 detector
E705 Fermilab E705 Spectrometer-Calorimeter
E731 Fermilab E731 Spectrometer-Calorimeter
E756 Fermilab E756 detector
E760 Fermilab E760 detector
E761 Fermilab E761 detector
E771 Fermilab E771 detector
E773 Fermilab E773 Spectrometer-Calorimeter
E789 Fermilab E789 detector
E791 Fermilab E791 detector
E799 Fermilab E799 Spectrometer-Calorimeter
E835 Fermilab E835 detector
EDE2 EDELWEISS II dark matter search Collaboration
EDE3 EDELWEISS III dark matter search Collaboration
EDEL EDELWEISS dark matter search Collaboration
EDGS EDGES: Global EoR (Epoch of Reionization) Signature experiment
EHS Four-pi detector at CERN
ELEC Electronic combination
EMC European muon collaboration detector at CERN
EMUL Emulsions
EPTA The European Pulsar Timing Array
ESR Electron spin resonance spectroscopy
EXO2 Enriched Xenon Observatory 200-kg liquid Xe TPC
FASR FASER light dark matter search at LHC
FAST Fiber Active Scintillator Target detector at PSI
FBC Freon bubble chamber
FENI FENICE (at the ADONE collider of Frascati)
FIT Fit to previously existing data
FLAT Large Area Telescope onboard the Fermi Gamma-Ray Space Telescope (Fermi-LAT)
FMPS Fermilab Multiparticle Spectrometer
FOCS FNAL E831 FOCUS Collab.
FRAB ADONE $B\overline{B}$ group detector
FRAG ADONE $\gamma\gamma$ group detector
FRAM ADONE MEA group detector
FREJ FREJUS Collaboration – modular flash chamber detector (calorimeter)
FUNK Finding U(1)'s of a Novel Kind experiment
GA24 Hodoscope Cherenkov γ calorimeter (IHEP GAMS-2000) (CERN GAMS-4000)
GALX GALLEX solar neutrino detector in the Gran Sasso Underground Lab.
GAM2 IHEP hodoscope Cherenkov γ calorimeter GAMS-2000
GAM4 CERN hodoscope Cherenkov γ calorimeter GAMS-4000
GAMS IHEP hodoscope Cherenkov γ calorimeter GAMS-4π
GLUX GlueX exotic hybrid mesons search at JLAB
GNME Global Network of Optical Magnetometers for Exotic searches (GNOME)
GNO Gallium Neutrino Observatory in the Gran Sasso Underground Lab.
GOLI CERN Goliath spectrometer
GRAL GRAAL Collaboration
H1 H1 detector at DESY/HERA
HAWC High Altitude Water Cherenkov Observatory experiment at Sierra Negra, Mexico
HBC Hydrogen bubble chamber
HDBC Hydrogen and deuterium bubble chambers
HDES HADES Collaboration at GSI in Darmstadt
HDMO Heidelberg-Moscow Experiment
HDMS Heidelberg Dark Matter Search Experiment
HEBC Helium bubble chamber
HEPT Helium proportional tubes
HERA H1 and ZEUS Collaborations at DESY/HERA
HERB HERA-B detector at DESY/HERA
HERM HERMES detector at DESY/HERA
HESS High Energy Stereoscopic System gamma-ray instrument
HFR HighFlow Reactor at the Institut Laue-Langevin
HFS Hyperfine structure
HLBC Heavy-liquid bubble chamber
HOME Homestake underground scintillation detector
HPGE High-purity Germanium detector
HPS Heavy Photon Search experiment at JLAB
HPW Harvard-Pennsylvania-Wisconsin detector
HRS SLAC high-resolution spectrometer
HYBR Hybrid: bubble chamber + electronics
HYCP HyperCP Collab. (FNAL E-871)
HYST HAYSTAC axion search experiment
IACT Imaging Air Cherenkov Telescope
ICAR ICARUS experiment at Gran Sasso Laboratory.
ICCB IceCube neutrino detector at South Pole
IGEX IGEX Collab.
IMB Irvine-Michigan-Brookhaven underground Cherenkov detector
IMB3 Irvine-Michigan-Brookhaven underground Cherenkov detector
INDU Magnetic induction
IPWA Energy-independent partial-wave analysis
ISTR IHEP ISTRA+ spectrometer-calorimeter
JADE JADE detector at DESY
JPAC Joint Physics Analysis Center (JPAC) Collaboration
K246 KEK E246 detector with polarimeter
K2K KEK to Super-Kamiokande
K391 KEK E391a detector
K470 KEK-E470 Stopping K detector
KAM2 KAMIOKANDE-II underground Cherenkov detector
KAMI KAMIOKANDE underground Cherenkov detector
KAR2 KARMEN2 calorimeter at the ISIS neutron spallation source at Rutherford
KARM KARMEN calorimeter at the ISIS neutron spallation source at Rutherford
KEDR detector operating at VEPP-4M collider (Novosibirsk)
KIMS Korea Invisible Mass Search experiment at YangYang, Korea
KLND KamLand Collab. (Japan)
KLOE KLOE detector at DAFNE (the Frascati e+e- collider Italy)
KOLR Kolar Gold Field underground detector
KOTO KOTO experiment with K_L^0 beam at J-PARC
KTEV KTeV Collaboration
L3 L3 detector at LEP
LASR Laser
LASS Large-angle superconducting solenoid spectrometer at SLAC
LATT Lattice calculations
LEBC Little European bubble chamber at CERN
LEGS BNL LEGS Collab.
LENA Nonmagnetic lead-glass NaI detector at DORIS
LEP From combination of all 4 LEP experiments: ALEPH, DELPHI, L3, OPAL
LEPS Low-Energy Pion Spectrometer at the Paul Scherrer Institute
LGW Lead Glass Wall collaboration at SPEAR/SLAC
LHC Combined analysis of LHC experiments
LHCB LHCb detector at CERN LHC
L+P Multichannel L + P model fit
LSD Mont Blanc liquid scintillator detector
LSND Liquid Scintillator Neutrino Detector
LSW Light Shining through a Wall
LUX Large Underground Xenon experiment at SURF
LZ LUX-ZEPLIN dark matter Xe CPT detector at SURF
MAC MAC detector at PEP/SLAC
MAJD Majorana Demonstrator experiment at SURF
MBNE Fermilab MiniBooNE neutrino experiment
MBR Molecular beam resonance technique
MCBN Fermilab MicroBooNE neutrino experiment
MCRO MACRO detector in Gran Sasso
MD1 Magnetic detector at VEPP-4, Novosibirsk
MDHI Multilayer Dielectric Haloscope Investigation
MDRP Millikan drop measurement
MEG Muon to electron conversion detector at PSI
MGFL MAGIC and Fermi-LAT Collaborations
MGIC MAGIC Telescopes gamma-ray observatory
MICA Underground mica deposits
MICR MICROSCOPE satellite test of weak equivalence principle
MINS Fermilab MINOS experiment
MIRA MIRABELLE Liquid-hydrogen bubble chamber
MLEV Magnetic levitation
MLS Modified Laurent Series
MMS Missing mass spectrometer
MOED MoEDAL magnetic monopoles search experiment at LHC
MPS Multiparticle spectrometer at BNL
MPS2 Multiparticle spectrometer upgrade at BNL
MPSF Multiparticle spectrometer at Fermilab
MPWA Model-dependent partial-wave analysis
MRK1 SLAC Mark-I detector
MRK2 SLAC Mark-II detector
MRK3 SLAC Mark-III detector
MRKJ Mark-J detector at DESY
MRS Magnetic resonance spectrometer
MUG2 Muon (g-2)
MWPC Multi-Wire Proportional Chamber

NA14 CERN NA14
NA31 CERN NA31 Spectrometer-Calorimeter
NA32 CERN NA32 Spectrometer
NA48 CERN NA48 Collaboration
NA49 CERN NA49 Collaboration
NA60 CERN NA60 Collaboration
NA62 CERN NA62 Experiment
NA64 CERN SPS NA64 Experiment
NAGE NEWAGE, New generation WIMP-search experiment with advanced gaseous tracking
NAIA NAIAD (NaI Advanced Detector) dark matter search experiment
ND NaI detector at VEPP-2M, Novosibirsk
NEOS NEOS Collaboration
NEWS NEWS-G direct dark matter search at LSM
NICE Serpukhov nonmagnetic precision spectrometer
NMR Nuclear magnetic resonance
NOMD NOMAD Collaboration, CERN SPS
NOVA NOvA experiment with Fermilab's NuMI neutrino beam
NTEV NuTeV Collab. at Fermilab
nTRV neutron Time-Reversal Violation
NUSX Mont Blanc NUSEX underground detector
OBLX OBELIX detector at LEAR
OKA OKA collaboration at U70 accelerator in Protvino, Russia
OLYA Detector at VEPP-2M and VEPP-4, Novosibirsk
OMEG CERN OMEGA spectrometer
OPAL OPAL detector at LEP
OPER OPERA experiment with emulsion tracking at Gran Sasso
ORGN ORGAN (Oscillating Resonant Group AxioN) experiment
ORPH ADMX-Orpheus Dark Matter Experiment
OSPK Optical spark chamber
PIBE The PIBETA detector at the Paul Scherrer Institute (PSI), Switzerland.
PICA PICASSO dark matter search experiment
PICO PICO bubble chamber experiment in SNOLAB underground laboratory
PIE3 πE3 beam-line of Paul Scherrer Institute
PLAS Plastic detector
PLUT DESY PLUTO detector
PMLA PAMELA space spectrometer on Resurs-DK1 satellite
PNDX PandaX dual-phase liquid xenon dark matter experiment at Jin-Ping
PPTA Parkes Pulsar Timing Array
PRMX The PRIMEX detector in Hall B at TJNAF
PWA Partial-wave analysis
QUAX QUAX axion search experiment
QULP QUALIPHIDE, quantum limited photons in the dark exp.
RADE CAST-RADES haloscope search for axions.
RDK2 NIST rare radioactive decay experiment
REDE Resonance depolarization
RENO RENO Collaboration
RICE Radio Ice Cherenkov Experiment
RVUE Review of previous data
SAGE US - Russian Gallium Experiment
SAPH SAPPHIRES collaboration search for sub-eV Axion LPs
SCDM SuperCDMS experiment at Soudan Underground Lab.
SELX FNAL SELEX Collab.
SENS Sub-Electron-Noise Skipper CCD Experimental Instrument (SENSEI)
SFM CERN split-field magnet
SHF SLAC Hybrid Facility Photon Collaboration
SHFT Search for Halo Axions with Ferromagnetic Toroids
SHUK SHUKET: search for U(1) dark matter with an electromagnetic telescope
SIGM Serpukhov CERN-IHEP magnetic spectrometer (SIGMA)
SILI Silicon detector
SIMP SIMPLE, dark matter detector at Laboratori Nazionali del Sud
SKAM Super-Kamiokande Collab.
SLAX Solar Axion Experiment in Canfranc Underground Laboratory
SLD SLC Large Detector for $e^+ e^-$ colliding beams at SLAC
SLIC ADMX SLIC (Superconducting LC Circuit Investigating Cold Axions)
SMPL SIMPLE, Superheated Instrument for Massive ParticLe Experiments
SND Novosibirisk Spherical neutral detector at VEPP-2M
SNDR SINDRUM spectrometer at PSI
SNO SNO Collaboration (Sudbury Neutrino Observatory)
SNO+ SNO+ Collaboration (Sudbury Neutrino Observatory)
SNSP SNSPD, Superconducting Nanowire Single-Photon Detectors
SOU2 Soudan 2 underground detector
SOUD Soudan underground detector
SPEC Spectrometer
SPED From maximum of speed plot or resonant amplitude
SPHR Bonn SAPHIR Collab.
SPNX SPHINX spectrometer at IHEP accelerator
SPRK Spark chamber
SQID SQUID device
STRC Streamer chamber
SVD2 SVD-2 experiment at IHEP, Protvino
T2K T2K Collaboration
TASE Taiwan Axion Search Experiment with a Haloscope, TASEH, experiment
TASS DESY TASSO detector
TEVA Combined analysis of CDF and DØ experiments
TEXO TEXONO Collab., ultra low energy Ge detector at Kuo-Sheng Laboratory
THEO Theoretical or heavily model-dependent result
TNF TNF-IHEP facility at 70 GeV IHEP accelerator
TOF Time-of-flight
TOPZ TOPAZ detector at KEK-TRISTAN
TPC TPC detector at PEP/SLAC
TPS Tagged photon spectrometer at Fermilab
TRAP Penning trap
TWST TWIST spectrometer at TRIUMF
UA1 UA1 detector at CERN
UA2 UA2 detector at CERN
UA5 UA5 detector at CERN
UCNA UCNA collaboration using polarizeed ultracold neutrons at LANSCE
UKDM UK Dark Matter Collab.
UPLD UPLOAD, upconversion low-noise oscillator axion detection experiment
VES Vertex Spectrometer Facility at 70 GeV IHEP accelerator
VLBI Very Long Baseline Interferometer
VNS VENUS detector at KEK-TRISTAN
VRTS Very Energetic Radiation Imaging Telescope Array System (VERITAS)
WA75 CERN WA75 experiment
WA82 CERN WA82 experiment
WA89 CERN WA89 experiment
WARP Liquid argon detector for CDM searches at Gran Sasso
WASA WASA detector at CELSIUS, Uppsala and at COSY, Juelich
WDMX WISP Dark Matter eXperiment (WISPDMX) for direct hidden photon search
WIRE Wire chamber
X100 XENON100 dark matter search experiment at Gran Sasso National Laboratory
XE10 XENON10 experiment at Gran Sasso National Laboratory
XE1T XENON1T dark matter search experiment at Gran Sasso National Laboratory
XEBC Xenon bubble chamber
XENT XENONnT dark matter search experiment at Gran Sasso National Laboratory
XMAS XMASS, liquid xenon scintillation detector at Kamioka Observatory
YUKA Graviton mass measurement based on Yukawa potential
ZEP2 ZEPLIN-II dark matter detector
ZEP3 ZEPLIN-III dark matter detector at Palmer Underground Lab.
ZEPL ZEPLIN-I galactic dark matter detector
ZEUS ZEUS detector at DESY/HERA

Conferences

Conferences are generally referred to by the location at which they were held (e.g., HAMBURG, TORONTO, CORNELL, BRIGHTON, etc.).

PRA	Physical Review A
PRAM	Pramana
PRC	Physical Review C
PRD	Physical Review D
PRL	Physical Review Letters
PRPL	Physics Reports (Physics Letters C)
PRSE	Proc. of the Royal Society of Edinburgh
PRSL	Proc. of the Royal Society of London, Section A
PRX	Physical Review X
PS	Physica Scripta
PTEP	Progress of Theoretical and Experimental Physics
PTP	Progress of Theoretical Physics
PTPS	Progress of Theoretical Physics Supplement
PTRSL	Phil. Trans. Royal Society of London
RA	Radiochimica Acta
RMP	Reviews of Modern Physics
RNC	La Rivista del Nuovo Cimento
RPP	Reports on Progress in Physics
RRP	Revue Roumaine de Physique
SADV	Science Advances
SCI	Science
SCIB	Science Bulletin
SCP	SciPost Physics
SCPMA	Science China Physics, Mechanics and Astronomy
SJNP	Soviet Journal of Nuclear Physics
SJPN	Soviet Journal of Particles and Nuclei
SPD	Soviet Physics Doklady (Magazine)
SPU	Soviet Physics - Uspekhi
SYM	Symmetry
UFN	Usp. Fiz. Nauk – Russian version of SPU
YAF	Yadernaya Fizika
ZETF	Zhurnal Eksperimental'noi i Teoreticheskoi Fiziki
ZETFP	Zhurnal Eksperimental'noi i Teoreticheskoi Fiziki, Pis'ma v Redakts
ZNAT	Zeitschrift fur Naturforschung
ZPHY	Zeitschrift fur Physik

Institutions

AACH	Phys. Inst. der Techn. Hochschule **Aachen** (Historical, use for general Inst. der Techn. Hochschule)	Aachen, Germany
AACH1	I Phys. Inst. B, RWTH **Aachen**	Aachen, Germany
AACH3	III Phys. Inst. A, RWTH **Aachen** Univ.	Aachen, Germany
AACHT	Inst. für Theoretische Teilchenphysik & Kosmologie, RWTH **Aachen**	Aachen, Germany
AARH	Univ. of **Aarhus**	Aarhus C, Denmark
ABO	**Åbo** Akademi Univ.	Turku, Finland
ADEL	**Adelphi** Univ.	Garden City, NY, USA
ADLD	The Univ. of **Adelaide**	Adelaide, SA, Australia
AERE	Atomic Energy Research Estab.	Didcot, United Kingdom
AFRR	**Armed Forces** Radiobiology Res. Inst.	Bethesda, MD, USA
AHMED	Physical Research Lab.	**Ahmedabad**, Gujarat, India
AICH	**Aichi** Univ. of Education	Aichi, Japan
AKIT	**Akita** Univ.	Akita, Japan
ALAH	Univ. of **Alabama (Huntsville)**	Huntsville, AL, USA
ALAT	Univ. of **Alabama (Tuscaloosa)**	Tuscaloosa, AL, USA
ALBA	**SUNY at Albany**	Albany, NY, USA
ALBE	Univ. of **Alberta**	Edmonton, AB, Canada
AMES	**Ames Lab.**	Ames, IA, USA
AMHT	**Amherst** College	Amherst, MA, USA
AMST	Univ. van **Amsterdam**	GL Amsterdam, The Netherlands
ANIK	**NIKHEF**	**Amsterdam**, The Netherlands
ANKA	**Middle East** Technical Univ.; Dept. of Physics; Experimental HEP Lab	Ankara, Turkey
ANL	**Argonne** National Lab.; High Energy Physics Division, Bldg. 362; Physics Division, Bldg. 203	Argonne, IL, USA

Abbreviations Used in the Particle Listings

ANSM	**St. Anselm** Coll.	Manchester, NH, USA
AQUI	Univ. di **LAquila**	**Aquila**, Italy
ARCBO	**Arecibo** Observatory	Arecibo, PR, USA
ARIZ	Univ. of **Arizona**	Tucson, AZ, USA
ARZS	**Arizona State** Univ.	Tempe, AZ, USA
ASCI	Russian Academy of Sciences	**Moscow**, Russian Federation
AST	**Academia Sinica**	Nankang, Taipei, Taiwan
ASTAR	Institute of Materials	Singapore, Singapore
ATEN	NCSR **"Demokritos"**	**Aghia** Paraskevi , Greece
ATHU	Univ. of **Athens**	Athens, Greece
AUCK	Univ. of **Auckland**	Auckland, New Zealand
BAKU	**Natl. Azerbaijan Academy of Sciences**, Inst. of Physics	**Baku**, Azerbaijan
BANG	Indian Inst. of Science	**Bangalore**, India
BANGB	**Bangabasi** College	Calcutta, India
BARC	Univ. Autónoma de **Barcelona**; Dept. de Fisica	Bellaterra (Barcelona), Spain
BARCE	Univ. Autónoma de **Barcelona**; Inst. de Física de Altas Energías	Bellaterra (Barcelona), Spain
BARI	Univ. e del Politecnico di **Bari**	Bari, Italy
BART	Univ. of **Delaware**; **Bartol** Research Inst.	Newark, DE, USA
BASL	Inst. für Physik der Univ. **Basel**	Basel, Switzerland
BAYR	Univ. **Bayreuth**	Bayreuth, Germany
BCEN	Centre d'Etudes Nucleaires de **Bordeaux-Gradignan**	Gradignan, France
BCIP	Natl. Inst. for Physics & Nuclear Eng. "Horia Hulubei" **(IFIN-HH)**	**Bucharest**-Magurele, Romania
BEIJ	**Beijing** Univ.	Beijing, China
BEIJT	**Inst. of Theoretical Physics**	**Beijing**, China
BELG	Inter-University Inst. for High Energies (ULB-VUB)	**Brussel**, Belgium
BELL	AT & T **Bell** Labs	Murray Hill, NJ, USA
BERG	Univ. of **Bergen**	Bergen, Norway
BERL	**DESY**, Deutsches Elektronen-Synchrotron	**Zeuthen**, Germany
BERN	Univ. of **Berne**	Berne, Switzerland
BGNA	Univ. di **Bologna**, & **INFN**, Sezione di Bologna; Via Irnerio, 46, I-40126 Bologna; Viale C. Berti Pichat, n. 6/2	Bologna, Italy
BHAB	**Bhabha Atomic** Research Center	Trombay, Bombay, India
BHEP	**Inst. of High Energy Physics**	**Beijing**, China
BIEL	Univ. **Bielefeld**	Bielefeld, Germany
BING	**SUNY at Binghamton**	Binghamton, NY, USA
BIRK	**Birkbeck** College, Univ. of London	London, United Kingdom
BIRM	Univ. of **Birmingham**	Edgbaston, Birmingham, United Kingdom
BLSU	**Bloomsburg** Univ.	Bloomsburg, PA, USA
BNL	**Brookhaven National Lab.**	Upton, NY, USA
BNORM	**Beijing Normal** Univ.	Beijing, China
BOCH	**Ruhr** Univ. **Bochum**	Bochum, Germany
BOHR	**Niels Bohr Inst.**	Copenhagen Ø, Denmark
BOIS	**Boise** State Univ.	Boise, ID, USA
BOMB	Univ. of **Bombay**	Bombay, India
BONN	**Univ. of Bonn**	Bonn, Germany
BORD	Centre d'Etudes Nucléaires de **Bordeaux** Gradignan **(CENBG)**	Gradignan, France
BOSE	S.N. **Bose** National Centre for Basis Sciences	Calcutta, India
BOSK	**"Rudjer Bošković"** Inst.	Zagreb, Croatia
BOST	**Boston** Univ.	Boston, MA, USA
BRAN	**Brandeis** Univ.	Waltham, MA, USA
BRCO	Univ. of **British Columbia**	Vancouver, BC, Canada
BRIS	Univ. of **Bristol**	Bristol, United Kingdom
BROW	**Brown** Univ.	Providence, RI, USA
BRUN	**Brunel** Univ.	Uxbridge, Middlesex, United Kingdom
BRUX	Univ. Libre de **Bruxelles**; Physique des Particules Elémentaires	Bruxelles, Belgium
BRUXT	Univ. Libre de **Bruxelles**; Physique Théorique	Bruxelles, Belgium
BUCH	Univ. of **Bucharest**	Bucharest-Magurele, Romania
BUDA	**Wigner** Research Centre for Physics	**Budapest**, Hungary
BUFF	**SUNY at Buffalo**	Buffalo, NY, USA
BURE	Inst. des Hautes Etudes Scientifiques	**Bures-sur-Yvette**, France
CAEN	Lab. de Physique Corpusculaire, **ENSICAEN**	**Caen**, France
CAGL	Univ. degli Studi di **Cagliari**	Monserrato (CA), Italy
CAGLI	**INFN**, Sezione di **Cagliari**	Monserrato (CA), Italy
CAIR	**Cairo** University	Orman, Giza, Cairo, Egypt
CAIW	**Carnegie Inst.** of Washington	Washington, DC, USA
CALB	Univ. della **Calabria**	Cosenza, Italy
CALC	Univ. of **Calcutta**	Calcutta, India
CAMB	**DAMTP**	Cambridge, United Kingdom
CAMP	Univ. Estadual de **Campinas** (UNICAMP)	**Campinas**, SP, Brazil
CANB	**Australian National Univ.**	Canberra, ACT, Australia
CANTB	Inst. de Física de Cantabria (CSIC–Univ. **Cantabria**)	Santander, Spain
CAPE	University of **Cape Town**	Rondebosch, Cape Town, South Africa
CARA	Univ. Central de **Venezuela**	Caracas, Venezuela
CARL	**Carleton** Univ.	Ottawa, ON, Canada
CARLC	**Carleton** College	Northfield, MN, USA
CASE	**Case** Western Reserve Univ.	Cleveland, OH, USA
CAST	**China** Center of Advanced Science and Technology	Beijing, China
CATA	Univ. di **Catania**	Catania, Italy
CATH	**Catholic** Univ. of America	Washington, DC, USA
CAVE	**Cavendish** Lab.	Cambridge, United Kingdom
CBNM	CBNM	**Geel**, Belgium
CBPF	Centro Brasileiro de Pesquisas Físicas – **BIB/CDI/CBPF**	**Rio de Janeiro**, RJ, Brazil
CCAC	**Allegheny** College	Meadville, PA, USA
CDEF	**Univ. Paris VII, Denis Diderot**	Paris, France
CEA	Cambridge Electron Accelerator (Historical in *Review*)	**Cambridge, MA**, USA
CEADE	Center for Apl. Studies for Nuclear Physics	Havana, Cuba
CEBAF	**Jefferson Lab—Thomas Jefferson National Accelerator Facility**	**Newport News**, VA, USA
CENG	Centre d'Etudes Nucleaires	**Grenoble**, France
CERN	**CERN**, European Organization for Nuclear Research	Genève, Switzerland
CFPA	Univ. of **California, (Berkeley)**	Berkeley, CA, USA
CHIC	Univ. of **Chicago**	Chicago, IL, USA
CIAE	**State Nuclear Power Research Inst.**	**Beijing**, China
CINC	Univ. of **Cincinnati**	Cincinnati, OH, USA
CINV	**CINVESTAV-IPN** Centro de Investigacion y de Estudios Avanzados del IPN	**México**, DF, Mexico
CIT	**California Inst. of Tech.**	Pasadena, CA, USA
CLER	Univ. de **Clermont-Ferrand**	Aubière, France
CLEV	**Cleveland** State Univ.	Cleveland, OH, USA
CMNS	**Comenius** Univ. (FMFI UK)	**Bratislava**, Slovakia
CMU	**Carnegie Mellon** Univ.	Pittsburgh, PA, USA
CNEA	**Comisión Nacional de Energía Atómica**	Buenos Aires, Argentina
CNRC	Centre for Research in Particle Physics	Ottawa, ON, Canada
CNRS	National Center for Scientific Research	Paris, France
CNYIT	C. N. Yang Institute	New York, USA
COIM	Univ. de Coimbra	**Coimbra**, Portugal
COLO	Univ. of **Colorado**	Boulder, CO, USA
COLU	**Columbia** Univ.	New York, NY, USA
CONC	**Concordia** University	Montreal, PQ, Canada
CORN	**Cornell** Univ.	Ithaca, NY, USA

Abbreviations Used in the Particle Listings

COSU	**Colorado State** Univ.	Fort Collins, CO, USA
CPPM	Centre National de la Recherche Scientifique, Luminy	**Marseille**, France
CRAC	Henryk Niewodnicza'nski Inst. of Nuclear Physics	**Kraków**, Poland
CRNL	**Chalk River** Labs.	Chalk River, ON, Canada
CSEB	California State University	Hayward, USA
CSOK	**Oklahoma** Central State Univ.	Edmond, OK, USA
CST	Univ. of **Science and Technology** of China	**Hefei**, Anhui 230026, China
CSULB	**California** State Univ.	Long Beach, CA, USA
CSUS	**California** State Univ.	Sacramento, CA, USA
CTUP	Czech Technical University	Prague, Czech Republic
CUNY	**City College** of **New York**	New York, NY, USA
CURCP	**Univ. Pierre et Marie Curie** (Paris VI), LCP	Paris, France
CURIN	**Univ. Pierre et Marie Curie** (Paris VI), LPNHE	Paris, France
CURIT	**Univ. Pierre et Marie Curie** (Paris VI), LPTHE	Paris, France
DALH	**Dalhousie** Univ.	Halifax, NS, Canada
DALI	**Dalian** Univ. of Tech.	Dalian, China
DARE	**Daresbury** Lab	Cheshire, United Kingdom
DARM	Tech. Hochschule **Darmstadt**	Darmstadt, Germany
DELA	Univ. of **Delaware**; Dept. of Physics & Astronomy	Newark, DE, USA
DELH	Univ. of **Delhi**	Delhi, India
DESY	**DESY**, Deutsches Elektronen-Synchrotron	**Hamburg**, Germany
DFAB	Escuela de Ingenieros	**Bilbao**, Spain
DOE	**Department of Energy**	Washington, DC, USA
DORT	Technische Univ. **Dortmund**	Dortmund, Germany
DUKE	**Duke** Univ.	Durham, NC, USA
DURH	Univ. of **Durham**	Durham , United Kingdom
DUUC	**University College** Dublin	Dublin, Ireland
ECT	Europ. Cent. for Theor. Studies in Nucl. Phys.	Trento, Italy
EDIN	Univ. of **Edinburgh**	Edinburgh, United Kingdom
EFI	Univ. of Chicago, **The Enrico Fermi Inst.**	**Chicago**, IL, USA
ELMT	**Elmhurst** College	Elmhurst, IL, USA
ENSP	**l'Ecole Normale Supérieure**	**Paris**, France
EOTV	**Eötvös** University	Budapest, Hungary
EPOL	**École Polytechnique**	**Palaiseau**, France
ERLA	Univ. **Erlangen-Nurnberg**	Erlangen, Germany
ESAP	ESAP Territorial Meta	Villavicencio, Colombia
ETH	Eidg. Technische Hochschule	Zürich, Switzerland
FERR	Univ. di **Ferrara**	Ferrara, Italy
FIRZ	Univ. degli Studi di **Firenze**	Sesto Fiorentino, Italy
FISK	**Fisk** Univ.	Nashville, TN, USA
FLOR	Univ. of **Florida**	Gainesville, FL, USA
FNAL	**Fermilab**	Batavia, IL, USA
FOM	**FOM**, Stichting voor Fundamenteel Onderzoek der Materie	JP **Utrecht**, The Netherlands
FRAN	**Frankfurt Inst. for Advanced Studies (FIAS)**	Frankfurt am Main, Germany
FRAS	Lab. Nazionali di **Frascati** dell'**INFN**	Frascati (Roma), Italy
FREIB	**Albert-Ludwigs** Univ.	**Freiburg**, Germany
FREIE	**Freie Univ. Berlin**	Berlin, Germany
FRIB	Univ. de **Fribourg**	Fribourg, Switzerland
FSU	**Florida State** Univ.; High Energy Physics	Tallahassee, FL, USA
FSUSC	**Florida State** Univ.; SCS (School of Computational Science)	Tallahassee, FL, USA
FUKI	**Fukui** Univ.	Fukui, Japan
FUKU	**Fukushima** Univ.	Fukushima, Japan
GENO	Univ. di **Genova**	Genova, Italy
GEOR	**E. Andronikashvili Inst. of Physics**	Tbilisi, Republic of Georgia
GESC	**General Electric** Co.	Schenectady, NY, USA
GEVA	Univ. de **Genève**	Genève, Switzerland
GIES	Univ. **Giessen**	Giessen, Germany
GIFU	**Gifu** Univ.	Gifu, Japan
GLAS	Univ. of **Glasgow**	Glasgow, United Kingdom
GMAS	**George Mason** Univ.	Fairfax, VA, USA
GOET	Univ. **Göttingen**	Göttingen, Germany
GOML	**Gomel State** Univ.	Gomel, Belarus
GRAN	Univ. de **Granada**	Granada, Spain
GRAZ	Univ. **Graz**	Graz, Austria
GRON	Univ. of **Groningen**	Groningen, The Netherlands
GSCO	**Geological Survey of Canada**	Ottawa, ON, Canada
GSI	GSI Helmholtzzentrum für Schwerionenforschung GmbH	**Darmstadt**, Germany
GUAN	Univ. de **Guanajuato**	León, Gto., Mexico
GUEL	Univ. of **Guelph**	Guelph, ON, Canada
GWU	**George Washington** Univ.	Washington, DC, USA
HAHN	**Hahn-Meitner** Inst. Berlin GmbH	Berlin, Germany
HAIF	**Technion** – Israel Inst. of Tech.	Technion, Haifa, Israel
HAMB	Univ. **Hamburg**	Hamburg, Germany
HANN	Univ. **Hannover**	Hannover, Germany
HARC	**Houston Advanced Research Ctr.**	The Woodlands, TX, USA
HARV	**Harvard** Univ.	Cambridge, MA, USA
HARV	**Harvard** Univ. (LPPC)	Cambridge, MA, USA
HAWA	Univ. of **Hawai'i**	Honolulu, HI, USA
HEBR	**Hebrew** Univ.	Jerusalem, Israel
HEID	Univ. **Heidelberg**; (unspecified division) (Historical in *Review*)	Heidelberg, Germany
HEIDH	Ruprecht-Karls Univ. **Heidelberg**	Heidelberg, Germany
HEIDP	Univ. **Heidelberg**; Physics Inst.	Heidelberg, Germany
HEIDT	Ruprecht-Karls-Univ. **Heidelberg**	Heidelberg, Germany
HELS	Univ. of **Helsinki**	University of Helsinki, Finland
HIAS	Hangzhou Inst. for Advanced Studies	Hangzhou, China
HINR	Inst. of Nuclear Research (**ATOMKI**)	**Debrecen**, Hungary
HIRO	**Hiroshima** Univ.	Higashi-Hiroshima, Japan
HOUS	Univ. of **Houston**	Houston, TX, USA
HPC	**Hewlett-Packard** Corp.	Cupertino, CA, USA
HSCA	**Harvard-Smithsonian** Center for Astrophysics	Cambridge, MA, USA
HYDER	Indian Inst. of Technology	Hyderabad, India
HZDR	Helmholtz-Zentrum Dresden-Rossendorf	Dresden, Germany
IAC	Instituto de Astrofsica de Canarias	Tenerife, Spain
IAS	**Inst. for Advanced Study**	Princeton, NJ, USA
IASD	**Dublin** Inst. for Advanced Studies	Dublin, Ireland
IBAR	**Ibaraki** Univ.	Ibaraki, Japan
IBM	**IBM** Corp.	Palo Alto, CA, USA
IBMY	**IBM**	Yorktown Heights, NY, USA
IBS	Inst. for **Boson Studies**	Pasadena, CA, USA
ICC	Universitat de Barcelona	Balcelona, Spain
ICCUB	Institut Ciences del Cosmos, Universitat Barcelona	Barcelona, Spain
ICEPP	The Univ. of **Tokyo**	Tokyo, Japan
ICREA	Instituci Catalana de Recerca i Estudis Avanats	Barcelona, Spain
ICRR	Univ. of **Tokyo**	Chiba, Japan
ICTP	**Abdus Salam** International Centre for Theoretical Physics	**Trieste**, Italy
IFIC	**IFIC** (Instituto de Física Corpuscular)	**Paterna (Valencia)**, Spain
IFRJ	Univ. Federal do **Rio de Janeiro**	Rio de Janeiro, RJ, Brazil
IFT	Instituto de Fisica Teorica	Madrid, Spain
IIT	**Illinois Inst. of Tech.**	Chicago, IL, USA
IITB	Indian Inst. of Tech. **IIT Bombay**	Powai, Mumbai, India
IITI	Indian Inst. of Tech. \ef IIT Indore	Simrol, Indore, India
IITJ	Indian Inst. of Tech. Jodhpur	Jodhpur, India
ILL	Univ. of **Illinois at Urbana-Champaign**	Urbana, IL, USA

Abbreviations Used in the Particle Listings

ILLC	Univ. of **Illinois at Chicago**	Chicago, IL, USA
ILLG	Inst. **Laue-Langevin**	Grenoble, France
IND	**Indiana** Univ.	Bloomington, IN, USA
INEL	E G and G **Idaho**, Inc.	Idaho Falls, ID, USA
INFN	Ist. Nazionale di Fisica Nuclear (Generic INFN, unknown location)	Various places, Italy
INFNL	**INFN**, Sezione di **Lecce**	Lecce, Italy
INNS	Univ. of **Innsbruck**	**Innsbruck**, Austria
INPK	Henryk Niewodniczański Inst. of Nuclear Physics	**Kraków**, Poland
INRM	**INR**, Inst. for Nucl. Research	**Moscow**, Russian Federation
INUS	**KEK**, High Energy Accelerator Research Organization	Tokyo, Japan
IOAN	Univ. of **Ioannina**	Ioannina, Greece
IOFF	A.F. **Ioffe** Phys. Tech. Inst.	St. **Petersburg**, Russian Federation
IOWA	Univ. of **Iowa**	Iowa City, IA, USA
IPN	**IPN**, Inst. de Phys. Nucl.	**Orsay**, France
IPNP	Univ. Pierre et Marie Curie (**Paris** VI)	Paris, France
IRAD	Inst. du Radium (Historical)	**Paris**, France
ISNG	Lab. de Physique Subatomique et de Cosmologie **(LPSC)**	**Grenoble**, France
ISU	**Iowa State** Univ.	Ames, IA, USA
ISUT	Isfahan University of Technology	Isfahan, Iran
ITEP	**ITEP**, Inst. of Theor. and Exp. Physics	**Moscow**, Russian Federation
ITHA	**Ithaca** College	Ithaca, NY, USA
IUPU	**Indiana** Univ., **Purdue** Univ. **Indianapolis**	Indianapolis, IN, USA
JADA	**Jadavpur** Univ.	Calcutta, India
JAGL	**Jagiellonian** Univ.	Kraków, Poland
JHU	**Johns Hopkins** Univ.	Baltimore, MD, USA
JINR	**JINR**, Joint Inst. for Nucl. Research	**Dubna**, Russian Federation
JPL	Jet Propulsion Laboratory	Pasadena, USA
JULI	Forschungszentrum **Jülich**	Jülich, Germany
JYV	Univ. of **Jyväskylä**	Jyväskylä, Finland
KAGO	Univ. of **Kagoshima**	Kagoshima-shi, Japan
KAIST	**Korea** Advanced Inst. of Science and Technology	Yusung ku, Daejeon, Republic of Korea
KANP	Indian Inst. of Tech.	**Kanpur**, UT, India
KANS	Univ. of **Kansas**	Lawrence, KS, USA
KARL	Univ. **Karlsruhe** (Historical in *Review*)	Karlsruhe, Germany
KARLE	**Karlsruhe** Inst. of Technology (KIT); Inst. for Experimental Nuclear Physics	Karlsruhe, Germany
KARLK	**Karlsruhe** Inst. of Technology (KIT)	Eggenstein-Leopoldshafen, Germany
KARLT	**Karlsruhe** Inst. of Technology (KIT); Inst. for Theoretical Physics	Karlsruhe, Germany
KAZA	**Kazakh** Inst. of High Energy Physics	Alma Ata, Kazakhstan
KEK	**KEK**, High Energy Accelerator Research Organization	Ibaraki-ken, Japan
KENT	Univ. of **Kent**	Canterbury, United Kingdom
KEYN	**Open** Univ.	Milton Keynes, United Kingdom
KFTI	**Kharkov** Inst. of Physics and Tech. (NSC KIPT)	Kharkov, Ukraine
KIAE	**Kurchatov** Inst.	**Moscow**, Russian Federation
KIAM	**Keldysh** Inst. of Applied Math., Acad. Sci., Russia	Moscow, Russian Federation
KIDR	**Vinča Inst. of Nuclear Sciences**	Belgrade, Serbia
KIEV	**Institute for Nuclear Research**	**Kyiv**, Ukraine
KINK	**Kinki** Univ.	Osaka, Japan
KIT	Karlsruhe Institute for Technology	Karlsruhe, Germany
KNTY	Univ. of **Kentucky**	Lexington, KY, USA
KOBE	**Kobe** Univ.	Kobe, Japan
KOMAB	Univ. of **Tokyo, Komaba**	Tokyo, Japan
KONAN	**Konan** Univ.	Kobe, Japan
KOSI	Inst. of Experimental Physics SAS	**Košice**, Slovakia
KYOT	**Kyoto** Univ.; Dept. of Physics, Graduate School of Science	Kyoto, Japan
KYOTU	**Kyoto** Univ.; **Yukawa** Inst. for Theor. Physics	Kyoto, Japan
KYUN	**Kyungpook** National Univ.	Daegu, Republic of Korea
KYUSH	**Kyushu** Univ.; Elementary ParticleTheory Group; Exp. Particle Physics Group; Research Center for Advanced Particle Physics	Fukuoka, Japan
LALO	**LAL**, Laboratoire de l'Accélérateur Linéaire	**Orsay**, France
LANC	**Lancaster** Univ.	Lancaster, United Kingdom
LANL	**Los Alamos National Lab.** (LANL)	Los Alamos, NM, USA
LAPL	Univ. Nacional de **La Plata**	La Plata, Argentina
LAPP	**LAPP**, Lab. d'Annecy-le-Vieux de Phys. des Particules	**Annecy-le-Vieux**, France
LAPTH	**LAPTh** Lab. d'Annecy-le-Vieux de Phys. Théorique	**Annecy-le-Vieux** CEDEX, France
LASL	U.C. **Los Alamos Scientific** Lab. (Old name for LANL)	Los Alamos, NM, USA
LATV	**Latvian** State Univ.	Riga, Latvia
LAUS	EPFL **Lausanne**	Lausanne, Switzerland
LAVL	Univ. **Laval**	Quebec, QC, Canada
LBL	**Lawrence Berkeley National Lab.**	Berkeley, CA, USA
LCGT	Univ. di **Torino**	Turin, Italy
LEBD	**Lebedev** Physical Inst.	**Moscow**, Russian Federation
LECE	Univ. di **Lecce**	Lecce, Italy
LEED	Univ. of **Leeds**	Leeds, United Kingdom
LEGN	Lab. Naz. di Legnaro	**Legnaro**, Italy
LEHI	**Lehigh** Univ.	Bethlehem, PA, USA
LEHM	**Lehman** College of CUNY	Bronx, NY, USA
LEID	Univ. **Leiden**	Leiden, The Netherlands
LEMO	**Le Moyne** Coll.	Syracuse, NY, USA
LENSU	**Saint-Petersburg** State Univ.	St. **Petersburg**, Russian Federation
LEUV	Katholieke Univ. **Leuven**	Leuven, Belgium
LIEG	Univ. de **Liège**	Liège, Belgium
LINZ	Univ. **Linz**	Linz, Austria
LISB	Inst. Nacional de Investigacion Cientifica	**Lisboa** CODEX, Portugal
LISBT	Centro de Física Teórica de Partículas **(CFTP)**	**Lisboa**, Portugal
LIVP	Univ. of **Liverpool**	Liverpool, United Kingdom
LJUB	Univerza v **Ljubljani**	Ljubljana, Slovenia
LLL	**Lawrence Livermore Lab.** (Old name for LLNL)	Livermore, CA, USA
LLNL	**Lawrence Livermore National Lab.**	Livermore, CA, USA
LNUDA	Liaoning Normal Univ.	Dalian, China
LOCK	**Lockheed** Palo Alto Res. Lab	Palo Alto, CA, USA
LOIC	**Imperial** College of Science Tech. & Medicine	London, United Kingdom
LOKC	**Univ. of London**, King's College	London, United Kingdom
LOQM	Queen Mary, **Univ. of London**	London, United Kingdom
LOUC	**University College** London	London, United Kingdom
LOUV	Univ. Catholique de **Louvain**	Louvain-la-Neuve, Belgium
LOWC	**Westfield** College (Historical, see LOQM (Queen Mary and Westfield joined))	London, United Kingdom
LRL	U.C. Lawrence Radiation Lab. (Old name for LBL)	**Berkeley**, CA, USA
LSU	**Louisiana** State Univ.	Baton Rouge, LA, USA
LUND	**Fysiska Institutionen**	**Lund**, Sweden
LUND	**Lund** Univ.	Lund, Sweden
LYON	Institute de Physique Nucléaire de **Lyon** (IPN)	Villeurbanne, France
MADE	**UAM/CSIC**, Inst. de Física Teórica	**Madrid**, Cantoblanco, Spain
MADR	**C.I.E.M.A.T**	**Madrid**, Spain
MADU	Univ. Autónoma de **Madrid**	Cantoblanco, Madrid, Spain

GAUGE AND HIGGS BOSONS

γ (photon)

$I(J^{PC}) = 0,1(1^{--})$

γ MASS

Results prior to 2008 are critiqued in GOLDHABER 10. All experimental results published prior to 2005 are summarized in detail by TU 05.

The following conversions are useful: 1 eV = 1.783×10^{-33} g = 1.957×10^{-6} m_e; $\lambda\!\!\!^{-}_C = (1.973 \times 10^{-7}$ m)$\times$(1 eV/m_γ).

[1] RYUTOV 07 extends the method of RYUTOV 97 to the radius of Pluto's orbit.

[2] WANG 23B use fast radio burst photon mass dependent dispersion relation to determine an upper limit of the photon mass.

[3] BONETTI 17 uses frequency-dependent time delays of repeating FRB with well-determined redshift, assuming the DM is caused by expected dispersion in IGM. There are several uncertainties, leading to mass limit 2.2×10^{-14} eV.

[4] BONETTI 16 uses frequency-dependent time delays of FRB, assuming the DM is caused by expected dispersion in IGM. There are several uncertainties, leading to mass limit 1.8×10^{-14} eV, if indeed the FRB is at the initially reported redshift.

[5] RETINO 16 looks for deviations from Ampere's law in the solar wind, using Cluster four spacecraft data. Authors quote a range of limits from 1.9×10^{-15} eV to 7.9×10^{-14} eV depending on the assumptions of the vector potential from the interplanetary magnetic field.

[6] EGOROV 14 studies chromatic dispersion of lensed quasar positions ("gravitational rainbows") that could be produced by any of several mechanisms, among them via photon mass. Limit not competitive but obtained on cosmological distance scales.

[7] ACCIOLY 10 limits come from possible alterations of anomalous magnetic moment of electron and gravitational deflection of electromagnetic radiation. Reported limits are not "claimed" by the authors and in any case are not competitive.

[8] When trying to measure m one must distinguish between measurements performed on large and small scales. If the photon acquires mass by the Higgs mechanism, the large-scale behavior of the photon might be effectively Maxwellian. If, on the other hand, one postulates the Proca regime for all scales, the very existence of the galactic field implies $m < 10^{-26}$ eV, as correctly calculated by YAMAGUCHI 59 and CHIBISOV 76.

[9] TU 06 continues the work of LUO 03, with extended LAKES 98 method, reporting the improved limit $\mu^2 A = (0.7 \pm 1.7) \times 10^{-13}$ T/m if $A = 0.2$ μG out to 4×10^{22} m. Reported result $\mu = (0.9 \pm 1.5) \times 10^{-52}$ g reduces to the frequentist mass limit 1.2×10^{-19} eV (FELDMAN 98).

[10] FULLEKRUG 04 adopted KROLL 71A method with newer and better Schumann resonance data. Result questionable because assumed frequency shift with photon mass is assumed to be linear. It is quadratic according to theorem by GOLDHABER 71B, KROLL 71, and PARK 71.

[11] LUO 03 extends LAKES 98 technique to set a limit on $\mu^2 A$, where μ^{-1} is the Compton wavelength $\lambda\!\!\!^{-}_C$ of the massive photon and A is the ambient vector potential. The important departure is that the apparatus rotates, removing sensitivity to the direction of A. They take $A = 10^{12}$ Tm, due to "cluster level fields." But see comment of GOLDHABER 03 and reply by LUO 03B.

[12] LAKES 98 reports limits on torque on a toroid Cavendish balance, obtaining a limit on $\mu^2 A < 2 \times 10^{-9}$ Tm/m^2 via the Maxwell-Proca equations, where μ^{-1} is the characteristic length associated with the photon mass and A is the ambient vector potential in the Lorentz gauge. Assuming $A \approx 1 \times 10^{12}$ Tm due to cluster fields he obtains $\mu^{-1} > 2 \times 10^{10}$ m, corresponding to $\mu < 1 \times 10^{-17}$ eV. A more conservative limit, using $A \approx (1$ μG)$\times$(600 pc) based on the galactic field, is $\mu^{-1} > 1 \times 10^{9}$ m or $\mu < 2 \times 10^{-16}$ eV.

[13] RYUTOV 97 uses a magnetohydrodynamics argument concerning survival of the Sun's field to the radius of the Earth's orbit. "To reconcile observations to theory, one has to reduce [the photon mass] by approximately an order of magnitude compared with" per DAVIS 75. "Secure limit, best by this method" (per GOLDHABER 10).

[14] FISCHBACH 94 analysis is based on terrestrial magnetic fields; approach analogous to DAVIS 75. Similar result based on a much smaller planet probably follows from more precise B field mapping. "Secure limit, best by this method" (per GOLDHABER 10).

[15] CHERNIKOV 92, motivated by possibility that photon exhibits mass only below some unknown critical temperature, searches for departure from Ampere's Law at 1.24 K. See also RYAN 85.

[16] RYAN 85, motivated by possibility that photon exhibits mass only below some unknown critical temperature, sets mass limit at $< (1.5 \pm 1.4) \times 10^{-42}$ g based on Coulomb's Law departure limit at 1.36 K. We report the result as frequentist 90% CL (FELDMAN 98).

[17] CHIBISOV 76 depends in critical way on assumptions such as applicability of virial theorem. Some of the arguments given only in unpublished references.

[18] DAVIS 75 analysis of Pioneer-10 data on Jupiter's magnetic field. "Secure limit, best by this method" (per GOLDHABER 10).

[19] FRANKEN 71 method is of dubious validity (KROLL 71A, JACKSON 99, GOLDHABER 10, and references therein).

[20] KROLL 71A used low frequency Schumann resonances in cavity between the conducting earth and resistive ionosphere, overcoming objections to resonant-cavity methods (JACKSON 99, GOLDHABER 10, and references therein). "Secure limit, best by this method" (per GOLDHABER 10).

[21] WILLIAMS 71 is landmark test of Coulomb's law. "Secure limit, best by this method" (per GOLDHABER 10).

γ CHARGE

OKUN 06 has argued that schemes in which all photons are charged are inconsistent. He says that if a neutral photon is also admitted to avoid this problem, then other problems emerge, such as those connected with the emission and absorption of charged photons by charged particles. He concludes that in the absence of a self-consistent phenomenological basis, interpretation of experimental data is at best difficult.

[1] ALTSCHUL 07B looks for Aharonov-Bohm phase shift in addition to geometric phase shift in radio interference fringes (VSOP mission).

[2] CAPRINI 05 uses isotropy of the cosmic microwave background to place stringent limits on possible charge asymmetry of the Universe. Charge limits are set on the photon, neutrino, and dark matter particles. Valid if charge asymmetries produced by different particles are not anticorrelated.

[3] KOBYCHEV 05 considers a variety of observable effects of photon charge for extragalactic compact radio sources. Best limits if source observed through a foreground cluster of galaxies.

[4] SEMERTZIDIS 03 reports the first laboratory limit on the photon charge in the last 30 years. Straightforward improvements in the apparatus could attain a sensitivity of 10^{-20} e.

[5] SIVARAM 95 requires that CMB photon charge density not overwhelm gravity. Result scales as $\Omega_M h^2$.

[6] RAFFELT 94 notes that COCCONI 88 neglects the fact that the time delay due to dispersion by free electrons in the interstellar medium has the same photon energy dependence as that due to bending of a charged photon in the magnetic field. His limit is based on the assumption that the entire observed dispersion is due to photon charge. It is a factor of 200 less stringent than the COCCONI 88 limit.

[7] See COCCONI 92 for less stringent limits in other frequency ranges. Also see RAFFELT 94 note.

graviton

$J = 2$

graviton MASS

It is likely that the graviton is massless. More than fifty years ago Van Dam and Veltman (VANDAM 70), Iwasaki (IWASAKI 70), and Zakharov (ZAKHAROV 70) almost simultaneously showed that in the linear approximation a theory with a finite graviton mass does not approach GR as the mass approaches zero. Attempts have been made to evade this "vDVZ discontinuity" by invoking modified gravity or nonlinear theory by De Rahm (DE-RHAM 17) and others. More recently, the analysis of gravitational wave dispersion has led to bounds that are largely independent of the underlying model, even if not the strongest. We quote the best of these as our best limit.

Experimental limits have been set based on a Yukawa potential (YUKA), dispersion relation (DISP), or other modified gravity theories (MGRV).

The following conversions are useful: 1 eV = 1.783×10^{-33} g = 1.957×10^{-6} m_e; $\lambda_C = (1.973 \times 10^{-7}$ m$) \times (1$ eV$/m_g)$.

[1] ABBOTT 21 assumed modified gravitational-wave dispersion to establish a limit on graviton mass, using LIGO-Virgo O1-O3a binary black hole (BBH) events.

[2] DEFELICE 21 studies the normal branch of the Minimal Theory of Massive Gravity (MTMG) to find that after five parameters are adjusted to obtain agreement with all presently available data, today's squared mass $m_g^2 = (2.5^{+4.5}_{-4.8}) \times 10^{-67}$ eV^2 or $m_g < 8.4 \times 10^{-33}$ eV, both at the 95% CL.

[3] BERNUS 20 use the latest solution of the ephemeris INPOP (19a) in order to improve the constraint in BERNUS 19 on the existence of a Yukawa suppression to the Newtonian potential, generically associated to a gravitons mass.

[4] SHAO 20 sets limit, 95% CL, based on non-observation of excess gravitational radiation in 14 well-timed binary pulsars in the context of the cubic Galileon model.

[5] ABBOTT 19, ABBOTT 17, and ABBOTT 16 assumed modified gravitational waves dispersion to establish limits on graviton mass.

[6] BERNUS 19 use the planetary ephemeris INPOP 17b to constraint the existence of a Yukawa suppression to the Newtonian potential, generically associated to a gravitons mass.

[7] MIAO 19 90% CL limit is based on orbital period decay rates of 9 binary pulsars using a Bayesian prior uniform in graviton mass. Limit becomes $< 5.2 \times 10^{-21}$ eV for a prior uniform in $\ln(m_g)$.

[8] DESAI 18 limit based on dynamical mass models of galaxy cluster Abell 1689.

[9] GUPTA 18 obtains graviton mass limits using stacked clusters from 3 disparate surveys.

[10] RANA 18 limit, 68% CL, obtained using weak lensing mass profiles out to the radius at which the cluster density falls to 200 times the critical density of the Universe. Limit is based on the fractional change between Newtonian and Yukawa accelerations for the 50 most massive galaxy clusters in the Local Cluster Substructure Survey. Limits for other CL's and other density cuts are also given.

[11] RANA 18 limit, 68% CL, obtained using mass measurements via the SZ effect out to the radius at which the cluster density falls to 500 times the critical density of the Universe for 182 optically confirmed galaxy clusters in an Altacama Cosmology Telescope survey. Limits for other CL's and other density cuts are also given.

[12] WILL 18 limit from perihelion advances of the planets, notably Earth, Mars, and Saturn. Alternate analysis yields $< 6 \times 10^{-24}$.

[13] ZAKHAROV 16 constrains range of Yukawa gravity interaction from S2 star orbit about black hole at Galactic center. The limit is $< 2.9 \times 10^{-21}$ eV for $\delta = 100$.

[14] BRITO 13 explore massive graviton (spin-2) fluctuations around rotating black holes.

[15] GRUZINOV 05 uses the DGP model (DVALI 00) showing that non-perturbative effects restore continuity with Einstein's equations as the gravition mass approaches zero, then bases his limit on Solar System observations.

[16] CHOUDHURY 04 concludes from a study of weak-lensing data that masses heavier than about the inverse of 100 Mpc seem to be ruled out if the gravitation field has the Yukawa form.

[17] GERSHTEIN 04 use non-Einstein field relativistic theory of gravity (RTG), with a massive graviton, to obtain the 95% CL mass limit implied by the value of $\Omega_{tot} = 1.02 \pm 0.02$ current at the time of publication.

[18] FINN 02 analyze the orbital decay rates of PSR B1913+16 and PSR B1534+12 with a possible graviton mass as a parameter. The combined frequentist mass limit is at 90%CL.

[19] As of 2020, limits on dP/dt are now about 0.1% (see T. Damour, "Experimental tests of gravitational theory," in this *Review*).

[20] GOLDHABER 74 establish this limit considering the binding of galactic clusters, corrected to Planck $h_0 = 0.67$.

W

$J = 1$

See the related review(s):
Mass and Width of the *W* Boson

W MASS

The *W*-mass listed here corresponds to the mass parameter in a Breit-Wigner distribution with mass-dependent width. To obtain the world averages of various measurements, common systematic uncertainties between experiments are evaluated and accounted for in combinations [SCHAEL 13A, AMOROSO 24].

Until 2022, the measurements of the *W*-boson mass at lepton and hadron colliders, LEP-2 (ALEPH, DELPHI, L3, and OPAL), Tevatron (CDF and D0), and LHC (ALEPH and LHCb), were in good agreement with each other [PDG 22]. However, with the new CDF result [AALTONEN 22] based on their complete Run-II data set, this is no longer the case.

The LHC-TeV MW Working Group, including *W*-mass experts from CDF, D0, ATLAS, CMS and LHCb [AMOROSO 24], has examined this issue in depth. They report that a combination of all *W*-mass measurements corrected to a common theory description and PDF set, has a probability of compatibility of 0.5% only, and is therefore disfavoured. A 91% probability of compatibility is obtained when the CDF-II measurement is removed. The corresponding value of the *W* boson mass is 80369.2 ± 13.3 MeV, which we quote as the World Average.

More information is given in [M. Grunewald and A. Gurtu, Mass and Width of the *W* Boson review, PDG 24] and in [AMOROSO 24].

[1] AAIJ 22C analyse *W* production in the muon decay channel, with the transverse momentum of the muon required to be between 28 and 52 GeV. Analysing the distribution of the muon charge divided by the muon transverse momentum of approximately 2.4 million selected *W* candidates, a value of M_W = 80354 ± 23(stat.)±10(exp.)±17(theo.)±9(PDF) MeV is obtained; we combine the three systematic uncertainties in quadrature.

[2] AALTONEN 22 select a data sample of about 4 million *W* boson candidates in 8.8 fb^{-1} of Run-II data. The mass is determined using the transverse mass, transverse lepton momentum and transverse missing momentum distributions of *W* decays into electrons or muons, accounting for correlations. This measurement supersedes AALTONEN 12E, but is not used in OUR EVALUATION.

[3] AABOUD 18J select 4.61M $W^+ \to \mu^+\nu_\mu$, 3.40M $W^+ \to e^+\nu_e$, 3.23M $W^- \to \mu^-\overline{\nu}_\mu$ and 2.49M $W^- \to e^-\overline{\nu}_e$ events in 4.6 fb^{-1} pp data at 7 TeV. The *W* mass is determined using the transverse mass and transverse lepton momentum distributions, accounting for correlations. The systematic error includes 0.011 GeV experimental and 0.014 GeV modelling uncertainties.

[4] Combination of results from ABAZOV 12F and ABAZOV 09AB as quoted in ABAZOV 12F.

[5] ABDALLAH 08A use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\ell\nu$ and $W^+W^- \to q\overline{q}q\overline{q}$ events for energies 172 GeV and above. The *W* mass was also extracted from the dependence of the WW cross section close to the production threshold and combined appropriately to obtain the final result. The systematic error includes ±0.025 GeV due to final state interactions and ±0.009 GeV due to LEP energy uncertainty.

[6] ABBIENDI 06 use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\ell\nu_\ell$ and $W^+W^- \to q\overline{q}q\overline{q}$ events. The result quoted here is obtained combining this mass value with the results using $W^+W^- \to \ell\nu_\ell\ell'\nu_{\ell'}$ events in the energy range 183–207 GeV (ABBIENDI 03C) and the dependence of the WW production cross-section on m_W at threshold. The systematic error includes ±0.009 GeV due to the uncertainty on the LEP beam energy.

[7] ACHARD 06 use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\ell\nu_\ell$ and $W^+W^- \to q\overline{q}q\overline{q}$ events in the C.M. energy range 189–209 GeV. The result quoted here is obtained combining this mass value with the results obtained from a direct *W* mass reconstruction at 172 and 183 GeV and with those from the dependence of the WW production cross-section on m_W at 161 and 172 GeV (ACCIARRI 99).

[8] SCHAEL 06 use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\ell\nu_\ell$ and $W^+W^- \to q\overline{q}q\overline{q}$ events in the C.M. energy range 183–209 GeV. The result quoted here is obtained combining this mass value with those obtained from the dependence of the *W* pair production cross-section on m_W at 161 and 172 GeV (BARATE 97 and BARATE 97S respectively). The systematic error includes ±0.009 GeV due to possible effects of final state interactions in the $q\overline{q}q\overline{q}$ channel and ±0.009 GeV due to the uncertainty on the LEP beam energy.

[9] ABAZOV 02D improve the measurement of the *W*-boson mass including $W \to e\nu_e$ events in which the electron is close to a boundary of a central electromagnetic calorimeter module. Properly combining the results obtained by fitting $m_T(W)$, $p_T(e)$, and $p_T(\nu)$, this sample provides a mass value of 80.574 ± 0.405 GeV. The value reported here is a combination of this measurement with all previous DØ *W*-boson mass measurements.

[10] ANDREEV 18A obtain this result in a combined electroweak and QCD analysis using all deep-inelastic e^+p and e^-p neutral current and charged current scattering cross sections published by the H1 Collaboration, including data with longitudinally polarized lepton beams.

[11] AALTONEN 12E select 470k $W \to e\nu$ decays and 625k $W \to \mu\nu$ decays in 2.2 fb^{-1} of Run-II data. The mass is determined using the transverse mass, transverse lepton momentum and transverse missing energy distributions, accounting for correlations. This result supersedes AALTONEN 07F. AALTONEN 14D gives more details on the procedures followed by the authors. This measurement is superseded by AALTONEN 22.

[12] ABAZOV 12F select 1677k $W \to e\nu$ decays in 4.3 fb^{-1} of Run-II data. The mass is determined using the transverse mass and transverse lepton momentum distributions, accounting for correlations.

[13] ABAZOV 09AB study the transverse mass, transverse electron momentum, and transverse missing energy in a sample of 0.5 million $W \to e\nu$ decays selected in Run-II data. The quoted result combines all three methods, accounting for correlations.

[14] AALTONEN 07F obtain high purity $W \to e\nu_e$ and $W \to \mu\nu_\mu$ candidate samples totaling 63,964 and 51,128 events respectively. The *W* mass value quoted above is derived by simultaneously fitting the transverse mass and the lepton, and neutrino p_T distributions.

[15] AKTAS 06 fit the Q^2 dependence ($300 < Q^2 < 30{,}000$ GeV^2) of the charged-current differential cross section with a propagator mass. The first error is experimental and the second corresponds to uncertainties due to input parameters and model assumptions.

[16] CHEKANOV 02C fit the Q^2 dependence ($200 < Q^2 < 60000$ GeV^2) of the charged-current differential cross sections with a propagator mass fit. The last error is due to the uncertainty on the probability density functions.

[17] AFFOLDER 01E fit the transverse mass spectrum of 30115 $W \to e\nu_e$ events (M_W= 80.473 ± 0.065 ± 0.092 GeV) and of 14740 $W \to \mu\nu_\mu$ events (M_W= 80.465 ± 0.100 ± 0.103 GeV) obtained in the run IB (1994-95). Combining the electron and muon results, accounting for correlated uncertainties, yields M_W= 80.470 ± 0.089 GeV. They combine this value with their measurement of ABE 95P reported in run IA (1992-93) to obtain the quoted value.

[18] BREITWEG 00D fit the Q^2 dependence ($200 < Q^2 < 22500$ GeV^2) of the charged-current differential cross sections with a propagator mass fit. The last error is due to the uncertainty on the probability density functions.

[19] ALITTI 92B result has two contributions to the systematic error (±0.83); one (±0.81) cancels in m_W/m_Z and one (±0.17) is noncancelling. These were added in quadrature. We choose the ALITTI 92B value without using the LEP m_Z value, because we perform our own combined fit.

[20] There are two contributions to the systematic error (±0.84): one (±0.81) which cancels in m_W/m_Z and one (±0.21) which is non-cancelling. These were added in quadrature.

[21] ABE 89I systematic error dominated by the uncertainty in the absolute energy scale.

[22] ALBAJAR 89 result is from a total sample of 299 $W \to e\nu$ events.

[23] ALBAJAR 89 result is from a total sample of 67 $W \to \mu\nu$ events.

[24] ALBAJAR 89 result is from $W \to \tau\nu$ events.

W/*Z* MASS RATIO

[1] AABOUD 18J select 4.61M $W^+ \to \mu^+\nu_\mu$, 3.40M $W^+ \to e^+\nu_e$, 3.23M $W^- \to \mu^-\overline{\nu}_\mu$ and 2.49M $W^- \to e^-\overline{\nu}_e$ events in 4.6 fb^{-1} pp data at 7 TeV. The W mass is determined using the transverse mass and transverse lepton momentum distributions, accounting for correlations. The systematic error includes 0.007 GeV experimental and 0.024 GeV modelling uncertainties.

W WIDTH

The W width listed here corresponds to the width parameter in a Breit-Wigner distribution with mass-dependent width. To obtain the world average, common systematic uncertainties between experiments are properly taken into account. The LEP-2 average W width based on published results is 2.195 ± 0.083 GeV [SCHAEL 13A]. The combined Tevatron data yields an average W width of 2.046±0.049 GeV [FERMILAB-TM-2460-E].

OUR FIT uses these average LEP and Tevatron width values and combines them assuming no correlations.

[1] ABAZOV 09AK obtain this result fitting the high-end tail (100-200 GeV) of the transverse mass spectrum in $W \to e\nu$ decays.

[2] AALTONEN 08B obtain this result fitting the high-end tail (90–200 GeV) of the transverse mass spectrum in semileptonic $W \to e\nu_e$ and $W \to \mu\nu_\mu$ decays.

[3] ABDALLAH 08A use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\ell\nu$ and $W^+W^- \to q\overline{q}q\overline{q}$ events. The systematic error includes ±0.065 GeV due to final state interactions.

[4] ABBIENDI 06 use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\ell\nu_\ell$ and $W^+W^- \to q\overline{q}q\overline{q}$ events. The systematic error includes ±0.003 GeV due to the uncertainty on the LEP beam energy.

[5] ACHARD 06 use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\ell\nu_\ell$ and $W^+W^- \to q\overline{q}q\overline{q}$ events in the C.M. energy range 189–209 GeV. The result quoted here is obtained combining this value of the width with the result obtained from a direct W mass reconstruction at 172 and 183 GeV (ACCIARRI 99).

[6] SCHAEL 06 use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\ell\nu_\ell$ and $W^+W^- \to q\overline{q}q\overline{q}$ events. The systematic error includes ±0.05 GeV due to possible effects of final state interactions in the $q\overline{q}q\overline{q}$ channel and ±0.01 GeV due to the uncertainty on the LEP beam energy.

[7] ABAZOV 02E obtain this result fitting the high-end tail (90–200 GeV) of the transverse-mass spectrum in semileptonic $W \to e\nu_e$ decays.

[8] AFFOLDER 00M fit the high transverse mass (100–200 GeV) $W \to e\nu_e$ and $W \to \mu\nu_\mu$ events to obtain $\Gamma(W)$= 2.04 ± 0.11(stat)±0.09(syst) GeV. This is combined with the earlier CDF measurement (ABE 95C) to obtain the quoted result.

[9] ABBOTT 00B measure R = 10.43 ± 0.27 for the $W \to e\nu_e$ decay channel. They use the SM theoretical predictions for $\sigma(W)/\sigma(Z)$ and $\Gamma(W \to e\nu_e)$ and the world average for B($Z \to ee$). The value quoted here is obtained combining this result (2.169 ± 0.070 GeV) with that of ABBOTT 99H.

[10] ABE 95W measured R = 10.90 ± 0.32 ± 0.29. They use m_W=80.23 ± 0.18 GeV, $\sigma(W)/\sigma(Z)$ = 3.35 ± 0.03, $\Gamma(W \to e\nu)$ = 225.9 ± 0.9 MeV, $\Gamma(Z \to e^+e^-)$ = 83.98 ± 0.18 MeV, and $\Gamma(Z)$ = 2.4969 ± 0.0038 GeV.

[11] ALITTI 92 measured $R = 10.4^{+0.7}_{-0.6} \pm 0.3$. The values of $\sigma(Z)$ and $\sigma(W)$ come from $O(\alpha_s^2)$ calculations using m_W = 80.14 ± 0.27 GeV, and m_Z = 91.175 ± 0.021 GeV along with the corresponding value of $\sin^2\theta_W$ = 0.2274. They use $\sigma(W)/\sigma(Z)$ = 3.26 ± 0.07 ± 0.05 and $\Gamma(Z)$ = 2.487 ± 0.010 GeV.

[12] ALBAJAR 91 measured $R = 9.5^{+1.1}_{-1.0}$ (stat. + syst.). $\sigma(W)/\sigma(Z)$ is calculated in QCD at the parton level using m_W = 80.18 ± 0.28 GeV and m_Z = 91.172 ± 0.031 GeV along with $\sin^2\theta_W$ = 0.2322 ± 0.0014. They use $\sigma(W)/\sigma(Z)$ = 3.23 ± 0.05 and $\Gamma(Z)$ = 2.498 ± 0.020 GeV. This measurement is obtained combining both the electron and muon channels.

W^+ DECAY MODES

W^- modes are charge conjugates of the modes below.

	Mode		Fraction (Γ_i/Γ)		Confidence level
Γ_1	$\ell^+\nu$	[a]	(10.86± 0.09) %		
Γ_2	$e^+\nu$		(10.71± 0.16) %		
Γ_3	$\mu^+\nu$		(10.63± 0.15) %		
Γ_4	$\tau^+\nu$		(11.38± 0.21) %		
Γ_5	hadrons		(67.41± 0.27) %		
Γ_6	$\pi^+\gamma$		< 7	$\times 10^{-6}$	95%
Γ_7	$D_s^+\gamma$		< 6	$\times 10^{-4}$	95%
Γ_8	cX		(33.3 ± 2.6) %		
Γ_9	$c\overline{s}$		(31 $^{+13}_{-11}$) %		
Γ_{10}	invisible	[b]	(1.4 ± 2.9) %		
Γ_{11}	$\pi^+\pi^+\pi^-$		< 1.01	$\times 10^{-6}$	95%

[a] ℓ indicates each type of lepton (e, μ, and τ), not sum over them.

[b] This represents the width for the decay of the W boson into a charged particle with momentum below detectability, p< 200 MeV.

W PARTIAL WIDTHS

Γ(invisible) Γ10

This represents the width for the decay of the W boson into a charged particle with momentum below detectability, p< 200 MeV.

VALUE (MeV)	DOCUMENT ID		TECN	COMMENT
30 $^{+52}_{-48}$ ±33	[1] BARATE	99I	ALEP	E_{cm}^{ee}= 161+172+183 GeV
• • • We do not use the following data for averages, fits, limits, etc. • • •				
	[2] BARATE	99L	ALEP	E_{cm}^{ee}= 161+172+183 GeV

[1] BARATE 99I measure this quantity using the dependence of the total cross section σ_{WW} upon a change in the total width. The fit is performed to the WW measured cross sections at 161, 172, and 183 GeV. This partial width is < 139 MeV at 95%CL.

[2] BARATE 99L use W-pair production to search for effectively invisible W decays, tagging with the decay of the other W boson to Standard Model particles. The partial width for effectively invisible decay is < 27 MeV at 95%CL.

W BRANCHING RATIOS

Overall fits are performed to determine the branching ratios of the W boson. Averages on $W \to e\nu$, $W \to \mu\nu$, and $W \to \tau\nu$, and their correlations are obtained by combining results from the four LEP experiments properly taking into account the common systematic uncertainties and their correlations [SCHAEL 13A]. A first fit determines the three individual leptonic braching ratios B($W \to e\nu$), B($W \to \mu\nu$), and B($W \to \tau\nu$). This fit has a χ^2 = 6.3 for 9 degrees of freedom. The correlation coefficients between the branching fractions are 0.14 ($e-\mu$), −0.20 ($e-\tau$), −0.12 ($\mu-\tau$). A second fit assumes lepton universality and determines the leptonic branching ratio B($W \to \ell\nu$) and the hadronic branching ratio is derived as B($W \to$ hadrons) = 1 − 3 B($W \to \ell\nu$). This fit has a χ^2 = 15.4 for 11 degrees of freedom.

[1] AABOUD 17Q make a precise determination of $W \to e\nu$ and $W \to \mu\nu$ production in the follwoing fiducial phase space: lepton pseudo-rapidity range $|\eta| < 2.5$, lepton and neutrino transverse momenta larger than 25 GeV each, and W transverse mass larger than 25 GeV. They determine the ratio of the W branching fractions $B(W \to e\nu)/B(W \to \mu\nu) = 0.9967 \pm 0.0004 \pm 0.0101 = 0.997 \pm 0.010$.

[2] AAIJ 16AJ make precise measurements of forward $W \to e\nu$ and $W \to \mu\nu$ production in proton–proton collisions at 8 TeV and determine the ratio of the W branching fractions $B(W \to e\nu)/B(W \to \mu\nu) = 1.020 \pm 0.002 \pm 0.019$.

[3] ABACHI 95D obtain this result from the measured $\sigma_W B(W \to \mu\nu)$= 2.09 ± 0.23 ± 0.11 nb and $\sigma_W B(W \to e\nu)$= 2.36 ± 0.07 ± 0.13 nb in which the first error is the combined statistical and systematic uncertainty, the second reflects the uncertainty in the luminosity.

[4] ABE 92I obtain $\sigma_W B(W \to \mu\nu)$= 2.21 ± 0.07 ± 0.21 and combine with ABE 91C $\sigma_W B((W \to e\nu))$ to give a ratio of the couplings from which we derive this measurement.

[1] ABBIENDI 06A measure $\langle N_{\text{charged}} \rangle = 38.74 \pm 0.12 \pm 0.26$ when both W bosons decay hadronically and $\langle N_{\text{charged}} \rangle = 19.39 \pm 0.11 \pm 0.09$ when one W boson decays semileptonically. The value quoted here is obtained under the assumption that there is no color reconnection between W bosons; the value is a weighted average taking into account correlations in the systematic uncertainties.
[2] ABREU,P 00F measure $\langle N_{\text{charged}} \rangle = 39.12 \pm 0.33 \pm 0.36$ and $38.11 \pm 0.57 \pm 0.44$ in the fully hadronic final states at 189 and 183 GeV respectively, and $\langle N_{\text{charged}} \rangle = 19.49 \pm 0.31 \pm 0.27$ and $19.78 \pm 0.49 \pm 0.43$ in the semileptonic final states. The value quoted is a weighted average without assuming any correlations.
[3] ABBIENDI 99N use the final states $W^+W^- \to q\overline{q}\ell\overline{\nu}_\ell$ to derive this value.
[4] ABREU 98C combine results from both the fully hadronic as well semileptonic WW final states after demonstrating that the W decay charged multiplicity is independent of the topology within errors.

TRIPLE GAUGE COUPLINGS (TGC'S)

Revised April 2017 by M.W. Grünewald (U. College Dublin) and A. Gurtu (Formerly Tata Inst.).

Fourteen independent couplings, seven each for ZWW and γWW, completely describe the VWW vertices within the most general framework of the electroweak Standard Model (SM) consistent with Lorentz invariance and U(1) gauge invariance. Of each of the seven TGCs, three conserve C and P individually, three violate CP, and one violates C and P individually while conserving CP. Assumption of C and P conservation and electromagnetic gauge invariance reduces the number of independent VWW couplings to five: one common set [1,2] is $(\kappa_\gamma, \kappa_Z, \lambda_\gamma, \lambda_Z, g_1^Z)$, where $\kappa_\gamma = \kappa_Z = g_1^Z = 1$ and $\lambda_\gamma = \lambda_Z = 0$ in the Standard Model at tree level. The parameters κ_Z and λ_Z are related to the other three due to constraints of gauge invariance as follows: $\kappa_Z = g_1^Z - (\kappa_\gamma - 1)\tan^2\theta_W$ and $\lambda_Z = \lambda_\gamma$, where θ_W is the weak mixing angle. The W magnetic dipole moment, μ_W, and the W electric quadrupole moment, q_W, are expressed as $\mu_W = e\,(1 + \kappa_\gamma + \lambda_\gamma)/2M_W$ and $q_W = -e\,(\kappa_\gamma - \lambda_\gamma)/M_W^2$.

Precision measurements of suitable observables at LEP1 has already led to an exploration of much of the TGC parameter space. At LEP2, the VWW coupling arises in W-pair production via s-channel exchange, or in single W production via the radiation of a virtual photon off the incident e^+ or e^-. At the Tevatron and the LHC, hard-photon bremsstrahlung off a produced W or Z signals the presence of a triple-gauge vertex. In order to extract the value of one TGC, the others are generally kept fixed to their SM values. While most analyses use the above gauge constraints in the extraction of TGCs, one analysis of W-pair events also determines the real and imaginary parts of all 14 couplings using unconstrained single-parameter fits [3]. The results are consistent. Some experiments have determined limits on the couplings under various non-LEP scenarios and assuming different values of the form factor Λ, where the coupling parameters are scaled by $1/(1 + s/\Lambda^2)^2$. For practical reasons it is not possible to quote all such determinations in the listings. For that the individual papers may be consulted. Recently, EFT-inspired sets of couplings [4,5], such as $c_{WWW}/\Lambda^2, c_W/\Lambda^2, c_B/\Lambda^2$ which are linearly related to the couplings discussed above, are also determined by the LHC experiments.

[1] ABDALLAH 10 use data on the final states $e^+e^- \to jj\ell\nu$, $jjjj$, jjX, ℓX, at center-of-mass energies between 189–209 GeV at LEP2, where j = jet, ℓ = lepton, and X represents missing momentum. The fit is carried out keeping all other parameters fixed at their SM values.

[2] SCHAEL 05A study single–photon, single–W, and WW–pair production from 183 to 209 GeV. The result quoted here is derived from the WW–pair production sample. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[3] ABBIENDI 04D combine results from W^+W^- in all decay channels. Only *CP*-conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $0.923 < g_1^Z < 1.054$.

[4] ACHARD 04D study WW–pair production, single–W production and single–photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained from the WW–pair production sample including data from 161 to 183 GeV, ACCIARRI 99Q. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[5] SIRUNYAN 20BA study electroweak production of a W boson in association with two jets, using W decays in the electron or muon channel. The isolated muons (electrons) are required to have a transverse momentum larger than 25 (30) GeV, while the transverse momentum of the two jets has to be larger than 50 and 30 GeV. A total of 2.382 (1.051) million events are selected in the muon (electron) channel, with a Standard Model expectation of 2.39 ± 0.17 (1.054 ± 0.058) million events. Analyzing the transverse momentum distribution of the charged leptons from W decay, the following 95% C.L. limit is obtained: $0.971 < g_1^Z < 1.044$. Combining this result with that from the closely-related electroweak Z-jet-jet production SIRUNYAN 18BZ, the limit becomes: $0.979 < g_1^Z < 1.034$.

[6] SIRUNYAN 19CL study WW and WZ production in lepton + jet events, with one W boson decaying leptonically (electron or muon), and another W or Z boson decaying hadronically, reconstructed as a single massive large-radius jet. In the electron channel 2,456 (2,235) events are selected in the $WW(WZ)$ category, while in the muon channel 3,996 (3572) events are selected in the $WW(WZ)$ category. Analysing the di-boson invariant mass distribution, the following 95% C.L. limit is obtained: $0.9939 < g_1^Z < 1.0074$.

[7] SIRUNYAN 18BZ study $pp \to Z$ *jet jet* events at 13 TeV where $Z \to e^+e^-/\mu^+\mu^-$. Isolated electrons and muons are selected with p_T of the leading/sub-leading lepton > 30/20 GeV and $|\eta| < 2.4$, with the di-lepton invariant mass within 15 GeV of the Z mass. The two highest p_T jets are selected with p_T of the leading/sub-leading jet > 50/30 GeV respectively and dijet invariant mass > 200 GeV. Templates in the transverse momentum of the Z are utilized to set limits on the triple gauge couplings in the EFT and the LEP parametrizations. The following 95% C.L. limit is obtained: $0.965 < g_1^Z < 1.042$.

[8] AABOUD 17S analyze electroweak production of a W boson in association with two jets at high dijet invariant mass, with the W boson decaying to electron or muon plus neutrino. In the signal region of dijet mass larger than 1 TeV and leading-jet transverse momentum larger than 600 GeV, 30 events are observed in the data with 39 ± 4 events expected in the Standard Model, yielding the following limit at 95% CL for the form factor cut-off scale $\Lambda_{FF} \to \infty$: $0.87 < g_1^Z < 1.12$.

[9] AABOUD 17U analyze production of WW or WZ boson pairs with one W boson decaying to electron or muon plus neutrino, and the other W or Z boson decaying hadronically. The hadronic decay system is reconstructed as either a resolved two-jet system or as a single large jet. Analysing the transverse momentum distribution of the hadronic system above 100 GeV yields the following limit at 95% CL for the form factor cut-off scale $\Lambda_{FF} \to \infty$: $0.979 < g_1^Z < 1.024$.

[10] KHACHATRYAN 17O analyse WZ production where each boson decays into electrons or muons. Events are required to have a tri-lepton invariant mass larger than 100 GeV, with one of the lepton pairs having an invariant mass within 20 GeV of the Z boson mass. The Z transverse momentum spectrum is analyzed to set a 95% C.L. limit of: $0.982 < g_1^Z < 1.035$.

[11] SIRUNYAN 17X study $pp \to WW/WZ \to \ell\nu q\overline{q}$ production at 8 TeV where ℓ is an electron or muon with $p_T > 30$ or 25 GeV respectively. Suitable cuts are put on the p_T of the dijet system and the missing E_T of the event yielding a total of 285 and 204 WV events observed in the electron and muon channels. The following 95% C.L. limit is obtained: $0.9913 < g_1^Z < 1.024$.

[12] AAD 16AR study WW production in pp collisions and select 6636 WW candidates in decay modes with electrons or muons with an expected background of 1546 ± 157 events. Assuming the LEP formulation and setting the form-factor Λ to infinity, a fit to the transverse momentum distribution of the leading charged lepton, leads to a 95% C.L. range of $0.984 < g_1^Z < 1.027$.

[13] AAD 16P study WZ production in pp collisions and select 2091 WZ candidates in 4 decay modes with electrons and muons, with an expected background of 1825 ± 7 events. Analyzing the WZ transverse momentum distribution, the resulting 95% C.L. limit is: $0.981 < g_1^Z < 1.029$.

[14] AAD 14Y determine the electroweak Z-dijet cross section in 8 TeV pp collisions. $Z \to ee$ and $Z \to \mu\mu$ decays are selected with the di-lepton $p_T > 20$ GeV and mass in the 81–101 GeV range. Minimum two jets are required with $p_T > 55$ and 45 GeV and no additional jets with $p_T > 25$ GeV in the rapidity interval between them. The normalized p_T balance between the Z and the two jets is required to be < 0.15. This leads to a selection of 900 events with dijet mass > 1 TeV. The number of signal and background events expected is 261 and 592 respectively. A Poisson likelihood method is used on an event by event basis to obtain the 95% CL limit $0.5 < g_1^Z < 1.26$ for a form factor value $\Lambda = \infty$.

[15] AAD 13AL study WW production in pp collisions and select 1325 WW candidates in decay modes with electrons or muons with an expected background of 369 ± 61 events. Assuming the LEP formulation and setting the form-factor Λ = infinity, a fit to the transverse momentum distribution of the leading charged lepton, leads to a 95% C.L. range of $0.961 < g_1^Z < 1.052$. Supersedes AAD 12AC.

[16] CHATRCHYAN 13BF determine the W^+W^- production cross section using unlike sign di-lepton (e or μ) events with high $\not{p}_T$. The leptons have $p_T > 20$ GeV/c and are isolated. 1134 candidate events are observed with an expected SM background of 247 ± 34. The p_T distribution of the leading lepton is fitted to obtain 95% C.L. limits of $0.905 \le g_1^Z \le 1.095$.

[17] AAD 12CD study WZ production in pp collisions and select 317 WZ candidates in three $\ell\nu$ decay modes with an expected background of 68.0 ± 10.0 events. The resulting 95% C.L. range is: $0.943 < g_1^Z < 1.093$. Supersedes AAD 12V.

[18] AALTONEN 12AC study WZ production in $p\overline{p}$ collisions and select 63 WZ candidates in three $\ell\nu$ decay modes with an expected background of 7.9 ± 1.0 events. Based on the cross section and shape of the Z transverse momentum spectrum, the following 95% C.L. range is reported: $0.92 < g_1^Z < 1.20$ for a form factor of $\Lambda = 2$ TeV.

[19] ABAZOV 12AG combine new results with already published results on $W\gamma$, WW and WZ production in order to determine the couplings with increased precision, superseding ABAZOV 08R, ABAZOV 11AC, ABAZOV 09AJ, ABAZOV 09AD. The 68% C.L. result for a formfactor cutoff of $\Lambda = 2$ TeV is $g_1^Z = 1.022^{+0.032}_{-0.030}$.

[20] ABAZOV 11 study the $p\overline{p} \to 3\ell\nu$ process arising in WZ production. They observe 34 WZ candidates with an estimated background of 6 events. An analysis of the p_T spectrum of the Z boson leads to a 95% C.L. limit of $0.944 < g_1^Z < 1.154$, for a form factor $\Lambda = 2$ TeV.

[21] AALTONEN 10K study $p\overline{p} \to W^+W^-$ with $W \to e/\mu\nu$. The p_T of the leading (second) lepton is required to be > 20 (10) GeV. The final number of events selected is 654 of which 320 ± 47 are estimated to be background. The 95% C.L. interval is $0.76 < g_1^Z < 1.34$ for $\Lambda = 1.5$ TeV and $0.78 < g_1^Z < 1.30$ for $\Lambda = 2$ TeV.

[22] ABAZOV 09AD study the $p\overline{p} \to \ell\nu$ 2jet process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is $0.88 < g_1^Z < 1.20$.

[23] ABAZOV 09AJ study the $p\overline{p} \to 2\ell 2\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of $0.86 < g_1^Z < 1.3$, for a form factor $\Lambda = 2$ TeV.

[24] ABDALLAH 08C determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \to W^+W^- \to (qq)(\ell\nu)$, where $\ell = e$ or μ. Values of all other couplings are fixed to their standard model values.

[25] ABAZOV 07Z set limits on anomalous TGCs using the measured cross section and $p_T(Z)$ distribution in WZ production with both the W and the Z decaying leptonically into electrons and muons. Setting the other couplings to their standard model values, the 95% C.L. limit for a form factor scale $\Lambda = 2$ TeV is $0.86 < g_1^Z < 1.35$.

[26] ABAZOV 05S study $\overline{p}p \to WZ$ production with a subsequent trilepton decay to $\ell\nu\ell'\overline{\ell}'$ (ℓ and $\ell' = e$ or μ). Three events (estimated background 0.71 ± 0.08 events) with WZ decay characteristics are observed from which they derive limits on the anomalous WWZ couplings. The 95% CL limit for a form factor scale $\Lambda = 1.5$ TeV is $0.51 < g_1^Z < 1.66$, fixing λ_Z and κ_Z to their Standard Model values.

[27] ABREU 01I combine results from e^+e^- interactions at 189 GeV leading to W^+W^- and $We\nu_e$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is $0.84 < g_1^Z < 1.13$.

[28] ABBOTT 99I perform a simultaneous fit to the $W\gamma$, $WW \to$ dilepton, $WW/WZ \to e\nu jj$, $WW/WZ \to \mu\nu jj$, and $WZ \to$ trilepton data samples. For $\Lambda = 2.0$ TeV, the 95%CL limits are $0.63 < g_1^Z < 1.57$, fixing λ_Z and κ_Z to their Standard Model values, and assuming Standard Model values for the $WW\gamma$ couplings.

[1] ABDALLAH 10 use data on the final states $e^+e^- \to jj\ell\nu$, $jjjj$, jjX, ℓX, at center-of-mass energies between 189–209 GeV at LEP2, where j = jet, ℓ = lepton, and X represents missing momentum. The fit is carried out keeping all other parameters fixed at their SM values.

[2] SCHAEL 05A study single–photon, single–W, and WW–pair production from 183 to 209 GeV. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[3] ABBIENDI 04D combine results from W^+W^- in all decay channels. Only CP-conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $0.73 < \kappa_\gamma < 1.07$.

[4] ACHARD 04D study WW–pair production, single–W production and single–photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained including data from 161 to 183 GeV, ACCIARRI 99Q. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[5] AABOUD 17U analyze production of WW or WZ boson pairs with one W boson decaying to electron or muon plus neutrino, and the other W or Z boson decaying hadronically. The hadronic decay system is reconstructed as either a resolved two-jet system or as a single large jet. Analysing the transverse momentum distribution of the hadronic system above 100 GeV yields the following limit at 95% CL for the form factor cut-off scale $\Lambda_{FF} \to \infty$: $0.939 < \kappa_\gamma < 1.064$.

[6] SIRUNYAN 17X study $pp \to WW/WZ \to \ell\nu q\overline{q}$ production at 8 TeV where ℓ is an electron or muon with $p_T > 30$ or 25 GeV respectively. Suitable cuts are put on the p_T of the dijet system and the missing E_T of the event yielding a total of 285 and 204 WV events observed in the electron and muon channels. The following 95% C.L. limit is obtained: $0.956 < \kappa_\gamma < 1.063$.

[7] CHATRCHYAN 14AB measure $W\gamma$ production cross section for $p_T^\gamma > 15$ GeV and $R(\ell\gamma) > 0.7$, which is the separation between the γ and the final state charged lepton (e or μ) in the azimuthal angle-pseudorapidity ($\phi - \eta$) plane. After background subtraction the number of $e\nu\gamma$ and $\mu\nu\gamma$ events is determined to be 3200 ± 325 and 4970 ± 543 respectively, compatible with expectations from the SM. This leads to a 95% CL limit of $0.62 < \kappa_\gamma < 1.29$, assuming other parameters have SM values.

[8] AAD 13AN study $W\gamma$ production in pp collisions. In events with no additional jet, 4449 (6578) W decays to electron (muon) are selected, with an expected background of 1662 ± 262 (2538 ± 362) events. Analysing the photon p_T spectrum above 100 GeV yields a 95% C.L. limit of $0.59 < \kappa_\gamma < 1.46$. Supersedes AAD 12BX.

[9] CHATRCHYAN 13BF determine the W^+W^- production cross section using unlike sign di-lepton (e or μ) events with high $\not{p}_T$. The leptons have $p_T > 20$ GeV/c and are isolated. 1134 candidate events are observed with an expected SM background of 247 ± 34. The p_T distribution of the leading lepton is fitted to obtain 95% C.L. limits of $0.79 \leq k_\gamma \leq 1.22$.

[10] ABAZOV 12AG combine new results with already published results on $W\gamma$, WW and WZ production in order to determine the couplings with increased precision, superseding ABAZOV 08R, ABAZOV 11AC, ABAZOV 09AJ, ABAZOV 09AD. The 68% C.L. result for a formfactor cutoff of $\Lambda = 2$ TeV is $\kappa_\gamma = 1.048^{+0.106}_{-0.105}$.

[11] ABAZOV 11AC study $W\gamma$ production in $p\overline{p}$ collisions at 1.96 TeV, with the W decay products containing an electron or a muon. They select 196 (363) events in the electron (muon) mode, with a SM expectation of 190 (372) events. A likelihood fit to the photon E_T spectrum above 15 GeV yields at 95% C.L. the result: $0.6 < \kappa_\gamma < 1.4$ for a formfactor $\Lambda = 2$ TeV.

[12] CHATRCHYAN 11M study $W\gamma$ production in pp collisions at $\sqrt{s} = 7$ TeV using 36 pb^{-1} pp data with the W decaying to electron and muon. The total cross section is measured for photon transverse energy $E_T^\gamma > 10$ GeV and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell,\gamma) > 0.7$. The number of candidate (background) events is 452 (228 ± 21) for the electron channel and 520 (277 ± 25) for the muon channel. Setting other couplings to their standard model value, they derive a 95% CL limit of $-0.11 < \kappa_\gamma < 2.04$.

[13] AALTONEN 10K study $p\overline{p} \to W^+W^-$ with $W \to e/\mu\nu$. The p_T of the leading (second) lepton is required to be > 20 (10) GeV. The final number of events selected is 654 of which 320 ± 47 are estimated to be background. The 95% C.L. interval is $0.37 < \kappa_\gamma < 1.72$ for $\Lambda = 1.5$ TeV and $0.43 < \kappa_\gamma < 1.65$ for $\Lambda = 2$ TeV.

[14] AARON 09B study single-W production in ep collisions at 0.3 TeV C.M. energy. They select 53 $W \to e/\mu$ events with a standard model expectation of 54.1 ± 7.4 events. Fitting the transverse momentum spectrum of the hadronic recoil system they obtain a 95% C.L. limit of $-3.7 < \kappa_\gamma < -1.5$ or $0.3 < \kappa_\gamma < 1.5$, where the ambiguity is due to the quadratic dependence of the cross section to the coupling parameter.

[15] ABAZOV 09AD study the $p\overline{p} \to \ell\nu$ 2jet process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is $0.56 < \kappa_\gamma < 1.55$.

[16] ABAZOV 09AJ study the $p\overline{p} \to 2\ell 2\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of $0.46 < \kappa_\gamma < 1.83$, for a form factor $\Lambda = 2$ TeV.

[17] ABAZOV 08R use 0.7 fb^{-1} $p\overline{p}$ data at $\sqrt{s} = 1.96$ TeV to select 263 $W\gamma + X$ events, of which 187 constitute signal, with the W decaying into an electron or a muon, which is required to be well separated from a photon with $E_T > 9$ GeV. A likelihood fit to the photon E_T spectrum yields a 95% CL limit $0.49 < \kappa_\gamma < 1.51$ with other couplings fixed to their Standard Model values.

[18] ABDALLAH 08C determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \to W^+W^- \to (qq)(\ell\nu)$, where $\ell = e$ or μ. Values of all other couplings are fixed to their standard model values.

[19] AALTONEN 07L set limits on anomalous TGCs using the $p_T(W)$ distribution in WW and WZ production with the W decaying to an electron or muon and the Z to 2 jets. Setting other couplings to their standard model value, the 95% C.L. limits are $0.54 < \kappa_\gamma < 1.39$ for a form factor scale $\Lambda = 1.5$ TeV.

[20] ABAZOV 06H study $\overline{p}p \to WW$ production with a subsequent decay $WW \to e^+\nu_e e^-\overline{\nu}_e$, $WW \to e^\pm\nu_e\mu^\mp\nu_\mu$ or $WW \to \mu^+\nu_\mu\mu^-\overline{\nu}_\mu$. The 95% C.L. limit for a form factor scale $\Lambda = 1$ TeV is $-0.05 < \kappa_\gamma < 2.29$, fixing λ_γ=0. With the assumption that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit ($\Lambda = 2$ TeV) is $0.68 < \kappa < 1.45$.

[21] ABAZOV 05J perform a likelihood fit to the photon E_T spectrum of $W\gamma$ + X events, where the W decays to an electron or muon which is required to be well separated from the photon. For $\Lambda = 2.0$ TeV the 95% CL limits are $0.12 < \kappa_\gamma < 1.96$. In the fit λ_γ is kept fixed to its Standard Model value.

[22] ABREU 01I combine results from e^+e^- interactions at 189 GeV leading to W^+W^-, $We\nu_e$, and $\nu\overline{\nu}\gamma$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is $0.87 < \kappa_\gamma < 1.68$.

[23] BREITWEG 00 search for W production in events with large hadronic p_T. For $p_T > 20$ GeV, the upper limit on the cross section gives the 95%CL limit $-3.7 < \kappa_\gamma < 2.5$ (for λ_γ=0).

[24] ABBOTT 99I perform a simultaneous fit to the $W\gamma$, $WW \to$ dilepton, $WW/WZ \to e\nu jj$, $WW/WZ \to \mu\nu jj$, and $WZ \to$ trilepton data samples. For $\Lambda = 2.0$ TeV, the 95%CL limits are $0.75 < \kappa_\gamma < 1.39$.

[1] ABDALLAH 10 use data on the final states $e^+e^- \to jj\ell\nu$, $jjjj$, jjX, ℓX, at center-of-mass energies between 189–209 GeV at LEP2, where j = jet, ℓ = lepton, and X represents missing momentum. The fit is carried out keeping all other parameters fixed at their SM values.

[2] SCHAEL 05A study single–photon, single–W, and WW–pair production from 183 to 209 GeV. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[3] ABBIENDI 04D combine results from W^+W^- in all decay channels. Only *CP*-conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $-0.13 < \lambda_\gamma < 0.01$.

[4] ACHARD 04D study WW–pair production, single–W production and single–photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained including data from 161 to 183 GeV, ACCIARRI 99Q. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[5] CHATRCHYAN 14AB measure $W\gamma$ production cross section for $p_T^\gamma > 15$ GeV and R($\ell\gamma$) > 0.7, which is the separation between the γ and the final state charged lepton (e or μ) in the azimuthal angle-pseudorapidity ($\phi - \eta$) plane. After background subtraction the number of $e\nu\gamma$ and $\mu\nu\gamma$ events is determined to be 3200 ± 325 and 4970 ± 543 respectively, compatible with expectations from the SM. This leads to a 95% CL limit of $-0.050 < \lambda_\gamma < 0.037$, assuming all other parameters have SM values.

[6] AAD 13AN study $W\gamma$ production in pp collisions. In events with no additional jet, 4449 (6578) W decays to electron (muon) are selected, with an expected background of 1662 ± 262 (2538 ± 362) events. Analysing the photon p_T spectrum above 100 GeV yields a 95% C.L. limit of $-0.065 < \lambda_\gamma < 0.061$. Supersedes AAD 12BX.

[7] ABAZOV 12AG combine new results with already published results on $W\gamma$, WW and WZ production in order to determine the couplings with increased precision, superseding ABAZOV 08R, ABAZOV 11AC, ABAZOV 09AJ, ABAZOV 09AD. The 68% C.L. result for a formfactor cutoff of $\Lambda = 2$ TeV is $\lambda_\gamma = 0.007^{+0.021}_{-0.022}$.

[8] ABAZOV 11AC study $W\gamma$ production in $p\overline{p}$ collisions at 1.96 TeV, with the W decay products containing an electron or a muon. They select 196 (363) events in the electron (muon) mode, with a SM expectation of 190 (372) events. A likelihood fit to the photon E_T spectrum above 15 GeV yields at 95% C.L. the result: $-0.08 < \lambda_\gamma < 0.07$ for a formfactor $\Lambda = 2$ TeV.

[9] CHATRCHYAN 11M study $W\gamma$ production in pp collisions at $\sqrt{s} = 7$ TeV using 36 pb^{-1} pp data with the W decaying to electron and muon. The total cross section is measured for photon transverse energy $E_T^\gamma > 10$ GeV and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell,\gamma) > 0.7$. The number of candidate (background) events is 452 (228 ± 21) for the electron channel and 520 (277 ± 25) for the muon channel. Setting other couplings to their standard model value, they derive a 95% CL limit of $-0.18 < \lambda_\gamma < 0.17$.

[10] AARON 09B study single-W production in ep collisions at 0.3 TeV C.M. energy. They select 53 $W \to e/\mu$ events with a standard model expectation of 54.1 ± 7.4 events. Fitting the transverse momentum spectrum of the hadronic recoil system they obtain a 95% C.L. limit of $-2.5 < \lambda_\gamma < 2.5$.

[11] ABAZOV 09AD study the $p\overline{p} \to \ell\nu$2jet process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is $-0.10 < \lambda_\gamma < 0.11$.

[12] ABAZOV 09AJ study the $p\overline{p} \to 2\ell2\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of $-0.14 < \lambda_\gamma < 0.18$, for a form factor $\Lambda = 2$ TeV.

[13] ABAZOV 08R use 0.7 fb^{-1} $p\overline{p}$ data at $\sqrt{s} = 1.96$ TeV to select 263 $W\gamma + X$ events, of which 187 constitute signal, with the W decaying into an electron or a muon, which is required to be well separated from a photon with $E_T > 9$ GeV. A likelihood fit to the photon E_T spectrum yields a 95% CL limit $-0.12 < \lambda_\gamma < 0.13$ with other couplings fixed to their Standard Model values.

[14] ABDALLAH 08C determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \to W^+W^- \to (qq)(\ell\nu)$, where $\ell = e$ or μ. Values of all other couplings are fixed to their standard model values.

[15] AALTONEN 07L set limits on anomalous TGCs using the $p_T(W)$ distribution in WW and WZ production with the W decaying to an electron or muon and the Z to 2 jets. Setting other couplings to their standard model value, the 95% C.L. limits are $-0.18 < \lambda_\gamma < 0.17$ for a form factor scale $\Lambda = 1.5$ TeV.

[16] ABAZOV 06H study $\overline{p}p \to WW$ production with a subsequent decay $WW \to e^+\nu_e e^-\overline{\nu}_e$, $WW \to e^\pm\nu_e\mu^\mp\nu_\mu$ or $WW \to \mu^+\nu_\mu\mu^-\overline{\nu}_\mu$. The 95% C.L. limit for a form factor scale $\Lambda = 1$ TeV is $-0.97 < \lambda_\gamma < 1.04$, fixing κ_γ=1. With the assumption that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit (Λ = 2 TeV) is $-0.29 < \lambda < 0.30$.

[17] ABAZOV 05J perform a likelihood fit to the photon E_T spectrum of $W\gamma$ + X events, where the W decays to an electron or muon which is required to be well separated from the photon. For $\Lambda = 2.0$ TeV the 95% CL limits are $-0.20 < \lambda_\gamma < 0.20$. In the fit κ_γ is kept fixed to its Standard Model value.

[18] ABREU 01I combine results from e^+e^- interactions at 189 GeV leading to W^+W^-, $We\nu_e$, and $\nu\overline{\nu}\gamma$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is $-0.11 < \lambda_\gamma < 0.23$.

[19] BREITWEG 00 search for W production in events with large hadronic p_T. For p_T >20 GeV, the upper limit on the cross section gives the 95%CL limit $-3.2 < \lambda_\gamma < 3.2$ for κ_γ fixed to its Standard Model value.

[20] ABBOTT 99I perform a simultaneous fit to the $W\gamma$, $WW \to$ dilepton, $WW/WZ \to e\nu jj$, $WW/WZ \to \mu\nu jj$, and $WZ \to$ trilepton data samples. For $\Lambda = 2.0$ TeV, the 95%CL limits are $-0.18 < \lambda_\gamma < 0.19$.

κ_Z

This coupling is *CP*-conserving (*C*- and *P*- separately conserving).

[1] ACHARD 04D study WW–pair production, single–W production and single–photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained using the WW–pair production sample. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[2] SIRUNYAN 20BA study electroweak production of a W boson in association with two jets, using W decays in the electron or muon channel. The isolated muons (electrons) are required to have a transverse momentum larger than 25 (30) GeV, while the transverse momentum of the two jets has to be larger than 50 and 30 GeV. A total of 2.382 (1.051) million events are selected in the muon (electron) channel, with a Standard Model expectation of 2.39±0.17 (1.054±0.058) million events. Analysing the transverse momentum distribution of the charged leptons from W decay, the following 95% C.L. limit is obtained: $0.956 < \kappa_Z < 1.044$. Combining this result with that from the closely-related electroweak Z-jet-jet production SIRUNYAN 18BZ, the limit becomes: $0.957 < \kappa_Z < 1.042$.

[3] SIRUNYAN 19CL study WW and WZ production in lepton + jet events, with one W boson decaying leptonically (electron or muon), and another W or Z boson decaying hadronically, reconstructed as a single massive large-radius jet. In the electron channel 2,456 (2,235) events are selected in the $WW(WZ)$ category, while in the muon channel 3,996 (3572) events are selected in the $WW(WZ)$ category. Analysing the di-boson invariant mass distribution, the following 95% C.L. limit is obtained: $0.9921 < \kappa_Z < 1.0082$.

[4] AABOUD 17S analyze electroweak production of a W boson in association with two jets at high dijet invariant mass, with the W boson decaying to electron or muon plus neutrino. In the signal region of dijet mass larger than 1 TeV and leading-jet transverse momentum larger than 600 GeV, 30 events are observed in the data with 39 ± 4 events expected in the Standard Model, yielding the following limit at 95% CL for the form factor cut-off scale $\Lambda_{FF} \to \infty$: $0.85 < \kappa_Z < 1.16$.

[5] KHACHATRYAN 17O analyse WZ production where each boson decays into electrons or muons. Events are required to have a tri-lepton invariant mass larger than 100 GeV, with one of the lepton pairs having an invariant mass within 20 GeV of the Z boson mass. The Z transverse momentum spectrum is analyzed to set a 95% C.L. limit of: $0.79 < \kappa_Z < 1.25$.

[6] AAD 16AR study WW production in pp collisions and select 6636 WW candidates in decay modes with electrons or muons with an expected background of 1546 ± 157 events. Assuming the LEP formulation and setting the form-factor Λ to infinity, a fit to the transverse momentum distribution of the leading charged lepton, leads to a 95% C.L. range of $0.975 < \kappa_Z < 1.020$.

[7] AAD 16P study WZ production in pp collisions and select 2091 WZ candidates in 4 decay modes with electrons and muons, with an expected background of 1825 ± 7 events. Analyzing the WZ transverse momentum distribution, the resulting 95% C.L. limit is: $0.81 < \kappa_Z < 1.30$.

[8] AAD 13AL study WW production in pp collisions and select 1325 WW candidates in decay modes with electrons or muons with an expected background of 369 ± 61 events. Assuming the LEP formulation and setting the form-factor Λ = infinity, a fit to the transverse momentum distribution of the leading charged lepton, leads to a 95% C.L. range of $0.957 < \kappa_Z < 1.043$. Supersedes AAD 12AC.

[9] AAD 12CD study WZ production in pp collisions and select 317 WZ candidates in three $\ell\nu$ decay modes with an expected background of 68.0 ± 10.0 events. The resulting 95% C.L. range is: $0.63 < \kappa_Z < 1.57$. Supersedes AAD 12V.

[10] AALTONEN 12AC study WZ production in $p\overline{p}$ collisions and select 63 WZ candidates in three $\ell\nu$ decay modes with an expected background of 7.9 ± 1.0 events. Based on

the cross section and shape of the Z transverse momentum spectrum, the following 95% C.L. range is reported: $0.61 < \kappa_Z < 1.90$ for a form factor of $\Lambda = 2$ TeV.

[11] ABAZOV 11 study the $p\overline{p} \to 3\ell\nu$ process arising in WZ production. They observe 34 WZ candidates with an estimated background of 6 events. An analysis of the p_T spectrum of the Z boson leads to a 95% C.L. limit of $0.600 < \kappa_Z < 1.675$, for a form factor $\Lambda = 2$ TeV.

[12] ABAZOV 06H study $\overline{p}p \to WW$ production with a subsequent decay $WW \to e^+\nu_e e^-\overline{\nu}_e$, $WW \to e^\pm\nu_e\mu^\mp\nu_\mu$ or $WW \to \mu^+\nu_\mu\mu^-\overline{\nu}_\mu$. The 95% C.L. limit for a form factor scale $\Lambda = 2$ TeV is $0.55 < \kappa_Z < 1.55$, fixing λ_Z=0. With the assumption that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit ($\Lambda = 2$ TeV) is $0.68 < \kappa < 1.45$.

[13] ABAZOV 05S study $\overline{p}p \to WZ$ production with a subsequent trilepton decay to $\ell\nu\ell'\overline{\ell}'$ (ℓ and $\ell' = e$ or μ). Three events (estimated background 0.71 ± 0.08 events) with WZ decay characteristics are observed from which they derive limits on the anomalous WWZ couplings. The 95% CL limit for a form factor scale $\Lambda = 1$ TeV is $-1.0 < \kappa_Z < 3.4$, fixing λ_Z and g_1^Z to their Standard Model values.

λ_Z

This coupling is *CP*-conserving (*C*- and *P*- separately conserving).

[1] ACHARD 04D study WW–pair production, single–W production and single–photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained using the WW–pair production sample. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[2] SIRUNYAN 20BA study electroweak production of a W boson in association with two jets, using W decays in the electron or muon channel. The isolated muons (electrons) are required to have a transverse momentum larger than 25 (30) GeV, while the transverse momentum of the two jets has to be larger than 50 and 30 GeV. A total of 2.382 (1.051) million events are selected in the muon (electron) channel, with a Standard Model expectation of 2.39 ± 0.17 (1.054 ± 0.058) million events. Analysing the transverse momentum distribution of the charged leptons from W decay, the following 95% C.L. limit is obtained: $-0.0088 < \lambda_Z < 0.0095$. Combining this result with that from the closely-related electroweak Z-jet-jet production SIRUNYAN 18BZ, the limit becomes: $-0.0071 < \lambda_Z < 0.0076$.

[3] SIRUNYAN 19CL study WW and WZ production in lepton + jet events, with one W boson decaying leptonically (electron or muon), and another W or Z boson decaying hadronically, reconstructed as a single massive large-radius jet. In the electron channel 2,456 (2,235) events are selected in the WW(WZ) category, while in the muon channel 3,996 (3572) events are selected in the WW(WZ) category. Analysing the di-boson invariant mass distribution, the following 95% C.L. limit is obtained: $-0.0065 < \lambda_Z < 0.0066$.

[4] SIRUNYAN 18BZ study $pp \to Z$ *jet jet* events at 13 TeV where $Z \to e^+e^-/\mu^+\mu^-$. Isolated electrons and muons are selected with p_T of the leading/sub-leading lepton > 30/20 GeV and $|\eta| < 2.4$, with the di-lepton invariant mass within 15 GeV of the Z mass. The two highest p_T jets are selected with p_T of the leading/sub-leading jet > 50/30 GeV respectively and dijet invariant mass > 200 GeV. Templates in the transverse momentum of the Z are utilized to set limits on the triple gauge couplings in the EFT and the LEP parametrizations. The following 95% C.L. limit is obtained $-0.010 < \lambda_Z < 0.010$.

[5] AABOUD 17S analyze electroweak production of a W boson in association with two jets at high dijet invariant mass, with the W boson decaying to electron or muon plus neutrino. In the signal region of dijet mass larger than 1 TeV and leading-jet transverse momentum larger than 600 GeV, 30 events are observed in the data with 39 ± 4 events expected in the Standard Model, yielding the following limit at 95% CL for the form factor cut-off scale $\Lambda_{FF} \to \infty$: $-0.053 < \lambda_Z < 0.042$.

[6] AABOUD 17U analyze production of WW or WZ boson pairs with one W boson decaying to electron or muon plus neutrino, and the other W or Z boson decaying hadronically. The hadronic decay system is reconstructed as either a resolved two-jet system or as a single large jet. Analysing the transverse momentum distribution of the hadronic system above 100 GeV yields the following limit at 95% CL for the form factor cut-off scale $\Lambda_{FF} \to \infty$: $-0.013 < \lambda_Z < 0.013$.

[7] KHACHATRYAN 17O analyse WZ production where each boson decays into electrons or muons. Events are required to have a tri-lepton invariant mass larger than 100 GeV, with one of the lepton pairs having an invariant mass within 20 GeV of the Z boson mass. The Z transverse momentum spectrum is analyzed to set a 95% C.L. limit of: $-0.018 < \lambda_Z < 0.016$.

[8] SIRUNYAN 17X study $pp \to WW/WZ \to \ell\nu q\overline{q}$ production at 8 TeV where ℓ is an electron or muon with p_T > 30 or 25 GeV respectively. Suitable cuts are put on the p_T of the dijet system and the missing E_T of the event yielding a total of 285 and 204 WV events observed in the electron and muon channels. The following 95% C.L. limit is obtained: $-0.011 < \lambda_Z < 0.011$.

[9] AAD 16AR study WW production in pp collisions and select 6636 WW candidates in decay modes with electrons or muons with an expected background of 1546 ± 157 events. Assuming the LEP formulation and setting the form-factor Λ to infinity, a fit to the transverse momentum distribution of the leading charged lepton, leads to a 95% C.L. range of $-0.019 < \lambda_Z < 0.019$.

[10] AAD 16P study WZ production in pp collisions and select 2091 WZ candidates in 4 decay modes with electrons and muons, with an expected background of 1825 ± 7 events. Analyzing the WZ transverse momentum distribution, the resulting 95% C.L. limit is: $-0.016 < \lambda_Z < 0.016$.

[11] AAD 14Y determine the electroweak Z-dijet cross section in 8 TeV pp collisions. $Z \to ee$ and $Z \to \mu\mu$ decays are selected with the di-lepton $p_T > 20$ GeV and mass in the 81–101 GeV range. Minimum two jets are required with $p_T > 55$ and 45 GeV and no additional jets with $p_T > 25$ GeV in the rapidity interval between them. The normalized p_T balance between the Z and the two jets is required to be < 0.15. This leads to a selection of 900 events with dijet mass > 1 TeV. The number of signal and background events expected is 261 and 592 respectively. A Poisson likelihood method is used on an event by event basis to obtain the 95% CL limit $-0.15 < \lambda_Z < 0.13$ for a form factor value $\Lambda = \infty$.

[12] AAD 13AL study WW production in pp collisions and select 1325 WW candidates in decay modes with electrons or muons with an expected background of 369 ± 61 events. Assuming the LEP formulation and setting the form-factor Λ = infinity, a fit to the transverse momentum distribution of the leading charged lepton, leads to a 95% C.L. range of $-0.062 < \lambda_Z < 0.059$. Supersedes AAD 12AC.

[13] CHATRCHYAN 13BF determine the W^+W^- production cross section using unlike sign di-lepton (e or μ) events with high $\not{p}_T$. The leptons have $p_T > 20$ GeV/c and are isolated. 1134 candidate events are observed with an expected SM background of 247 ± 34. The p_T distribution of the leading lepton is fitted to obtain 95% C.L. limits of $-0.048 \leq \lambda_Z \leq 0.048$.

[14] AAD 12CD study WZ production in pp collisions and select 317 WZ candidates in three $\ell\nu$ decay modes with an expected background of 68.0 ± 10.0 events. The resulting 95% C.L. range is: $-0.046 < \lambda_Z < 0.047$. Supersedes AAD 12V.

[15] AALTONEN 12AC study WZ production in $p\overline{p}$ collisions and select 63 WZ candidates in three $\ell\nu$ decay modes with an expected background of 7.9 ± 1.0 events. Based on the cross section and shape of the Z transverse momentum spectrum, the following 95% C.L. range is reported: $-0.08 < \lambda_Z < 0.10$ for a form factor of $\Lambda = 2$ TeV.

[16] ABAZOV 11 study the $p\overline{p} \to 3\ell\nu$ process arising in WZ production. They observe 34 WZ candidates with an estimated background of 6 events. An analysis of the p_T spectrum of the Z boson leads to a 95% C.L. limit of $-0.077 < \lambda_Z < 0.093$, for a form factor $\Lambda = 2$ TeV.

[17] AALTONEN 10K study $p\overline{p} \to W^+W^-$ with $W \to e/\mu\nu$. The p_T of the leading (second) lepton is required to be > 20 (10) GeV. The final number of events selected is 654 of which 320 ± 47 are estimated to be background. The 95% C.L. interval is $-0.16 < \lambda_Z < 0.16$ for $\Lambda = 1.5$ TeV and $-0.14 < \lambda_Z < 0.15$ for $\Lambda = 2$ TeV.

[18] ABAZOV 07Z set limits on anomalous TGCs using the measured cross section and $p_T(Z)$ distribution in WZ production with both the W and the Z decaying leptonically into electrons and muons. Setting the other couplings to their standard model values, the 95% C.L. limit for a form factor scale $\Lambda = 2$ TeV is $-0.17 < \lambda_Z < 0.21$.

[19] ABAZOV 06H study $\overline{p}p \to WW$ production with a subsequent decay $WW \to e^+\nu_e e^-\overline{\nu}_e$, $WW \to e^\pm\nu_e\mu^\mp\nu_\mu$ or $WW \to \mu^+\nu_\mu\mu^-\overline{\nu}_\mu$. The 95% C.L. limit for a form factor scale $\Lambda = 2$ TeV is $-0.39 < \lambda_Z < 0.39$, fixing κ_Z=1. With the assumption that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit ($\Lambda = 2$ TeV) is $-0.29 < \lambda < 0.30$.

[20] ABAZOV 05S study $\overline{p}p \to WZ$ production with a subsequent trilepton decay to $\ell\nu\ell'\overline{\ell}'$ (ℓ and $\ell' = e$ or μ). Three events (estimated background 0.71 ± 0.08 events) with WZ decay characteristics are observed from which they derive limits on the anomalous WWZ couplings. The 95% CL limit for a form factor scale $\Lambda = 1.5$ TeV is $-0.48 < \lambda_Z < 0.48$, fixing g_1^Z and κ_Z to their Standard Model values.

g_5^Z

[1] ABBIENDI 04D combine results from W^+W^- in all decay channels. Only *CP*-conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $-0.28 < g_5^Z < +0.21$.

[2] ACHARD 04D study WW–pair production, single–W production and single–photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained using the WW–pair production sample. Each parameter is determined from a single–parameter fit in which the other parameters assume their Standard Model values.

[3] ACCIARRI 99Q study W-pair, single-W, and single photon events.

[4] EBOLI 00 extract this indirect value of the coupling studying the non-universal one-loop contributions to the experimental value of the $Z \to b\overline{b}$ width (Λ=1 TeV is assumed).

g_4^Z

This coupling is *CP*-violating (*C*-violating and *P*-conserving).

W ANOMALOUS MAGNETIC MOMENT

The full magnetic moment is given by $\mu_W = e(1+\kappa+\lambda)/2m_W$. In the Standard Model, at tree level, $\kappa = 1$ and $\lambda = 0$. Some papers have defined $\Delta\kappa = 1-\kappa$ and assume that $\lambda = 0$. Note that the electric quadrupole moment is given by $-e(\kappa-\lambda)/m_W^2$. A description of the parameterization of these moments and additional references can be found in HAGIWARA 87 and BAUR 88. The parameter Λ appearing in the theoretical limits below is a regularization cutoff which roughly corresponds to the energy scale where the structure of the *W* boson becomes manifest.

		[8] VANDERBIJ	87	THEO	
		[9] GRAU	85	THEO	
		[10] SUZUKI	85	THEO	
		[11] HERZOG	84	THEO	

[1] ABREU 01I combine results from e^+e^- interactions at 189 GeV leading to W^+W^-, $We\nu_e$, and $\nu\overline{\nu}\gamma$ final states with results from ABREU 99L at 183 GeV to determine Δg_1^Z, $\Delta\kappa_\gamma$, and λ_γ. $\Delta\kappa_\gamma$ and λ_γ are simultaneously floated in the fit to determine μ_W.

[2] ABE 95G report $-1.3 < \kappa < 3.2$ for λ=0 and $-0.7 < \lambda < 0.7$ for κ=1 in $p\overline{p} \to e\nu_e\gamma$X and $\mu\nu_\mu\gamma$X at $\sqrt{s} = 1.8$ TeV.

[3] ALITTI 92C measure $\kappa = 1^{+2.6}_{-2.2}$ and $\lambda = 0^{+1.7}_{-1.8}$ in $p\overline{p} \to e\nu\gamma +$ X at $\sqrt{s} = 630$ GeV. At 95%CL they report $-3.5 < \kappa < 5.9$ and $-3.6 < \lambda < 3.5$.

[4] SAMUEL 92 use preliminary CDF and UA2 data and find $-2.4 < \kappa < 3.7$ at 96%CL and $-3.1 < \kappa < 4.2$ at 95%CL respectively. They use data for $W\gamma$ production and radiative *W* decay.

[5] SAMUEL 91 use preliminary CDF data for $p\overline{p} \to W\gamma$X to obtain $-11.3 \leq \Delta\kappa \leq 10.9$. Note that their $\kappa = 1-\Delta\kappa$.

[6] GRIFOLS 88 uses deviation from ρ parameter to set limit $\Delta\kappa \lesssim 65$ (M_W^2/Λ^2).

[7] GROTCH 87 finds the limit $-37 < \Delta\kappa < 73.5$ (90% CL) from the experimental limits on $e^+e^- \to \nu\overline{\nu}\gamma$ assuming three neutrino generations and $-19.5 < \Delta\kappa < 56$ for four generations. Note their $\Delta\kappa$ has the opposite sign as our definition.

[8] VANDERBIJ 87 uses existing limits to the photon structure to obtain $|\Delta\kappa| < 33$ (m_W/Λ). In addition VANDERBIJ 87 discusses problems with using the ρ parameter of the Standard Model to determine $\Delta\kappa$.

[9] GRAU 85 uses the muon anomaly to derive a coupled limit on the anomalous magnetic dipole and electric quadrupole (λ) moments $1.05 > \Delta\kappa \ln(\Lambda/m_W) + \lambda/2 > -2.77$. In the Standard Model $\lambda = 0$.

[10] SUZUKI 85 uses partial-wave unitarity at high energies to obtain $|\Delta\kappa| \lesssim 190\ (m_W/\Lambda)^2$. From the anomalous magnetic moment of the muon, SUZUKI 85 obtains $|\Delta\kappa| \lesssim 2.2/\ln(\Lambda/m_W)$. Finally SUZUKI 85 uses deviations from the ρ parameter and obtains a very qualitative, order-of-magnitude limit $|\Delta\kappa| \lesssim 150\ (m_W/\Lambda)^4$ if $|\Delta\kappa| \ll 1$.

[11] HERZOG 84 consider the contribution of *W*-boson to muon magnetic moment including anomalous coupling of $WW\gamma$. Obtain a limit $-1 < \Delta\kappa < 3$ for $\Lambda \gtrsim 1$ TeV.

c_{WWW}/Λ^2, c_W/Λ^2, c_B/Λ^2

These couplings are used in EFT-based approaches to anomalous couplings. They are linearly related to the couplings discussed above.

[1] TUMASYAN 22AB study *WZ* production, measuring cross sections and various distributions. Analysing the *WZ* invariant mass distribution, the following 95% C.L. limits are derived in units of TeV^{-2}: $-2.5 < c_W/\Lambda^2 < 0.3$, $-1.0 < c_{WWW}/\Lambda^2 < 1.2$, $-43 < c_b/\Lambda^2 < 113$, $-0.62 < \tilde{c}_{WWW}/\Lambda^2 < 0.53$, $-32 < \tilde{c}_W/\Lambda^2 < 32$.

[2] TUMASYAN 22E measure $W\gamma$ production where the *W* boson decays to electrons or muons. Analysing the photon transverse momentum distribution in bins of lepton azimuth, the following 95% C.L. limit is derived in units of TeV^{-2}: $-0.062 < c_{3W}/\Lambda^2 < 0.052$. This limit is derived including the non-SM, SM and their interference effects.

[3] AAD 21AC study the differential cross-section for the electroweak production of dijets in association with a *Z* boson, where the *Z* boson decays to electrons or muons. The number of events selected in the data is 10,870 (12,125) in the electron (muon) channel. Analyzing the distribution of the azimuthal separation of the two jets, the following 95% C.L. limits are derived in units of TeV^{-2}: $-2.7 < c_{WWW}/\Lambda^2 < 5.8$, $-1.6 < \tilde{c}_{WWW}/\Lambda^2 < 2.0$, $-0.19 < c_W/\Lambda^2 < 0.41$, $-0.11 < \tilde{c}_W/\Lambda^2 < 0.14$, $-6.31 < c_{HWB}/\Lambda^2 < 1.01$, $0.23 < \tilde{c}_{HWB}/\Lambda^2 < 2.35$.

[4] AAD 21W analyze W^+W^- production in association with at least one jet. Events with exactly one oppositely-charged electron-muon pair and at least one hadronic jet of transverse momentum larger than 30 GeV (120 GeV) are selected. In the data, 89,239 (5,825) events are found, with a total Standard-Model expectation of 91600 ± 2500 (5980 ± 150). Analyzing the electron-muon invariant mass distribution, the following limit at 95% C.L. is obtained: $-0.33 < c_W/\Lambda^2 < 0.33$ ($-0.60 < c_W/\Lambda^2 < 0.58$), for a fixed choice of $\Lambda = 1$ TeV.

[5] SIRUNYAN 21G measure $W\gamma$ production where the W decays into electrons or muons. In the data, 385,224 (395,818) events are selected in the electron (muon) channel, with a total Standard-Model expectation of 396913±54686 (396257±22837) events. Analysing the photon transverse momentum distribution, the following 95% C.L. limits are derived in units of TeV^{-2}: $-0.90 < c_{WWW}/\Lambda^2 < 0.91$, $-40 < c_B/\Lambda^2 < 41$, $-0.45 < c_{\overline{W}WW}/\Lambda^2 < 0.45$, $-20 < c_{\overline{W}}/\Lambda^2 < 20$.

[6] SIRUNYAN 20BA study electroweak production of a W boson in association with two jets, using W decays in the electron or muon channel. The isolated muons (electrons) are required to have a transverse momentum larger than 25 (30) GeV, while the transverse momentum of the two jets has to be larger than 50 and 30 GeV. A total of 2.382 (1.051) million events are selected in the muon (electron) channel, with a Standard Model expectation of 2.39±0.17 (1.054±0.058) million events. Analysing the transverse momentum distribution of the charged leptons from W decay, the following 95% C.L. limits are obtained in units of TeV^{-2}: $-2.3 < c_{WWW}/\Lambda^2 < 2.5$, $-8.8 < c_W/\Lambda^2 < 16$, $-45 < c_B/\Lambda^2 < 46$. Combining these results with those from the closely-related electroweak Z-jet-jet production SIRUNYAN 18BZ, the limits become: $-1.8 < c_{WWW}/\Lambda^2 < 2.0$, $-5.8 < c_W/\Lambda^2 < 10$, $-43 < c_B/\Lambda^2 < 45$.

[7] SIRUNYAN 20BF study W^+W^- production with the W bosons decaying to electrons or muons. The leading (subleading) lepton is required to have a transverse momentum larger than 25 (20) GeV. Events with a same-flavor di-lepton invariant mass within 15 GeV of the Z mass are rejected, as are event with a third lepton of transverse momentum larger than 10 GeV. In the same- (different-) flavor category a total of 9,604 (20,270) events are selected while the number of expected events is 9640 ± 490 (20280 ± 430). Analyzing the different-flavor di-lepton invariant mass distribution, the following 95% C.L. limits are obtained in units of TeV^{-2}: $-1.8 < c_{WWW}/\Lambda^2 < 1.8$, $-3.6 < c_W/\Lambda^2 < 2.8$, $-9.4 < c_B/\Lambda^2 < 8.5$.

[8] AABOUD 19BA study WW production in decay modes with an electron and a muon. The charged leptons are each required to have a transverse momentum larger than 27 GeV and rapidity less than 2.5. The electron-muon system is required to have a mass larger than 55 GeV and a transverse momentum larger than 30 GeV. The missing transverse energy must be larger than 20 GeV. Events containing a jet with transverse momentum exceeding 35 GeV and rapidity smaller than 4.5 are rejected. A total of 12,659 events are selected in the data, with an expected background of 4240 ± 477 events. Analysing the transverse momentum spectrum of the leading charged lepton, the following 95% C.L. limits are derived in units of TeV^{-2}: $-3.4 < c_{WWW}/\Lambda^2 < 3.3$, $-7.4 < c_W/\Lambda^2 < 4.1$, $-21 < c_B/\Lambda^2 < 18$, $-1.6 < c_{\overline{W}WW}/\Lambda^2 < 1.6$, $-76 < c_{\overline{W}}/\Lambda^2 < 76$.

[9] SIRUNYAN 19AD study inclusive WZ production, with W and Z decaying to electrons or muons. The leading (subleading) charged lepton candidate from the Z boson decay is required to have a transverse momentum larger than 25 GeV (10 GeV). The charged lepton candidate from the W boson decay is required to have a transverse momentum larger than 25 GeV. The invariant mass of the two leptons from Z decay is required to be within 15 GeV of the Z mass, while the invariant mass of the tri-lepton system is required to exceed 100 GeV. A total of 3,831 tri-lepton events are observed, with a fitted SM WZ signal of 3166 ± 62 events and a fitted background of 666 ± 45 events. The approximated WZ invariant mass distribution is analyzed to set 95% C.L. limits as follows: $-4.1 < c_W/\Lambda^2 < 1.1$, $-2.0 < c_{WWW}/\Lambda^2 < 2.1$, $-100 < c_B/\Lambda^2 < 160$, in units of TeV^{-2}.

[10] SIRUNYAN 19CL study WW and WZ production in lepton + jet events, with one W boson decaying leptonically (electron or muon), and another W or Z boson decaying hadronically, reconstructed as a single massive large-radius jet. In the electron channel 2,456 (2,235) events are selected in the $WW(WZ)$ category, while in the muon channel 3,996 (3572) events are selected in the $WW(WZ)$ category. Analysing the di-boson invariant mass distribution, the following 95% C.L. limits are obtained in units of TeV^{-2}: $-1.58 < c_{WWW}/\Lambda^2 < 1.59$, $-2.00 < c_W/\Lambda^2 < 2.65$, $-8.78 < c_B/\Lambda^2 < 8.54$.

[11] AABOUD 18Q study $pp \to ZZ$ events at $\sqrt{s} = 13$ TeV with $Z \to e^+e^-$ or $Z \to \mu^+\mu^-$. The number of events observed in the $4e$, $2e\,2\mu$, and 4μ channels is 249, 465, and 303 respectively. Analysing the p_T spectrum of the leading Z boson, the following the following 95% C.L. limits are derived in units of TeV^{-4}: $-5.9 < c_{\widetilde{B}W}/\Lambda^4 < 5.9$, $-3.0 < c_{WW}/\Lambda^4 < 3.0$, $-3.3 < c_{BW}/\Lambda^4 < 3.3$, $-2.7 < c_{BB}/\Lambda^4 < 2.8$.

[12] SIRUNYAN 18BZ study $pp \to Z$ *jet jet* events at 13 TeV where $Z \to e^+e^-/\mu^+\mu^-$. Isolated electrons and muons are selected with p_T of the leading/sub-leading lepton > 30/20 GeV and $|\eta| < 2.4$, with the di-lepton invariant mass within 15 GeV of the Z mass. The two highest p_T jets are selected with p_T of the leading/sub-leading jet > 50/30 GeV respectively and dijet invariant mass > 200 GeV. Templates in the transverse momentum of the Z are utilized to set limits on the triple gauge couplings in the EFT and the LEP parametrizations. The following 95% C.L. limits are obtained in units of TeV^{-2}: $-2.6 < c_{WWW}/\Lambda^2 < 2.6$ and $-8.4 < c_W/\Lambda^2 < 10.1$.

[13] AABOUD 17S analyze electroweak production of a W boson in association with two jets at high dijet invariant mass, with the W boson decaying to electron or muon plus neutrino. In the signal region of dijet mass larger than 1 TeV and leading-jet transverse momentum larger than 600 GeV, 30 events are observed in the data with 39 ± 4 events expected in the Standard Model, yielding the following limits at 95% CL for the form factor cut-off scale $\Lambda_{FF} \to \infty$: $-33 < c_W/\Lambda^2 < 30$, $-170 < c_B/\Lambda^2 < 160$, $-13 < c_{WWW}/\Lambda^2 < 9$, $-580 < c_{\widetilde{W}}/\Lambda^2 < 580$, $-11 < c_{\widetilde{W}WW}/\Lambda^2 < 11$, in units of TeV^{-2}.

[14] AABOUD 17U analyze production of WW or WZ boson pairs with one W boson decaying to electron or muon plus neutrino, and the other W or Z boson decaying hadronically. The hadronic decay system is reconstructed as either a resolved two-jet system or as a single large jet. Analysing the transverse momentum distribution of the hadronic system above 100 GeV yields the following limits at 95% CL for the form factor cut-off scale $\Lambda_{FF} \to \infty$: $-3.1 < c_{WWW}/\Lambda^2 < 3.1$, $-19 < c_B/\Lambda^2 < 20$, $-5.1 < c_W/\Lambda^2 < 5.8$, in units of TeV^{-2}.

[15] KHACHATRYAN 17O analyse WZ production where each boson decays into electrons or muons. Events are required to have a tri-lepton invariant mass larger than 100 GeV, with one of the lepton pairs having an invariant mass within 20 GeV of the Z boson mass. The Z transverse momentum spectrum is analyzed to set 95% C.L. limits of: $-260 < c_B/\Lambda^2 < 210$, $-4.2 < c_W/\Lambda^2 < 8.0$, $-4.6 < c_{WWW}/\Lambda^2 < 4.2$, in units of TeV^{-2}.

[16] SIRUNYAN 17X study $pp \to WW/WZ \to \ell\nu q\overline{q}$ production at 8 TeV where ℓ is an electron or muon with $p_T > 30$ or 25 GeV respectively. Suitable cuts are put on the p_T of the dijet system and the missing E_T of the event yielding a total of 285 and 204 WV events observed in the electron and muon channels. The following 95% C.L. limits in units of TeV^{-2} are obtained: $-2.7 < c_{WWW}/\Lambda^2 < 2.7$, $-14 < c_B/\Lambda^2 < 17$, $-2.0 < c_W/\Lambda^2 < 5.7$.

[17] AAD 16AR study WW production in pp collisions and select 6636 WW candidates in decay modes with electrons or muons with an expected background of 1546 ± 157 events. Assuming an EFT formulation, a fit to the transverse momentum distribution of the leading charged lepton, leads to 95% C.L. ranges of: $-4.61 < c_{WWW}/\Lambda^2 < 4.60$, $-5.87 < c_W/\Lambda^2 < 10.54$ and $-20.9 < c_B/\Lambda^2 < 26.3$,in units of TeV^{-2}.

[18] AAD 16P study WZ production in pp collisions and select 2091 WZ candidates in 4 decay modes with electrons and muons, with an expected background of 1825 ± 7 events. Analyzing the WZ transverse momentum distribution, the resulting 95% C.L. limits are: $-3.9 < c_{WWW}/\Lambda^2 < 4.0$, $-4.3 < c_W/\Lambda^2 < 6.8$, and $-320 < c_B/\Lambda^2 < 210$, in units of TeV^{-2}.

[19] KHACHATRYAN 16BI determine the W^+W^- production cross section using unlike sign di-lepton (e or μ) events with high p_T. The leptons have $p_T > 20$ GeV/c and are isolated. Events are required to have no jets above p_T of 30 GeV/c. 4847 (2233) events are selected with different (same) flavor leptons, with an expected total background of 1179 ± 123 (643 ± 73) events. Analysing the di-lepton invariant mass spectrum, the following values are obtained: $c_{WWW}/\Lambda^2 = 0.1 \pm 3.2$, $c_W/\Lambda^2 = -3.6^{+5.0}_{-4.5}$ and $c_B/\Lambda^2 = -3.2^{+15.0}_{-14.5}$, in units of TeV^{-2}. The limits at 95% C.L. are: $-5.7 < c_{WWW}/\Lambda^2 < 5.9$, $-11.4 < c_W/\Lambda^2 < 5.4$ and $-29.2 < c_B/\Lambda^2 < 23.9$, in units of TeV^{-2}.

ANOMALOUS *W/Z* QUARTIC COUPLINGS

Revised March 2024 by M.W. Grünewald (U. College Dublin) and A. Gurtu (CERN; TIFR Mumbay).

Quartic couplings, $WWZZ$, $WWZ\gamma$, $WW\gamma\gamma$, and $ZZ\gamma\gamma$, were studied at LEP and Tevatron at energies at which the Standard Model predicts negligible contributions to multiboson production. Thus, to parametrize limits on these couplings, an effective theory approach is adopted which supplements the Standard Model Lagrangian with higher dimensional operators which include quartic couplings. The LEP collaborations chose the lowest dimensional representation of operators (dimension 6) which presumes the SU(2)×U(1) gauge symmetry is broken by means other than the conventional Higgs scalar doublet [1–3]. In this representation possible quartic couplings, a_0, a_c, a_n, are expressed in terms of the following dimension-6 operators [1,2];

$$L_6^0 = -\frac{e^2}{16\Lambda^2}\, a_0\, F^{\mu\nu}\, F_{\mu\nu}\vec{W}^\alpha \cdot \vec{W}_\alpha$$
$$L_6^c = -\frac{e^2}{16\Lambda^2}\, a_c\, F^{\mu\alpha}\, F_{\mu\beta}\vec{W}^\beta \cdot \vec{W}_\alpha$$
$$L_6^n = -i\frac{e^2}{16\Lambda^2}\, a_n \epsilon_{ijk}\, W_{\mu\alpha}^{(i)}\, W_\nu^{(j)}\, W^{(k)\alpha} F^{\mu\nu}$$
$$\widetilde{L}_6^0 = -\frac{e^2}{16\Lambda^2}\, \widetilde{a}_0\, F^{\mu\nu}\, \widetilde{F}_{\mu\nu}\vec{W}^\alpha \cdot \vec{W}_\alpha$$
$$\widetilde{L}_6^n = -i\frac{e^2}{16\Lambda^2}\, \widetilde{a}_n \epsilon_{ijk}\, W_{\mu\alpha}^{(i)}\, W_\nu^{(j)}\, W^{(k)\alpha} \widetilde{F}^{\mu\nu}$$

where F, W are photon and W fields, L_6^0 and L_6^c conserve C, P separately ($\widetilde{L}_6^0$ conserves only C) and generate anomalous $W^+W^-\gamma\gamma$ and $ZZ\gamma\gamma$ couplings, L_6^n violates CP ($\widetilde{L}_6^n$ violates both C and P) and generates an anomalous $W^+W^-Z\gamma$ coupling, and Λ is an energy scale for new physics. For the $ZZ\gamma\gamma$ coupling the CP-violating term represented by L_6^n does not contribute. These couplings are assumed to be real and to vanish at tree level in the Standard Model.

Within the same framework as above, a more recent description of the quartic couplings [3] treats the anomalous parts of the $WW\gamma\gamma$ and $ZZ\gamma\gamma$ couplings separately, leading to two sets parametrized as a_0^V/Λ^2 and a_c^V/Λ^2, where $V = W$ or Z.

With the discovery of a Higgs at the LHC in 2012, it is then useful to go to the next higher dimensional representation (dimension 8 operators) in which the gauge symmetry is

broken by the conventional Higgs scalar doublet [3,4]. There are 14 operators which can contribute to the anomalous quartic coupling signal. Some of the operators have analogues in the dimension 6 scheme. The CMS collaboration, [5], have used this parametrization, in which the connections between the two schemes are also summarized:

$$\begin{aligned}\mathcal{L}_{AQGC} = &-\frac{e^2}{8}\frac{a_0^W}{\Lambda^2}F_{\mu\nu}F^{\mu\nu}W^{+a}W_a^- \\ &-\frac{e^2}{16}\frac{a_c^W}{\Lambda^2}F_{\mu\nu}F^{\mu a}(W^{+\nu}W_a^- + W^{-\nu}W_a^+) \\ &-e^2g^2\frac{\kappa_0^W}{\Lambda^2}F_{\mu\nu}Z^{\mu\nu}W^{+a}W_a^- \\ &-\frac{e^2g^2}{2}\frac{\kappa_c^W}{\Lambda^2}F_{\mu\nu}Z^{\mu a}(W^{+\nu}W_a^- + W^{-\nu}W_a^+) \\ &+\frac{f_{T,0}}{\Lambda^4}Tr[\widehat{W}_{\mu\nu}\widehat{W}^{\mu\nu}]\times Tr[\widehat{W}_{\alpha\beta}\widehat{W}^{\alpha\beta}]\end{aligned}$$

The energy scale of possible new physics is Λ, and $g = e/sin(\theta_W)$, e being the unit electric charge and θ_W the Weinberg angle. The field tensors are described in [3,4].

The two dimension 6 operators a_0^W/Λ^2 and a_c^W/Λ^2 are associated with the $WW\gamma\gamma$ vertex. Among dimension 8 operators, κ_0^W/Λ^2 and κ_c^W/Λ^2 are associated with the $WWZ\gamma$ vertex, whereas the parameter $f_{T,0}/\Lambda^4$ contributes to both vertices. There is a relationship between these two dimension 6 parameters and the dimension 8 parameters $f_{M,i}/\Lambda^4$ as follows [3]:

$$\frac{a_0^W}{\Lambda^2} = -\frac{4M_W^2}{g^2}\frac{f_{M,0}}{\Lambda^4} - \frac{8M_W^2}{g'^2}\frac{f_{M,2}}{\Lambda^4}$$

$$\frac{a_c^W}{\Lambda^2} = -\frac{4M_W^2}{g^2}\frac{f_{M,1}}{\Lambda^4} - \frac{8M_W^2}{g'^2}\frac{f_{M,3}}{\Lambda^4}$$

where $g' = e/cos(\theta_W)$ and M_W is the invariant mass of the W boson. This relation provides a translation between limits on dimension 6 operators $a_{0,c}^W$ and $f_{M,j}/\Lambda^4$. It is further required [4] that $f_{M,0} = 2f_{M,2}$ and $f_{M,1} = 2f_{M,3}$ which suppresses contributions to the $WWZ\gamma$ vertex. The complete set of Lagrangian contributions as presented in [4] corresponds to 19 anomalous couplings in total – $f_{S,i}$, $i = 1, 2$, $f_{M,i}$, $i = 0, \ldots, 8$ and $f_{T,i}, i = 0, \ldots, 9$ – each scaled by $1/\Lambda^4$.

Another approach to couplings is the so called K-matrix framework [7], in which the anomalous couplings can be expressed in terms of two parameters α_4 and α_5, which account for all BSM effects.

The LHC collaborations have published couplings results based on various theoretical frameworks. It is hoped that the collaborations will agree to use at least one common set of parameters to express these limits to enable the reader to make a comparison, and to allow for a possible LHC combination.

Anomalous W quartic couplings are measured by the experiments at LEP, the Tevatron, and the LHC. Some of the recent results from the Tevatron and LHC experiments individually surpass the combined LEP-2 results in precision (see below). As discussed in the review on the "Anomalous W/Z quartic couplings (QGCS)," the measurements are typically done using different operator expansions which then do not allow the results to be compared and averaged. At least one common framework should be agreed upon for the use in the future publications by the experiments.

Some publications from LHC experiments derive limits for various assumed values of the form-factor cutoff Λ_{FF}. The values quoted below are for $\Lambda_{FF} \to \infty$.

[1] AAD 24C study the production of four charged leptons (electrons or muons) in association with two jets. Analysing the 4-lepton invariant mass distribution and the di-jet invarinat mass distribution leads to the following 95% C.L. limits: $-0.98 < f_{T,0}/\Lambda^4 < 0.93$, $-1.2 < f_{T,1}/\Lambda^4 < 1.2$, $-2.5 < f_{T,2}/\Lambda^4 < 2.4$, $-2.5 < f_{T,5}/\Lambda^4 < 2.4$, $-3.9 < f_{T,6}/\Lambda^4 < 3.9$, $-8.5 < f_{T,7}/\Lambda^4 < 8.1$, $-2.1 < f_{T,8}/\Lambda^4 < 2.1$, $-4.5 < f_{T,9}/\Lambda^4 < 4.5$, in units of TeV^{-4}. The article also reports limits on these couplings by cutting the EFT expansion at various values of the cut-off scale.

[2] AAD 23BH study $pp \to Z\gamma\gamma$ events with the Z boson decaying to electron or muon pairs. The number of observed data events is 148 for the electron mode and 171 for the muon mode. The respective number of (data-background) events is 105.5 ± 12.2(stat)±8.1(syst) and 120.4 ± 13.1(stat)±9.4(syst). The corresponding number of predicted signal events is 91.5 ± 0.9 and 119.5 ± 1.0 using SHERPA (NLO), and 91.0 ± 1.0 and 118.1 ± 1.2 using MADGRAPH 5 AMC (NLO), where the error is statistical only. Analysing the transverse momentum distribution of the dilepton system, the following 95% C.L. limits are derived: $-9.87 < f_{T,0}/\Lambda^4 < 9.33$, $-9.88 < f_{T,1}/\Lambda^4 < 9.34$, $-20.31 < f_{T,2}/\Lambda^4 < 18.68$, $-4.64 < f_{T,5}/\Lambda^4 < 4.54$, $-7.04 < f_{T,6}/\Lambda^4 < 6.94$, $-15.55 < f_{T,7}/\Lambda^4 < 15.04$, $-1.64 < f_{T,8}/\Lambda^4 < 1.61$, $-3.26 < f_{T,9}/\Lambda^4 < 3.26$, in units of TeV^{-4}.

[3] AAD 23K measure Z production in association with a photon and two jets in proton-proton collisions at 13 TeV CM energy, where the Z boson decays into neutrinos. Within a sensitive fiducial phase-space region, 356 signal events are selected, with an expectation of 357 ± 30. Analysing the photon transverse energy distribution, the following 95% C.L. limits are derived in units of TeV^{-4}: $-0.094 < f_{T,0}/\Lambda^4 < 0.084$, $-0.088 < f_{T,5}/\Lambda^4 < 0.099$, $-0.059 < f_{T,8}/\Lambda^4 < 0.059$, $-0.13 < f_{T,9}/\Lambda^4 < 0.13$, $-4.6 < f_{M,0}/\Lambda^4 < 4.6$, $-7.7 < f_{M,1}/\Lambda^4 < 7.7$, $-1.9 < f_{M,2}/\Lambda^4 < 1.9$.

[4] TUMASAYAN 23AK study electroweak $W\gamma$ production in association with 2 jets. The events selected for the couplings analysis are required to have a dijet invariant mass in excess of 800 GeV, jet-jet separation of at least 2.5 in rapidity, invariant mass of the $W\gamma$ system larger than 150 GeV and transverse photon momentum larger than 100 GeV. Analysing the $W\gamma$ invariant mass distribution, varying one coupling at a time while fixing the others to their Standard Model value, leads to the following 95% C.L. limits: $-5.6 < f_{M,0}/\Lambda^4 < 5.5$, $-7.8 < f_{M,1}/\Lambda^4 < 8.1$, $-1.9 < f_{M,2}/\Lambda^4 < 1.9$, $-2.7 < f_{M,3}/\Lambda^4 < 2.7$, $-3.7 < f_{M,4}/\Lambda^4 < 3.6$, $-3.9 < f_{M,5}/\Lambda^4 < 3.9$, $-14 < f_{M,7}/\Lambda^4 < 14$, $-0.47 < f_{T,0}/\Lambda^4 < 0.51$, $-0.31 < f_{T,1}/\Lambda^4 < 0.34$, $-0.85 < f_{T,2}/\Lambda^4 < 1.0$, $-0.31 < f_{T,5}/\Lambda^4 < 0.33$, $-0.25 < f_{T,6}/\Lambda^4 < 0.27$, $-0.67 < f_{T,7}/\Lambda^4 < 0.73$, in units of TeV^{-4}.

[5] TUMASAYAN 23AM use the combined CMS-TOTEM detector system to study exclusive $\gamma\gamma \to WW$ and $\gamma\gamma \to ZZ$ production in pp collisions at 13 TeV. The W and Z are identified through their hadronic decays with the added requirements of the invariant mass of the di-boson pair to be larger than 1 TeV, and the relative beam proton momentum loss between 0.04 and 0.20. The following limits are obtained at 95% C.L.: (i) on the dimension-6 (LEP like) couplings, in units of GeV^{-2}: $|a_0^W/\Lambda^2| < 4.3 \times 10^{-6}$, $|a_C^W/\Lambda^2| < 1.6 \times 10^{-5}$, $|a_0^Z/\Lambda^2| < 0.9 \times 10^{-5}$, $|a_C^Z/\Lambda^2| < 4.0 \times 10^{-5}$. (ii) on the dimension-8 operators, in units of TeV^{-4}: $|f_{M,0}/\Lambda^4| < 66.0$, $|f_{M,1}/\Lambda^4| < 245.5$, $|f_{M,2}/\Lambda^4| < 9.8$, $|f_{M,3}/\Lambda^4| < 73.0$, $|f_{M,4}/\Lambda^4| < 36.0$, $|f_{M,5}/\Lambda^4| < 67.0$, $|f_{M,7}/\Lambda^4| < 490.9$.

[6] SIRUNYAN 21 study electroweak Z-pair production in association with two jets, with the Z bosons decaying to oppositely-charged electron or muon pairs. Leptons with high transverse momentum are selected, with the di-lepton invariant mass of the two Z boson candidates between 60 GeV and 120 GeV, and the four-lepton invariant mass larger than 180 GeV. A total of 365 events are selected in the data, while the number of expected events is 370 ± 48. Analyzing the four-lepton invariant mass distribution, the following 95% C.L. limits are derived: $-0.24 < f_{T,0}/\Lambda^4 < 0.22$, $-0.31 < f_{T,1}/\Lambda^4 < 0.31$, $-0.63 < f_{T,2}/\Lambda^4 < 0.59$, $-0.43 < f_{T,8}/\Lambda^4 < 0.43$, $-0.92 < f_{T,9}/\Lambda^4 < 0.92$, in units of TeV^{-4}.

[7] TUMASAYAN 21A study electroweak $Z\gamma$ production in association with two jets, where the Z boson decays to electron or muon pairs and the pair of two jets has high invariant mass, superseeding SIRUNYAN 20AL. The number of observed (expected) electron events in the barrel and endcap regions are 375 (349 ± 9) and 174 (166 ± 6) events, respectively, while for muon events the respective numbers are 584 (612 ± 13) and 320 (303 ± 8). Analysing the $Z\gamma$ invariant mass distribution, the following 95% C.L. limits are derived: $-15.8 < f_{M,0}/\Lambda^4 < 16.0$, $-35.0 < f_{M,1}/\Lambda^4 < 34.7$, $-6.55 < f_{M,2}/\Lambda^4 < 6.49$, $-13.0 < f_{M,3}/\Lambda^4 < 13.0$, $-13.0 < f_{M,4}/\Lambda^4 < 12.7$, $-22.2 < f_{M,5}/\Lambda^4 < 21.3$, $-56.6 < f_{M,7}/\Lambda^4 < 55.9$, $-0.64 < f_{T,0}/\Lambda^4 < 0.57$, $-0.81 < f_{T,1}/\Lambda^4 < 0.90$, $-1.68 < f_{T,2}/\Lambda^4 < 1.54$, $-0.58 < f_{T,5}/\Lambda^4 < 0.64$, $-1.30 < f_{T,6}/\Lambda^4 < 1.33$, $-2.15 < f_{T,7}/\Lambda^4 < 2.43$, $-0.47 < f_{T,8}/\Lambda^4 < 0.47$, $-0.91 < f_{T,9}/\Lambda^4 < 0.91$, in units of TeV^{-4}.

[8] TUMASAYAN 21B measure W or Z boson production in association with two photons, using the leptonic decays modes of W and Z with electrons or muons. The number of selected $W \to e(\mu)\nu$ events is 1987 (2384) and the number of selected $Z \to ee(\mu\mu)$ events is 110 (272) respectively. Analyzing the transverse momentum of the di-photon system, the following 95 % C.L. limits are derived in units of TeV^{-4}: In the W production channel, the observed limits are: $-39.9 < f_{M,2}/\Lambda^4 < 39.5$, $-63.8 < f_{M,3}/\Lambda^4 < 65.0$, $-1.30 < f_{T,0}/\Lambda^4 < 1.30$, $-1.70 < f_{T,1}/\Lambda^4 < 1.66$, $-3.64 < f_{T,2}/\Lambda^4 < 3.64$, $-0.52 < f_{T,5}/\Lambda^4 < 0.60$, $-0.60 < f_{T,6}/\Lambda^4 < 0.68$, $-1.16 < f_{T,7}/\Lambda^4 < 1.16$. In the Z production channel, the observed limits are: $-5.70 < f_{T,0}/\Lambda^4 < 5.46$, $-5.70 < f_{T,1}/\Lambda^4 < 5.46$, $-11.4 < f_{T,2}/\Lambda^4 < 10.9$, $-2.92 < f_{T,5}/\Lambda^4 < 2.92$, $-3.80 < f_{T,6}/\Lambda^4 < 3.88$, $-7.88 < f_{T,7}/\Lambda^4 < 7.72$, $-1.06 < f_{T,8}/\Lambda^4 < 1.10$, $-1.82 < f_{T,9}/\Lambda^4 < 1.82$, in units of TeV^{-4}.

[9] SIRUNAYN 20 study WZ and same-sign WW production in association with two jets, using the leptonic decays modes of the W and Z bosons with electrons or muons. Overall, 524 WW events and 229 WZ events are selected, with a Standard Model expectation of 535 ± 52 and 216 ± 21 events, respectively. Analyzing the transverse mass spectrum of the di-boson system and the di-jet invariant mass, the following 95% C.L. limits are derived, not using any unitarization procedure: $-0.25 < f_{T,0}/\Lambda^4 < 0.28$, $-0.12 < f_{T,1}/\Lambda^4 < 0.14$, $-0.35 < f_{T,2}/\Lambda^4 < 0.48$, $-2.7 < f_{M,0}/\Lambda^4 < 2.9$, $-4.1 < f_{M,1}/\Lambda^4 < 4.2$, $-5.4 < f_{M,6}/\Lambda^4 < 5.8$, $-5.7 < f_{M,7}/\Lambda^4 < 6.0$, $-5.7 < f_{S,0}/\Lambda^4 < 6.1$, $-16 < f_{S,1}/\Lambda^4 < 17$, in units of TeV^{-4}. The article also reports limits on these couplings by cutting the EFT expansion at the unitarity limit.

[10] SIRUNYAN 20AL study electroweak production of a Z boson and a photon in association with two jets in the electron and muon decay modes of the Z. A signal with a significance of 3.9 standard deviations is observed, compared to a Standard Model expectation of 5.2 standard deviations. Combining with KHACHATRYAN 17AA data at 8 TeV the final observed and expected signal significance is 4.7 and 5.5 standard deviations. Analyzing the Z-photon invariant mass distribution, the following 95% C.L. limits are derived: $-19.5 < f_{M,0}/\Lambda^4 < 20.3$, $-40.5 < f_{M,1}/\Lambda^4 < 39.5$, $-8.22 < f_{M,2}/\Lambda^4 < 8.10$, $-17.7 < f_{M,3}/\Lambda^4 < 17.9$, $-15.3 < f_{M,4}/\Lambda^4 < 15.8$, $-25.1 < f_{M,5}/\Lambda^4 < 24.5$, $-38.9 < f_{M,6}/\Lambda^4 < 40.6$, $-60.3 < f_{M,7}/\Lambda^4 < 62.5$, $-0.74 < f_{T,0}/\Lambda^4 < 0.69$, $-0.98 < f_{T,1}/\Lambda^4 < 0.96$, $-1.97 < f_{T,2}/\Lambda^4 < 1.86$, $-0.70 < f_{T,5}/\Lambda^4 < 0.75$, $-1.64 < f_{T,6}/\Lambda^4 < 1.68$, $-2.59 < f_{T,7}/\Lambda^4 < 2.82$, $-0.47 < f_{T,8}/\Lambda^4 < 0.47$, $-1.27 < f_{T,9}/\Lambda^4 < 1.27$, in units of TeV^{-4}.

[11] SIRUNYAN 20BD study electroweak $W\gamma$ production in association with two jets, where the W boson decays to electron or muon and the two jets have high invariant mass. The number of observed (expected) electron events with the photon in the barrel and endcap regions are 393 (397.1 ± 18.5) and 159 (145.2 ± 10.0) respectively, while for muon events the respective numbers are 565 (537.9 ± 21.4) and 201 (188.2 ± 10.5). Analyzing the $W\gamma$ invariant mass distribution, the following 95% C.L. limits are derived: $-8.1 < f_{M,0}/\Lambda^4 < 8.0$, $-12 < f_{M,1}/\Lambda^4 < 12$, $-2.8 < f_{M,2}/\Lambda^4 < 2.8$, $-4.4 < f_{M,3}/\Lambda^4 < 4.4$, $-5.0 < f_{M,4}/\Lambda^4 < 5.0$, $-8.3 < f_{M,5}/\Lambda^4 < 8.3$, $-16 < f_{M,6}/\Lambda^4 < 16$, $-21 < f_{M,7}/\Lambda^4 < 20$, $-0.6 < f_{T,0}/\Lambda^4 < 0.6$, $-0.4 < f_{T,1}/\Lambda^4 < 0.4$, $-1.0 < f_{T,2}/\Lambda^4 < 1.2$, $-0.5 < f_{T,5}/\Lambda^4 < 0.5$, $-0.4 < f_{T,6}/\Lambda^4 < 0.4$, $-0.9 < f_{T,7}/\Lambda^4 < 0.9$, in units of TeV^{-4}.

[12] SIRUNYAN 19BM search for the final state $W^+W^-W^\pm$ using W decays to electrons or muons. Two event samples are considered, events with three leptons, or events with two oppositely charged leptons accompanied by two jets. In a kinematic region selected to enhance the effect of anomalous couplings, no events are selected in the data, and 95% C.L. upper limits are obtained as follows: $-1.2 < f_{T,0}/\Lambda^4 < 1.2$, $-3.3 < f_{T,1}/\Lambda^4 < 3.3$, $-2.7 < f_{T,2}/\Lambda^4 < 2.6$, in units of TeV^{-4} and without application of a form factor.

[13] SIRUNYAN 19BP study WZ plus 2 jets production, using W and Z decay channels with electrons or muons. In the data, 75 events are selected, with a fitted SM signal of 15.1 ± 1.6 events and a fitted background of 62.4 ± 2.8 events. The transverse mass distribution of the WZ system is analyzed to set the following limits at 95% C.L., in units of TeV^{-4}: $-9.15 < f_{M,0}/\Lambda^4 < 9.15$, $-9.15 < f_{M,1}/\Lambda^4 < 9.45$, $-26.5 < f_{S,0}/\Lambda^4 < 27.5$, $-41.2 < f_{S,1}/\Lambda^4 < 42.8$, $-0.75 < f_{T,0}/\Lambda^4 < 0.81$, $-0.49 < f_{T,1}/\Lambda^4 < 0.55$, $-1.49 < f_{T,2}/\Lambda^4 < 1.85$.

[14] SIRUNYAN 19CQ search for anomalous electroweak production of vector boson pairs in association with two jets. Events are selected by requiring two jets with a large invariant mass and rapidity separation, one or two leptons (electrons or muons), and a W or Z boson decaying hadronically. In the WV (ZV) channel, 347 (47) events are selected in the data, with a total expected background of 352 ± 19 (50.3 ± 5.8) events. Analysing the mass distribution of the WV or ZV system, the following 95% C.L. limits are obtained: $-2.7 < f_{S,0}/\Lambda^4 < 2.7$, $-3.4 < f_{S,1}/\Lambda^4 < 3.4$, $-0.69 < f_{M,0}/\Lambda^4 < 0.70$, $-2.0 < f_{M,1}/\Lambda^4 < 2.1$, $-1.3 < f_{M,6}/\Lambda^4 < 1.3$, $-3.4 < f_{M,7}/\Lambda^4 < 3.4$, $-0.12 < f_{T,0}/\Lambda^4 < 0.11$, $-0.12 < f_{T,1}/\Lambda^4 < 0.13$, $-0.28 < f_{T,2}/\Lambda^4 < 0.28$, in units of TeV^{-4}.

[15] SIRUNYAN 18CC study pp collisions at $\sqrt{s} = 13$ TeV leading to a pair of same-sign W pairs decaying leptonically (e or μ) associated with a pair of jets. Isolated leptons with $p_T > 25$ (20) GeV for the leading (trailing) lepton, with $|\eta| < 2.5$ (2.4) for e (μ) and jets with $p_T > 30$ GeV, $|\eta| < 5.0$, $|\Delta\eta_{jj}| > 2.5$ and $m_{jj} > 500$ GeV is required. Further cuts are applied to minimize $Z \to ee$ events, non-prompt leptons and hadronically decaying taus. The number of selected events is 201, with an expected SM signal of 66.9 ± 2.4 and background of 138 ± 13 events. Analysing the dilepton invariant mass spectrum the following 95% C.L. limits are derived: $-7.7 < f_{S,0}/\Lambda^4 < 7.7$, $-21.6 < f_{S,1}/\Lambda^4 < 21.8$, $-6.0 < f_{M,0}/\Lambda^4 < 5.9$, $-8.7 < f_{M,1}/\Lambda^4 < 9.1$, $-11.9 < f_{M,6}/\Lambda^4 < 11.8$, $-13.3 < f_{M,7}/\Lambda^4 < 12.9$, $-0.62 < f_{T,0}/\Lambda^4 < 0.65$, $-0.28 < f_{T,1}/\Lambda^4 < 0.31$, $-0.89 < f_{T,2}/\Lambda^4 < 1.02$.

[16] AABOUD 17AA analyze $W^\pm W^\pm$ production in association with two jets and W decay modes with electrons or muons. In the kinematic region of VBS the effect of anomalous QGCs is enhanced by requiring the transverse mass of the WW system to be larger than 400 GeV. In the data, 8 events are selected with a total background expected from SM processes of 3.8 ± 0.6 events. Assuming the other QGC coupling to have the SM value of zero, the observed event yield is used to determine 95% CL limits on the QGCs: $-0.14 < \alpha_4 < 0.15$ and $-0.22 < \alpha_5 < 0.22$. Supersedes AAD 14AM.

[17] AABOUD 17AG determine the $WW\gamma$ and $WZ\gamma$ cross sections in 8 TeV pp interactions by studying the final states $e\nu\mu\nu\gamma$ and $e\nu jj\gamma$ or $\mu\nu jj\gamma$. Upper limits on the production cross sections are derived in a fiducial region optimized for BSM physics. These are used to derive the following 95% C.L. upper limits for quartic couplings assuming the form scale factor, $\Lambda_{FF} = \infty$ (all in units of 10^3 TeV^{-4}): $-0.3 < f_{M,0}/\Lambda^4 < 0.3$, $-0.5 < f_{M,1}/\Lambda^4 < 0.5$, $-1.8 < f_{M,2}/\Lambda^4 < 1.8$, $-1.1 < f_{M,4}/\Lambda^4 < 1.1$, $-1.7 < f_{M,5}/\Lambda^4 < 1.7$, $-0.6 < f_{M,6}/\Lambda^4 < 0.6$, $-1.1 < f_{M,7}/\Lambda^4 < 1.1$, $-0.1 < f_{T,0}/\Lambda^4 < 0.1$, $-0.2 < f_{T,1}/\Lambda^4 < 0.2$, $-0.4 < f_{T,4}/\Lambda^4 < 0.4$, $-1.5 < f_{T,5}/\Lambda^4 < 1.6$, $-1.9 < f_{T,6}/\Lambda^4 < 1.9$, $-4.3 < f_{T,7}/\Lambda^4 < 4.3$.

[18] AABOUD 17D analyze electroweak diboson (WV, $V = W, Z$) production in association with a high-mass dijet system. In the data, 32 events are selected with an expected total background of 32 ± 12 events. Analysing the transverse mass distribution of the WV system, the following limits are set at 95% C.L.: $-0.024 < \alpha_4 < 0.030$ and $-0.028 < \alpha_5 < 0.033$.

[19] AABOUD 17J analyze the $Z\gamma$ production in association with a high-mass dijet system, with the Z boson decaying into a pair of electrons, muons, or neutrinos. In the charged lepton (neutrino) channel, events are selected with a dijet mass larger than 500 (600) GeV and a transverse photon energy larger than 250 (150) GeV, with 2 (4) events selected in the data and 0.30 ± 0.08 (1.6 ± 0.5) expected background events. The observed event yield is used to determine 95% CL limits as follows: $-4.1 \times 10^3 <$

$f_{T,9}/\Lambda^4 < 4.2\times10^3$, $-1.9\times10^3 < f_{T,8}/\Lambda^4 < 2.1\times10^3$, $-1.9\times10^1 < f_{T,0}/\Lambda^4 < 1.6\times10^1$, $-1.6\times10^2 < f_{M,0}/\Lambda^4 < 1.8\times10^2$, $-3.5\times10^2 < f_{M,1}/\Lambda^4 < 3.4\times10^2$, $-8.9\times10^2 < f_{M,2}/\Lambda^4 < 8.9\times10^2$, $-1.7\times10^3 < f_{M,3}/\Lambda^4 < 1.7\times10^3$, in units of TeV^{-4} and without application of a form factor.

[20] AABOUD 17M analyze tri-boson $W^\pm W^\pm W^\mp$ production in decay channels with three charged leptons or two like-sign charged leptons with two jets, where the lepton can be an electron or muon. In the data, 24 tri-lepton events and 21 di-lepton plus jets events are selected, compared to a total event yield expected in the SM of 30.8 ± 3.0 and 21.9 ± 2.0, respectively. Analysing the tri-lepton transverse mass or the transverse momentum sum of the two leptons, two jets and the missing transverse energy, the following limits at 95% CL are derived for the form factor cut-off scale $\Lambda_{FF}\to\infty$: $-0.13 < f_{S,0}/\Lambda^4 < 0.18$, $-0.21 < f_{S,1}/\Lambda^4 < 0.27$, in units of 10^4 TeV^{-4}, which are converted into the following limits: $-0.49 < \alpha_4 < 0.75$ and $-0.48 < \alpha_5 < 0.62$.

[21] KHACHATRYAN 17AA analyse electroweak production of $Z\gamma$ in association with two hadronic jets, with the Z boson decaying to electron or muon pairs. Events with photon transverse momentum larger than 60 GeV and di-jet invariant mass larger than 400 GeV are selected. The $Z\gamma$ inavariant mass spectrum is analysed to set 95% C.L. limits as follows: $-71 < f_{M,0}/\Lambda^4 < 75$, $-190 < f_{M,1}/\Lambda^4 < 182$, $-32 < f_{M,2}/\Lambda^4 < 31$, $-58 < f_{M,3}/\Lambda^4 < 59$, $-3.8 < f_{T,0}/\Lambda^4 < 3.4$, $-4.4 < f_{T,1}/\Lambda^4 < 4.4$, $-9.9 < f_{T,2}/\Lambda^4 < 9.0$, $-1.8 < f_{T,8}/\Lambda^4 < 1.8$, $-4.0 < f_{T,9}/\Lambda^4 < 4.0$, in units of TeV^{-4} and without application of a form factor.

[22] KHACHATRYAN 17M analyse electroweak production of $W\gamma$ in association with two hadronic jets, with the W boson decaying to electrons or muons. Events with photon transverse momentum larger than 200 GeV and di-jet invariant mass larger than 200 GeV are selected. The W transverse momentum spectrum is analysed to set 95% C.L. limits as follows: $-77 < f_{M,0}/\Lambda^4 < 74$, $-125 < f_{M,1}/\Lambda^4 < 129$, $-26 < f_{M,2}/\Lambda^4 < 26$, $-43 < f_{M,3}/\Lambda^4 < 44$, $-40 < f_{M,4}/\Lambda^4 < 40$, $-65 < f_{M,5}/\Lambda^4 < 65$, $-129 < f_{M,6}/\Lambda^4 < 129$, $-164 < f_{M,7}/\Lambda^4 < 162$, $-5.4 < f_{T,0}/\Lambda^4 < 5.6$, $-3.7 < f_{T,1}/\Lambda^4 < 4.0$, $-11 < f_{T,2}/\Lambda^4 < 12$, $-3.8 < f_{T,5}/\Lambda^4 < 3.8$, $-2.8 < f_{T,6}/\Lambda^4 < 3.0$, $-7.3 < f_{T,7}/\Lambda^4 < 7.7$, in units of TeV^{-4} and without application of a form factor.

[23] SIRUNYAN 17AD study pp collisions at $\sqrt{s}=13$ TeV to determine the cross section of $ZZjj$ with the Z decaying to ee or $\mu\mu$. The ZZ mass distribution is used to set upper limits on the anomalous quartic couplings. The 95% upper limits for the relevant quartic couplings in units of TeV^{-4} are: $-0.46 < f_{T,0}/\Lambda^4 < 0.44$, $-0.61 < f_{T,1}/\Lambda^4 < 0.61$, $-1.2 < f_{T,2}/\Lambda^4 < 1.2$, $-0.84 < f_{T,8}/\Lambda^4 < 0.84$, $-1.8 < f_{T,9}/\Lambda^4 < 1.8$.

[24] SIRUNYAN 17AR study pp collisions at $\sqrt{s}=8$ TeV to determine the cross section of $pp\to W\gamma\gamma$ and $pp\to Z\gamma\gamma$ where $W\to\ell\nu$ and $Z\to\ell^+\ell^-$, ℓ being an electron or a muon. The number of W events in the e and μ channels is 63 and 108 respectively, and the number of Z events in the e and μ channels is 117 and 141. To increase sensitivity, the transverse momentum of the leading photon is required to be larger than 70 GeV. The 95% C.L. upper limits in units of TeV^{-4} are $-701 < f_{M,2}/\Lambda^4 < 683$, $-1170 < f_{M,3}/\Lambda^4 < 1220$, $-33.5 < f_{T,0}/\Lambda^4 < 34.0$, $-44.3 < f_{T,1}/\Lambda^4 < 44.8$, $-93.8 < f_{T,2}/\Lambda^4 < 93.2$.

[25] AABOUD 16E study WW production in two-photon mediated pp collisions at 8 TeV where the W boson decays into an electron or muon, probing the $\gamma\gamma WW$ vertex for anomalous quartic gauge couplings. The lepton p_T is required to be larger than 30 GeV. Limits on anomalous couplings are determined from events with p_T larger than 120 GeV where the aQGC effect is enhanced and the SM background reduced; in the data corresponding to an integrated luminosity of 20.2fb^{-1}, 1 event is selected with an expected SM background of 0.37 ± 0.13 events. The 95% C.L. limits without a form-factor cutoff ($\Lambda_{\text{cutoff}}\to\infty$) are as follows: $-1.7 < a_0^W/\Lambda^2 < 1.7$ and $-6.4 < a_C^W/\Lambda^2 < 6.3$ in units of 10^{-6} GeV^{-2}. In terms of another set of variables: $-6.6 < f_{M,0}/\Lambda^4 < 6.6$ and $-24 < f_{M,1}/\Lambda^4 < 25$ in units of 10^{-11} GeV^{-4}.

[26] AAD 16Q study $Z\gamma\gamma$ production in pp collisions. In events with no additional jets, 29 (22) Z decays to electron (muon) pairs are selected, with an expected background of 3.3 ± 1.1 (6.5 ± 2.0) events, as well as 19 Z decays to netrino pairs with an expected background of 8.3 ± 4.4 events. Analysing the photon transverse momentum distribution for $m_{\gamma\gamma}$ above 200 GeV (300 GeV) for lepton (neutrino) events, yields the 95% C.L. limits: $-1.6\times10^4 < f_{M,2}/\Lambda^4 < 1.6\times10^4$, $-2.9\times10^4 < f_{M,3}/\Lambda^4 < 2.7\times10^4$, $-0.86\times10^2 < f_{T,0}/\Lambda^4 < 1.03\times10^2$, $-0.69\times10^3 < f_{T,5}/\Lambda^4 < 0.68\times10^3$, $-0.74\times10^4 < f_{T,9}/\Lambda^4 < 0.74\times10^4$ in units of TeV^{-4} and without application of a form factor Λ_{FF}.

[27] KHACHATRYAN 16AX searches for anomalous $WW\gamma\gamma$ quartic gauge couplings in the two-photon-mediated process $pp\to ppWW$, assuming the $WW\gamma$ triple gauge boson couplings to be at their Standard Model values. 13 events containing an $e^\pm\mu^\mp$ pair with $p_T(e,\mu)>30$ GeV are selected in a total luminosity of 19.7 fb^{-1}, with an expected $\gamma\gamma\to WW$ signal of 5.3 ± 0.1 events and an expected background of 3.9 ± 0.5 events. When combining with the data collected at 7 TeV (CHATRCHYAN 13AA), and not assuming a form factor, the following 1-parameter limits at 95% C.L. are obtained from the $p_T(e,\mu)$ spectrum: $|a_0^W/\Lambda^2| < 1.1\times10^{-6}$ GeV^{-2} ($a_C^W=0$), and $|a_C^W/\Lambda^2| < 4.1\times10^{-6}$ GeV^{-2} ($a_0^W=0$). In terms of another set of variables: $|f_{M,0}/\Lambda^4| < 4.2\times10^{-12}$ GeV^{-4}, $|f_{M,1}/\Lambda^4| < 16\times10^{-12}$ GeV^{-4}, $|f_{M,2}/\Lambda^4| < 2.1\times10^{-12}$ GeV^{-4}, $|f_{M,3}/\Lambda^4| < 7.8\times10^{-12}$ GeV^{-4}.

[28] AAD 15N study $W\gamma\gamma$ events in 8 TeV pp interactions, where the W decays into an electron or a muon. The events are characterized by an isolated lepton, a missing transverse energy due to the decay neutrino, and two isolated photons, with the p_T of the lepton and the photons being >20 GeV. The number of candidate events observed in the electron channel for N(jet) $\geq$ 0 and N(jet) = 0 is 47 and 15, the corresponding numbers for the muon channel being 110 and 53. The backgrounds expected are 30.2 ± 7.4, 8.7 ± 3.0, 52.1 ± 12.2, and 24.4 ± 8.3 respectively. The 95% C.L. limits on the values of the parameters $f_{T,0}/\Lambda^4$, $f_{M,2}/\Lambda^4$ and $f_{M,3}/\Lambda^4$ are -0.9–0.9×10^2, -0.8–0.8×10^4, and -1.5–1.4×10^4 respectively, without application of a form factor Λ_{FF}.

[29] KHACHATRYAN 15D study vector-boson-scattering tagged by two jets, requiring two same-sign charged leptons arising from $W^\pm W^\pm$ production and decay. The two jets must have a transverse momentum larger than 30 GeV, while the leptons, electrons or muons, must have a transverse momentum >20 GeV. The dijet mass is required to be >500 GeV, the dilepton mass >50 GeV, with additional requirement of differing from the Z mass by >15 GeV. In the two categories W^+W^+ and W^-W^-, 10 and 2 data events are observed in a data sample corresponding to an integrated luminosity of 19.4 fb^{-1}, with an expected background of 3.1 ± 0.6 and 2.6 ± 0.5 events. Analysing the distribution of the dilepton invariant mass, the following limits at 95% C.L. are obtained, in units of TeV^{-4}: $-38 < f_{S,0}/\Lambda^4 < 40$, $-118 < f_{S,1}/\Lambda^4 < 120$, $-33 < f_{M,0}/\Lambda^4 < 32$, $-44 < f_{M,1}/\Lambda^4 < 47$, $-65 < f_{M,6}/\Lambda^4 < 63$, $-70 < f_{M,7}/\Lambda^4 < 66$, $-4.2 < f_{T,0}/\Lambda^4 < 4.6$, $-1.9 < f_{T,1}/\Lambda^4 < 2.2$, $-5.2 < f_{T,2}/\Lambda^4 < 6.4$.

[30] AAD 14AM analyze electroweak production of WW jet jet same-charge diboson plus two jets production, with the W bosons decaying to electron or muon, to study the quartic $WWWW$ coupling. In a kinematic region enhancing the electroweak production over the strong production, 34 events are observed in the data while 29.8 ± 2.4 events are expected with a backgound of 15.9 ± 1.9 events. Assuming the other QGC coupling to have the SM value of zero, the observed event yield is used to determine 95% CL limits on the quartic gauge couplings: $-0.14 < \alpha_4 < 0.16$ and $-0.23 < \alpha_5 < 0.24$.

[31] CHATRCHYAN 14Q study $WV\gamma$ production in 8 TeV pp collisions, in the single lepton final state, with $W\to\ell\nu$, $Z\to$ dijet or $W\to\ell\nu$, $W\to$ dijet, the dijet mass resolution precluding differentiation between the W and Z. p_T and pseudo-rapidity cuts are put on the lepton, the photon and the two jets to minimize backgrounds. The dijet mass is required to be between 70–100 GeV and $|\Delta\eta_{jj}|<1.4$. The selected number of muon (electron) events are 183 (139), with SM expectation being 194.2 ± 11.5 (147.9 ± 10.7) including signal and background. The photon E_T distribution is used to set limits on the anomalous quartic couplings. The following 95% CL limits are deduced (all in units of TeV^{-2} or TeV^{-4}): $-21 < a_0^W/\Lambda^2 < 20$, $-34 < a_c^W/\Lambda^2 < 32$, $-12 < \kappa_0^W/\Lambda^2 < 10$ and $-18 < \kappa_c^W/\Lambda^2 < 17$; and $-25 < f_{T,0}/\Lambda^4 < 24$ TeV^{-4}.

[32] ABAZOV 13D searches for anomalous $WW\gamma\gamma$ quartic gauge couplings in the two-photon-mediated process $pp\to ppWW$, assuming the $WW\gamma$ triple gauge boson couplings to be at their Standard Model values. 946 events containing an e^+e^- pair with missing energy are selected in a total luminosity of 9.7 fb^{-1}, with an expectation of 983 ± 108 events from Standard-Model processes. The following 1-parameter limits at 95% CL are otained: $|a_0^W/\Lambda^2| < 4.3\times10^{-4}$ GeV^{-2} ($a_c^W=0$), $|a_c^W/\Lambda^2| < 1.5\times10^{-3}$ GeV^{-2} ($a_0^W=0$).

[33] CHATRCHYAN 13AA searches for anomalous $WW\gamma\gamma$ quartic gauge couplings in the two-photon-mediated process $pp\to ppWW$, assuming the $WW\gamma$ triple gauge boson couplings to be at their Standard Model values. 2 events containing an $e^\pm\mu^\mp$ pair with $p_T(e,\mu)>30$ GeV are selected in a total luminosity of 5.05 fb^{-1}, with an expected $ppWW$ signal of 2.2 ± 0.4 events and an expected background of 0.84 ± 0.15 events. The following 1-parameter limits at 95% CL are otained from the $p_T(e,\mu)$ spectrum: $|a_0^W/\Lambda^2| < 4.0\times10^{-6}$ GeV^{-2} ($a_c^W=0$), $|a_c^W/\Lambda^2| < 1.5\times10^{-5}$ GeV^{-2} ($a_0^W=0$).

[34] ABBIENDI 04B select 187 $e^+e^-\to W^+W^-\gamma$ events in the C.M. energy range 180–209 GeV, where $E_\gamma>2.5$ GeV, the photon has a polar angle $|\cos\theta_\gamma|<0.975$ and is well isolated from the nearest jet and charged lepton, and the effective masses of both fermion-antifermion systems agree with the W mass within $3\,\Gamma_W$. The measured differential cross section as a function of the photon energy and photon polar angle is used to extract the 95% CL limits: -0.020 GeV^{-2} $<a_0/\Lambda^2<0.020$ GeV^{-2}, -0.053 GeV^{-2} $<a_c/\Lambda^2<0.037$ GeV^{-2} and -0.16 GeV^{-2} $<a_n/\Lambda^2<0.15$ GeV^{-2}.

[35] ABBIENDI 04L select 20 $e^+e^-\to\nu\overline{\nu}\gamma\gamma$ acoplanar events in the energy range 180–209 GeV and 176 $e^+e^-\to q\overline{q}\gamma\gamma$ events in the energy range 130–209 GeV. These samples are used to constrain possible anomalous $W^+W^-\gamma\gamma$ and $ZZ\gamma\gamma$ quartic couplings. Further combining with the $W^+W^-\gamma$ sample of ABBIENDI 04B the following one–parameter 95% CL limits are obtained: $-0.007 < a_0^Z/\Lambda^2 < 0.023$ GeV^{-2}, $-0.029 < a_c^Z/\Lambda^2 < 0.029$ GeV^{-2}, $-0.020 < a_0^W/\Lambda^2 < 0.020$ GeV^{-2}, $-0.052 < a_c^W/\Lambda^2 < 0.037$ GeV^{-2}.

[36] In the CM energy range 183 to 209 GeV HEISTER 04A select 30 $e^+e^-\to\nu\overline{\nu}\gamma\gamma$ events with two acoplanar, high energy and high transverse momentum photons. The photon–photon acoplanarity is required to be $>5^\circ$, $E_\gamma/\sqrt{s}>0.025$ (the more energetic photon having energy $>0.2\sqrt{s}$), $p_{T_\gamma}/E_{\text{beam}}>0.05$ and $|\cos\theta_\gamma|<0.94$. A likelihood fit to the photon energy and recoil missing mass yields the following one–parameter 95% CL limits: $-0.012 < a_0^Z/\Lambda^2 < 0.019$ GeV^{-2}, $-0.041 < a_c^Z/\Lambda^2 < 0.044$ GeV^{-2}, $-0.060 < a_0^W/\Lambda^2 < 0.055$ GeV^{-2}, $-0.099 < a_c^W/\Lambda^2 < 0.093$ GeV^{-2}.

[37] ABDALLAH 03I select 122 $e^+e^-\to W^+W^-\gamma$ events in the C.M. energy range 189–209 GeV, where $E_\gamma>5$ GeV, the photon has a polar angle $|\cos\theta_\gamma|<0.95$ and is well isolated from the nearest charged fermion. A fit to the photon energy spectra yields $a_c/\Lambda^2=0.000^{+0.019}_{-0.040}$ GeV^{-2}, $a_0/\Lambda^2=-0.004^{+0.018}_{-0.010}$ GeV^{-2}, $\tilde{a}_0/\Lambda^2=-0.007^{+0.019}_{-0.008}$ GeV^{-2}, $a_n/\Lambda^2=-0.09^{+0.16}_{-0.05}$ GeV^{-2}, and $\tilde{a}_n/\Lambda^2=+0.05^{+0.07}_{-0.15}$ GeV^{-2}, keeping the other parameters fixed to their Standard Model values (0). The 95% CL limits are: -0.063 GeV^{-2} $<a_c/\Lambda^2<+0.032$ GeV^{-2}, -0.020 GeV^{-2} $<a_0/\Lambda^2<+0.020$ GeV^{-2}, -0.020 GeV^{-2} $<\tilde{a}_0/\Lambda^2<+0.020$ GeV^{-2}, -0.18 GeV^{-2} $<a_n/\Lambda^2<+0.14$ GeV^{-2}, -0.16 GeV^{-2} $<\tilde{a}_n/\Lambda^2<+0.17$ GeV^{-2}.

[38] ACHARD 02F select 86 $e^+e^-\to W^+W^-\gamma$ events at 192–207 GeV, where $E_\gamma>5$ GeV and the photon is well isolated. They also select 43 acoplanar $e^+e^-\to\nu\overline{\nu}\gamma\gamma$ events in this energy range, where the photon energies are >5 GeV and >1 GeV and the photon polar angles are between 14° and 166°. All these 43 events are in the recoil mass region corresponding to the Z (75–110 GeV). Using the shape and normalization of the photon spectra in the $W^+W^-\gamma$ events, and combining with the 42 event sample from 189 GeV data (ACCIARRI 00T), they obtain: $a_0/\Lambda^2=0.000\pm0.010$ GeV^{-2}, $a_c/\Lambda^2=-0.013\pm0.023$ GeV^{-2}, and $a_n/\Lambda^2=-0.002\pm0.076$ GeV^{-2}. Further combining the analyses of $W^+W^-\gamma$ events with the low recoil mass region of $\nu\overline{\nu}\gamma\gamma$ events (including samples collected at $183+189$ GeV), they obtain the following one-parameter 95% CL

Gauge & Higgs Boson Particle Listings

W, Z

limits: -0.015 GeV^{-2} $< a_0/\Lambda^2 < 0.015$ GeV^{-2}, -0.048 GeV^{-2} $< a_c/\Lambda^2 < 0.026$ GeV^{-2}, and -0.14 GeV^{-2} $< a_n/\Lambda^2 < 0.13$ GeV^{-2}.

Z Boson

Z MASS

OUR AVERAGE is given by the weighted average of the combined CDF result and the combined LEP result, assuming no correlations between CDF and LEP. The combined LEP result, 91.1876 ± 0.0021 GeV, is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). The LEP fit is performed using the Z mass and width, the Z hadronic pole cross section, the ratios of hadronic to leptonic partial widths, and the Z pole forward-backward lepton asymmetries. This set is believed to be most free of correlations.

The Z-boson mass listed here corresponds to the mass parameter in a Breit-Wigner distribution with mass dependent width. The value is 34 MeV greater than the real part of the position of the pole (in the energy-squared plane) in the Z-boson propagator. Also the LEP experiments have generally assumed a fixed value of the γ–Z interferences term based on the

standard model. Keeping this term as free parameter leads to a somewhat larger error on the fitted Z mass. See ACCIARRI 00Q and ABBIENDI 04G for a detailed investigation of both these issues.

91.14 ±0.12	480	[14] ABRAMS	89B	MRK2	E_{cm}^{ee}= 89–93 GeV
93.1 ±1.0 ±3.0	24	[15] ALBAJAR	89	UA1	$E_{cm}^{p\overline{p}}$= 546,630 GeV

[1] AALTONEN 22 analyse Z decays in the di-muon and di-electron channels using their full Run-II data set. They obtain Z mass values of 91192.0 ± 6.4(stat.) ±4.0(syst.) MeV and 91194.3 ± 13.8(stat.) ±7.6(syst.) MeV, respectively. Combining these results using the systematic uncertainty contributions and their correlations as given in AALTONEN 22, we obtain an average of 91192.3 ± 5.8(stat.) ±4.1(syst.) MeV.

[2] This result combines ABBIENDI 01A, ABREU 00F, ACCIARRI 00C, BARATE 00C, taking correlated uncertainties into account.

[3] ANDREEV 18A obtain this result in a combined electroweak and QCD analysis using all deep-inelastic e^+p and e^-p neutral current and charged current scattering cross sections published by the H1 Collaboration, including data with longitudinally polarized lepton beams.

[4] ABBIENDI 04G obtain this result using the S–matrix formalism for a combined fit to their cross section and asymmetry data at the Z peak and their data at 130–209 GeV. The authors have corrected the measurement for the 34 MeV shift with respect to the Breit–Wigner fits.

[5] ACHARD 04C select $e^+e^- \to Z\gamma$ events with hard initial–state radiation. Z decays to $q\overline{q}$ and muon pairs are considered. The fit results obtained in the two samples are found consistent to each other and combined considering the uncertainty due to ISR modelling as fully correlated.

[6] ABBIENDI 01A error includes approximately 2.3 MeV due to statistics and 1.8 MeV due to LEP energy uncertainty. This result is included in the LEP average LEP-SLC 06.

[7] The error includes 1.6 MeV due to LEP energy uncertainty. This result is included in the LEP average LEP-SLC 06.

[8] The error includes 1.8 MeV due to LEP energy uncertainty. This result is included in the LEP average LEP-SLC 06.

[9] ACCIARRI 00Q interpret the s-dependence of the cross sections and lepton forward-backward asymmetries in the framework of the S-matrix formalism. They fit to their cross section and asymmetry data at high energies, using the results of S-matrix fits to Z-peak data (ACCIARRI 00C) as constraints. The 130–189 GeV data constrains the γ/Z interference term. The authors have corrected the measurement for the 34.1 MeV shift with respect to the Breit-Wigner fits. The error contains a contribution of ±2.3 MeV due to the uncertainty on the γZ interference.

[10] BARATE 00C error includes approximately 2.4 MeV due to statistics, 0.2 MeV due to experimental systematics, and 1.7 MeV due to LEP energy uncertainty. This result is included in the LEP average LEP-SLC 06.

[11] MIYABAYASHI 95 combine their low energy total hadronic cross-section measurement with the ACTON 93D data and perform a fit using an S-matrix formalism. As expected, this result is below the mass values obtained with the standard Breit-Wigner parametrization.

[12] Enters fit through W/Z mass ratio given in the W Particle Listings. The ALITTI 92B systematic error (±0.93) has two contributions: one (±0.92) cancels in m_W/m_Z and one (±0.12) is noncancelling. These were added in quadrature.

[13] First error of ABE 89 is combination of statistical and systematic contributions; second is mass scale uncertainty.

[14] ABRAMS 89B uncertainty includes 35 MeV due to the absolute energy measurement.

[15] ALBAJAR 89 result is from a total sample of 33 $Z \to e^+e^-$ events.

Z WIDTH

OUR EVALUATION is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). Corrections as discussed in VOUTSINAS 20 and JANOT 20 are also included.

2.5024±0.0042	3.96M	[6] ACCIARRI	00C	L3	E_{cm}^{ee}= 88–94 GeV
2.5025±0.0041	3.97M	[7] ACCIARRI	00Q	L3	E_{cm}^{ee}= LEP1 + 130–189 GeV
2.4951±0.0043	4.57M	[8] BARATE	00C	ALEP	E_{cm}^{ee}= 88–94 GeV
2.50 ±0.21 ±0.06		[9] ABREU	96R	DLPH	E_{cm}^{ee}= 91.2 GeV
3.8 ±0.8 ±1.0	188	ABE	89C	CDF	$E_{cm}^{p\overline{p}}$= 1.8 TeV
2.42 $^{+0.45}_{-0.35}$	480	[10] ABRAMS	89B	MRK2	E_{cm}^{ee}= 89–93 GeV
2.7 $^{+1.2}_{-1.0}$ ±1.3	24	[11] ALBAJAR	89	UA1	$E_{cm}^{p\overline{p}}$= 546,630 GeV
2.7 ±2.0 ±1.0	25	[12] ANSARI	87	UA2	$E_{cm}^{p\overline{p}}$= 546,630 GeV

[1] JANOT 20 applies a correction to LEP-SLC 06 using an updated Bhabha cross section calculation. This result also includes a correction to account for correlated luminosity bias as presented in VOUTSINAS 20.

[2] VOUTSINAS 20 applies a correction to LEP-SLC 06 to account for correlated luminosity bias.

[3] ABBIENDI 04G obtain this result using the S–matrix formalism for a combined fit to their cross section and asymmetry data at the Z peak and their data at 130–209 GeV. The authors have corrected the measurement for the 1 MeV shift with respect to the Breit–Wigner fits.

[4] ABBIENDI 01A error includes approximately 3.6 MeV due to statistics, 1 MeV due to event selection systematics, and 1.3 MeV due to LEP energy uncertainty.

[5] The error includes 1.2 MeV due to LEP energy uncertainty.

[6] The error includes 1.3 MeV due to LEP energy uncertainty.

[7] ACCIARRI 00Q interpret the s-dependence of the cross sections and lepton forward-backward asymmetries in the framework of the S-matrix formalism. They fit to their cross section and asymmetry data at high energies, using the results of S-matrix fits to Z-peak data (ACCIARRI 00C) as constraints. The 130–189 GeV data constrains the γ/Z interference term. The authors have corrected the measurement for the 0.9 MeV shift with respect to the Breit-Wigner fits.

[8] BARATE 00C error includes approximately 3.8 MeV due to statistics, 0.9 MeV due to experimental systematics, and 1.3 MeV due to LEP energy uncertainty.

[9] ABREU 96R obtain this value from a study of the interference between initial and final state radiation in the process $e^+e^- \to Z \to \mu^+\mu^-$.

[10] ABRAMS 89B uncertainty includes 50 MeV due to the miniSAM background subtraction error.

[11] ALBAJAR 89 result is from a total sample of 33 $Z \to e^+e^-$ events.

[12] Quoted values of ANSARI 87 are from direct fit. Ratio of Z and W production gives either $\Gamma(Z) < (1.09 \pm 0.07) \times \Gamma(W)$, CL = 90% or $\Gamma(Z) = (0.82^{+0.19}_{-0.14} \pm 0.06) \times \Gamma(W)$. Assuming Standard-Model value $\Gamma(W)$ = 2.65 GeV then gives $\Gamma(Z) < 2.89 \pm 0.19$ or $= 2.17^{+0.50}_{-0.37} \pm 0.16$.

[a] ℓ indicates each type of lepton (e, μ, and τ), not sum over them.

[b] Here ℓ indicates e or μ.

[c] The value is for the sum of the charge states or particle/antiparticle states indicated.

[d] This value is updated using the product of (i) the $Z \to b\overline{b}$ fraction from this listing and (ii) the b-hadron fraction in an unbiased sample of weakly decaying b-hadrons produced in Z-decays provided by the Heavy Flavor Averaging Group (HFLAV, http://www.slac.stanford.edu/xorg/hflav/osc/PDG_2009/#FRACZ).

[e] See the Particle Listings below for the γ energy range used in this measurement.

[f] For $m_{\gamma\gamma} = (60 \pm 5)$ GeV.

Z PARTIAL WIDTHS

$\Gamma(e^+e^-)$ Γ_1

For the LEP experiments, this parameter is not directly used in the overall fit but is derived using the fit results; see the note "The Z boson" and ref. LEP-SLC 06.

$\Gamma(\ell^+\ell^-)$ Γ_4

ℓ indicates each type of lepton (e, μ, and τ), not sum over them.

In our fit $\Gamma(\ell^+\ell^-)$ is defined as the partial Z width for the decay into a pair of massless charged leptons. This parameter is not directly used in the 5-parameter fit assuming lepton universality but is derived using the fit results. See the note "The Z boson" and ref. LEP-SLC 06.

$\Gamma(\text{invisible})$ Γ_7

The Z boson also decays to final states invisible in any detector, for example, the decay to a neutrino pair as predicted in the Standard Model. Measurements of Γ(invisible) fall into two categories: direct or indirect. Direct measurements look for final states with missing energy, missing momentum, or missing mass, corresponding to the invisible decay of a produced Z boson, including single-photon final states which arise from initial-state radiation. The indirect determination is based on Z lineshape analyses performed at the LEP collider, where the invisible decay width is calculated by subtracting all visible partial decay widths from the total decay width of the Z boson. Within the framework of the Standard Model these two determinations should be identical, but not in non-SM scenarios.

[1] TUMASYAN 23E analyses leptonic Z decay modes, with the invisible Z decay identified by missing momentum.

[2] The LEP Collaborations perform a combined fit to their line-shape results and determine this quantity as a difference between the total width and the sum of all the visible widths, assuming lepton universality. This result combines ABBIENDI 01A, ABREU 00F, ACCIARRI 00C, BARATE 00C, taking correlated uncertainties into account.

[3] This analysis selects single-photon events arising from inital state radiation.

[4] This is an indirect determination of Γ(invisible) from a fit to the visible Z decay modes. It is included in the determination of the LEP average LEP-SLC 06 reported above.

$\Gamma(\text{hadrons})$ Γ_8

This parameter is not directly used in the 5-parameter fit assuming lepton universality, but is derived using the fit results. See the note "The Z boson" and ref. LEP-SLC 06.

1.01 ±0.05	[1] AAIJ	18AR	LHCB	E_{cm}^{pp} = 8 TeV
1.0010±0.0026	[2] LEP-SLC	06		E_{cm}^{ee} = 88–94 GeV

[1] AAIJ 18AR obtain the result from the ratio of the measured $pp \to Z + X$ cross sections in the corresponding Z decay channels.
[2] This parameter is not directly used in the overall fit but is derived using the fit results; see the note "The Z boson" and ref. LEP-SLC 06.

$\Gamma(\ell^+\ell^-\ell^+\ell^-)/\Gamma_{total}$ Γ_6/Γ

Here ℓ indicates either e or μ. The branching fractions in this node are given within the phase-space defined by the requirements that (i) the 4-lepton invariant mass is between 80 GeV and 100 GeV, and (ii) any opposite-sign same-flavor lepton pair has a di-lepton invariant mass larger than 4 GeV.

4.55±0.17 OUR AVERAGE					
4.41±0.13±0.27		[1] AAD	21AQ	ATLS	E_{cm}^{pp} = 13 TeV
4.70±0.32±0.25		[2] AABOUD	19N	ATLS	E_{cm}^{pp} = 13 TeV
$4.83^{+0.23+0.35}_{-0.22-0.32}$	509	[3] SIRUNYAN	18BT	CMS	E_{cm}^{pp} = 13 TeV
$4.9\ ^{+0.8}_{-0.7}\ ^{+0.4}_{-0.2}$	39	[4] KHACHATRY...16CC		CMS	E_{cm}^{pp} = 13 TeV
4.31±0.34±0.17	172	AAD	14N	ATLS	E_{cm}^{pp} = 7, 8 TeV
$4.6\ ^{+1.0}_{-0.9}\ \pm0.2$	28	[5] CHATRCHYAN	12BN	CMS	E_{cm}^{pp} = 7 TeV

[1] AAD 21AQ analyze differential cross-sections in four-lepton events. Based on the measured cross section in the $Z \to 4\ell$ channel, a branching fraction of $B(Z \to 4\ell) = (4.41 \pm 0.13 \pm 0.23 \pm 0.09 \pm 0.12) \times 10^{-6}$ is obtained, where the uncertainties are statistical, systematic, theory and luminosity, respectively.
[2] AABOUD 19N reports $(4.70 \pm 0.32 \pm 0.21 \pm 0.14) \times 10^{-6}$, where the uncertainties are statistical, systematic, and luminosity. We have combined the latter two in quadrature.
[3] SIRUNYAN 18BT report the $Z \to 4\ell$ branching fraction $= (4.83^{+0.23+0.32}_{-0.22-0.29} \pm 0.08 \pm 0.12) \times 10^{-6}$, where the uncertainties are statistical, systematic, due to theory, and luminosity. The last three have been added in quadrature to obtain the total systematic error.
[4] KHACHATRYAN 16CC reports $(4.9^{+0.8+0.3+0.2+0.1}_{-0.7-0.2-0.1-0.1}) \times 10^{-6}$ value, where the uncertainties are statistical, systematic, theory, and due to luminosity. We have combined uncertainties in quadrature.
[5] CHATRCHYAN 12BN reports $(4.2^{+0.9}_{-0.8} \pm 0.2) \times 10^{-6}$ value. Their result (both central value and uncertainties) is scaled up by 10% to account for the different phase-space definition used here (see RAINBOLT 19).

• • • We do not use the following data for averages, fits, limits, etc. • • •				
0.1623±0.0085±0.0209	[6] ABREU	95D	DLPH	E_{cm}^{ee}= 88–94 GeV

[1] ABE 05F use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $c\overline{c}$ events using a double tag method. The single c-tag is obtained with a neural network trained to perform flavor discrimination using as input several signatures (corrected secondary vertex mass, vertex decay length, multiplicity and total momentum of the hemisphere). A multitag approach is used, defining 4 regions of the output value of the neural network and R_c is extracted from a simultaneous fit to the count rates of the 4 different tags. The quoted systematic error includes an uncertainty of ±0.0006 due to the uncertainty on R_b.

[2] ABREU 00 obtain this result properly combining the measurement from the D^{*+} production rate (R_c= 0.1610 ± 0.0104 ± 0.0077 ± 0.0043 (BR)) with that from the overall charm counting (R_c= 0.1692 ± 0.0047 ± 0.0063 ± 0.0074 (BR)) in $c\overline{c}$ events. The systematic error includes an uncertainty of ±0.0054 due to the uncertainty on the charmed hadron branching fractions.

[3] BARATE 00B use exclusive decay modes to independently determine the quantities $R_c \times f(c \to X)$, X=D^0, D^+, D_s^+, and Λ_c. Estimating $R_c \times f(c \to \Xi_c/\Omega_c)$= 0.0034, they simply sum over all the charm decays to obtain R_c= 0.1738 ± 0.0047 ± 0.0088 ± 0.0075(BR). This is combined with all previous ALEPH measurements (BARATE 98T and BUSKULIC 94G, R_c= 0.1681 ± 0.0054 ± 0.0062) to obtain the quoted value.

[4] ACKERSTAFF 98E use an inclusive/exclusive double tag. In one jet $D^{*\pm}$ mesons are exclusively reconstructed in several decay channels and in the opposite jet a slow pion (opposite charge inclusive $D^{*\pm}$) tag is used. The b content of this sample is measured by the simultaneous detection of a lepton in one jet and an inclusively reconstructed $D^{*\pm}$ meson in the opposite jet. The systematic error includes an uncertainty of ±0.006 due to the external branching ratios.

[5] ALEXANDER 96R obtain this value via direct charm counting, summing the partial contributions from D^0, D^+, D_s^+, and Λ_c^+, and assuming that strange-charmed baryons account for the 15% of the Λ_c^+ production. An uncertainty of ±0.005 due to the uncertainties in the charm hadron branching ratios is included in the overall systematics.

[6] ABREU 95D perform a maximum likelihood fit to the combined p and p_T distributions of single and dilepton samples. The second error includes an uncertainty of ±0.0124 due to models and branching ratios.

$R_b = \Gamma(b\overline{b})/\Gamma(\text{hadrons})$ Γ_{12}/Γ_8

OUR FIT is obtained by a simultaneous fit to several c- and b-quark measurements as explained in the note "The Z boson" and ref. LEP-SLC 06.

The Standard Model predicts R_b=0.21581 for m_t=174.3 GeV and M_H=150 GeV.

[1] ABE 05F use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $b\overline{b}$ events using a double tag method. The single b–tag is obtained with a neural network trained to perform flavor discrimination using as input several signatures (corrected secondary vertex mass, vertex decay length, multiplicity and total momentum of the hemisphere; the key tag is obtained requiring the secondary vertex corrected mass to be above the D–meson mass). ABE 05F obtain R_b =0.21604 ± 0.00098 ± 0.00074 where the systematic error includes an uncertainty of ±0.00012 due to the uncertainty on R_c. The value reported here is obtained properly combining with ABE 98D. The quoted systematic error includes an uncertainty of ±0.00012 due to the uncertainty on R_c.

[2] ACCIARRI 00 obtain this result using a double-tagging technique, with a high p_T lepton tag and an impact parameter tag in opposite hemispheres.

[3] ABBIENDI 99B tag $Z \to b\overline{b}$ decays using leptons and/or separated decay vertices. The b-tagging efficiency is measured directly from the data using a double-tagging technique.

[4] ABREU 99B obtain this result combining in a multivariate analysis several tagging methods (impact parameter and secondary vertex reconstruction, complemented by event shape variables). For R_c different from its Standard Model value of 0.172, R_b varies as $-0.024\times(R_c-0.172)$.

[5] BARATE 97F combine the lifetime-mass hemisphere tag (BARATE 97E) with event shape information and lepton tag to identify $Z \to b\overline{b}$ candidates. They further use c- and uds-selection tags to identify the background. For R_c different from its Standard Model value of 0.172, R_b varies as $-0.019\times(R_c - 0.172)$.

[6] ABREU 95D perform a maximum likelihood fit to the combined p and p_T distributions of single and dilepton samples. The second error includes an uncertainty of ±0.0023 due to models and branching ratios.

[7] BUSKULIC 94G perform a simultaneous fit to the p and p_T spectra of both single and dilepton events.

[8] JACOBSEN 91 tagged $b\overline{b}$ events by requiring coincidence of ≥ 3 tracks with significant impact parameters using vertex detector. Systematic error includes lifetime and decay uncertainties (±0.014).

$<2.6\times10^{-6}$	95	[3] AAD	15I	ATLS	$E_{\text{cm}}^{pp}=8$ TeV

[1] SIRUNYAN 19AJ study $Z\to J/\psi\gamma$ with $J/\psi\to\mu^+\mu^-$. Candidate events are selected by requiring a pair of oppositely charged muons and a well isolated photon. The leading (subleading) muon is require to have a transverse momentum larger than 20 GeV (4 GeV), while the photon must have a transverse energy larger than 33 GeV. Requiring the invariant mass of the $\mu\mu$ ($\mu\mu\gamma$) system in the range 3.0 to 3.2 (81 to 101) GeV, selects 183 data events which is consistent with the expected background. The 95% C.L. limit on the Z branching fraction is obtained assuming the J/ψ to be unpolarized.

[2] AABOUD 18BL study $Z\to J/\psi\gamma$ in 13 TeV pp interactions. Two triggers were used: isolated photon of $p_T>35(25)$ GeV and a muon with $p_T>18(24)$ GeV. The J/ψ is detected via its dimuon decay and it is required that the azimuthal angle between the photon and the J/ψ in the plane transverse to the beam direction is $>\pi/2$. The number of observed/expected background events is $92/89\pm6$ in the dimuon mass range 2.9–3.3 GeV leading to the quoted 95% C.L. limit.

[3] AAD 15I use events with the highest p_T muon in the pair required to have $p_T>20$ GeV, the dimuon mass required to be within 0.2 GeV of the $J/\psi(1S)$ mass and it's transverse momentum required to be >36 GeV. The photon is also required to have it's $p_T>36$ GeV.

VALUE	DOCUMENT ID		TECN	COMMENT
$0.67\pm0.18\pm0.05$	[1] SIRUNYAN	18DZ	CMS	pp at 13 TeV

[1] SIRUNYAN 18DZ observe the decay $Z\to\ \Psi\ell^+\ell^-$ in pp collisions at $\sqrt{s}=13$ TeV, where Ψ includes J/ψ as well as $\psi(2S)\to J/\psi X$, and $\ell^+\ell^-$ represents an electron or muon pair while the J/ψ is detected via its $\mu^+\mu^-$ decay channel. To reduce systematic errors they determine the ratio of the branching fraction of this decay to that of $Z\to\mu^+\mu^-\mu^+\mu^-$ within phase-space cuts imposed on lepton transverse momentum and pseudo rapidity, dilepton invariant mass, and J/ψ transverse momentum. The number of selected $\Psi\mu^+\mu^-$ (Ψe^+e^-) candidate events is 29 (18). Analyzing the $\mu^+\mu^-$ and $\mu^+\mu^-\ell^+\ell^-$ invariant mass distributions, a yield of 13.0 ± 3.9 (11.2 ± 3.4) events for the $\Psi\mu^+\mu^-$ (Ψe^+e^-) mode is obtained. The ratio of the branching fractions is determined as $0.67\pm0.18\pm0.05$ within the selected phase-space cuts. Assuming extrapolation to full phase space cancels in the ratio, and using their measured value of $\text{B}(Z\to\mu^+\mu^-\mu^+\mu^-)=(1.20\pm0.08)\times10^{-6}$, they estimate $\text{B}(Z\to J/\psi\ell^+\ell^-)=8\times10^{-7}$.

searched for	[2] ABREU	97E	DLPH	E_{cm}^{ee}= 88–94 GeV
searched for	[3] BARATE	97H	ALEP	E_{cm}^{ee}= 88–94 GeV

[1] ACKERSTAFF 98O searched for the decay modes $B_c \to J/\psi\pi^+$, $J/\psi a_1^+$, and $J/\psi\ell^+\nu_\ell$, with $J/\psi \to \ell^+\ell^-$, $\ell = e,\mu$. The number of candidates (background) for

the three decay modes is 2 (0.63 ± 0.2), 0 (1.10 ± 0.22), and 1 (0.82 ± 0.19) respectively. Interpreting the 2 $B_c \to J/\psi\pi^+$ candidates as signal, they report $\Gamma(B_c^+ X)\times B(B_c \to J/\psi\pi^+)/\Gamma(\text{hadrons}) = (3.8^{+5.0}_{-2.4} \pm 0.5)\times 10^{-5}$. Interpreted as background, the 90% CL bounds are $\Gamma(B_c^+ X)*B(B_c \to J/\psi\pi^+)/\Gamma(\text{hadrons}) < 1.06\times 10^{-4}$, $\Gamma(B_c^+ X)*B(B_c \to J/\psi a_1^+)/\Gamma(\text{hadrons}) < 5.29\times 10^{-4}$, $\Gamma(B_c^+ X)*B(B_c \to J/\psi\ell^+\nu_\ell)/\Gamma(\text{hadrons}) < 6.96\times 10^{-5}$.

[2] ABREU 97E searched for the decay modes $B_c \to J/\psi\pi^+$, $J/\psi\ell^+\nu_\ell$, and $J/\psi(3\pi)^+$, with $J/\psi \to \ell^+\ell^-$, $\ell = e,\mu$. The number of candidates (background) for the three decay modes is 1 (1.7), 0 (0.3), and 1 (2.3) respectively. They report the following 90% CL limits: $\Gamma(B_c^+ X)*B(B_c \to J/\psi\pi^+)/\Gamma(\text{hadrons}) < (1.05\text{–}0.84)\times 10^{-4}$, $\Gamma(B_c^+ X)*B(B_c \to J/\psi\ell\nu_\ell)/\Gamma(\text{hadrons}) < (5.8\text{–}5.0)\times 10^{-5}$, $\Gamma(B_c^+ X)*B(B_c \to J/\psi(3\pi)^+)/\Gamma(\text{hadrons}) < 1.75\times 10^{-4}$, where the ranges are due to the predicted B_c lifetime (0.4–1.4) ps.

[3] BARATE 97H searched for the decay modes $B_c \to J/\psi\pi^+$ and $J/\psi\ell^+\nu_\ell$ with $J/\psi \to \ell^+\ell^-$, $\ell = e,\mu$. The number of candidates (background) for the two decay modes is 0 (0.44) and 2 (0.81) respectively. They report the following 90% CL limits: $\Gamma(B_c^+ X)*B(B_c \to J/\psi\pi^+)/\Gamma(\text{hadrons}) < 3.6\times 10^{-5}$ and $\Gamma(B_c^+ X)*B(B_c \to J/\psi\ell^+\nu_\ell)/\Gamma(\text{hadrons}) < 5.2\times 10^{-5}$.

$\Gamma(\Lambda_c^+ X)/\Gamma(\text{hadrons})$ Γ_{54}/Γ_8

VALUE	DOCUMENT ID		TECN	COMMENT
0.022±0.005 OUR AVERAGE				
0.024±0.005±0.006	[1] ALEXANDER	96R	OPAL	E_{cm}^{ee} = 88–94 GeV
0.021±0.003±0.005	[2] BUSKULIC	96Y	ALEP	E_{cm}^{ee} = 88–94 GeV

[1] ALEXANDER 96R measure $R_b \times f(b \to \Lambda_c^+ X) \times B(\Lambda_c^+ \to pK^-\pi^+) = (0.122 \pm 0.023 \pm 0.010)\%$ in hadronic Z decays; the value quoted here is obtained using our best value $B(\Lambda_c^+ \to pK^-\pi^+) = (5.0 \pm 1.3)\%$. The first error is the total experiment's error and the second error is the systematic error due to the branching fraction uncertainty.

[2] BUSKULIC 96Y obtain the production fraction of Λ_c^+ baryons in hadronic Z decays $f(b \to \Lambda_c^+ X) = 0.110 \pm 0.014 \pm 0.006$ using $B(\Lambda_c^+ \to pK^-\pi^+) = (4.4 \pm 0.6)\%$; we have rescaled using our best value $B(\Lambda_c^+ \to pK^-\pi^+) = (5.0 \pm 1.3)\%$ obtaining $f(b \to \Lambda_c^+ X) = 0.097 \pm 0.013 \pm 0.025$ where the first error is their total experiment's error and the second error is the systematic error due to the branching fraction uncertainty. The value quoted here is obtained multiplying this production fraction by our value of $R_b = \Gamma(b\overline{b})/\Gamma(\text{hadrons})$.

$\Gamma(\Xi_c^0 X)/\Gamma(\text{hadrons})$ Γ_{55}/Γ_8

seen	[1] ABDALLAH	05C	DLPH	E_{cm}^{ee} = 88–94 GeV

[1] ABDALLAH 05C searched for the charmed strange baryon Ξ_c^0 in the decay channel $\Xi_c^0 \to \Xi^-\pi^+$ ($\Xi^- \to \Lambda\pi^-$). The production rate is measured to be $f_{\Xi_c^0} \times B(\Xi_c^0 \to \Xi^-\pi^+) = (4.7 \pm 1.4 \pm 1.1)\times 10^{-4}$ per hadronic Z decay.

$\Gamma(\Xi_b X)/\Gamma(\text{hadrons})$ Γ_{56}/Γ_8

Here Ξ_b is used as a notation for the strange b-baryon states Ξ_b^- and Ξ_b^0.

VALUE	DOCUMENT ID		TECN	COMMENT
• • • We do not use the following data for averages, fits, limits, etc. • • •				
seen	[1] ABDALLAH	05C	DLPH	E_{cm}^{ee} = 88–94 GeV
seen	[2] BUSKULIC	96T	ALEP	E_{cm}^{ee} = 88–94 GeV
seen	[3] ABREU	95V	DLPH	E_{cm}^{ee} = 88–94 GeV

[1] ABDALLAH 05C searched for the beauty strange baryon Ξ_b in the inclusive semileptonic decay channel $\Xi_b \to \Xi^-\ell^-\overline{\nu}_\ell X$. Evidence for the Ξ_b production is seen from the observation of $\Xi^\mp$ production accompanied by a lepton of the same sign. From the excess of "right-sign" pairs $\Xi^\mp\ell^\mp$ compared to "wrong-sign" pairs $\Xi^\mp\ell^\pm$ the production rate is measured to be $B(b \to \Xi_b) \times B(\Xi_b \to \Xi^-\ell^-X) = (3.0 \pm 1.0 \pm 0.3)\times 10^{-4}$ per lepton species, averaged over electrons and muons.

[2] BUSKULIC 96T investigate Ξ-lepton correlations and find a significant excess of "right–sign" pairs $\Xi^\mp\ell^\mp$ compared to "wrong–sign" pairs $\Xi^\mp\ell^\pm$. This excess is interpreted as evidence for Ξ_b semileptonic decay. The measured product branching ratio is $B(b \to \Xi_b) \times B(\Xi_b \to X_c X\ell^-\overline{\nu}_\ell) \times B(X_c \to \Xi^- X') = (5.4 \pm 1.1 \pm 0.8)\times 10^{-4}$ per lepton species, averaged over electrons and muons, with X_c a charmed baryon.

[3] ABREU 95V observe an excess of "right-sign" pairs $\Xi^\mp\ell^\mp$ compared to "wrong-sign" pairs $\Xi^\mp\ell^\pm$ in jets: this excess is interpreted as evidence for the beauty strange baryon Ξ_b production, with $\Xi_b \to \Xi^-\ell^-\overline{\nu}_\ell X$. They find that the probability for this signal to come from non b-baryon decays is less than 5×10^{-4} and that Λ_b decays can account for less than 10% of these events. The Ξ_b production rate is then measured to be $B(b \to \Xi_b) \times B(\Xi_b \to \Xi^-\ell^-X) = (5.9 \pm 2.1 \pm 1.0)\times 10^{-4}$ per lepton species, averaged over electrons and muons.

$\Gamma(b\text{-baryon } X)/\Gamma(\text{hadrons})$ Γ_{57}/Γ_8

"OUR EVALUATION" is obtained using our current values for $f(b \to b\text{-baryon})$ and $R_b = \Gamma(b\overline{b})/\Gamma(\text{hadrons})$. We calculate $\Gamma(b\text{-baryon } X)/\Gamma(\text{hadrons}) = R_b \times f(b \to b\text{-baryon})$.

Z HADRONIC POLE CROSS SECTION

OUR EVALUATION is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). Corrections as discussed in VOUTSINAS 20 and JANOT 20 are also included. This quantity is defined as

$$\sigma_h^0 = \frac{12\pi}{M_Z^2} \frac{\Gamma(e^+e^-)\,\Gamma(\text{hadrons})}{\Gamma_Z^2}$$

It is one of the parameters used in the Z lineshape fit.

VALUE (nb)	EVTS	DOCUMENT ID		TECN	COMMENT
41.4802±0.0325 OUR EVALUATION					
41.4802±0.0325		[1] JANOT	20		
• • • We do not use the following data for averages, fits, limits, etc. • • •					
41.500 ±0.037		[2] VOUTSINAS	20		
41.541 ±0.037		LEP-SLC	06		E_{cm}^{ee} = 88–94 GeV
41.501 ±0.055	4.10M	[3] ABBIENDI	01A	OPAL	E_{cm}^{ee}= 88–94 GeV
41.578 ±0.069	3.70M	ABREU	00F	DLPH	E_{cm}^{ee}= 88–94 GeV
41.535 ±0.055	3.54M	ACCIARRI	00C	L3	E_{cm}^{ee}= 88–94 GeV
41.559 ±0.058	4.07M	[4] BARATE	00C	ALEP	E_{cm}^{ee}= 88–94 GeV
42 ±4	450	ABRAMS	89B	MRK2	E_{cm}^{ee}= 89.2–93.0 GeV

[1] JANOT 20 applies a correction to LEP-SLC 06 using an updated Bhabha cross section calculation. This result also includes a correction to account for correlated luminosity bias as presented in VOUTSINAS 20.

[2] VOUTSINAS 20 applies a correction to LEP-SLC 06 to account for correlated luminosity bias.

[3] ABBIENDI 01A error includes approximately 0.031 due to statistics, 0.033 due to event selection systematics, 0.029 due to uncertainty in luminosity measurement, and 0.011 due to LEP energy uncertainty.

[4] BARATE 00C error includes approximately 0.030 due to statistics, 0.026 due to experimental systematics, and 0.025 due to uncertainty in luminosity measurement.

Z VECTOR COUPLINGS

These quantities are the effective vector couplings of the Z to charged leptons and quarks. Their magnitude is derived from a measurement of the Z lineshape and the forward-backward lepton asymmetries as a function of energy around the Z mass. The relative sign among the vector to axial-vector couplings is obtained from a measurement of the Z asymmetry parameters, A_e, A_μ, and A_τ. By convention the sign of g_A^e is fixed to be negative (and opposite to that of g^{ν_e} obtained using ν_e scattering measurements). For the light quarks, the sign of the couplings is assigned consistently with this assumption. The LEP/SLD-based fit values quoted below correspond to global nine- or five-parameter fits to lineshape, lepton forward-backward asymmetry, and A_e, A_μ, and A_τ measurements. See the note "The Z boson" and ref. LEP-SLC 06 for details. Where $p\overline{p}$ and ep data is quoted, OUR FIT value corresponds to a weighted average of this with the LEP/SLD fit result.

−0.0414 ±0.0020		[4] ABE	95J	SLD	$E_{\rm cm}^{ee}$= 91.31 GeV

[1] ACOSTA 05M determine the forward–backward asymmetry of e^+e^- pairs produced via $q\overline{q} \to Z/\gamma^* \to e^+e^-$ in 15 M(e^+e^-) effective mass bins ranging from 40 GeV to 600 GeV. These results are used to obtain the vector and axial–vector couplings of the Z to e^+e^-, assuming the quark couplings are as predicted by the standard model. Higher order radiative corrections have not been taken into account.

[2] ABBIENDI 01O use their measurement of the τ polarization in addition to the lineshape and forward–backward lepton asymmetries.

[3] ACCIARRI 00C use their measurement of the τ polarization in addition to forward–backward lepton asymmetries.

[4] ABE 95J obtain this result combining polarized Bhabha results with the A_{LR} measurement of ABE 94C. The Bhabha results alone give $-0.0507 \pm 0.0096 \pm 0.0020$.

Z AXIAL-VECTOR COUPLINGS

These quantities are the effective axial-vector couplings of the Z to charged leptons and quarks. Their magnitude is derived from a measurement of the Z lineshape and the forward-backward lepton asymmetries as a function of energy around the Z mass. The relative sign among the vector to axial-vector couplings is obtained from a measurement of the Z asymmetry parameters, A_e, A_μ, and A_τ. By convention the sign of g_A^e is fixed to be negative (and opposite to that of g^{ν_e} obtained using ν_e scattering measurements). For the light quarks, the sign of the couplings is assigned consistently with this assumption. The LEP/SLD-based fit values quoted below correspond to global nine- or five-parameter fits to lineshape, lepton forward–backward asymmetry, and A_e, A_μ, and A_τ measurements. See the note "The Z boson" and ref. LEP-SLC 06 for details. Where $p\overline{p}$ and ep data is quoted, OUR FIT value corresponds to a weighted average of this with the LEP/SLD fit result.

VALUE	DOCUMENT ID		TECN	COMMENT
0.502 ± 0.017	[1] VILAIN	94	CHM2	From $\nu_\mu e$ scattering

[1] VILAIN 94 derive this value from their measurement of the couplings $g_A^{e\nu_\mu} = -0.503 \pm 0.017$ and $g_V^{e\nu_\mu} = -0.035 \pm 0.017$ obtained from $\nu_\mu e$ scattering. We have re-evaluated this value using the current PDG values for g_A^e and g_V^e.

Z ASYMMETRY PARAMETERS

For each fermion-antifermion pair coupling to the Z these quantities are defined as

$$A_f = \frac{2 g_V^f g_A^f}{(g_V^f)^2 + (g_A^f)^2}$$

where g_V^f and g_A^f are the effective vector and axial-vector couplings. For their relation to the various lepton asymmetries see the note "The Z boson" and ref. LEP-SLC 06.

A_e

Using polarized beams, this quantity can also be measured as $(\sigma_L - \sigma_R)/(\sigma_L + \sigma_R)$, where σ_L and σ_R are the e^+e^- production cross sections for Z bosons produced with left-handed and right-handed electrons respectively.

[1] ABBIENDI 01O fit for A_e and A_τ from measurements of the τ polarization at varying τ production angles. The correlation between A_e and A_τ is less than 0.03.

[2] ABE 01B use the left-right production and left-right forward-backward decay asymmetries in leptonic Z decays to obtain a value of 0.1544 ± 0.0060. This is combined with left-right production asymmetry measurement using hadronic Z decays (ABE 00B) to obtain the quoted value.

[3] HEISTER 01 obtain this result fitting the τ polarization as a function of the polar production angle of the τ.

[4] ABREU 00E obtain this result fitting the τ polarization as a function of the polar τ production angle. This measurement is a combination of different analyses (exclusive τ decay modes, inclusive hadronic 1-prong reconstruction, and a neural network analysis).

[5] Derived from the measurement of forward-backward τ polarization asymmetry.

[6] ABE 97 obtain this result from a measurement of the observed left-right charge asymmetry, A_Q^{obs} = 0.225 ± 0.056 ± 0.019, in hadronic Z decays. If they combine this value of A_Q^{obs} with their earlier measurement of A_{LR}^{obs} they determine A_e to be 0.1574 ± 0.0197 ± 0.0067 independent of the beam polarization.

[7] ABE 95J obtain this result from polarized Bhabha scattering.

A_μ

This quantity is directly extracted from a measurement of the left-right forward-backward asymmetry in $\mu^+\mu^-$ production at SLC using a polarized electron beam. This double asymmetry eliminates the dependence on the Z-e-e coupling parameter A_e.

VALUE	EVTS	DOCUMENT ID		TECN	COMMENT
0.142±0.015	16844	[1] ABE	01B	SLD	E_{cm}^{ee}= 91.24 GeV

0.153±0.012	1.7M	[2] AAD	15BT	ATLS	E_{cm}^{pp} = 7 TeV

[1] ABE 01B obtain this direct measurement using the left-right production and left-right forward-backward polar angle asymmetries in $\mu^+\mu^-$ decays of the Z boson obtained with a polarized electron beam.

[2] AAD 15BT study $pp \to Z \to \ell^+\ell^-$ events where ℓ is an electron or a muon in the dilepton mass region 70–1000 GeV. The background in the Z peak region is estimated to be $< 1\%$ for the muon channel. The muon asymmetry parameter is derived from the measured forward-backward asymmetry assuming the value of the quark asymmetry parameter from the SM. For this reason it is not used in the average.

A_τ

The LEP Collaborations derive this quantity from the measurement of the τ polarization in $Z \to \tau^+\tau^-$. The SLD Collaboration directly extracts this quantity from its measured left-right forward-backward asymmetry in $Z \to \tau^+\tau^-$ produced using a polarized e^- beam. This double asymmetry eliminates the dependence on the Z-e-e coupling parameter A_e.

0.1476±0.0088±0.0062	137092	ACCIARRI	98H	L3	E_{cm}^{ee}= 88–94 GeV

[1] ABBIENDI 01O fit for A_e and A_τ from measurements of the τ polarization at varying τ production angles. The correlation between A_e and A_τ is less than 0.03.

[2] ABE 01B obtain this direct measurement using the left-right production and left-right forward-backward polar angle asymmetries in $\tau^+\tau^-$ decays of the Z boson obtained with a polarized electron beam.

[3] HEISTER 01 obtain this result fitting the τ polarization as a function of the polar production angle of the τ.

[4] ABREU 00E obtain this result fitting the τ polarization as a function of the polar τ production angle. This measurement is a combination of different analyses (exclusive τ decay modes, inclusive hadronic 1-prong reconstruction, and a neural network analysis).

A_s

The SLD Collaboration directly extracts this quantity by a simultaneous fit to four measured s-quark polar angle distributions corresponding to two states of e^- polarization (positive and negative) and to the K^+K^- and $K^\pm K_S^0$ strange particle tagging modes in the hadronic final states.

VALUE	EVTS	DOCUMENT ID		TECN	COMMENT
0.895±0.066±0.062	2870	[1] ABE	00D	SLD	E_{cm}^{ee}= 91.2 GeV

[1] ABE 00D tag $Z \to s\overline{s}$ events by an absence of B or D hadrons and the presence in each hemisphere of a high momentum $K^\pm$ or K_S^0.

A_c

This quantity is directly extracted from a measurement of the left-right forward-backward asymmetry in $c\overline{c}$ production at SLC using polarized electron beam. This double asymmetry eliminates the dependence on the Z-e-e coupling parameter A_e. OUR FIT is obtained by a simultaneous fit to several c- and b-quark measurements as explained in the note "The Z boson" and ref. LEP-SLC 06.

VALUE	DOCUMENT ID		TECN	COMMENT
0.670 ±0.027 OUR FIT				
0.6712±0.0224±0.0157	[1] ABE	05	SLD	E_{cm}^{ee}= 91.24 GeV
• • • We do not use the following data for averages, fits, limits, etc. • • •				
0.583 ±0.055 ±0.055	[2] ABE	02G	SLD	E_{cm}^{ee}= 91.24 GeV
0.688 ±0.041	[3] ABE	01C	SLD	E_{cm}^{ee}= 91.25 GeV

[1] ABE 05 use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $c\overline{c}$ events tagging on the invariant mass of reconstructed secondary decay vertices. The charge of the underlying c–quark is obtained with an algorithm that takes into account the net charge of the vertex as well as the charge of tracks emanating from the vertex and identified as kaons. This yields (9970 events) A_c = 0.6747 ± 0.0290 ± 0.0233. Taking into account all correlations with earlier results reported in ABE 02G and ABE 01C, they obtain the quoted overall SLD result.

[2] ABE 02G tag b and c quarks through their semileptonic decays into electrons and muons. A maximum likelihood fit is performed to extract simultaneously A_b and A_c.

[3] ABE 01C tag $Z \to c\overline{c}$ events using two techniques: exclusive reconstruction of D^{*+}, D^+ and D^0 mesons and the soft pion tag for $D^{*+} \to D^0\pi^+$. The large background from D mesons produced in $b\overline{b}$ events is separated efficiently from the signal using precision vertex information. When combining the A_c values from these two samples, care is taken to avoid double counting of events common to the two samples, and common systematic errors are properly taken into account.

A_b

This quantity is directly extracted from a measurement of the left-right forward-backward asymmetry in $b\overline{b}$ production at SLC using polarized electron beam. This double asymmetry eliminates the dependence on the Z-e-e coupling parameter A_e. OUR FIT is obtained by a simultaneous fit to several c- and b-quark measurements as explained in the note "The Z boson" and ref. LEP-SLC 06.

0.923 ±0.020 OUR FIT					
0.9170±0.0147±0.0145		[1] ABE	05	SLD	E_{cm}^{ee}= 91.24 GeV
• • • We do not use the following data for averages, fits, limits, etc. • • •					
0.907 ±0.020 ±0.024	48028	[2] ABE	03F	SLD	E_{cm}^{ee}= 91.24 GeV
0.919 ±0.030 ±0.024		[3] ABE	02G	SLD	E_{cm}^{ee}= 91.24 GeV
0.855 ±0.088 ±0.102	7473	[4] ABE	99L	SLD	E_{cm}^{ee}= 91.27 GeV

[1] ABE 05 use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $b\overline{b}$ events tagging on the invariant mass of reconstructed secondary decay vertices. The charge of the underlying b–quark is obtained with an algorithm that takes into account the net charge of the vertex as well as the charge of tracks emanating from the vertex and identified as kaons. This yields (25917 events) A_b = 0.9173 ± 0.0184 ± 0.0173. Taking into account all correlations with earlier results reported in ABE 03F, ABE 02G and ABE 99L, they obtain the quoted overall SLD result.

[2] ABE 03F obtain an enriched sample of $b\overline{b}$ events tagging on the invariant mass of a 3-dimensional topologically reconstructed secondary decay. The charge of the underlying b quark is obtained using a self-calibrating track-charge method. For the 1996–1998 data sample they measure A_b = 0.906 ± 0.022 ± 0.023. The value quoted here is obtained combining the above with the result of ABE 98I (1993–1995 data sample).

[3] ABE 02G tag b and c quarks through their semileptonic decays into electrons and muons. A maximum likelihood fit is performed to extract simultaneously A_b and A_c.

[4] ABE 99L obtain an enriched sample of $b\overline{b}$ events tagging with an inclusive vertex mass cut. For distinguishing b and $\overline{b}$ quarks they use the charge of identified $K^\pm$.

TRANSVERSE SPIN CORRELATIONS IN $Z \to \tau^+\tau^-$

The correlations between the transverse spin components of $\tau^+\tau^-$ produced in Z decays may be expressed in terms of the vector and axial-vector couplings:

$$C_{TT} = \frac{|g_A^\tau|^2 - |g_V^\tau|^2}{|g_A^\tau|^2 + |g_V^\tau|^2}$$

$$C_{TN} = -2\frac{|g_A^\tau||g_V^\tau|}{|g_A^\tau|^2 + |g_V^\tau|^2}\sin(\Phi_{g_V^\tau} - \Phi_{g_A^\tau})$$

C_{TT} refers to the transverse-transverse (within the collision plane) spin correlation and C_{TN} refers to the transverse-normal (to the collision plane) spin correlation.

The longitudinal τ polarization P_τ ($= -A_\tau$) is given by:

$$P_\tau = -2\frac{|g_A^\tau||g_V^\tau|}{|g_A^\tau|^2 + |g_V^\tau|^2}\cos(\Phi_{g_V^\tau} - \Phi_{g_A^\tau})$$

Here Φ is the phase and the phase difference $\Phi_{g_V^\tau} - \Phi_{g_A^\tau}$ can be obtained using both the measurements of C_{TN} and P_τ.

C_{TT}

[1] BARATE 97D combine their value of C_{TN} with the world average $P_\tau = -0.140 \pm 0.007$ to obtain $\tan(\Phi_{g_V^\tau} - \Phi_{g_A^\tau}) = -0.57 \pm 0.97$.

FORWARD-BACKWARD $e^+e^- \to f\overline{f}$ CHARGE ASYMMETRIES

These asymmetries are experimentally determined by tagging the respective lepton or quark flavor in e^+e^- interactions. Details of heavy flavor (c- or b-quark) tagging at LEP are described in the note on "The Z boson" and ref. LEP-SLC 06. The Standard Model predictions for LEP data have been (re)computed using the ZFITTER package (version 6.36) with input parameters M_Z=91.187 GeV, M_{top}=174.3 GeV, M_{Higgs}=150 GeV, α_S=0.119, $\alpha^{(5)}(M_Z)$= 1/128.877 and the Fermi constant $G_F = 1.16637 \times 10^{-5}$ GeV^{-2} (see the note on "The Z boson" for references). For non-LEP data the Standard Model predictions are as given by the authors of the respective publications.

$A_{FB}^{(0,e)}$ CHARGE ASYMMETRY IN $e^+e^- \to e^+e^-$

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). For the Z peak, we report the pole asymmetry defined by $(3/4)A_e^2$ as determined by the nine-parameter fit to cross-section and lepton forward-backward asymmetry data.

[1] ABDALLAH 04F tag b– and c–quarks using semileptonic decays combined with charge flow information from the hemisphere opposite to the lepton. Enriched samples of $c\overline{c}$ and $b\overline{b}$ events are obtained using lifetime information.

[2] ABBIENDI 03P tag heavy flavors using events with one or two identified leptons. This allows the simultaneous fitting of the b and c quark forward-backward asymmetries as well as the average B^0-$\overline{B}^0$ mixing.

[3] HEISTER 02H measure simultaneously b and c quark forward-backward asymmetries using their semileptonic decays to tag the quark charge. The flavor separation is obtained with a discriminating multivariate analysis.

[4] ABREU 99Y tag $Z \to b\overline{b}$ and $Z \to c\overline{c}$ events by an exclusive reconstruction of several D meson decay modes (D^{*+}, D^0, and D^+ with their charge-conjugate states).

[5] BARATE 98O tag $Z \to c\overline{c}$ events requiring the presence of high-momentum reconstructed D^{*+}, D^+, or D^0 mesons.

[6] ALEXANDER 97C identify the b and c events using a D/D^* tag.

[7] ADRIANI 92D use both electron and muon semileptonic decays.

$A_{FB}^{(0,b)}$ CHARGE ASYMMETRY IN $e^+e^- \to b\overline{b}$

OUR FIT, which is obtained by a simultaneous fit to several c- and b-quark measurements as explained in the note "The Z boson" and ref. LEP-SLC 06, refers to the **Z pole** asymmetry. The experimental values, on the other hand, correspond to the measurements carried out at the respective energies.

[1] ABDALLAH 05 obtain an enriched samples of $b\overline{b}$ events using lifetime information. The quark (or antiquark) charge is determined with a neural network using the secondary vertex charge, the jet charge and particle identification.

[2] ABDALLAH 04F tag b– and c–quarks using semileptonic decays combined with charge flow information from the hemisphere opposite to the lepton. Enriched samples of $c\overline{c}$ and $b\overline{b}$ events are obtained using lifetime information.

[3] ABBIENDI 03P tag heavy flavors using events with one or two identified leptons. This allows the simultaneous fitting of the b and c quark forward-backward asymmetries as well as the average B^0-$\overline{B}^0$ mixing.

[4] ABBIENDI 02I tag $Z^0 \to b\overline{b}$ decays using a combination of secondary vertex and lepton tags. The sign of the b-quark charge is determined using an inclusive tag based on jet, vertex, and kaon charges.

[5] HEISTER 02H measure simultaneously b and c quark forward-backward asymmetries using their semileptonic decays to tag the quark charge. The flavor separation is obtained with a discriminating multivariate analysis.

[6] HEISTER 01D tag $Z \to b\overline{b}$ events using the impact parameters of charged tracks complemented with information from displaced vertices, event shape variables, and lepton identification. The b-quark direction and charge is determined using the hemisphere charge method along with information from fast kaon tagging and charge estimators of primary and secondary vertices. The change in the quoted value due to variation of A_{FB}^c and R_b is given as $+0.103\ (A_{FB}^c - 0.0651) - 0.440\ (R_b - 0.21585)$.

[7] ABREU 99Y tag $Z \to b\overline{b}$ and $Z \to c\overline{c}$ events by an exclusive reconstruction of several D meson decay modes (D^{*+}, D^0, and D^+ with their charge-conjugate states).

[8] ACCIARRI 99D tag $Z \to b\overline{b}$ events using high p and p_T leptons. The analysis determines simultaneously a mixing parameter $\chi_b = 0.1192 \pm 0.0068 \pm 0.0051$ which is used to correct the observed asymmetry.

[9] ACCIARRI 98U tag $Z \to b\overline{b}$ events using lifetime and measure the jet charge using the hemisphere charge.

[10] ALEXANDER 97C identify the b and c events using a D/D^* tag.

CHARGE ASYMMETRY IN $e^+e^- \to q\overline{q}$

Summed over five lighter flavors.

Experimental and Standard Model values are somewhat event-selection dependent. Standard Model expectations contain some assumptions on B^0-$\overline{B}^0$ mixing and on other electroweak parameters.

ANOMALOUS $ZZ\gamma$, $Z\gamma\gamma$, AND ZZV COUPLINGS

Revised September 2013 by M.W. Grünewald (U. College Dublin and U. Ghent) and A. Gurtu (Formerly Tata Inst.).

In on-shell $Z\gamma$ production, deviations from the Standard Model for the $Z\gamma\gamma^*$ and $Z\gamma Z^*$ couplings may be described in terms of eight parameters, h_i^V $(i = 1, 4;\ V = \gamma, Z)$ [1]. The parameters h_i^γ describe the $Z\gamma\gamma^*$ couplings and the parameters h_i^Z the $Z\gamma Z^*$ couplings. In this formalism h_1^V and h_2^V lead to CP-violating and h_3^V and h_4^V to CP-conserving effects. All these anomalous contributions to the cross section increase rapidly with center-of-mass energy. In order to ensure unitarity, these parameters are usually described by a form-factor representation, $h_i^V(s) = h_{i0}^V/(1 + s/\Lambda^2)^n$, where Λ is the energy scale for the manifestation of a new phenomenon and n is a sufficiently large power. By convention one uses $n = 3$ for $h_{1,3}^V$ and $n = 4$ for $h_{2,4}^V$. Usually limits on h_i^V's are put assuming some value of Λ, sometimes ∞.

In on-shell ZZ production, deviations from the Standard Model for the $ZZ\gamma^*$ and ZZZ^* couplings may be described by means of four anomalous couplings f_i^V $(i = 4, 5; V = \gamma, Z)$ [2]. As above, the parameters f_i^γ describe the $ZZ\gamma^*$ couplings and the parameters f_i^Z the ZZZ^* couplings. The anomalous couplings f_5^V lead to violation of C and P symmetries while f_4^V introduces CP violation. Also here, formfactors depending on a scale Λ are used.

All these couplings h_i^V and f_i^V are zero at tree level in the Standard Model; they are measured in e^+e^-, $p\bar{p}$ and pp collisions at LEP, Tevatron and LHC.

h_i^V

Combining the LEP-2 results taking into account the correlations, the following 95% CL limits are derived [SCHAEL 13A]:

$$-0.12 < h_1^Z < +0.11, \quad -0.07 < h_2^Z < +0.07,$$
$$-0.19 < h_3^Z < +0.06, \quad -0.04 < h_4^Z < +0.13,$$
$$-0.05 < h_1^\gamma < +0.05, \quad -0.04 < h_2^\gamma < +0.02,$$
$$-0.05 < h_3^\gamma < +0.00, \quad +0.01 < h_4^\gamma < +0.05.$$

Some of the recent results from the Tevatron and LHC experiments individually surpass the combined LEP-2 results in precision (see below).

[1] AAD 16Q study $Z\gamma$ production in pp collisions. In events with no additional jets, 10268 (12738) Z decays to electron (muon) pairs are selected, with an expected background of 1291 ± 340 (1537 ± 408) events, as well as 1039 Z decays to neutrino pairs with an expected background of 450 ± 96 events. Analyzing the photon transverse momentum distribution above 250 GeV (400 GeV) for lepton (neutrino) events, yields the 95% C.L. limits: $-7.8 \times 10^{-4} < h_3^Z < 8.6 \times 10^{-4}$, $-3.0 \times 10^{-6} < h_4^Z < 2.9 \times 10^{-6}$, $-9.5 \times 10^{-4} < h_3^\gamma < 9.9 \times 10^{-4}$, $-3.2 \times 10^{-6} < h_4^\gamma < 3.2 \times 10^{-6}$.

[2] KHACHATRYAN 16AE determine the $Z\gamma \to \nu\overline{\nu}\gamma$ cross section by selecting events with a photon of $E_T > 145$ GeV and $\not{E}_T > 140$ GeV. 630 candidate events are observed with an expected SM background of 269 ± 26. The E_T spectrum of the photon is used to set 95% C.L. limits as follows: $-1.5 \times 10^{-3} < h_3^Z < 1.6 \times 10^{-3}$, $-3.9 \times 10^{-6} < h_4^Z < 4.5 \times 10^{-6}$, $-1.1 \times 10^{-3} < h_3^\gamma < 0.9 \times 10^{-3}$, $-3.8 \times 10^{-6} < h_4^\gamma < 4.3 \times 10^{-6}$.

[3] KHACHATRYAN 15AC study $Z\gamma$ events in 8 TeV pp interactions, where the Z decays into 2 same-flavor, opposite sign leptons (e or μ) and a photon with $p_T > 15$ GeV. The p_T of a lepton is required to be > 20 GeV/c, their effective mass > 50 GeV, and the photon should have a separation $\Delta R > 0.7$ with each lepton. The observed p_T distribution of the photons is used to extract the 95% C.L. limits: $-3.8 \times 10^{-3} < h_3^Z < 3.7 \times 10^{-3}$, $-3.1 \times 10^{-5} < h_4^Z < 3.0 \times 10^{-5}$, $-4.6 \times 10^{-3} < h_3^\gamma < 4.6 \times 10^{-3}$, $-3.6 \times 10^{-5} < h_4^\gamma < 3.5 \times 10^{-5}$.

[4] CHATRCHYAN 14AB measure $Z\gamma$ production cross section for $p_T^\gamma > 15$ GeV and $R(\ell\gamma) > 0.7$, which is the separation between the γ and the final state charged lepton (e or μ) in the azimuthal angle-pseudorapidity ($\phi - \eta$) plane. The di-lepton mass is required to be > 50 GeV. After background subtraction the number of $ee\gamma$ and $\mu\mu\gamma$ events is determined to be 3160 ± 120 and 5030 ± 233 respectively, compatible with expectations from the SM. This leads to a 95% CL limits of $-1 \times 10^{-2} < h_3^\gamma < 1 \times 10^{-2}$, $-9 \times 10^{-5} < h_4^\gamma < 9 \times 10^{-5}$, $-9 \times 10^{-3} < h_3^Z < 9 \times 10^{-3}$, $-8 \times 10^{-5} < h_4^Z < 8 \times 10^{-5}$, assuming h_1^V and h_2^V have SM values, $V = \gamma$ or Z.

[5] AAD 13AN study $Z\gamma$ production in pp collisions. In events with no additional jet, 1417 (2031) Z decays to electron (muon) pairs are selected, with an expected background of 156 ± 54 (244 ± 64) events, as well as 662 Z decays to neutrino pairs with an expected background of 302 ± 42 events. Analysing the photon p_T spectrum above 100 GeV yields the 95% C.L. limts: $-0.013 < h_3^Z < 0.014$, $-8.7 \times 10^{-5} < h_4^Z < 8.7 \times 10^{-5}$, $-0.015 < h_3^\gamma < 0.016$, $-9.4 \times 10^{-5} < h_4^\gamma < 9.2 \times 10^{-5}$. Supersedes AAD 12BX.

[6] CHATRCHYAN 13BI determine the $Z\gamma \to \nu\overline{\nu}\gamma$ cross section by selecting events with a photon of $E_T > 145$ GeV and a $\not{E}_T > 130$ GeV. 73 candidate events are observed with an expected SM background of 30.2 ± 6.5. The E_T spectrum of the photon is used to set 95% C.L. limits as follows: $|h_3^Z| < 2.7 \times 10^{-3}$, $|h_4^Z| < 1.3 \times 10^{-5}$, $|h_3^\gamma| < 2.9 \times 10^{-3}$, $|h_4^\gamma| < 1.5 \times 10^{-5}$.

[7] ABAZOV 12S study $Z\gamma$ production in $p\overline{p}$ collisions at $\sqrt{s} = 1.96$ TeV using 6.2 fb^{-1} of data where the Z decays to electron (muon) pairs and the photon has at least 10 GeV of transverse momentum. In data, 304 (308) di-electron (di-muon) events are observed with an expected background of 255 ± 16 (285 ± 24) events. Based on the photon p_T spectrum, and including also earlier data and the $Z \to \nu\overline{\nu}$ decay mode (from ABAZOV 09L), the following 95% C.L. limits are reported: $|h_{03}^Z| < 0.026$, $|h_{04}^Z| < 0.0013$, $|h_{03}^\gamma| < 0.027$, $|h_{04}^\gamma| < 0.0014$ for a form factor scale of $\Lambda = 1.5$ TeV.

[8] AALTONEN 11S study $Z\gamma$ events in $p\overline{p}$ interactions at $\sqrt{s} = 1.96$ TeV with integrated luminosity 5.1 fb^{-1} for $Z \to e^+e^-/\mu^+\mu^-$ and 4.9 fb^{-1} for $Z \to \nu\overline{\nu}$. For the charged lepton case, the two leptons must be of the same flavor with the transverse momentum/energy of one > 20 GeV and the other > 10 GeV. The isolated photon must have $E_T > 50$ GeV. They observe 91 events with 87.2 ± 7.8 events expected from standard model processes. For the $\nu\overline{\nu}$ case they require solitary photons with $E_T > 25$ GeV and missing $E_T > 25$ GeV and observe 85 events with standard model expectation of 85.9 ± 5.6 events. Taking the form factor $\Lambda = 1.5$ TeV they derive 95% C.L. limits as $|h_3^{\gamma,Z}| < 0.022$ and $|h_4^{\gamma,Z}| < 0.0009$.

[9] CHATRCHYAN 11M study $Z\gamma$ production in pp collisions at $\sqrt{s} = 7$ TeV using 36 pb^{-1} pp data, where the Z decays to e^+e^- or $\mu^+\mu^-$. The total cross sections are measured for photon transverse energy $E_T^\gamma > 10$ GeV and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell,\gamma) > 0.7$ with the dilepton invariant mass requirement of $M_{\ell\ell} > 50$ GeV. The number of $e^+e^-\gamma$ and $\mu^+\mu^-\gamma$ candidates is 81 and 90 with estimated backgrounds of 20.5 ± 2.5 and 27.3 ± 3.2 events respectively. The 95% CL limits for $ZZ\gamma$ couplings are $-0.05 < h_3^Z < 0.06$ and $-0.0005 < h_4^Z < 0.0005$, and for $Z\gamma\gamma$ couplings are $-0.07 < h_3^\gamma < 0.07$ and $-0.0005 < h_4^\gamma < 0.0006$.

[10] ABAZOV 09L study $Z\gamma$, $Z \to \nu\overline{\nu}$ production in $p\overline{p}$ collisions at 1.96 TeV C.M. energy. They select 51 events with a photon of transverse energy E_T larger than 90 GeV, with an expected background of 17 events. Based on the photon E_T spectrum and including also Z decays to charged leptons (from ABAZOV 07M), the following 95% CL limits are reported: $|h_{30}^\gamma| < 0.033$, $|h_{40}^\gamma| < 0.0017$, $|h_{30}^Z| < 0.033$, $|h_{40}^Z| < 0.0017$.

[11] ABAZOV 07M use 968 $p\overline{p} \to e^+e^-/\mu^+\mu^-\gamma X$ candidates, at 1.96 TeV center of mass energy, to tag $p\overline{p} \to Z\gamma$ events by requiring $E_T(\gamma) > 7$ GeV, lepton-gamma separation $\Delta R_{\ell\gamma} > 0.7$, and di-lepton invariant mass > 30 GeV. The cross section is in agreement with the SM prediction. Using these $Z\gamma$ events they obtain 95% C.L. limits on each h_i^V, keeping all others fixed at their SM values. They report: $-0.083 < h_{30}^Z <$

0.082, $-0.0053 < h_{40}^Z < 0.0054$, $-0.085 < h_{30}^\gamma < 0.084$, $-0.0053 < h_{40}^\gamma < 0.0054$, for the form factor scale $\Lambda = 1.2$ TeV.

[12] Using data collected at $\sqrt{s} = 183$–208, ABDALLAH 07C select 1,877 $e^+e^- \to Z\gamma$ events with $Z \to q\overline{q}$ or $\nu\overline{\nu}$, 171 $e^+e^- \to ZZ$ events with $Z \to q\overline{q}$ or lepton pair (except an explicit τ pair), and 74 $e^+e^- \to Z\gamma^*$ events with a $q\overline{q}\mu^+\mu^-$ or $q\overline{q}e^+e^-$ signature, to derive 95% CL limits on h_i^V. Each limit is derived with other parameters set to zero. They report: $-0.23 < h_1^Z < 0.23$, $-0.30 < h_3^Z < 0.16$, $-0.14 < h_1^\gamma < 0.14$, $-0.049 < h_3^\gamma < 0.044$.

[13] ACHARD 04H select 3515 $e^+e^- \to Z\gamma$ events with $Z \to q\overline{q}$ or $\nu\overline{\nu}$ at $\sqrt{s} = 189$–209 GeV to derive 95% CL limits on h_i^V. For deriving each limit the other parameters are fixed at zero. They report: $-0.153 < h_1^Z < 0.141$, $-0.087 < h_2^Z < 0.079$, $-0.220 < h_3^Z < 0.112$, $-0.068 < h_4^Z < 0.148$, $-0.057 < h_1^\gamma < 0.057$, $-0.050 < h_2^\gamma < 0.023$, $-0.059 < h_3^\gamma < 0.004$, $-0.004 < h_4^\gamma < 0.042$.

[14] ABBIENDI,G 00C study $e^+e^- \to Z\gamma$ events (with $Z \to q\overline{q}$ and $Z \to \nu\overline{\nu}$) at 189 GeV to obtain the central values (and 95% CL limits) of these couplings: $h_1^Z = 0.000 \pm 0.100$ $(-0.190, 0.190)$, $h_2^Z = 0.000 \pm 0.068$ $(-0.128, 0.128)$, $h_3^Z = -0.074^{+0.102}_{-0.103}$ $(-0.269, 0.119)$, $h_4^Z = 0.046 \pm 0.068$ $(-0.084, 0.175)$, $h_1^\gamma = 0.000 \pm 0.061$ $(-0.115, 0.115)$, $h_2^\gamma = 0.000 \pm 0.041$ $(-0.077, 0.077)$, $h_3^\gamma = -0.080^{+0.039}_{-0.041}$ $(-0.164, -0.006)$, $h_4^\gamma = 0.064^{+0.033}_{-0.030}$ $(+0.007, +0.134)$. The results are derived assuming that only one coupling at a time is different from zero.

[15] ABBOTT 98M study $p\overline{p} \to Z\gamma + X$, with $Z \to e^+e^-$, $\mu^+\mu^-$, $\overline{\nu}\nu$ at 1.8 TeV, to obtain 95% CL limits at $\Lambda = 750$ GeV: $|h_{30}^Z| < 0.36$, $|h_{40}^Z| < 0.05$ (keeping $h_i^\gamma = 0$), and $|h_{30}^\gamma| < 0.37$, $|h_{40}^\gamma| < 0.05$ (keeping $h_i^Z = 0$). Limits on the CP-violating couplings are $|h_{10}^Z| < 0.36$, $|h_{20}^Z| < 0.05$ (keeping $h_i^\gamma = 0$), and $|h_{10}^\gamma| < 0.37$, $|h_{20}^\gamma| < 0.05$ (keeping $h_i^Z = 0$).

[16] ABREU 98K determine a 95% CL upper limit on $\sigma(e^+e^- \to \gamma +$ invisible particles$) <$ 2.5 pb using 161 and 172 GeV data. This is used to set 95% CL limits on $|h_{30}^\gamma| < 0.8$ and $|h_{30}^Z| < 1.3$, derived at a scale $\Lambda = 1$ TeV and with $n = 3$ in the form factor representation.

f_i^V

Combining the LEP-2 results taking into account the correlations, the following 95% CL limits are derived [SCHAEL 13A]:

$$-0.28 < f_4^Z < +0.32, \qquad -0.34 < f_5^Z < +0.35,$$
$$-0.17 < f_4^\gamma < +0.19, \qquad -0.35 < f_5^\gamma < +0.32.$$

Some of the recent results from the Tevatron and LHC experiments individually surpass the combined LEP-2 results in precision (see below).

[1] AAD 23CH measure ZZ production with the Z bosons decaying to electrons or muons. Analysing the angular information of the final-state four-lepton system, the following limits are derived at 95% C.L.: $-0.012 < f_4^Z < 0.012$, $-0.015 < f_4^\gamma < 0.015$.

[2] SIRUNYAN 21Q measure ZZ production where both Z bosons decay in the electron or muon channel. Analyzing the four-lepton invariant mass distribution, the following limits are derived at 95% C.L. in units of 10^{-4}: $-6.6 < f_4^Z < 6.0$, $-5.5 < f_5^Z < 7.5$, $-7.8 < f_4^\gamma < 7.1$, $-6.8 < f_5^\gamma < 7.5$. This set of parameters is linearly related to a set of EFT parameters, resulting in the following limits at 95% C.L. in units of TeV^{-4}: $-2.3 < c_{\widetilde{B}W}/\Lambda^4 < 2.5$, $-1.4 < c_{WW}/\Lambda^4 < 1.2$, $-1.4 < c_{BW}/\Lambda^4 < 1.3$, $-1.2 < c_{BB}/\Lambda^4 < 1.2$.

[3] AABOUD 19AY study ZZ production in the $\ell\ell\nu\nu$ decay channel. Events with a pair of isolated high-transverse momentum charged leptons (electron pairs or muon pairs), and with large missing energy, are selected. In the data, 371 (416) di-electron (di-muon) events are found, with a total expected background of 128 ± 8 (143 ± 8) events. Analysing the transverse momentum distribution of the charged dilepton system above 150 GeV, the following 95% C.L. limits are derived in units of 10^{-3}: $-1.2 < f_4^\gamma < 1.2$, $-1.0 < f_4^Z < 1.0$, $-1.2 < f_5^\gamma < 1.2$, $-1.0 < f_5^Z < 1.0$.

[4] AABOUD 18Q study $pp \to ZZ$ events at $\sqrt{s} = 13$ TeV with $Z \to e^+e^-$ or $Z \to \mu^+\mu^-$. The number of events observed in the $4e$, $2e\,2\mu$, and 4μ channels is 249, 465, and 303 respectively. Analysing the p_T spectrum of the leading Z boson, the following the following 95% C.L. limits are derived in units of 10^{-4}: $-1.8 < f_4^\gamma < 1.8$, $-1.5 < f_4^Z < 1.5$, $-1.8 < f_5^\gamma < 1.8$, $-1.5 < f_5^Z < 1.5$.

[5] SIRUNYAN 18BT study $ppZZ$ events at $\sqrt{s} = 13$ TeV with $Z \to e^+e^-$ or $Z \to \mu^+\mu^-$. The number of events observed in the $4e$, $2e2\mu$, and 4μ channels is 220, 543 and 335 respectively. Analysing the 4-lepton invariant mass spectrum, the following 95% C.L. limits are derived in units of 10^{-3}: $-1.2 < f_4^\gamma < 1.3$, $-1.2 < f_4^Z < 1.0$, $-1.2 < f_5^\gamma < 1.3$, $-1.0 < f_5^Z < 1.3$.

[6] KHACHATRYAN 15B study ZZ production in 8 TeV pp collisions. In the decay modes $ZZ \to 4e$, 4μ, $2e2\mu$, 54, 75, 148 events are observed, with an expected background of 2.2 ± 0.9, 1.2 ± 0.6, and 2.4 ± 1.0 events, respectively. Analysing the 4-lepton invariant mass spectrum in the range from 110 GeV to 1200 GeV, the following 95% C.L. limits are obtained: $|f_4^Z| < 0.004$, $|f_5^Z| < 0.004$, $|f_4^\gamma| < 0.005$, $|f_5^\gamma| < 0.005$.
