REVIEW OF PARTICLE PHYSICS*

Particle Data Group

Abstract

The *Review* summarizes much of particle physics and cosmology. Using data from previous editions, plus 2,717 new measurements from 869 papers, we list, evaluate, and average measured properties of gauge bosons and the recently discovered Higgs boson, leptons, quarks, mesons, and baryons. We summarize searches for hypothetical particles such as supersymmetric particles, heavy bosons, axions, dark photons, etc. Particle properties and search limits are listed in Summary Tables. We give numerous tables, figures, formulae, and reviews of topics such as Higgs Boson Physics, Supersymmetry, Grand Unified Theories, Neutrino Mixing, Dark Energy, Dark Matter, Cosmology, Particle Detectors, Colliders, Probability and Statistics. Most of the 120 reviews are updated, including many that are heavily revised.

The *Review* is divided into two volumes. Volume 1 includes the Summary Tables and 97 review articles. Volume 2 consists of the Particle Listings and contains also 23 reviews that address specific aspects of the data presented in the Listings.

The complete *Review* (both volumes) is published online on the website of the Particle Data Group (pdg.lbl.gov) and in a journal. Volume 1 is available in print as the *PDG Book*. A *Particle Physics Booklet* with the Summary Tables and essential tables, figures, and equations from selected review articles is available in print, as a web version optimized for use on phones, and as an Android app.

The 2024 edition of the *Review of Particle Physics* should be cited as:
S. Navas *et al.* (Particle Data Group), Phys. Rev. D **110**, 030001 (2024)

DOI: 10.1103/PhysRevD.110.030001

For the online version see pdg.lbl.gov:

*The publication of the *Review of Particle Physics* is supported by the Director, Office of Science, Office of High Energy Physics of the U.S. Department of Energy under Contract No. DE–AC02–05CH11231; by an implementing arrangement between the governments of Japan (MEXT: Ministry of Education, Culture, Sports, Science and Technology) and the United States (DOE) on cooperative research and development; by the Italian National Institute of Nuclear Physics (INFN); and by the European Laboratory for Particle Physics (CERN). Individual collaborators receive support for their PDG activities from their respective institutes or funding agencies.

HIGHLIGHTS OF THE 2024 EDITION OF THE REVIEW OF PARTICLE PHYSICS

All PDG data and review articles are available online at **pdg.lbl.gov**.

869 new papers with 2,717 new measurements

120 reviews (most are revised)

- 320 new measurements from *LHC* experiments (ATLAS, CMS and LHCb).
- Extensive *Higgs boson* coverage from 231 new papers and 557 measurements with latest results on mass, couplings, decay width and branching ratios, plus searches for other neutral and charged Higgs bosons.
- *Supersymmetry*: 36 new papers with 148 measurements with major exclusions.
- *Top quark*: 35 new papers provide latest results on mass, coupling, and the discovery of four top quark production at LHC.
- *W mass*: CDF published a new measurement of the W mass. It is more precise than the world average at the time, but the two results disagree. See comments in Particle Listings and our W mass review referencing the extensive studies done by the *LHC* TeV M_W working group.
- *c-, b-hadron physics*: 161 papers and 597 measurements provide world-best data on lifetimes, mixing, CP violation, CKM angles, and constraints on new physics.
- *Neutrino Physics*: 10 new papers with measurements on neutrino mass, mixing, and CP-violation.
- *Meson resonances*: Substantial improvements, including new cross particle fits involving $J/\psi(1S)$, $\psi 2S)$ and $\eta_c(1S)$, merging of $\pi_1(1400)$ and $\pi_1(1600)$ with non-$q\bar{q}$ quantum numbers into same node, listing of complex pole positions when available, and inclusion of recently observed states. Several mesons now considered established added to Summary Tables.
- New *naming scheme* for the many recently discovered mesons and baryons with c or b quarks that are not compatible with conventional $q\bar{q}$ or qqq structures. Listed in "Other mesons" and "Exotic baryons" sections.
- Major revision of *Higgs Physics* review summarizes latest LHC results and constraints on new physics.
- Major revision of *Cosmic rays* review, now covering all components of cosmic rays including neutrinos (which were previously discussed in Neutrino Telescopes in Particle Detectors for Non-Accelerator Physics).
- Major revison of *Large time-projection chambers for rare event detection* in Particle Detectors for Non-Accelerator Physics.
- Major revision of *Top Quark* review summarizes latest LHC results and constraints on new physics from top quark.
- Major revision of *Heavy Non-$q\bar{q}$ Mesons* review follows new naming scheme for states not compatible with $q\bar{q}$ or qqq structures.
- *Semiconductor detectors* section of Particle Detectors at Accelerators review includes recent developments.
- New section on goodness-of-fit tests and expanded discussion of statistical tests in *Statistics* review.
- Updated EWK fit in *Electroweak Model and Constraints on New Physics* review.
- *Semileptonic B Hadron Decays, Determination of V_{cb} and V_{ub}* includes latest results and discusses long-standing issues with inclusive and exclusive measurements.
- Updated cross section results in the *Neutrino Cross Section Measurements* review.
- Updated τ decay parameters and branching ratio (BR) fits, including new treatment of BR($a1(1260) \to \pi\gamma$).

VOLUME 1: SUMMARY TABLES AND REVIEWS

(Continued on next page.)

INTRODUCTION

ONLINE PARTICLE PHYSICS INFORMATION

Introduction

1 Overview

The *Review of Particle Physics* is a comprehensive review of the field of Particle Physics and of related areas in Cosmology. It is divided into two volumes. Volume 1 includes the "Summary Tables" and "Reviews, Tables, and Plots". Volume 2 consists of the "Particle Listings".

The *Review* is updated each year and made available on the PDG website (pdg.lbl.gov). In even-numbered years, the *Review* is also published in a journal and printed as the *PDG Book* together with an abridged *Particle Physics Booklet* containing Summary Tables and essential tables, figures, and equations from selected review articles. This edition is an updating through January 2024.

The Summary Tables give our best values and limits for particle properties such as masses, widths or lifetimes, and branching fractions, as well as an extensive summary of searches for hypothetical particles and a summary of experimental tests of conservation laws.

The 95 review articles in Reviews, Tables and Plots cover a wide variety of theoretical and experimental topics. Together with the Summary Tables they provide an exhaustive reference for the practicing particle physicist. Two more review articles, Online Particle Physics Information and Tests of Conservation Laws, can be found in the introduction and Summary Tables, respectively.

The Particle Listings are a compilation/evaluation of data on particle properties. They contain all the data used to get the values given in the Summary Tables. They also give information on unconfirmed particles and particle searches. In this edition, the Particle Listings include 2,717 new measurements from 869 papers, in addition to the 46,838 measurements from 12,909 papers that first appeared in previous editions [1]. 23 review articles are part of the Particle Listings and address specific aspects of the data presented in the Listings. Because of the large quantity of data, the Particle Listings are not an archive of all published data on particle properties. We refer interested readers to earlier editions for data now considered to be obsolete.

We organize the particles into six categories:

- Gauge and Higgs bosons
- Leptons
- Quarks
- Mesons
- Baryons
- Searches not in other sections

The last category only includes searches for particles that do not belong to the previous groups. For example, it includes searches for supersymmetric particles, compositeness and extra dimensions, while searches for heavy charged leptons are with the leptons.

In Sec. 2 of this Introduction, we list the main areas of responsibility of the authors of the Particle Listings. Our many consultants, without whom we would not have been able to produce this *Review*, are acknowledged in Sec. 3. In Sec. 4, we mention briefly the naming scheme for hadrons, and in Sec. 5, we discuss our procedures for choosing among measurements of particle properties and for obtaining best values of the properties from the measurements.

The accuracy and usefulness of this *Review* depend in large part on interaction between its users and the authors. We appreciate comments, criticisms, and suggestions for improvements of any kind. Please send them to pdg@lbl.gov from where they will be forwarded to the appropriate author according to the list of responsibilities in Sec. 2 below.

In addition to the online publication at pdg.lbl.gov, the *Review* is available in different formats:

- The printed *PDG Book* includes volume 1 only, *i.e.* it contains the Summary Tables and most review articles. Since the 2016 edition [2] the detailed tables from the Particle Listings are no longer printed.
- The *Particle Physics Booklet* includes the Summary Tables plus essential tables, figures, and equations from selected review articles. Starting with the Booklets of the 2018 edition, we have excluded most text and explanations in order to revert back to a more pocket-sized format. The Booklet is available in print, as a web version optimized for use on phones, and as an Android app (see pdg.lbl.gov/booklet).
- *pdgLive* (pdgLive.lbl.gov) is a web application giving more interactive access to PDG data than the static web pages and PDF files that are also available.
- Files that can be downloaded from the PDG website include a table of masses, widths, and PDG Monte Carlo particle ID numbers; PDF files of volume 1 (PDG Book), volume 2 (Particle Listings) and Booklet; individual review articles; all figures; and an archive file containing the complete PDG website (except for pdgLive).
- Starting with the 2024 edition, the data published in the *Review of Particle Physics* is available in machine-readable format through a new PDG API (Application Programming Interface). See pdg.lbl.gov/api for details.

Copies of the *PDG Book* or the *Particle Physics Booklet* can be ordered from our website or directly at pdg.lbl.gov/order. For special requests only, please email pdg@lbl.gov in North and South America, Australia, and the Far East, and pdg-products@cern.ch in all other areas.

This *Review* is considered to be a single comprehensive review of particle physics and related areas. Therefore we prefer that it be cited as a whole, rather than citing *e.g.* an individual review article that is part of this *Review*. For the 2024 edition, the proper citation is:

S. Navas *et al.* (Particle Data Group), Phys. Rev. D **110**, 030001 (2024).

If you wish to refer to a specific part of the *Review*, for example to the Higgs boson review article, the following form should be used:

Status of Higgs Boson Physics in S. Navas *et al.* (Particle Data Group), Phys. Rev. D **110**, 030001 (2024).

2 Particle Listings responsibilities

* Asterisk indicates the people to contact with questions or comments about Particle Listings sections. Please contact them by e-mail to pdg@lbl.gov.

- Gauge and Higgs bosons

γ	A. Bettini, D.E. Groom*
Gluons	R.M. Barnett,* A.V. Manohar
Graviton	A. Bettini,* D.E. Groom
W, Z	M. Grünewald,* A. Gurtu*
Higgs bosons	S. Heinemeyer,* K. Hikasa, J. Tanaka
Heavy bosons	R. Bonventre,* K.A. Olive, M. Tanabashi
Axions	C. O'Hare, K.A. Olive, G. Raffelt,* F. Takahashi

- Leptons

Neutrinos	M. Goodman, C.-J. Lin,* K. Nakamura, K.A. Olive, A. Piepke
Double-β decay	A. Bettini*, A. Piepke
e, μ	A. Bettini,* C. Grab
τ	A. Lusiani, K. Mönig*

- Quarks

Quarks	R.M. Barnett,* A.V. Manohar
Top quark	Y. Sumino, W.-M. Yao*
b', t'	Y. Sumino, W.-M. Yao*
Free quark	A. Bettini,* C.-J. Lin

- Mesons

π, η	A. Bettini,* C. Grab
K (stable)	G. D'Ambrosio, C.-J. Lin*
D (stable)	G. Casarosa, J. Rademacker, D. Robinson*
B (stable)	A. Cerri,* P. Eerola, M. Kreps, Y. Kwon, W.-M. Yao*

Unstable mesons	C. Amsler,* T. Gutsche, C. Hanhart, J.J. Hernández-Rey, C. Lourenco, A. Masoni, M. Mikhasenko, R.E. Mitchell, S. Navas, C. Patrignani, C. Schwanda, S. Spanier, G. Venanzoni, C.Z. Yuan

- Baryons

Stable baryons	C. Grab, D. Robinson*
Unstable baryons	V. Burkert, V. Crede, U. Thoma, L. Tiator, R.L. Workman*
Charmed baryons	G. Casarosa, J. Rademacker, D. Robinson*
Bottom baryons	A. Cerri,* P. Eerola, M. Kreps, Y. Kwon, W.-M. Yao*

- Miscellanoues searches

Monopole	A. Bettini,* D. Milstead
Supersymmetry	H.K. Dreiner,* A. de Gouvêa, I.-A. Melzer-Pellmann, K.A. Olive, I. Vivarelli
Technicolor	K. Agashe,* K.A. Olive, M. Tanabashi
Compositeness	M. Tanabashi, J. Terning*
Extra Dimensions	T. Gherghetta, K.A. Olive, D. Robinson*
WIMP, DM, Other	H. Baer, A. Bettini,* W.-M. Yao*

3 Consultants

The Particle Data Group benefits greatly from the assistance of hundreds of physicists who are asked to referee review articles and verify every piece of data entered into this *Review*. Of special value is the advice of the PDG Advisory Committee, which meets biennially and thoroughly reviews all aspects of our operation. The members of the 2022 committee are:

S. Demers (Yale)
D. d'Enterria (CERN)
J. Frieman (FNAL)
S. Gori (UCSC)
T. Nakada (EPFL)
M. Yokoyama (Tokyo)

We have especially relied on the expertise of the following people for advice on particular topics:

- I. Abt (MPP, Garching)
- R. Acciarri (FNAL)
- M. Albaladejo (IFIC, Valencia)
- S. Alderweireldt (Edinburgh U.)
- S. Alioli (INFN, Milano-Bicocca)
- A. Antognini (ETH Zurich)
- E. Aprile (Columbia U.)
- E. Armengaud (CEA Saclay, DSM/IRFU/SPP)
- M. Artuso (Syracuse U.)
- N. Asbah (CERN)
- P. Athron (Nanjing U.)
- G. Azuelos (U. de Montreal)
- P. Azzurri (INFN, Pisa)
- R. Battiston (Trento U.)
- R.A. Battye (Manchester U.)
- O. Behnke (DESY, Hamburg)
- G. Bell (Siegen U.)
- J. Bellido Caceres (Adelaide U.)
- V. Belyaev (ITEP)
- N.P. Berger (LAPP)
- F. Betti (Edinburgh U.)
- T. Biekotter (KIT)
- P. Blasi (GSSI)
- M. Bona (QMUL)
- C. Bonifazi (ICAS and ICIFI, UNSAM)
- D. Bose (Indian Inst. Tech., Kharagpur)
- E. Brost (BNL)
- R. Bruce (CERN)
- D.A. Bryman (TRIUMF)
- C. Buck (MPIK)
- M. Cadeddu (INFN, Cagliari)
- X. Calmet (Sussex U.)
- M. Calvi (INFN, Milano-Bicocca)
- J. Cao (IHEP Beijing)
- F. Capozzi (L'Aquila U.)
- L. Capriotti (INFN, Ferrara)

4 Naming scheme for hadrons

We introduced in the 1986 edition [3] a new naming scheme for the hadrons. Changes from older terminology affected mainly the heavier mesons made of u, d, and s quarks. Otherwise, the only important change to known hadrons was that the $F^{\pm}$ became the $D_s^{\pm}$. None of the lightest pseudoscalar or vector mesons changed names, nor did the $c\overline{c}$ or $b\overline{b}$ mesons (we do, however, now use χ_c for the $c\overline{c}$ χ states), nor did any of the established baryons. The Summary Tables give both the new and old names whenever a change has occurred.

In the 2018 edition [4], the naming scheme was extended to address the naming of charmonium and bottomonium states that were commonly referred to as X, Y, or Z states in the literature. The further discovery of various exotic hadron states — including in particular tetraquarks and pentaquarks containing $qq\bar{q}\bar{q}$ and $q\bar{q}qqq$ minimal quark content, respectively — has rendered the 2018 extension insufficient. In this edition, the naming scheme is revised and extended to cover all experimentally-known states. The current scheme is described in "Naming Scheme for Hadrons" (p. 1) of this *Review*. A table details the correspondence between the names newly adopted by the PDG and those that have previously appeared in the literature.

We give here our conventions on typesetting style. Particle symbols are italic (or slanted) characters: e^-, p, Λ, π^0, K_L, D_s^+, b. Charge is indicated by a superscript: B^-, Δ^{++}. Charge is not normally indicated for p, n, or the quarks, and is optional for neutral isosinglets: η or η^0. Antiparticles and particles are distinguished by charge for charged leptons and mesons: τ^+, K^-. Otherwise, distinct antiparticles are indicated by a bar (overline): $\overline{\nu}_\mu$, $\bar{t}$, $\overline{p}$, $\overline{K}^0$, and $\overline{\Sigma}^+$ (the antiparticle of the Σ^-).

5 Procedures

5.1 *Selection and treatment of data*

The Particle Listings contain all relevant data known to us that are published in journals. With very few exceptions, we do not include results from preprints or conference reports. Nor do we include data that are of historical importance only (the Listings are not an archival record). We search every volume of 30 journals through our cutoff date for relevant data. We also include later published papers that are sent to us by the authors (or others).

In the Particle Listings, we clearly separate measurements that are used to calculate or estimate values given in the Summary Tables from measurements that are not used. We give explanatory comments in many such cases. Among the reasons a measurement might be excluded are the following:

- It is superseded by or included in later results.
- No error is given.
- It involves assumptions we question.
- It has a poor signal-to-noise ratio, low statistical significance, or is otherwise of poorer quality than other data available.
- It is clearly inconsistent with other results that appear to be more reliable. Usually we then state the criterion, which sometimes is quite subjective, for selecting "more reliable" data for averaging. See Sec. 5.4.
- It is not independent of other results.
- It is not the best limit (see below).
- It is quoted from a preprint or a conference report.

In some cases, *none* of the measurements is entirely reliable and no average is calculated. For example, the masses of many of the baryon resonances, obtained from partial-wave analyses, are quoted as estimated ranges thought to probably include the true values, rather than as averages with errors. This is discussed in the Baryon Particle Listings.

For upper limits, we normally quote in the Summary Tables the strongest limit. We do not average or combine upper limits except in a very few cases where they may be re-expressed as measured numbers with Gaussian errors.

As is customary, we assume that particle and antiparticle share the same spin, mass, and mean life. The Tests of Conservation Laws table, following the Summary Tables, lists tests of CPT as well as other conservation laws.

We use the following indicators in the Particle Listings to tell how we get values from the tabulated measurements:

- OUR AVERAGE —From a weighted average of selected data.
- OUR FIT —From a constrained or overdetermined multiparameter fit of selected data.
- OUR EVALUATION —Not from a direct measurement, but evaluated from measurements of related quantities.
- OUR ESTIMATE —Based on the observed range of the data. Not from a formal statistical procedure.
- OUR LIMIT —For special cases where the limit is evaluated by us from measured ratios or other data. Not from a direct measurement.

An experimentalist who sees indications of new a particle will of course want to know what has been seen in that region in the past. Hence, we include in the Particle Listings all reported states that, in our opinion, have sufficient statistical merit and that have not been disproved by more reliable data. However, we promote to the Summary Tables only those states that we feel are well-established. This judgment is, of course, somewhat subjective and no precise criteria can be given. For more detailed discussions, see the reviews section on Particle Properties.

5.2 *Averages and fits*

We divide this discussion on obtaining averages and errors into three sections: (1) treatment of errors; (2) unconstrained averaging; (3) constrained fits.

5.2.1 *Treatment of errors*

In what follows, the "error" δx means that the range $x \pm \delta x$ is intended to be a 68.3% confidence interval about the central value x. We treat this error as if it were Gaussian. Thus, when the error *is* Gaussian, δx is the usual one standard deviation (1σ). Many experimenters now give statistical and systematic errors separately, in which case we usually quote both errors, with the statistical error first. For averages and fits, we then add the two errors in quadrature and use this combined error for δx.

When experimenters quote asymmetric errors $(\delta x)^+$ and $(\delta x)^-$ for a measurement x, the error that we use for that measurement in making an average or a fit with other measurements is a continuous function of these three quantities. When the resultant average or fit $\overline{x}$ is less than $x - (\delta x)^-$, we use $(\delta x)^-$; when it is greater than $x + (\delta x)^+$, we use $(\delta x)^+$. In between, the error we use is a linear function of x. Since the errors we use are functions of the result, we iterate to get the final result. Asymmetric output errors are determined from the input errors assuming a linear relation between the input and output quantities.

In fitting or averaging, we usually do not include correlations between different measurements, but we try to select data in such a way as to reduce correlations. Correlated errors are, however, treated explicitly when there are a number of results of the form $A_i \pm \sigma_i \pm \Delta$ that have identical systematic errors Δ. In this case, one can first average the $A_i \pm \sigma_i$ and then combine the resulting statistical error with Δ. One obtains, however, the same result by averaging $A_i \pm (\sigma_i^2 + \Delta_i^2)^{1/2}$, where $\Delta_i = \sigma_i \Delta [\sum (1/\sigma_j^2)]^{1/2}$. This procedure has the advantage that, with the modified systematic errors Δ_i, each measurement may be treated as independent and averaged in the usual way with other data. Therefore, when appropriate, we adopt this procedure. We tabulate Δ and invoke an automated procedure that computes Δ_i before averaging, and we include a note saying that there are common systematic errors.

Another common case of correlated errors occurs when experimenters measure two quantities and then quote the two and their

difference, *e.g.*, m_1, m_2, and $\Delta = m_2 - m_1$. We cannot enter all of m_1, m_2 and Δ into a constrained fit because they are not independent. In some cases, it is a good approximation to ignore the quantity with the largest error and put the other two into the fit. However, in some cases correlations are such that the errors on m_1, m_2 and Δ are comparable and none of the three values can be ignored. In this case, we put all three values into the fit and invoke an automated procedure to increase the errors prior to fitting such that the three quantities can be treated as independent measurements in the constrained fit. We include a note saying that this has been done.

5.2.2 *Unconstrained averaging*

To average data, we use a standard weighted least-squares procedure and in some cases, discussed below, increase the errors with a "scale factor." We begin by assuming that measurements of a given quantity are uncorrelated, and calculate a weighted average and error as

$$\overline{x} \pm \delta\overline{x} = \frac{\sum_i w_i\, x_i}{\sum_i w_i} \pm \left(\sum_i w_i\right)^{-1/2} \ , \qquad (1)$$

where

$$w_i = 1/(\delta x_i)^2 \ .$$

Here x_i and δx_i are the value and error reported by the ith experiment, and the sums run over the N experiments. We then calculate $\chi^2 = \sum w_i(\overline{x} - x_i)^2$ and compare it with $N-1$, which is the expectation value of χ^2 if the measurements are from a Gaussian distribution.

If $\chi^2/(N-1)$ is less than or equal to 1, and there are no known problems with the data, we accept the results.

If $\chi^2/(N-1)$ is very large, we may choose not to use the average at all. Alternatively, we may quote the calculated average, but then make an educated guess of the error, a conservative estimate designed to take into account known problems with the data.

Finally, if $\chi^2/(N-1)$ is greater than 1, but not greatly so, we still average the data, but then also do the following:

(a) We increase our quoted error, $\delta\overline{x}$ in Eq. (1), by a scale factor S defined as

$$S = \left[\chi^2/(N-1)\right]^{1/2} \ . \qquad (2)$$

Our reasoning is as follows. The large value of the χ^2 is likely to be due to underestimation of errors in at least one of the experiments. Not knowing which of the errors are underestimated, we assume they are all underestimated by the same factor S. If we scale up all the input errors by this factor, the χ^2 becomes $N-1$, and of course the output error $\delta\overline{x}$ scales up by the same factor. See Ref. [5].

When combining data with widely varying errors, we modify this procedure slightly. We evaluate S using only the experiments with smaller errors. Our cutoff or ceiling on δx_i is arbitrarily chosen to be

$$\delta_0 = 3N^{1/2}\ \delta\overline{x} \ ,$$

where $\delta\overline{x}$ is the unscaled error of the mean of all the experiments. Our reasoning is that although the low-precision experiments have little influence on the values $\overline{x}$ and $\delta\overline{x}$, they can make significant contributions to the χ^2, and the contribution of the high-precision experiments thus tends to be obscured. Note that if each experiment has the same error δx_i, then $\delta\overline{x}$ is $\delta x_i/N^{1/2}$, so each δx_i is well below the cutoff. (More often, however, we simply exclude measurements with relatively large errors from averages and fits: new, precise data chase out old, imprecise data.)

Our scaling procedure has the property that if there are two values with comparable errors separated by much more than their stated errors (with or without a number of other values of lower accuracy), the scaled-up error $\delta\,\overline{x}$ is approximately half the interval between the two discrepant values.

We emphasize that our scaling procedure for *errors* in no way affects central values. And if you wish to recover the unscaled error $\delta\overline{x}$, simply divide the quoted error by S.

(b) If the number M of experiments with an error smaller than δ_0 is at least three, and if $\chi^2/(M-1)$ is greater than 1.25, we show in the Particle Listings an ideogram of the data. Figure 1 is an example. Sometimes one or two data points lie apart from the main body; other times the data split into two or more groups. We extract no numbers from these ideograms; they are simply visual aids, which the reader may use as he or she sees fit.

Each measurement in an ideogram is represented by a Gaussian with a central value x_i, error δx_i, and area proportional to $1/\delta x_i$. The choice of $1/\delta x_i$ for the area is somewhat arbitrary. With this choice, the center of gravity of the ideogram corresponds to an average that uses weights $1/\delta x_i$ rather than the $(1/\delta x_i)^2$ actually used in the averages. This may be appropriate when some of the experiments have seriously underestimated systematic errors. However, since for this choice of area the height of the Gaussian for each measurement is proportional to $(1/\delta\, x_i)^2$, the peak position of the ideogram will often favor the high-precision measurements at least as much as does the least-squares average. See our 1986 edition [3] for a detailed discussion of the use of ideograms.

5.2.3 *Constrained fits*

In some cases, such as branching ratios or masses and mass differences, a constrained fit may be needed to obtain the best values of a set of parameters. For example, most branching ratios and rate measurements are analyzed by making a simultaneous least-squares fit to all the data and extracting the partial decay fractions P_i, the partial widths Γ_i, the full width Γ (or mean life), and the associated error matrix.

Assume, for example, that a state has m partial decay fractions P_i, where $\sum P_i = 1$. These have been measured in N_r different ratios R_r, where, e.g., $R_1 = P_1/P_2$, $R_2 = P_1/P_3$, *etc.* [We can handle any ratio R of the form $\sum \alpha_i\, P_i / \sum \beta_i\, P_i$, where α_i and β_i are constants, usually 1 or 0. The forms $R = P_iP_j$ and $R = (P_iP_j)^{1/2}$ are also allowed.] Further, assume that *each* ratio R has been measured by N_k experiments (we designate each experiment with a subscript k, e.g., R_{1k}). We then find the best values of the fractions P_i by minimizing the χ^2 as a function of the $m-1$ independent parameters:

$$\chi^2 = \sum_{r=1}^{N_r} \sum_{k=1}^{N_k} \left(\frac{R_{rk} - R_r}{\delta R_{rk}}\right)^2 , \qquad (3)$$

where the R_{rk} are the measured values and R_r are the fitted values of the branching ratios.

In addition to the fitted values $\overline{P}_i$, we calculate an error matrix $\langle \delta\overline{P}_i\ \delta\overline{P}_j \rangle$. We tabulate the diagonal elements of $\delta\,\overline{P}_i = \langle \delta\,\overline{P}_i\ \delta\,\overline{P}_i \rangle^{1/2}$ (except that some errors are scaled as discussed below). In the Particle Listings, we give the complete correlation matrix; we also calculate the fitted value of each ratio, for comparison with the input data, and list it above the relevant input, along with a simple unconstrained average of the same input.

Three comments on the example above:

(1) There was no connection assumed between measurements of the full width and the branching ratios. But often we also have information on partial widths Γ_i as well as the total width Γ. In this case we must introduce Γ as a parameter in the fit, along with the P_i, and we give correlation matrices for the widths in the Particle Listings.

(2) We try to pick those ratios and widths that are as independent and as close to the original data as possible. When one experiment measures all the branching fractions and constrains their sum to be one, we leave one of them (usually the least well-determined one) out of the fit to make the set of input data more nearly independent. We now do allow for correlations between input data.

(3) We calculate scale factors for both the R_r and P_i when the measurements for any R give a larger-than-expected contribution to the χ^2. According to Eq. (3), the double sum for χ^2 is first summed over experiments $k = 1$ to N_k, leaving a single sum over ratios $\chi^2 = \sum \chi^2_r$. One is tempted to define a scale factor for the ratio r as $S_r^2 = \chi^2_r/\langle\chi^2_r\rangle$. However, since $\langle\chi^2_r\rangle$ is not a fixed quantity (it is somewhere between N_k and N_{k-1}), we do not know

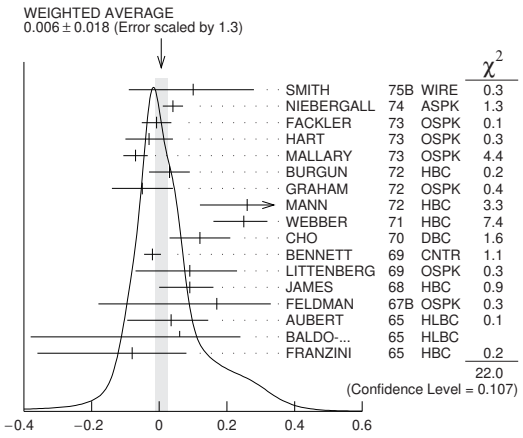

Figure 1: A typical ideogram. The arrow at the top shows the position of the weighted average, while the width of the shaded pattern shows the error in the average after scaling by the factor S. The column on the right gives the χ^2 contribution of each of the experiments. Note that the next-to-last experiment, denoted by the incomplete error flag ($\perp$), is not used in the calculation of S (see the text).

how to evaluate this expression. Instead, we define

$$S_r^2 = \frac{1}{N_k}\sum_{k=1}^{N_k}\frac{\left(R_{rk}-\overline{R}_r\right)^2}{\langle(R_{rk}-\overline{R}_r)^2\rangle}. \qquad (4)$$

With this definition the expected value of S_r^2 is one. We can show that

$$\langle(R_{rk}-\overline{R}_r)^2\rangle = \langle(\delta R_{rk})^2\rangle - (\delta\overline{R}_r)^2, \qquad (5)$$

where $\delta\overline{R}_r$ is the fitted error for ratio r.

The fit is redone using errors for the branching ratios that are scaled by the larger of S_r and unity, from which new and often larger errors $\delta\overline{P}_i'$ are obtained. The scale factors we finally list in such cases are defined by $S_i = \delta\overline{P}_i'/\delta\overline{P}_i$. However, in line with our policy of not letting S affect the central values, we give the values of $\overline{P}_i$ obtained from the original (unscaled) fit.

There is one special case in which the errors that are obtained by the preceding procedure may be changed. When a fitted branching ratio (or rate) $\overline{P}_i$ turns out to be less than three standard deviations ($\delta\overline{P}_i'$) from zero, a new smaller error $(\delta\overline{P}_i'')^-$ is calculated on the low side by requiring the area under the Gaussian between $\overline{P}_i - (\delta\overline{P}_i'')^-$ and $\overline{P}_i$ to be 68.3% of the area between zero and $\overline{P}_i$. A similar correction is made for branching fractions that are within three standard deviations of one. This keeps the quoted errors from overlapping the boundary of the physical region.

5.3 *Rounding*

While the results shown in the Particle Listings are usually exactly those published by the experiments, the numbers that appear in the Summary Tables (means, averages and limits) are subject to a set of rounding rules.

The basic rule states that if the three highest order digits of the error lie between 100 and 354, we round to two significant digits. If they lie between 355 and 949, we round to one significant digit. Finally, if they lie between 950 and 999, we round up to 1000 and keep two significant digits. In all cases, the central value is given with a precision that matches that of the error. So, for example, the result (coming from an average) 0.827 ± 0.119 would appear as 0.83 ± 0.12, while 0.827 ± 0.367 would turn into 0.8 ± 0.4.

In cases where there are asymmetric errors, if these errors differ by less than 10 percent of the average of the two errors, the average is instead used as a symmetric error in the displayed result and the rounding is determined by this average. Otherwise, the narrower of the two asymmetric errors is used to determine the rounding on both.

Rounding of this form is also performed on the value of limits that come from calculations (but not on limits that are directly taken from a single source).

Finally, we should point out that in several instances, when a group of results come from a single fit to a set of data, we have chosen to keep two significant digits for all the results. This happens, for instance, for several properties of the W and Z bosons and the τ lepton.

5.4 *Discussion*

The problem of averaging data containing discrepant values is nicely discussed by Taylor in Ref. [6]. He considers a number of algorithms that attempt to incorporate inconsistent data into a meaningful average. However, it is difficult to develop a procedure that handles simultaneously in a reasonable way two basic types of situations: (a) data that lie apart from the main body of the data are incorrect (contain unreported errors); and (b) the opposite—it is the main body of data that is incorrect. Unfortunately, as Taylor shows, case (b) is not infrequent. He concludes that the choice of procedure is less significant than the initial choice of data to include or exclude.

We place much emphasis on this choice of data. Often we solicit the help of outside experts (consultants). Sometimes, however, it is simply impossible to determine which of a set of discrepant measurements are correct. Our scale-factor technique is an attempt to address this ignorance by increasing the error. In effect, we are saying that present experiments do not allow a precise determination of this quantity because of unresolvable discrepancies, and one must await further measurements. The reader is warned of this situation by the size of the scale factor, and if he or she desires can go back to the literature (via the Particle Listings) and redo the average with a different choice of data.

Our situation is less severe than most of the cases Taylor considers, such as estimates of the fundamental constants like $\hbar$, *etc.* Most of the errors in his case are dominated by systematic effects. For our data, statistical errors are often at least as large as systematic errors, and statistical errors are usually easier to estimate. A notable exception occurs in partial-wave analyses, where different techniques applied to the same data yield different results. In this case, as stated earlier, we often do not make an average but just quote a range of values.

A brief history of early Particle Data Group averages is given in Ref. [5]. Our History Plots show the time evolution of some of our values of a few particle properties. Sometimes large changes occur. These usually reflect the introduction of significant new data or the discarding of older data. Older data are discarded in favor of newer data when it is felt that the newer data have smaller systematic errors, or have more checks on systematic errors, or have made corrections unknown at the time of the older experiments, or simply have much smaller errors. Sometimes, the scale factor becomes large near the time at which a large jump takes place, reflecting the uncertainty introduced by the new and inconsistent data. By and large, however, a full scan of our history plots shows a dull progression toward greater precision at central values quite consistent with the first data points shown.

We conclude that the reliability of the combination of experimental data and our averaging procedures is usually good, but it is important to be aware that fluctuations outside of the quoted errors can and do occur.

ACKNOWLEDGMENTS

The publication of the *Review of Particle Physics* is supported by the Director, Office of Science, Office of High Energy Physics of the U.S. Department of Energy under Contract No. DE–AC02–05CH11231; by an implementing arrangement between the governments of Japan (MEXT: Ministry of Education, Culture, Sports, Science and Technology) and the United States (DOE) on cooperative research and development; by the Italian National Institute of Nuclear Physics (INFN); and by the European Laboratory for Particle Physics (CERN). Individual collaborators receive support for their PDG activities from their respective institutes or funding agencies.

We thank all those who have assisted in the many phases of preparing this *Review*. We particularly thank the many who have

responded to our requests for verification of data entered in the Listings, and those who have made suggestions or pointed out errors.

We are grateful to the staff at CERN, DESY, IHEP Beijing, KEK, LBNL, and NISER who take care of the mailing and distribution of our products.

This work used resources of the National Energy Research Scientific Computing Center, a DOE Office of Science User Facility supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

Online Particle Physics Information

Revised August 2023 by K. Assamagan (BNL) and H.B. O'Connell (FNAL).

1 Introduction

Online resources are used in a diverse and expanding set of ways in particle physics. Many of these resources have become central to our collective work. We provide a brief curated selection of the major resources here. An expanded and regularly updated online repository is referred to below and can be found at

`https://github.com/particledatagroup/hep-resources`

By contrast, it is meant to be inclusive and catalog all useful resources related to particle physics. The community is warmly invited to contribute in order to ensure a broad and up to date coverage of relevant resources. Practical details are available online.

2 Particle Data Group (PDG) resources

- **Review of Particle Physics (RPP):** A comprehensive report on the fields of particle physics and related areas of cosmology and astrophysics, including both review articles and a compilation/evaluation of data on particle properties. The review section includes articles, tables and plots on a wide variety of theoretical and experimental topics of interest to particle physicists and astrophysicists. The particle properties section provides tables of published measurements as well as the Particle Data Group's best values and limits for particle properties such as masses, widths, lifetimes, and branching fractions, as well as an extensive summary of searches for hypothetical particles. RPP is published as a large book every two years, with partial updates made available once each year on the web.

  All the contents of the book version of RPP are available online:

  `https://pdg.lbl.gov`

  The printed book can be ordered:

  `https://pdg.lbl.gov/order`

  Of historical interest is the complete RPP collection which can be found online:

  `https://pdg.lbl.gov/publications`

- **Particle Physics booklet:** An abridged version of the Review of Particle Physics, available as a pocket-sized 250-page booklet. It is one of the most useful summaries of physics data. The booklet contains an abbreviated set of reviews and the summary tables from the most recent edition of the Review of Particle Physics.

  The PDF file of the booklet can be downloaded:

  `https://pdg.lbl.gov/current/booklet.pdf`

  The printed booklet can be ordered:

  `https://pdg.lbl.gov/order`

  A mobile version of the booklet is also available:

  `https://pdg.lbl.gov/booklet`

- **PDGLive:** A web application for browsing the contents of the PDG database that contains the information published in the Review of Particle Physics. It allows one to navigate to a particle of interest, see a summary of the information available, and then proceed to the detailed information published in the Review of Particle Physics. Data entries are directly linked to the corresponding bibliographic information in INSPIRE.

  `https://pdglive.lbl.gov`

- **Computer-readable files:** Data files that can be downloaded from the PDG include tables of particle masses and widths, PDG Monte Carlo particle numbers, and cross-section data. The files are updated with each new edition of the Review of Particle Physics.

  `https://pdg.lbl.gov/files`

- **PDG API:** In addition to the fixed-format data files that have been available for many years, PDG is developing new tools to access PDG data in machine-readable format (currently available as beta versions).

  `https://pdg.lbl.gov/api`

3 Particle physics information platform

INSPIRE: INSPIRE serves as a one-stop information platform for the particle physics community, comprising interlinked databases on literature, authors, jobs, seminars, conferences, institutions and experiments (each described in more detail below). Run in collaboration by CERN (which hosts INSPIRE), DESY, Fermilab, IHEP, IN2P3 and SLAC, it has been serving the scientific community for almost 50 years. Previously hosted at SLAC and known as SPIRES, it was the first website outside Europe and the first database on the web. Close interaction with the user community and with arXiv, ADS, HEPData, ORCID, PDG and publishers is the backbone of INSPIRE's evolution. Since 2020, it is running on a modernized platform that is continuously being improved.

`https://inspirehep.net/`

4 Literature databases

Most research articles in the field of high-energy physics are first made available on the arXiv eprint server, where researchers can learn about the latest developments by browsing through the new announcements five days a week. They are indexed, together with all other publications in high-energy physics and related fields, in the INSPIRE literature collection. For neighboring fields such as astrophysics or mathematics, other databases are more exhaustive.

- **ADS:** The SAO/NASA Astrophysics Data System is a Digital Library portal offering access to 15 million bibliographic records in Astronomy and Physics. The ADS search engine also indexes the full-text for many publications in this collection and tracks citations. The system also provides access and links to a wealth of external resources, including electronic articles hosted by publishers and arXiv, data catalogs and a variety of data products hosted by the astronomy archives worldwide. The ADS can be accessed at:

  `http://ads.harvard.edu/`

- **arXiv.org:** A repository of full-text articles in physics, astronomy, mathematics, computer science, statistics, nonlinear sciences, quantitative finance, quantitative biology, electrical engineering and systems science, and economics. Papers are submitted by registered authors to arXiv, often as preprints in advance of submission to a journal for publication; includes postprints, working papers, and other relevant material. Established in 1991, the repository is interlinked with ADS and INSPIRE, among others. Readers can browse subject categories or search by author, title, abstract, date, and other fields. Receive daily update alerts for subfields by email or RSS.

  `https://arXiv.org`

- **INSPIRE Literature:** The literature collection, the flagship of the INSPIRE suite, serves more than 1.5 million bibliographic records with a growing number of full-text articles attached and metadata including author affiliations, abstracts, references, experiments, keywords as well as links to arXiv, ADS, PDG, HEPData, publisher platforms and other servers. It provides fast metadata searches that can be eas-

ily refined using facets, plots extracted from full text, author disambiguation, author profile pages and citation analysis.

`https://inspirehep.net/literature`

- **MathSciNet:** This database of almost 4 million items provides reviews, abstracts and bibliographic information for much of the mathematical sciences literature. Over 125,000 new items, most of them classified according to the Mathematics Subject Classification, and more than 90,000 reviews of the current published literature are added each year. Author identification allows users to search for publications by author and citation data allows users to track the history and influence of research publications.

`https://www.ams.org/mathscinet`

OSTI.GOV: A portal to free, publicly available DOE-sponsored R&D results including technical reports, bibliographic citations, journal articles, conference papers, books, multimedia and data information. It consolidates OSTI's home page and the now-retired primary search tool SciTech Connect. It contains over 3 million records, including citations to 1.5 million journal articles, 1 million of which have digital object identifiers (DOIs) linking to full-text articles on publishers' websites.

`https://www.osti.gov/`

5 Journals

- **CERN Journal List:** This list of journals and conference series publishing particle physics content provides information on Open Access, copyright policies and terms of use for CERN authors.

`https://scientific-info.cern/submit-and-publish/publish-open-access`

- **INSPIRE Journals:** A database of almost 4,000 journals relevant to HEP and related fields. Each entry displays the papers published in the journal that are included in the INSPIRE Literature database.

`https://inspirehep.net/journals`

- **SCOAP^3 Journals:** A list of journals currently financed by the SCOAP^3 consortium. All HEP publications in those journals are made freely available under Open Access conditions at no cost for the authors.

`https://www.scoap3.org/phase3-journals/`

6 Conference and seminars databases

- **INSPIRE Conferences:** The database of more than 26,000 past, present, and future conferences, schools, and meetings relevant to high-energy physics and related fields is searchable by title, acronym, series, date and location. Included are information about published proceedings, links to conference contributions in the INSPIRE HEP database, and links to the conference website when available. New conferences can be submitted from the entry page.

`https://inspirehep.net/conferences`

- **INSPIRE Seminars:** Created to support the surge of online seminars during the COVID-19 pandemic, this database already contains more than 2,700 seminars in high-energy physics and related fields. Seminars can be filtered by date, series and subject and exported to a calendar. Direct links to join the online seminar and external resources are included. All seminars are community-maintained and can be submitted from the entry page.

`https://inspirehep.net/seminars`

- **researchseminars.org:** A list of research seminars and conferences, organized by topic and seminars series or conference.

`https://researchseminars.org/`

7 Research institutions

- **INSPIRE Institutions:** INSPIRE Institutions contains over 11,500 institutes, laboratories, and universities, where research on particle physics and astrophysics is led. Every record includes, whenever possible, as detailed information, such as address, web links, experiments, and links to INSPIRE papers authored by people affiliated to that institution. One can search for a particular institution by name, acronym, and location.

`https://inspirehep.net/institutions`

- **Research Organization Registry (ROR):** The Research Organization Registry (ROR) is a global, community-led registry of open persistent identifiers for research organizations. It includes IDs and metadata for more than 100,000 organizations and counting. Registry updates are curated through a community process and released on a rolling basis.

`https://ror.org/`

8 People

- **INSPIRE Authors:** Searchable worldwide database of more than a hundred thousand active, departed, retired, and deceased people associated with particle physics and related fields. The affiliation history of these researchers, their e-mail addresses, ORCIDs, web pages, experiments they participated in, PhD advisor, information on their graduate students and links to their papers and seminars are provided, as well as a user interface to update this information.

`https://inspirehep.net/authors`

- **ORCID**: Registry providing persistent digital identifiers allowing to unambiguously identify researchers. Through integration in key research workflows such as manuscript and grant submission, it supports automated linkages between scientists and their professional activities ensuring that their work is recognized.

`https://orcid.org`

9 Experiments

- **INSPIRE Experiments:** Contains more than 3,700 past, present, and future experiments in particle physics. It lists and classifies both accelerator and non-accelerator experiments as well as theory collaborations. Includes official experiment name and number, location, and collaboration lists. Simple searches by participant, title, experiment number, institution, date approved, accelerator, or detector, return a description of the experiment, including a complete list of authors, title, overview of the experiment's goals and methods, and a link to the experiment's web page if available. Recently, it has expanded its scope to include particle accelerators besides experiments and to link them together.

`https://inspirehep.net/experiments`

- **Cosmic ray/Gamma ray/Neutrino and similar experiments:** This extensive collection of experiment websites is organized by focus of study and by location. Additional sections link to educational materials, organizations, and other useful resources. The site is maintained at the Max Planck Institute for Nuclear Physics, Heidelberg.

`https://www.mpi-hd.mpg.de/hfm/CosmicRay/CosmicRaySites.html`

- **Wikipedia particle experiments:** A list of particle experiments with Wikipedia pages.

`https://en.wikipedia.org/wiki/Category:Particle_experiments`

10 Jobs

- **AAS Job Register:** The American Astronomical Society publishes once a month graduate, postgraduate, faculty and other positions mainly in astronomy and astrophysics.

`https://jobregister.aas.org/`

- **Academic Jobs Online:** A full-service online recruiting site for academic institutions worldwide in all disciplines and areas.

`https://academicjobsonline.org/`

- **APS Careers:** A gateway for physicists, students, and physics enthusiasts to information about physics jobs and careers. It contains Physics job listings, career advice, upcoming workshops and meetings, and career and job-related resources provided by the American Physical Society.

`https://www.aps.org/careers/employment/`

- **INSPIRE Jobs:** Lists academic and research jobs in high energy physics, nuclear physics, accelerator physics and astrophysics with the option to post a job or to receive email notices of new job listings. Several hundreds of jobs are listed all year round, with more activity during the application season.

  `https://inspirehep.net/jobs`

- **IOP Careers:** Career information and resources primarily aimed at university students are provided by the UK Institute of Physics.

  `https://www.iop.org/careers-physics/your-future-with-physics`

- **Physics Today Jobs:** Online recruitment advertising website for Physics Today magazine, published by the American Institute of Physics. Physics Today Jobs is the managing partner of the AIP Career Network, an online job board network for the physical science, engineering, and computing disciplines. Over 6,000 resumes are currently available, and nearly 5,000 jobs were posted in 2018.

  `https://jobs.physicstoday.org/`

- **Physicsworld Jobs:** A recruitment service run by IOP Publishing that connects employers from different industry sectors with jobseekers who have a background in physics and engineering.

  `https://www.physicsworldjobs.com/`

11 Software packages and repositories

A vast number of software tools are used for various aspects of high-energy physics research. Due to their number, their often specialized purpose and the quickly-changing nature of software, no attempt has been made to present them in this chapter. The accompanying online version contains an extensive categorized list of software.

12 Data repositories and preservation

Initiatives to preserve and disseminate data produced during different stages of research, from Monte Carlo events to machine-readable versions of tables in papers, have grown in recent years. Unfortunately, there currently exists no central resource aggregating all these data as is the case for the more established means of scholarly communication. Instead, there are a number of repositories targeting different types of data and research subjects. They are listed in the online version.

13 Particle physics education and outreach

Particle physics public engagement efforts are widespread, with laboratories, experiments, universities and individual researchers engaged in a range of efforts. The online version of this chapter provides links to resources for particle physicists wanting to become engaged in public education as well as resources that physicists can provide directly to students, teachers or lay people. There are classroom activities, interactive websites, films, and direct links to education offices at institutions and experiments. Many researchers also engage the public via a variety of social media platforms. Additionally, a selection of news sites relevant for experts and for the general public are provided.

14 Regional HEP efforts

The online version of this chapter provides links to summaries of regional HEP activities across Europe, Japan, the US, Africa, Latin America, and other regions that may be classified as developing or emerging. This list of summaries is not exhaustive and is based on the expert knowledge of the authors at the time of information gathering; the narrative was developed in July 2023 and will require periodic updates as the HEP landscape changes.

SUMMARY TABLES OF PARTICLE PHYSICS

* There are also search limits in the Summary Tables for the Gauge and Higgs Bosons, the Leptons, the Quarks, and the Mesons.

SUMMARY TABLES OF PARTICLE PROPERTIES

GAUGE AND HIGGS BOSONS

γ (photon)

$I(J^{PC}) = 0,1(1^{--})$

Mass $m < 1 \times 10^{-18}$ eV
Charge $q < 1 \times 10^{-46}$ e (mixed charge)
Charge $q < 1 \times 10^{-35}$ e (single charge)
Mean life τ = Stable

g (gluon)

$I(J^{P}) = 0(1^{-})$

Mass $m = 0$ [a]
SU(3) color octet

graviton

$J = 2$

Mass $m < 1.76 \times 10^{-23}$ eV

W

$J = 1$

Charge $= \pm 1$ e
Mass $m = 80.3692 \pm 0.0133$ GeV [b]
W/Z mass ratio $= 0.88136 \pm 0.00015$
$m_Z - m_W = 10.818 \pm 0.013$ GeV
$m_{W^+} - m_{W^-} = -0.029 \pm 0.028$ GeV
Full width $\Gamma = 2.085 \pm 0.042$ GeV
$\langle N_{\pi^\pm} \rangle = 15.70 \pm 0.35$
$\langle N_{K^\pm} \rangle = 2.20 \pm 0.19$
$\langle N_p \rangle = 0.92 \pm 0.14$
$\langle N_{\text{charged}} \rangle = 19.39 \pm 0.08$

W^- modes are charge conjugates of the modes below.

W^+ DECAY MODES		Fraction (Γ_i/Γ)		Confidence level	p (MeV/c)
$\ell^+\nu$	[c]	(10.86 ± 0.09) %			–
$e^+\nu$		(10.71 ± 0.16) %			40185
$\mu^+\nu$		(10.63 ± 0.15) %			40185
$\tau^+\nu$		(11.38 ± 0.21) %			40165
hadrons		(67.41 ± 0.27) %			–

Mass $m >$ 5150 GeV, CL = 95% ($p\overline{p}$ direct search)
Z_{LR} of SU(2)$_L$×SU(2)$_R$×U(1) (with $g_L = g_R$)
Mass $m >$ 630 GeV, CL = 95% ($p\overline{p}$ direct search)
Mass $m >$ 1162 GeV, CL = 95% (electroweak fit)
Z_χ of SO(10) → SU(5)×U(1)$_\chi$ (with $g_\chi = e/\cos\theta_W$)
Mass $m >$ 4800 GeV, CL = 95% ($p\overline{p}$ direct search)
Z_ψ of E_6 → SO(10)×U(1)$_\psi$ (with $g_\psi = e/\cos\theta_W$)
Mass $m >$ 4560 GeV, CL = 95% ($p\overline{p}$ direct search)
Z_η of E_6 → SU(3)×SU(2)×U(1)×U(1)$_\eta$ (with $g_\eta = e/\cos\theta_W$)
Mass $m >$ 3.900 × 10^3 GeV, CL = 95% ($p\overline{p}$ direct search)

Scalar Leptoquarks

$m >$ 1800 GeV, CL = 95% (1st gen., pair prod., B(eq)=1)
$m >$ 1755 GeV, CL = 95% (1st gen., single prod., B(eq)=1)
$m >$ 1700 GeV, CL = 95% (2nd gen., pair prod., B(μq)=1)
$m >$ 660 GeV, CL = 95% (2nd gen., single prod., B(μq)=1)
$m >$ 1460 GeV, CL = 95% (3rd gen., pair prod., B(τb)=1)
$m >$ 1280 GeV, CL = 95% (3rd gen., single prod., B(τb)=1)
(See the Particle Listings for assumptions on leptoquark quantum numbers and branching fractions.)

Diquarks

Mass $m >$ 7200 GeV, CL = 95% (E_6 diquark)

Axigluon

Mass $m >$ 6600 GeV, CL = 95%

Axions (A^0) and Other Very Light Bosons, Searches for

See the review on "Axions and other similar particles."

The best limit for the half-life of neutrinoless double beta decay with Majoron emission is $> 7.2 \times 10^{24}$ years (CL = 90%).

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as S = $\sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] Theoretical value. A mass as large as a few MeV may not be precluded.
[b] This value does not include the AALTONEN 22 measurement by CDF. See the W mass section in the listings for details.
[c] ℓ indicates each type of lepton (e, μ, and τ), not sum over them.
[d] This represents the width for the decay of the W boson into a charged particle with momentum below detectability, p< 200 MeV.
[e] The Z-boson mass listed here corresponds to a Breit-Wigner resonance parameter. It lies approximately 34 MeV above the real part of the position of the pole (in the energy-squared plane) in the Z-boson propagator.
[f] This partial width takes into account Z decays into $\nu\overline{\nu}$ and any other possible undetected modes.
[g] This ratio has not been corrected for the τ mass.
[h] Here $A \equiv 2g_V g_A/(g_V^2+g_A^2)$.
[i] Here ℓ indicates e or μ.
[j] The value is for the sum of the charge states or particle/antiparticle states indicated.
[k] This value is updated using the product of (i) the $Z \to b\overline{b}$ fraction from this listing and (ii) the b-hadron fraction in an unbiased sample of weakly decaying b-hadrons produced in Z-decays provided by the Heavy Flavor Averaging Group (HFLAV, http://www.slac.stanford.edu/xorg/hflav/osc/PDG_2009/#FRACZ).
[l] See the Z Particle Listings for the γ energy range used in this measurement.
[n] For $m_{\gamma\gamma}$ = (60 ± 5) GeV.

Lepton Summary Table

LEPTONS

e

$J = \frac{1}{2}$

Mass $m = (548.579909065 \pm 0.000000016) \times 10^{-6}$ u
Mass $m = 0.51099895000 \pm 0.00000000015$ MeV
$|m_{e^+} - m_{e^-}|/m < 8 \times 10^{-9}$, CL = 90%
$|q_{e^+} + q_{e^-}|/e < 4 \times 10^{-8}$
Magnetic moment anomaly
$(g-2)/2 = (1159.65218062 \pm 0.00000012) \times 10^{-6}$
$(g_{e^+} - g_{e^-}) / g_{\text{average}} = (-0.5 \pm 2.1) \times 10^{-12}$
Electric dipole moment $d < 0.041 \times 10^{-28}$ $e$cm, CL = 90%
Mean life $\tau > 6.6 \times 10^{28}$ yr, CL = 90% [a]

μ

$J = \frac{1}{2}$

Mass $m = 0.1134289259 \pm 0.0000000025$ u
Mass $m = 105.6583755 \pm 0.0000023$ MeV
Mean life $\tau = (2.1969811 \pm 0.0000022) \times 10^{-6}$ s
$\tau_{\mu^+}/\tau_{\mu^-} = 1.00002 \pm 0.00008$
$c\tau = 658.6384$ m
Magnetic moment anomaly $(g-2)/2 = (11659205.9 \pm 2.2) \times 10^{-10}$
$(g_{\mu^+} - g_{\mu^-}) / g_{\text{average}} = (-0.11 \pm 0.12) \times 10^{-8}$
Electric dipole moment $|d| < 1.8 \times 10^{-19}$ $e$cm, CL = 95%

Decay parameters [b]

$\rho = 0.74979 \pm 0.00026$
$\eta = 0.057 \pm 0.034$
$\delta = 0.75047 \pm 0.00034$
$\xi P_\mu = 1.0009^{+0.0016}_{-0.0007}$ [c]
$\xi P_\mu \delta/\rho = 1.0018^{+0.0016}_{-0.0007}$ [c]
$\xi' = 1.00 \pm 0.04$
$\xi'' = 0.98 \pm 0.04$
$\alpha/A = (0 \pm 4) \times 10^{-3}$
$\alpha'/A = (-10 \pm 20) \times 10^{-3}$
$\beta/A = (4 \pm 6) \times 10^{-3}$
$\beta'/A = (2 \pm 7) \times 10^{-3}$
$\overline{\eta} = 0.02 \pm 0.08$

μ^+ modes are charge conjugates of the modes below.

μ^- DECAY MODES		Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)
$e^-\overline{\nu}_e\nu_\mu$		$\approx 100\%$		53
$e^-\overline{\nu}_e\nu_\mu\gamma$	[d]	$(6.0 \pm 0.5) \times 10^{-8}$		53
$e^-\overline{\nu}_e\nu_\mu e^+e^-$	[e]	$(3.4 \pm 0.4) \times 10^{-5}$		53
Lepton Family number (LF) violating modes				
$e^-\nu_e\overline{\nu}_\mu$	LF	[f] < 1.2 %	90%	53
$e^-\gamma$	LF	$< 4.2 \times 10^{-13}$	90%	53
$e^-e^+e^-$	LF	$< 1.0 \times 10^{-12}$	90%	53
$e^-2\gamma$	LF	$< 7.2 \times 10^{-11}$	90%	53

τ

$J = \frac{1}{2}$

Mass $m = 1776.93 \pm 0.09$ MeV
$(m_{\tau^+} - m_{\tau^-})/m_{\text{average}} < 2.8 \times 10^{-4}$, CL = 90%
Mean life $\tau = (290.3 \pm 0.5) \times 10^{-15}$ s
$c\tau = 87.03$ μm
Magnetic moment anomaly $= -0.057$ to 0.024, CL = 95%
$\text{Re}(d_\tau) = -0.185$ to 0.061×10^{-16} $e$cm, CL = 95%
$\text{Im}(d_\tau) = -0.103$ to 0.0230×10^{-16} $e$cm, CL = 95%

Weak dipole moment

$\text{Re}(d_\tau^w) < 0.50 \times 10^{-17}$ $e$cm, CL = 95%
$\text{Im}(d_\tau^w) < 1.1 \times 10^{-17}$ $e$cm, CL = 95%

Weak anomalous magnetic dipole moment

$\text{Re}(\alpha_\tau^w) < 1.1 \times 10^{-3}$, CL = 95%
$\text{Im}(\alpha_\tau^w) < 2.7 \times 10^{-3}$, CL = 95%
$\tau^\pm \to \pi^\pm K_S^0 \nu_\tau$ (RATE DIFFERENCE) / (RATE SUM) = (-0.36 ± 0.25)%

Decay parameters

See the τ Particle Listings for a note concerning τ-decay parameters.

$\rho(e \text{ or } \mu) = 0.745 \pm 0.008$
$\rho(e) = 0.747 \pm 0.010$
$\rho(\mu) = 0.763 \pm 0.020$
$\xi(e \text{ or } \mu) = 0.985 \pm 0.030$
$\xi(e) = 0.994 \pm 0.040$
$\xi(\mu) = 1.030 \pm 0.059$
$\eta(e \text{ or } \mu) = 0.013 \pm 0.020$
$\eta(\mu) = 0.094 \pm 0.073$
$(\delta\xi)(e \text{ or } \mu) = 0.746 \pm 0.021$
$(\delta\xi)(e) = 0.734 \pm 0.028$
$(\delta\xi)(\mu) = 0.778 \pm 0.037$
$\xi(\pi) = 0.993 \pm 0.022$
$\xi(\rho) = 0.994 \pm 0.008$
$\xi(a_1) = 1.001 \pm 0.027$
$\xi(\text{all hadronic modes}) = 0.995 \pm 0.007$
$\xi'(\mu) = 0.2 \pm 1.0$
$\overline{\eta}(\mu) = -1.3 \pm 1.7$
$(\xi\kappa)(e \text{ or } \mu) = 0.5 \pm 0.4$
$(\xi\kappa)(e) = -0.4 \pm 1.2$
$(\xi\kappa)(\mu) = 0.8 \pm 0.6$

τ^+ modes are charge conjugates of the modes below. "$h^\pm$" stands for $\pi^\pm$ or $K^\pm$. "ℓ" stands for e or μ. "Neutrals" stands for γ's and/or π^0s.

τ^- DECAY MODES		Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)

Lepton Family number (LF), Lepton number (L), or Baryon number (B) violating modes

L means lepton number violation (*e.g.* $\tau^- \to e^+\pi^-\pi^-$). Following common usage, LF means lepton family violation *and not* lepton number violation (*e.g.* $\tau^- \to e^-\pi^+\pi^-$). B means baryon number violation.

$e^-\gamma$	LF	< 3.3	$\times 10^{-8}$	CL=90%	888
$e^-\gamma\gamma$	LF	< 2.5	$\times 10^{-4}$	CL=90%	888

Heavy Charged Lepton Searches

$L^\pm$ – charged lepton

Mass $m >$ 100.8 GeV, CL = 95% [h] Decay to νW.

$L^\pm$ – stable charged heavy lepton

Mass $m >$ 102.6 GeV, CL = 95%

Neutrino Properties

See the note on "Neutrino properties listings" in the Particle Listings.

Mass $m <$ 0.8 eV, CL = 90% (tritium decay)
Mean life/mass, $\tau/m >$ 300 s/eV, CL = 90% (reactor)
Mean life/mass, $\tau/m >$ 7×10^9 s/eV (solar)
Mean life/mass, $\tau/m >$ 15.4 s/eV, CL = 90% (accelerator)
Magnetic moment $\mu < 0.064 \times 10^{-10}\ \mu_B$, CL = 90% (solar + radiochemical)

Number of Neutrino Types

Number $N = 2.996 \pm 0.007$ (Standard Model fits to LEP-SLC data)
Number $N = 2.92 \pm 0.05$ (S = 1.2) (Direct measurement of invisible Z width)

Neutrino Mixing

The following values are obtained through data analyses based on the 3-neutrino mixing scheme described in the review "Neutrino Masses, Mixing, and Oscillations."

$\sin^2(\theta_{12}) = 0.307 \pm 0.013$
$\Delta m^2_{21} = (7.53 \pm 0.18) \times 10^{-5}$ eV^2
$\sin^2(\theta_{23}) = 0.553^{+0.016}_{-0.024}$ (S = 1.1) (Inverted order)
$\sin^2(\theta_{23}) = 0.558^{+0.015}_{-0.021}$ (Normal order)
$\Delta m^2_{32} = (-2.529 \pm 0.029) \times 10^{-3}$ eV^2 (Inverted order)
$\Delta m^2_{32} = (2.455 \pm 0.028) \times 10^{-3}$ eV^2 (Normal order)
$\sin^2(\theta_{13}) = (2.19 \pm 0.07) \times 10^{-2}$ (S = 1.2)
δ, CP violating phase $= 1.19 \pm 0.22\ \pi$ rad (S = 1.2)
$\langle \Delta m^2_{21} - \Delta\overline{m}^2_{21} \rangle < 1.1 \times 10^{-4}$ eV^2, CL = 99.7%
$\langle \Delta m^2_{32} - \Delta\overline{m}^2_{32} \rangle = (-0.12 \pm 0.25) \times 10^{-3}$ eV^2

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] This is the best limit for the mode $e^- \to \nu\gamma$.

[*b*] See the review on "Muon Decay Parameters" for definitions and details.

[*c*] P_μ is the longitudinal polarization of the muon from pion decay. For $V-A$ coupling, $P_\mu = 1$ and $\rho = \delta = 3/4$.

[*d*] This only includes events with energy of $e > 45$ MeV and energy of $\gamma > 40$ MeV. Since the $e^- \overline{\nu}_e \nu_\mu$ and $e^- \overline{\nu}_e \nu_\mu \gamma$ modes cannot be clearly separated, we regard the latter mode as a subset of the former.

[*e*] See the relevant Particle Listings for the energy limits used in this measurement.

[*f*] A test of additive vs. multiplicative lepton family number conservation.

[*g*] Basis mode for the τ.

[*h*] $L^\pm$ mass limit depends on decay assumptions; see the Full Listings.

Quark Summary Table

QUARKS

The u-, d-, and s-quark masses are the $\overline{\rm MS}$ masses at the scale μ = 2 GeV. The c- and b-quark masses are the $\overline{\rm MS}$ masses renormalized at the $\overline{\rm MS}$ mass, i.e. $\overline{m} = \overline{m}(\mu = \overline{m})$. The t-quark mass is extracted from event kinematics (see the review "The Top Quark").

u

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

$m_u = 2.16 \pm 0.07$ MeV, CL = 90% Charge = $\frac{2}{3}$ e $I_z = +\frac{1}{2}$
$m_u/m_d = 0.462 \pm 0.020$, CL = 90%

d

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

$m_d = 4.70 \pm 0.07$ MeV, CL = 90% Charge = $-\frac{1}{3}$ e $I_z = -\frac{1}{2}$
m_s/m_d = 17–22
$\overline{m} = (m_u+m_d)/2 = 3.49 \pm 0.07$ MeV, CL = 90%

s

$I(J^P) = 0(\frac{1}{2}^+)$

$m_s = 93.5 \pm 0.8$ MeV, CL = 90% Charge = $-\frac{1}{3}$ e Strangeness = -1
m_s / $((m_u + m_d)/2) = 27.33^{+0.18}_{-0.14}$, CL = 90%

c

$I(J^P) = 0(\frac{1}{2}^+)$

$m_c = 1.2730 \pm 0.0046$ GeV, CL = 90% Charge = $\frac{2}{3}$ e Charm = $+1$
$m_b - m_c = 3.45 \pm 0.05$ GeV

b

$I(J^P) = 0(\frac{1}{2}^+)$

$m_b = 4.183 \pm 0.007$ GeV, CL = 90% Charge = $-\frac{1}{3}$ e Bottom = -1

t

$I(J^P) = 0(\frac{1}{2}^+)$

Charge = $\frac{2}{3}$ e Top = $+1$

Mass (direct measurements) $m = 172.57 \pm 0.29$ GeV [a,b] (S = 1.5)
Mass (from cross-section measurements) $m = 162.5^{+2.1}_{-1.5}$ GeV [a]
Mass (Pole from cross-section measurements) $m = 172.4 \pm 0.7$ GeV
$m_t - m_{\overline{t}} = -0.15 \pm 0.20$ GeV (S = 1.1)
Full width $\Gamma = 1.42^{+0.19}_{-0.15}$ GeV (S = 1.4)

Free Quark Searches

All searches since 1977 have had negative results.

NOTES

[a] A discussion of the definition of the top quark mass in these measurements can be found in the review "The Top Quark."

[b] Based on published top mass measurements using data from Tevatron Run-I and Run-II and LHC at $\sqrt{s} = 7$ TeV. Including the most recent unpublished results from Tevatron Run-II, the Tevatron Electroweak Working Group reports a top mass of 173.2 ± 0.9 GeV. See the note "The Top Quark' in the Quark Particle Listings of this *Review*.

[c] This limit is for $\Gamma(t \to \gamma q)/\Gamma(t \to Wb)$.

[d] This limit is for $\Gamma(t \to Zq)/\Gamma(t \to Wb)$.

LIGHT UNFLAVORED MESONS ($S = C = B = 0$)

For $I = 1$ (π, b, ρ, a): $u\overline{d}$, $(u\overline{u}-d\overline{d})/\sqrt{2}$, $d\overline{u}$;
for $I = 0$ (η, η', h, h', ω, ϕ, f, f'): $c_1(u\overline{u}+d\overline{d})+c_2(s\overline{s})$

$\pi^\pm$

$I^G(J^P) = 1^-(0^-)$

Mass $m = 139.57039 \pm 0.00018$ MeV (S = 1.8)
Mean life $\tau = (2.6033 \pm 0.0005) \times 10^{-8}$ s (S = 1.2)
$c\tau = 7.8045$ m

$\pi^\pm \to \ell^\pm \nu\gamma$ form factors [a]

$F_V = 0.0254 \pm 0.0017$
$F_A = 0.0119 \pm 0.0001$
F_V slope parameter $a = 0.10 \pm 0.06$
$R = 0.059^{+0.009}_{-0.008}$

π^- modes are charge conjugates of the modes below.

For decay limits to particles which are not established, see the section on Searches for Axions and Other Very Light Bosons.

π^+ DECAY MODES		Fraction (Γ_i/Γ)	Confidence level	p (MeV/c)

Meson Summary Table

$K^\pm$ decay form factors [a,q]

Assuming μ-e universality

$\lambda_+(K^+_{\mu3}) = \lambda_+(K^+_{e3}) = (2.959 \pm 0.025) \times 10^{-2}$

$\lambda_0(K^+_{\mu3}) = (1.76 \pm 0.25) \times 10^{-2}$ (S = 2.7)

Not assuming μ-e universality

$\lambda_+(K^+_{e3}) = (2.956 \pm 0.025) \times 10^{-2}$

$\lambda_+(K^+_{\mu3}) = (3.09 \pm 0.25) \times 10^{-2}$ (S = 1.5)

$\lambda_0(K^+_{\mu3}) = (1.73 \pm 0.27) \times 10^{-2}$ (S = 2.6)

K_{e3} form factor quadratic fit

λ'_+ ($K^\pm_{e3}$) linear coeff. $= (2.59 \pm 0.04) \times 10^{-2}$

λ''_+($K^\pm_{e3}$) quadratic coeff. $= (0.186 \pm 0.021) \times 10^{-2}$

λ'_+ (LINEAR $K^\pm_{\mu3}$ FORM FACTOR FROM QUADRATIC FIT) $= (24 \pm 4) \times 10^{-3}$

λ''_+ (QUADRATIC $K^\pm_{\mu3}$ FORM FACTOR) $= (1.8 \pm 1.5) \times 10^{-3}$

M_V (VECTOR POLE MASS FOR $K^\pm_{e3}$ DECAY) = 890.3 ± 2.8 MeV

M_V (VECTOR POLE MASS FOR $K^\pm_{\mu3}$ DECAY) = 878 ± 12 MeV

M_S (SCALAR POLE MASS FOR $K^\pm_{\mu3}$ DECAY) = 1210 ± 50 MeV

Λ_+ (DISPERSIVE VECTOR FORM FACTOR IN $K^\pm_{e3}$ DECAY) $= (2.460 \pm 0.017) \times 10^{-2}$

Λ_+ (DISPERSIVE VECTOR FORM FACTOR IN $K^\pm_{\mu3}$ DECAY) $= (25.4 \pm 0.9) \times 10^{-3}$

ln(C) (DISPERSIVE SCALAR FORM FACTOR in $K^\pm_{\mu3}$ decays) $= (182 \pm 16) \times 10^{-3}$

K^+_{e3} $|f_S/f_+| = (-0.08^{+0.34}_{-0.40}) \times 10^{-2}$

K^+_{e3} $|f_T/f_+| = (-1.2^{+1.3}_{-1.1}) \times 10^{-2}$

$K^+_{\mu3}$ $|f_S/f_+| = (0.2 \pm 0.6) \times 10^{-2}$

$K^+_{\mu3}$ $|f_T/f_+| = (-0.1 \pm 0.7) \times 10^{-2}$

$K^+ \to e^+\nu_e\gamma$ $|F_A + F_V| = 0.133 \pm 0.008$ (S = 1.3)

$K^+ \to \mu^+\nu_\mu\gamma$ $|F_A + F_V| = 0.165 \pm 0.013$

$K^+ \to e^+\nu_e\gamma$ $|F_A - F_V| < 0.49$, CL = 90%

$K^+ \to \mu^+\nu_\mu\gamma$ $|F_A - F_V| = -0.153 \pm 0.033$ (S = 1.1)

Charge radius

$\langle r \rangle = 0.560 \pm 0.031$ fm

Forward-backward asymmetry

$A_{FB}(K^\pm_{\pi\mu\mu}) = \frac{\Gamma(\cos(\theta_{K\mu})>0) - \Gamma(\cos(\theta_{K\mu})<0)}{\Gamma(\cos(\theta_{K\mu})>0) + \Gamma(\cos(\theta_{K\mu})<0)} < 0.9 \times 10^{-2}$, CL = 90%

K^- modes are charge conjugates of the modes below.

Γ_+/Γ_- in $\overline{K}^*(892)^0\ell^+\nu_\ell = 0.22 \pm 0.06$ (S = 1.6)

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K^0_S modes, not as $\overline{K}^0$ modes. Nearly always it is a K^0_S that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\Gamma(K^0_S) = \Gamma(\overline{K}^0)$.

$r_2 \equiv a_1/a_0$ in $D^0 \to \pi^-\ell^+\nu_\ell = -0.2 \pm 2.2$ (S = 1.7)

Most decay modes (other than the semileptonic modes) that involve a neutral K meson are now given as K^0_S modes, not as $\overline{K}^0$ modes. Nearly always it is a K^0_S that is measured, and interference between Cabibbo-allowed and doubly Cabibbo-suppressed modes can invalidate the assumption that $2\Gamma(K^0_S) = \Gamma(\overline{K}^0)$.

BOTTOM MESONS ($B = \pm 1$)

$B^+ = u\overline{b}$, $B^0 = d\overline{b}$, $\overline{B}^0 = \overline{d}b$, $B^- = \overline{u}b$, similarly for B^*'s

B-particle organization

Many measurements of B decays involve admixtures of B hadrons. Previously we arbitrarily included such admixtures in the $B^{\pm}$ section, but because of their importance we have created two new sections: "$B^{\pm}/B^0$ Admixture" for $\Upsilon(4S)$ results and "$B^{\pm}/B^0/B_s^0$/b-baryon Admixture" for results at higher energies. Most inclusive decay branching fractions and χ_b at high energy are found in the Admixture sections. B^0-$\overline{B}^0$ mixing data are found in the B^0 section, while B_s^0-$\overline{B}_s^0$ mixing data and B-$\overline{B}$ mixing data for a B^0/B_s^0 admixture are found in the B_s^0 section. CP-violation data are found in the $B^{\pm}$, B^0, and $B^{\pm}$ B^0 Admixture sections. b-baryons are found near the end of the Baryon section.

The organization of the B sections is now as follows, where bullets indicate particle sections and brackets indicate reviews.

- $B^{\pm}$

  mass, mean life, CP violation, branching fractions

Meson Summary Table

$B^\pm$ $I(J^P) = \frac{1}{2}(0^-)$

I, *J*, *P* need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B^\pm} = 5279.41 \pm 0.07$ MeV
Mean life $\tau_{B^\pm} = (1.638 \pm 0.004) \times 10^{-12}$ s
$c\tau = 491.1\ \mu$m

CP violation

B^- modes are charge conjugates of the modes below. Modes which do not identify the charge state of the B are listed in the $B^\pm/B^0$ ADMIXTURE section.

The branching fractions listed below assume 50% $B^0\overline{B}^0$ and 50% B^+B^- production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^*, and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, *e.g.*, $B \to D^\pm X$, the values usually are multiplicities, not branching fractions. They can be greater than one.

B^0

$I(J^P) = \frac{1}{2}(0^-)$

I, *J*, *P* need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B^0} = 5279.72 \pm 0.08$ MeV
$m_{B^0} - m_{B^\pm} = 0.31 \pm 0.05$ MeV
Mean life $\tau_{B^0} = (1.517 \pm 0.004) \times 10^{-12}$ s
$c\tau = 454.8\ \mu$m
$\tau_{B^+}/\tau_{B^0} = 1.076 \pm 0.004$ (direct measurements)

B^0-$\overline{B}^0$ mixing parameters

χ_d (B^0-$\overline{B}^0$ mixing probability) $= 0.1860 \pm 0.0011$
$\Delta m_{B^0} = m_{B^0_H} - m_{B^0_L} = (0.5069 \pm 0.0019) \times 10^{12}\ \hbar\ \mathrm{s}^{-1}$
$= (3.336 \pm 0.013) \times 10^{-10}$ MeV
$x_d = \Delta m_{B^0}/\Gamma_{B^0} = 0.7697 \pm 0.0035$
$\mathrm{Re}(\lambda_{CP}\ /\ |\lambda_{CP}|)\ \mathrm{Re(z)} = 0.047 \pm 0.022$
$\Delta\Gamma\ \mathrm{Re(z)} = -0.007 \pm 0.004$ ps^{-1}
$\mathrm{Re(z)} = (-4 \pm 4) \times 10^{-2}$ (S = 1.4)
$\mathrm{Im(z)} = (-0.8 \pm 0.4) \times 10^{-2}$

CP violation parameters

$\mathrm{Re}(\epsilon_{B^0})/(1+|\epsilon_{B^0}|^2) = (-0.5 \pm 0.4) \times 10^{-3}$

$\overline{B}^0$ modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing. Modes which do not identify the charge state of the B are listed in the $B^\pm/B^0$ ADMIXTURE section.

The branching fractions listed below assume 50% $B^0\overline{B}^0$ and 50% B^+B^- production at the $\Upsilon(4S)$. We have attempted to bring older measurements up to date by rescaling their assumed $\Upsilon(4S)$ production ratio to 50:50 and their assumed D, D_s, D^*, and ψ branching ratios to current values whenever this would affect our averages and best limits significantly.

Indentation is used to indicate a subchannel of a previous reaction. All resonant subchannels have been corrected for resonance branching fractions to the final state so the sum of the subchannel branching fractions can exceed that of the final state.

For inclusive branching fractions, *e.g.*, $B \to D^\pm X$, the values usually are multiplicities, not branching fractions. They can be greater than one.

$B^\pm/B^0$ ADMIXTURE

CP violation

$A_{CP}(B \to K^*(892)\gamma) = -0.003 \pm 0.011$

$A_{CP}(B \to s\gamma) = 0.015 \pm 0.011$

$A_{CP}(B \to (s+d)\gamma) = 0.010 \pm 0.031$

$A_{CP}(B \to X_s\ell^+\ell^-) = 0.04 \pm 0.11$

$A_{CP}(B \to X_s\ell^+\ell^-)$ $(1.0 < q^2 < 6.0\ \text{GeV}^2/c^4) = -0.06 \pm 0.22$

$A_{CP}(B \to X_s\ell^+\ell^-)$ $(10.1 < q^2 < 12.9$ or $q^2 > 14.2\ \text{GeV}^2/c^4)$ $= 0.19 \pm 0.18$

$A_{CP}(B \to K^* e^+ e^-) = -0.18 \pm 0.15$

$A_{CP}(B \to K^*\mu^+\mu^-) = -0.03 \pm 0.13$

$A_{CP}(B \to K^*\ell^+\ell^-) = -0.04 \pm 0.07$

$A_{CP}(B \to \eta\text{anything}) = -0.13^{+0.04}_{-0.05}$

$\Delta A_{CP}(X_s\gamma) = A_{CP}(B^\pm \to X_s\gamma) - A_{CP}(B^0 \to X_s\gamma) = 0.041 \pm 0.023$

$\overline{A}_{CP}(B \to X_s\gamma) = (A_{CP}(B^+ \to X_s\gamma) + A_{CP}(B^0 \to X_s\gamma))/2 = 0.009 \pm 0.012$

$\Delta A_{CP}(B \to K^*\gamma) = A_{CP}(B^+ \to K^{*+}\gamma) - A_{CP}(B^0 \to K^{*0}\gamma) = 0.024 \pm 0.028$

$\overline{A}_{CP}(B \to K^*\gamma) = (A_{CP}(B^+ \to K^{*+}\gamma) + A_{CP}(B^0 \to K^{*0}\gamma))/2 = -0.001 \pm 0.014$

The branching fraction measurements are for an admixture of B mesons at the $\Upsilon(4S)$. The values quoted assume that $\text{B}(\Upsilon(4S) \to B\overline{B}) = 100\%$.

For inclusive branching fractions, *e.g.*, $B \to D^\pm$ *anything*, the treatment of multiple D's in the final state must be defined. One possibility would be to count the number of events with one-or-more D's and divide by the total number of B's. Another possibility would be to count the total number of D's and divide by the total number of B's, which is the definition of average multiplicity. The two definitions are identical if only one D is allowed in the final state. Even though the "one-or-more" definition seems sensible, for practical reasons inclusive branching fractions are almost always measured using the multiplicity definition. For heavy final state particles, authors call their results inclusive branching fractions while for light particles some authors call their results multiplicities. In the B sections, we list all results as inclusive branching fractions, adopting a multiplicity definition. This means that inclusive branching fractions can exceed 100% and that inclusive partial widths can exceed total widths, just as inclusive cross sections can exceed total cross section.

$\overline{B}$ modes are charge conjugates of the modes below. Reactions indicate the weak decay vertex and do not include mixing.

$B^\pm/B^0/B_s^0/b$-baryon ADMIXTURE

These measurements are for an admixture of bottom particles at high energy (LHC, LEP, Tevatron, S$p\overline{p}$S).

Mean life $\tau = (1.5673 \pm 0.0029) \times 10^{-12}$ s

Mean life $\tau = (1.72 \pm 0.10) \times 10^{-12}$ s Charged b-hadron admixture

Mean life $\tau = (1.58 \pm 0.14) \times 10^{-12}$ s Neutral b-hadron admixture

$\tau_{\text{charged } b\text{-hadron}}/\tau_{\text{neutral } b\text{-hadron}} = 1.09 \pm 0.13$

$|\Delta\tau_b|/\tau_{b,\overline{b}} = -0.001 \pm 0.014$

The branching fraction measurements are for an admixture of B mesons and baryons at energies above the $\Upsilon(4S)$. Only the highest energy results (LHC, LEP, Tevatron, S$p\overline{p}$S) are used in the branching fraction averages. In the following, we assume that the production fractions are the same at the LHC, LEP, and at the Tevatron.

For inclusive branching fractions, *e.g.*, $B\to D^\pm$ anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

The modes below are listed for a $\overline{b}$ initial state. b modes are their charge conjugates. Reactions indicate the weak decay vertex and do not include mixing.

$\overline{b}$ DECAY MODES	Fraction (Γ_i/Γ)	Scale factor/ Confidence level	p (MeV/c)
PRODUCTION FRACTIONS			

The production fractions for weakly decaying b-hadrons at high energy have been calculated from the best values of mean lives, mixing parameters, and branching fractions in this edition by the Heavy Flavor Averaging Group (HFLAV) as described in the note "B^0-$\overline{B}^0$ Mixing" in the B^0 Particle Listings. We no longer provide world averages of the b-hadron production fractions, where results from LEP, Tevatron and LHC are averaged together; indeed the available data (from CDF and LHCb) shows that the fractions depend on the kinematics (in particular the p_T) of the produced b hadron. Hence we would like to list the fractions in Z decays instead, which are well-defined physics observables. The production fractions in $p\overline{p}$ collisions at the Tevatron are also listed at the end of the section. Values assume

$\mathrm{B}(\overline{b}\to B^+) = \mathrm{B}(\overline{b}\to B^0)$

$\mathrm{B}(\overline{b}\to B^+) + \mathrm{B}(\overline{b}\to B^0) + \mathrm{B}(\overline{b}\to B_s^0) + \mathrm{B}(b\to b\text{-baryon}) = 100\%$.

The correlation coefficients between production fractions are also reported:

$cor(B_s^0, b\text{-baryon}) = 0.064$

$cor(B_s^0, B^\pm{=}B^0) = -0.633$

$cor(b\text{-baryon}, B^\pm{=}B^0) = -0.813$.

The notation for production fractions varies in the literature (f_d, d_{B^0}, $f(b\to\overline{B}^0)$, $\mathrm{Br}(b\to\overline{B}^0)$). We use our own branching fraction notation here, $\mathrm{B}(\overline{b}\to B^0)$.

Note these production fractions are b-hadronization fractions, not the conventional branching fractions of b-quark to a B-hadron, which may have considerable dependence on the initial and final state kinematic and production environment.

Meson Summary Table

BOTTOM, STRANGE MESONS ($B = \pm 1, S = \mp 1$)

$B_s^0 = s\overline{b}$, $\overline{B}_s^0 = \overline{s}b$, similarly for B_s^*'s

B_s^0

$I(J^P) = 0(0^-)$

I, J, P need confirmation. Quantum numbers shown are quark-model predictions.

Mass $m_{B_s^0} = 5366.93 \pm 0.10$ MeV

$m_{B_s^0} - m_B = 87.37 \pm 0.12$ MeV

Mean life $\tau = (1.520 \pm 0.005) \times 10^{-12}$ s

$c\tau = 455.7\ \mu$m

$\Delta\Gamma_{B_s^0} = \Gamma_{B_{sL}^0} - \Gamma_{B_{sH}^0} = (0.083 \pm 0.005) \times 10^{12}$ s^{-1} (S = 1.8)

B_s^0-$\overline{B}_s^0$ mixing parameters

$\Delta m_{B_s^0} = m_{B_{sH}^0} - m_{B_{sL}^0} = (17.765 \pm 0.006) \times 10^{12}\ \hbar$ s^{-1}

$= (1.1693 \pm 0.0004) \times 10^{-8}$ MeV

$x_s = \Delta m_{B_s^0}/\Gamma_{B_s^0} = 26.99 \pm 0.09$

χ_s (B_s^0-$\overline{B}_s^0$ mixing parameter) $= 0.499318 \pm 0.000005$

CP violation parameters in B_s^0

$\mathrm{Re}(\epsilon_{B_s^0}) / (1 + |\epsilon_{B_s^0}|^2) = (-0.15 \pm 0.70) \times 10^{-3}$

$C_{KK}(B_s^0 \to K^+K^-) = 0.162 \pm 0.035$

$S_{KK}(B_s^0 \to K^+K^-) = 0.14 \pm 0.05$ (S = 1.3)

$r_B(B_s^0 \to D_s^\mp K^\pm) = 0.37^{+0.10}_{-0.09}$

$r_B(B_s^0 \to D_s^\mp K^\pm\pi^\pm\pi^\mp) = 0.47 \pm 0.08$

$\delta_B(B_s^0 \to D_s^\pm K^\mp) = (358 \pm 14)^\circ$

$\delta_B(B_s^0 \to D_s^\pm K^\mp\pi^\pm\pi^\mp) = (-6^{+10}_{-13})^\circ$

CP Violation phase β_s ($b \to c\overline{c}s$) $= (2.0 \pm 0.8) \times 10^{-2}$ rad

CP Violation phase β_s ($b \to s\overline{s}s$) $= (3.7 \pm 3.5) \times 10^{-2}$ rad

$|\lambda|$ ($B_s^0 \to J/\psi(1S)\phi$) $= 0.988 \pm 0.009$

$|\lambda|$ ($b \to c\overline{c}s$) $= 0.989 \pm 0.008$

A, CP violation parameter $= -0.79 \pm 0.08$

C, CP violation parameter $= 0.19 \pm 0.06$

S, CP violation parameter $= 0.17 \pm 0.06$

$A_{CP}^L(B_s \to J/\psi\overline{K}^*(892)^0) = -0.05 \pm 0.06$

$A_{CP}^\parallel(B_s \to J/\psi\overline{K}^*(892)^0) = 0.17 \pm 0.15$

$A_{CP}^\perp(B_s \to J/\psi\overline{K}^*(892)^0) = -0.05 \pm 0.10$

$A_{CP}(B_s \to \pi^+K^-) = 0.224 \pm 0.012$

$A_{CP}(B_s^0 \to [K^+K^-]_D\overline{K}^*(892)^0) = -0.04 \pm 0.07$

$A_{CP}(B_s^0 \to [\pi^+K^-]_D K^*(892)^0) = -0.01 \pm 0.04$

$A_{CP}(B_s^0 \to [\pi^+\pi^-]_D K^*(892)^0) = 0.06 \pm 0.13$

$S(B_s^0 \to \phi\gamma) = 0.43 \pm 0.32$

$C(B_s^0 \to \phi\gamma) = 0.11 \pm 0.31$

$A^\Delta(B_s^0 \to \phi\gamma) = -0.7 \pm 0.4$

$\Delta a_\perp < 1.2 \times 10^{-12}$ GeV, CL = 95%

$\Delta a_\parallel = (-0.9 \pm 1.5) \times 10^{-14}$ GeV

$\Delta a_X = (1.0 \pm 2.2) \times 10^{-14}$ GeV

$\Delta a_Y = (-3.8 \pm 2.2) \times 10^{-14}$ GeV

$\mathrm{Re}(\xi) = -0.022 \pm 0.033$

$\mathrm{Im}(\xi) = 0.004 \pm 0.011$

These branching fractions all scale with B($\overline{b} \to B_s^0$).

The branching fraction B($B_s^0 \to D_s^-\ell^+\nu_\ell$anything) is not a pure measurement since the measured product branching fraction B($\overline{b} \to B_s^0$) × B($B_s^0 \to D_s^-\ell^+\nu_\ell$anything) was used to determine B($\overline{b} \to B_s^0$), as described in the note on "B^0-$\overline{B}^0$ Mixing"

For inclusive branching fractions, *e.g.*, $B \to D^\pm$anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

Due to the complexity of the $c\overline{c}$ threshold region, in this listing, "seen" ("not seen") means that a cross section for the mode in question has been measured at effective $\sqrt{s}$ near this particle's central mass value, more (less) than 2σ above zero, without regard to any peaking behavior in $\sqrt{s}$ or absence thereof. See mode listing(s) for details and references.

Mass $m = 4415 \pm 5$ MeV
Full width $\Gamma = 110 \pm 22$ MeV (S = 2.3)

Due to the complexity of the $c\overline{c}$ threshold region, in this listing, "seen" ("not seen") means that a cross section for the mode in question has been measured at effective $\sqrt{s}$ near this particle's central mass value, more (less) than 2σ above zero, without regard to any peaking behavior in $\sqrt{s}$ or absence thereof. See mode listing(s) for details and references.

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when S > 1, which often indicates that the measurements are inconsistent. When S > 1.25, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame.

[a] See the review on "Form Factors for Radiative Pion and Kaon Decays" for definitions and details.

[b] Measurements of $\Gamma(e^+\nu_e)/\Gamma(\mu^+\nu_\mu)$ always include decays with γ's, and measurements of $\Gamma(e^+\nu_e\gamma)$ and $\Gamma(\mu^+\nu_\mu\gamma)$ never include low-energy γ's. Therefore, since no clean separation is possible, we consider the modes with γ's to be subreactions of the modes without them, and let $[\Gamma(e^+\nu_e) + \Gamma(\mu^+\nu_\mu)]/\Gamma_{\rm total} = 100\%$.

[c] See the $\pi^\pm$ Particle Listings for the energy limits used in this measurement; low-energy γ's are not included.

[d] Derived from an analysis of neutrino-oscillation experiments.

[e] Forbidden by angular momentum conservation.

[f] C parity forbids this to occur as a single-photon process.

[g] As measured in $e^+e^- \to \rho^0$.

[h] The $\omega\rho$ interference is then due to $\omega\rho$ mixing only, and is expected to be small. If $e\mu$ universality holds, $\Gamma(\rho^0 \to \mu^+\mu^-) = \Gamma(\rho^0 \to e^+e^-) \times 0.99785$.

[i] Our estimate. See the Particle Listings for details.

[j] See the "Note on $a_1(1260)$" in the $a_1(1260)$ Particle Listings in PDG 06, Journal of Physics **G33** 1 (2006).

[k] See also the $\omega(1650)$.

[l] See also the $\omega(1420)$.

[n] See the note in the $K^\pm$ Particle Listings.

[o] Neglecting photon channels. See, *e.g.*, A. Pais and S.B. Treiman, Phys. Rev. **D12**, 2744 (1975).

[p] The definition of the slope parameters of the $K \to 3\pi$ Dalitz plot is as follows (see also "Note on Dalitz Plot Parameters for $K \to 3\pi$ Decays" in the $K^\pm$ Particle Listings):

$$|M|^2 = 1 + g(s_3 - s_0)/m^2_{\pi^+} + \cdots .$$

[q] For more details and definitions of parameters see the Particle Listings.

[r] See the $K^\pm$ Particle Listings for the energy limits used in this measurement.

[s] Most of this radiative mode, the low-momentum γ part, is also included in the parent mode listed without γ's.

[t] Structure-dependent part.

[u] Direct-emission branching fraction.

[v] Violates angular-momentum conservation.

[x] Derived from measured values of ϕ_{+-}, ϕ_{00}, $|\eta|$, $|m_{K^0_L} - m_{K^0_S}|$, and $\tau_{K^0_S}$, as described in the introduction to "Tests of Conservation Laws."

[y] The CP-violation parameters are defined as follows (see also "Note on CP Violation in $K_S \to 3\pi$" and "Note on CP Violation in K^0_L Decay" in the Particle Listings):

$$\eta_{+-} = |\eta_{+-}|e^{i\phi_{+-}} = \frac{A(K^0_L \to \pi^+\pi^-)}{A(K^0_S \to \pi^+\pi^-)} = \epsilon + \epsilon'$$

$$\eta_{00} = |\eta_{00}|e^{i\phi_{00}} = \frac{A(K^0_L \to \pi^0\pi^0)}{A(K^0_S \to \pi^0\pi^0)} = \epsilon - 2\epsilon'$$

$$\delta = \frac{\Gamma(K^0_L \to \pi^-\ell^+\nu) - \Gamma(K^0_L \to \pi^+\ell^-\nu)}{\Gamma(K^0_L \to \pi^-\ell^+\nu) + \Gamma(K^0_L \to \pi^+\ell^-\nu)} ,$$

$$|{\rm Im}(\eta_{+-0})|^2 = \frac{\Gamma(K^0_S \to \pi^+\pi^-\pi^0)^{CP\ \rm viol.}}{\Gamma(K^0_L \to \pi^+\pi^-\pi^0)} ,$$

$$|{\rm Im}(\eta_{000})|^2 = \frac{\Gamma(K^0_S \to \pi^0\pi^0\pi^0)}{\Gamma(K^0_L \to \pi^0\pi^0\pi^0)} .$$

where for the last two relations CPT is assumed valid, *i.e.*, $\mathrm{Re}(\eta_{+-0}) \simeq 0$ and $\mathrm{Re}(\eta_{000}) \simeq 0$.

[z] See the K^0_S Particle Listings for the energy limits used in this measurement.

[aa] The value is for the sum of the charge states or particle/antiparticle states indicated.

[bb] $\mathrm{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.

[cc] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K^0_L \to \pi^+\pi^-\gamma$(DE).

[dd] See the K^0_L Particle Listings for the energy limits used in this measurement.

[ee] Allowed by higher-order electroweak interactions.

[ff] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

[gg] See our minireview under the $K_2(1770)$ in the 2004 edition of this *Review*.

[hh] This result applies to $Z^0 \to c\overline{c}$ decays only. Here ℓ^+ is an average (not a sum) of e^+ and μ^+ decays.

[ii] See the Particle Listings for the (complicated) definition of this quantity.

[jj] The branching fraction for this mode may differ from the sum of the submodes that contribute to it, due to interference effects. See the relevant papers in the Particle Listings.

[kk] These subfractions of the $K^-2\pi^+$ mode are uncertain: see the Particle Listings.

[ll] See the listings under "$D \to K\pi\pi\pi$ partial wave analyses" and our 2008 Review (Physics Letters **B667** 1 (2008)) for measurements of submodes of this mode.

[nn] The unseen decay modes of the resonances are included.

[oo] This is *not* a test for the ΔC=1 weak neutral current, but leads to the $\pi^+\ell^+\ell^-$ final state.

[pp] This mode is not a useful test for a ΔC=1 weak neutral current because both quarks must change flavor in this decay.

[qq] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.

[rr] This value is obtained by subtracting the branching fractions for 2-, 4- and 6-prongs from unity.

[ss] This is the sum of our $K^-2\pi^+\pi^-$, $K^-2\pi^+\pi^-\pi^0$, $\overline{K}{}^0 2\pi^+2\pi^-$, $K^+2K^-\pi^+$, $2\pi^+2\pi^-$, $2\pi^+2\pi^-\pi^0$, $K^+K^-\pi^+\pi^-$, and $K^+K^-\pi^+\pi^-\pi^0$, branching fractions.

[tt] This is the sum of our $K^-3\pi^+2\pi^-$ and $3\pi^+3\pi^-$ branching fractions.

[uu] The branching fractions for the $K^-e^+\nu_e$, $K^*(892)^-e^+\nu_e$, $\pi^-e^+\nu_e$, and $\rho^-e^+\nu_e$ modes add up to 6.17 ± 0.17 %.

[vv] This is a doubly Cabibbo-suppressed mode.

[xx] Submodes of the $D^0 \to K^0_S\pi^+\pi^-\pi^0$ mode with a K^* and/or ρ were studied by COFFMAN 92B, but with only 140 events. With nothing new for 18 years, we refer to our 2008 edition, Physics Letters **B667** 1 (2008), for those results.

[yy] This branching fraction includes all the decay modes of the resonance in the final state.

[zz] This limit assumes the average of $\mathrm{B}(D^0 \to K^-e^+\nu_e)$ and $\mathrm{B}(D^0 \to K^-\mu^+\nu_\mu)$ for the $\mathrm{B}(D^0 \to K^-\ell^+\nu_\ell)$ value.

[aaa] This is the purely e^+ semileptonic branching fraction: the e^+ fraction from τ^+ decays has been subtracted off. The sum of our (non-τ) e^+ exclusive fractions — an $e^+\nu_e$ with an η, η', ϕ, K^0, or K^{*0} — is 5.99 ± 0.31 %.

[bbb] This fraction includes η from η' decays.

[ccc] The sum of our exclusive η' fractions — $\eta'e^+\nu_e$, $\eta'\mu^+\nu_\mu$, $\eta'\pi^+$, $\eta'\rho^+$, and $\eta'K^+$ — is 11.8 ± 1.6%.

[ddd] This branching fraction includes all the decay modes of the final-state resonance.

[eee] A test for $u\overline{u}$ or $d\overline{d}$ content in the D^+_s. Neither Cabibbo-favored nor Cabibbo-suppressed decays can contribute, and $\omega - \phi$ mixing is an unlikely explanation for any fraction above about 2×10^{-4}.

[fff] We decouple the $D^+_s \to \phi\pi^+$ branching fraction obtained from mass projections (and used to get some of the other branching fractions) from the $D^+_s \to \phi\pi^+$, $\phi \to K^+K^-$ branching fraction obtained from

the Dalitz-plot analysis of $D_s^+ \to K^+K^-\pi^+$. That is, the ratio of these two branching fractions is not exactly the $\phi \to K^+K^-$ branching fraction 0.491.

[*ggg*] This is the average of a model-independent and a *K*-matrix parametrization of the $\pi^+\pi^-$ *S*-wave and is a sum over several f_0 mesons.

[*hhh*] An ℓ indicates an e or a μ mode, not a sum over these modes.

[*iii*] An $CP(\pm 1)$ indicates the $CP{=}+1$ and $CP{=}-1$ eigenstates of the D^0-$\overline{D}^0$ system.

[*jjj*] D denotes D^0 or $\overline{D}^0$.

[*kkk*] D^{*0}_{CP+} decays into $D^0\pi^0$ with the D^0 reconstructed in *CP*-even eigenstates K^+K^- and $\pi^+\pi^-$.

[*lll*] $\overline{D}^{**}$ represents an excited state with mass $2.2 < \mathrm{M} < 2.8$ GeV/c^2.

[*nnn*] $\chi_{c1}(3872)^+$ is a hypothetical charged partner of the $\chi_{c1}(3872)$.

[*ooo*] $\Theta(1710)^{++}$ is a possible narrow pentaquark state and $G(2220)$ is a possible glueball resonance.

[*ppp*] $(\overline{\Lambda}_c^- p)_s$ denotes a low-mass enhancement near 3.35 GeV/c^2.

[*qqq*] Stands for the possible candidates of $K^*(1410)$, $K_0^*(1430)$ and $K_2^*(1430)$.

[*rrr*] B^0 and B_s^0 contributions not separated. Limit is on weighted average of the two decay rates.

[*sss*] This decay refers to the coherent sum of resonant and nonresonant $J^P = 0^+$ $K\pi$ components with $1.60 < m_{K\pi} < 2.15$ GeV/c^2.

[*ttt*] $X(214)$ is a hypothetical particle of mass 214 MeV/c^2 reported by the HyperCP experiment, Physical Review Letters **94** 021801 (2005)

[*uuu*] $\Theta(1540)^+$ denotes a possible narrow pentaquark state.

[*vvv*] ψ_{DS} is a GeV-scale dark sector antibaryon (mass range 1–4 GeV/c^2).

[*xxx*] Here *S* and *P* are the hypothetical scalar and pseudoscalar particles with masses of 2.5 GeV/c^2 and 214.3 MeV/c^2, respectively.

[*yyy*] These values are model dependent.

[*zzz*] Here "anything" means at least one particle observed.

[*aaaa*] This is a B($B^0 \to D^{*-}\ell^+\nu_\ell$) value.

[*bbaa*] D^{**} stands for the sum of the $D(1\,^1P_1)$, $D(1\,^3P_0)$, $D(1\,^3P_1)$, $D(1\,^3P_2)$, $D(2\,^1S_0)$, and $D(2\,^1S_1)$ resonances.

[*ccaa*] $D^{(*)}\overline{D}^{(*)}$ stands for the sum of $D^*\overline{D}^*$, $D^*\overline{D}$, $D\overline{D}^*$, and $D\overline{D}$.

[*ddaa*] $X(3915)$ denotes a near-threshold enhancement in the $\omega J/\psi$ mass spectrum.

[*eeaa*] Inclusive branching fractions have a multiplicity definition and can be greater than 100%.

[*ffaa*] D_j represents an unresolved mixture of pseudoscalar and tensor D^{**} (*P*-wave) states.

[*ggaa*] Not a pure measurement. See note at head of B_s^0 Decay Modes.

[*hhaa*] For $E_\gamma > 100$ MeV.

[*iiaa*] $\Theta(1540)$ is a hypothetical pentaquark state of 1.54 GeV/c^2 mass and a width of less than 25 MeV/c^2.

[*jjaa*] Includes $p\overline{p}\pi^+\pi^-\gamma$ and excludes $p\overline{p}\eta$, $p\overline{p}\omega$, $p\overline{p}\eta'$.

[*kkaa*] For a narrow state A with mass less than 960 MeV.

[*llaa*] For a narrow scalar or pseudoscalar A^0 with mass 0.21–3.0 GeV.

[*nnaa*] For a dark photon U with mass between 100 and 2100 MeV.

[*ooaa*] For a narrow resonance in the range $2.2 < M(X) < 2.8$ GeV.

[*ppaa*] J^{PC} known by production in e^+e^- via single photon annihilation. I^G is not known; interpretation of this state as a single resonance is unclear because of the expectation of substantial threshold effects in this energy region.

[*qqaa*] $2m_\tau < \mathrm{M}(\tau^+\tau^-) < 9.2$ GeV

[*rraa*] 2 GeV $< m_{K^+K^-} <$ 3 GeV

[*ssaa*] $X\overline{X}$ = vectors with $m < 3.1$ GeV

[*ttaa*] X and $\overline{X}$ = zero spin with $m < 4.5$ GeV

[*uuaa*] 1.5 GeV $< m_X <$ 5.0 GeV

[*vvaa*] 201 MeV $< \mathrm{M}(\mu^+\mu^-) <$ 3565 MeV

[*xxaa*] 0.5 GeV $< m_X <$ 9.0 GeV, where m_X is the invariant mass of the hadronic final state.

[*yyaa*] Spectroscopic labeling for these states is theoretical, pending experimental information.

[*zzaa*] 1.5 GeV $< m_X <$ 5.0 GeV

[*aabb*] 1.5 GeV $< m_X <$ 5.0 GeV

[*bbbb*] For $m_{\tau^+\tau^-}$ in the ranges 4.03–9.52 and 9.61–10.10 GeV.

Meson Summary Table

See also the table of suggested $q\overline{q}$ quark-model assignments in the Quark Model section.

• Indicates particles that appear in the preceding Meson Summary Table. We do not regard the other entries as being established.

Baryon Summary Table

This short table gives the name, the quantum numbers (where known), and the status of baryons in the Review. Only the baryons with 3- or 4-star status are included in the Baryon Summary Table. Due to insufficient data or uncertain interpretation, the other entries in the table are not established baryons. The names with masses are of baryons that decay strongly. The spin-parity J^P (when known) is given with each particle. For the strongly decaying particles, the J^P values are considered to be part of the names.

**** Existence is certain, and properties are at least fairly well explored.

*** Existence ranges from very likely to certain, but further confirmation is desirable and/or quantum numbers, branching fractions, etc. are not well determined.

** Evidence of existence is only fair.

* Evidence of existence is poor.

N BARYONS ($S = 0$, $I = 1/2$)

p, $N^+ = uud$; n, $N^0 = udd$

p

$I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$

Magnetic polarizability $\beta = (2.5 \pm 0.4) \times 10^{-4}$ fm^3 (S = 1.2)
Charge radius, μp Lamb shift = 0.84087 ± 0.00039 fm [d]
Charge radius = 0.8409 ± 0.0004 fm [d]
Magnetic radius = 0.851 ± 0.026 fm [e]
Mean life $\tau > 9 \times 10^{29}$ years, CL = 90% ($p \to$ invisible mode)

See the "Note on Nucleon Decay" in our 1994 edition (Phys. Rev. **D50**, 1173) for a short review.

The "partial mean life" limits tabulated here are the limits on τ/B_i, where τ is the total mean life and B_i is the branching fraction for the mode in question. For N decays, p and n indicate proton and neutron partial lifetimes.

$\Lambda_c(2595)^+$ $I(J^P) = 0(\frac{1}{2}^-)$

The spin-parity follows from the fact that $\Sigma_c(2455)\pi$ decays, with little available phase space, are dominant. This assumes that $J^P = 1/2^+$ for the $\Sigma_c(2455)$.

Mass $m = 2592.25 \pm 0.28$ MeV
$m - m_{\Lambda_c^+} = 305.79 \pm 0.24$ MeV
Full width $\Gamma = 2.6 \pm 0.6$ MeV

$\Lambda_c^+\pi\pi$ and its submode $\Sigma_c(2455)\pi$ — the latter just barely — are the only strong decays allowed to an excited Λ_c^+ having this mass; and the submode seems to dominate.

$\Lambda_c(2595)^+$ DECAY MODES		Fraction (Γ_i/Γ)	p (MeV/c)
$\Lambda_c^+\pi^+\pi^-$	[s]	—	117
$\Sigma_c(2455)^{++}\pi^-$		24 ± 7 %	3

$A_{FB}^{\ell h}$ in $\Lambda_b \to \Lambda\mu^+\mu^- = 0.25 \pm 0.04$

The branching fractions B(b-baryon $\to \Lambda\ell^-\overline{\nu}_\ell$anything) and B($\Lambda_b^0 \to \Lambda_c^+\ell^-\overline{\nu}_\ell$anything) are not pure measurements because the underlying measured products of these with B($b \to b$-baryon) were used to determine B($b \to b$-baryon), as described in the note "Production and Decay of b-Flavored Hadrons."

For inclusive branching fractions, *e.g.*, $\Lambda_b \to \overline{\Lambda}_c$anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

b-baryon ADMIXTURE (Λ_b, Ξ_b, Ω_b)

These branching fractions are actually an average over weakly decaying b-baryons weighted by their production rates at the LHC, LEP, and Tevatron, branching ratios, and detection efficiencies. They scale with the b-baryon production fraction B($b \to$ b-baryon).

The branching fractions B(b-baryon $\to \Lambda \ell^- \overline{\nu}_\ell$anything) and B($\Lambda_b^0 \to \Lambda_c^+ \ell^- \overline{\nu}_\ell$anything) are not pure measurements because the underlying measured products of these with B($b \to$ b-baryon) were used to determine B($b \to$ b-baryon), as described in the note "Production and Decay of b-Flavored Hadrons."

For inclusive branching fractions, *e.g.*, $B \to D^\pm$anything, the values usually are multiplicities, not branching fractions. They can be greater than one.

b-baryon ADMIXTURE DECAY MODES (Λ_b,Ξ_b,Ω_b)	Fraction (Γ_i/Γ)	Scale factor	p (MeV/c)
$p\mu^-\overline{\nu}$anything	($5.8^{+\ 2.3}_{-\ 2.0}$) %		–
$p\ell\overline{\nu}_\ell$anything	(5.6± 1.2) %		–
$p$anything	(70 ±22) %		–
$\Lambda\ell^-\overline{\nu}_\ell$anything	(3.8± 0.6) %		–
$\Lambda\ell^+\nu_\ell$anything	(3.2± 0.8) %		–
Λanything	(39 ± 7) %		–
$\Xi^-\ell^-\overline{\nu}_\ell$anything	(4.6± 1.4) $\times 10^{-3}$	1.2	–

NOTES

This Summary Table only includes established baryons. The Particle Listings include evidence for other baryons. The masses, widths, and branching fractions for the resonances in this Table are Breit-Wigner parameters, but pole positions are also given for most of the N and Δ resonances.

For most of the resonances, the parameters come from various partial-wave analyses of more or less the same sets of data, and it is not appropriate to treat the results of the analyses as independent or to average them together. Furthermore, the systematic errors on the results are not well understood. Thus, we usually only give ranges for the parameters. We then also give a best guess for the mass (as part of the name of the resonance) and for the width. The *Note on N and Δ Resonances* and the *Note on Λ and Σ Resonances* in the Particle Listings review the partial-wave analyses.

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

A decay momentum p is given for each decay mode. For a 2-body decay, p is the momentum of each decay product in the rest frame of the decaying particle. For a 3-or-more-body decay, p is the largest momentum any of the products can have in this frame. For any resonance, the *nominal* mass is used in calculating p. A dagger ("†") in this column indicates that the mode is forbidden when the nominal masses of resonances are used, but is in fact allowed due to the nonzero widths of the resonances.

[a] The masses of the p and n are most precisely known in u (unified atomic mass units). The conversion factor to MeV, 1 u = 931.494061(21) MeV, is less well known than are the masses in u.

[b] The $|m_p - m_{\overline{p}}|/m_p$ and $|q_p + q_{\overline{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\overline{p}}/m_{\overline{p}}|/(q_p/m_p)$.

[c] The limit is from neutrality-of-matter experiments; it assumes $q_n = q_p + q_e$. See also the charge of the neutron.

[d] The μp and ep values for the charge radius are much too different to average them. The disagreement is not yet understood.

[e] There is a lot of disagreement about the value of the proton magnetic charge radius. See the Listings.

[f] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.

[g] Lee and Yang in 1956 proposed the existence of a mirror world in an attempt to restore global parity symmetry—thus a search for oscillations between the two worlds. Oscillations between the worlds would be maximal when the magnetic fields B and B' were equal. The limit for any B' in the range 0 to 12.5 μT is >12 s (95% CL).

[h] The parameters g_A, g_V, and g_{WM} for semileptonic modes are defined by $\overline{B}_f[\gamma_\lambda(g_V + g_A\gamma_5) + i(g_{WM}/m_{B_i})\ \sigma_{\lambda\nu}\ q^\nu]B_i$, and ϕ_{AV} is defined by $g_A/g_V = |g_A/g_V|e^{i\phi_{AV}}$. See the "Note on Baryon Decay Parameters" in the neutron Particle Listings.

[i] Time-reversal invariance requires this to be 0° or 180°.

[j] This coefficient is zero if time invariance is not violated.

[k] This limit is for γ energies between 0.4 and 782 keV.

[l] The decay parameters γ and Δ are calculated from α and ϕ using

$$\gamma = \sqrt{1-\alpha^2}\ \cos\phi\,, \qquad \tan\Delta = -\tfrac{1}{\alpha}\ \sqrt{1-\alpha^2}\ \sin\phi\,.$$

See the "Note on Baryon Decay Parameters" in the neutron Particle Listings.

[n] See the Listings for the pion momentum range used in this measurement.

[o] Our estimate. See the Particle Listings for details.

[p] A theoretical value using QED.

[q] This branching fraction includes all the decay modes of the final-state resonance.

[r] Here γ_D stands for a dark photon.

[s] See AALTONEN 11H, Fig. 8, for the calculated ratio of $\Lambda_c^+\pi^0\pi^0$ and $\Lambda_c^+\pi^+\pi^-$ partial widths as a function of the $\Lambda_c(2595)^+ - \Lambda_c^+$ mass difference. At our value of the mass difference, the ratio is about 4.

[t] A test that the isospin is indeed 0, so that the particle is indeed a Λ_c^+.

[u] Assuming isospin conservation, so that the other third is $\Lambda_c^+\pi^0\pi^0$.

[v] P_c^+ is a pentaquark-charmonium state.

[x] Not a pure measurement. See note at head of Λ_b^0 Decay Modes.

[y] Here h^- means π^- or K^-.

Searches Summary Table

SEARCHES not in other sections

Magnetic Monopole Searches

The most sensitive experiments obtain negative results.
Best cosmic-ray supermassive monopole flux limit:
$< 1.4 \times 10^{-16}$ cm^{-2}sr^{-1}s^{-1} for $1.1 \times 10^{-4} < \beta < 1$

Supersymmetric Particle Searches

All supersymmetric mass bounds here are model dependent.

The limits assume:

1) $\widetilde{\chi}_1^0$ is the lightest supersymmetric particle; 2) R-parity is conserved, unless stated otherwise;

See the Particle Listings for a Note giving details of supersymmetry.

$\widetilde{\chi}_i^0$ — neutralinos (mixtures of $\widetilde{\gamma}$, $\widetilde{Z}^0$, and $\widetilde{H}_i^0$)

Mass $m_{\widetilde{\chi}_1^0} > 0$ GeV, CL = 95%
[general MSSM, non-universal gaugino masses]

Mass $m_{\widetilde{\chi}_1^0} > 46$ GeV, CL = 95%
[all tanβ, all m_0, all $m_{\widetilde{\chi}_2^0} - m_{\widetilde{\chi}_1^0}$]

Mass $m_{\widetilde{\chi}_2^0} > 62.4$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}_2^0} - m_{\widetilde{\chi}_1^0}$]

Mass $m_{\widetilde{\chi}_3^0} > 99.9$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}_2^0} - m_{\widetilde{\chi}_1^0}$]

Mass $m_{\widetilde{\chi}_4^0} > 116$ GeV, CL = 95%
[1<tanβ <40, all m_0, all $m_{\widetilde{\chi}_2^0} - m_{\widetilde{\chi}_1^0}$]

Mass $m_{\widetilde{\chi}}$ none 200–670 GeV, CL = 95% [R-Parity Violating]
[wino production, $\widetilde{\chi} \to b + \ell/\nu + t/b$ via λ'_{i33} coupling]

$\widetilde{\chi}_i^\pm$ — charginos (mixtures of $\widetilde{W}^\pm$ and $\widetilde{H}_i^\pm$)

Mass $m_{\widetilde{\chi}_1^\pm} > 94$ GeV, CL = 95%
[tan$\beta < 40$, $m_{\widetilde{\chi}_1^\pm} - m_{\widetilde{\chi}_1^0} > 3$ GeV, all m_0]

Mass $m_{\widetilde{\chi}_1^\pm} > 1000$ GeV, CL = 95%
[2ℓ+$\not{E}_T$, Tchi1chi1C, $m_{\widetilde{\chi}_1^0}$=0 GeV]

Mass $m_{\widetilde{\chi}_1^\pm} > 1600$ GeV, CL = 95% [R-Parity Violating]
[Tchi1n2l , $\widetilde{\chi}_1^0 \to \ell^\pm\ell^\mp\nu$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}_1^0} = 1200$ GeV]

$\widetilde{\chi}^\pm$ — long-lived chargino

Mass $m_{\widetilde{\chi}^\pm} > 1050$ GeV, CL = 95%
[$\widetilde{\chi}^\pm \to \widetilde{\chi}_1^0\pi^\pm$, wino LSP, stable]

Mass $m_{\widetilde{\chi}^\pm} > 1050$ GeV, CL = 95%
[$\widetilde{\chi}^\pm \to \widetilde{\chi}_1^0\pi^\pm$, wino LSP,$\tau$=20 ns]

$\widetilde{\nu}$ — sneutrino

Mass $m > 41$ GeV, CL = 95% [model independent]

Mass $m > 94$ GeV, CL = 95%
[CMSSM, $1 \leq \tan\beta \leq 40$, $m_{\widetilde{e}_R} - m_{\widetilde{\chi}_1^0} > 10$ GeV]

Mass $m > 4200$ GeV, CL = 95% [R-Parity Violating]
[$1e + 1\mu$, $\nu_\tau \to e\mu$, λ=$\lambda' = 0.1$]

$\widetilde{e}$ — scalar electron (selectron)

Mass $m > 107$ GeV, CL = 95% [all $m_{\widetilde{e}_L}$–$m_{\widetilde{\chi}_1^0}$]

Mass $m > 700$ GeV, CL = 95%

[2 hadronic $\tau + \not{E}_T$, $\widetilde{\tau}_{R,L} \to \tau\widetilde{\chi}_1^0$, $m_{\widetilde{\chi}_1^0} = 1$ GeV]

Mass $m > 90$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{\tau}_R$, indirect, $\Delta m > 5$ GeV]

Mass $m > 1200$, CL = 95% [R-Parity Violating]
[$\geq 4\ell$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}_1^0} = 900$ GeV (m-degenerate $\widetilde{\ell}_L$, $\widetilde{\nu}$)]

Mass $m > 286$ GeV, CL = 95% [long-lived $\widetilde{\tau}$]

$\widetilde{q}$ – squarks of the first two quark generations

Mass $m > 1.220 \times 10^3$ GeV, CL = 95%
[jets + $\not{E}_T$, Tsqk1, 1 non-degenerate $\widetilde{q}$, $m_{\widetilde{\chi}_1^0} = 0$ GeV]

Mass $m > 1.600 \times 10^3$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{q} \to q\widetilde{\chi}_1^0$, $\widetilde{\chi}_1^0 \to \ell\ell\nu$, λ_{121},$\lambda_{122} \neq 0$, $m_{\widetilde{g}}$=2400GeV]

$\widetilde{q}$ — long-lived squark

Mass $m > 1340$, CL = 95% [$\widetilde{t}$ R-hadrons]

Mass $m > 1250$, CL = 95% [$\widetilde{b}$ R-hadrons]

$\widetilde{b}$ — scalar bottom (sbottom)

Mass $m > 1.270 \times 10^3$ GeV, CL = 95%
[b-jets + $\not{E}_T$, Tsbot1, $m_{\widetilde{\chi}_1^0}$=0 GeV]

Mass $m > 307$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{b} \to t\,d$ or $t\,s$, λ''_{332} or λ''_{331} coupling]

$\widetilde{t}$ — scalar top (stop)

Mass $m > 1.310 \times 10^3$ GeV, CL = 95%
[jets + $\not{E}_T$, Tstop1, $m_{\widetilde{\chi}_1^0} < 300$ GeV]

Mass $m > 1100$ GeV, CL = 95% [R-Parity Violating]
[$\widetilde{t} \to b\,e$, Tstop2RPV, prompt]

Mass $m > 460$ GeV, CL = 95%
[R-Parity Violating, long-lived $\widetilde{t}$, $\widetilde{t} \to d\overline{\ell}$, 0.01cm $< c\tau <$ 1000 cm]

$\widetilde{g}$ — gluino

Mass $m > 2.300 \times 10^3$ GeV, CL = 95%
[jets + $\not{E}_T$, Tglu1A, $m_{\widetilde{\chi}_1^0} < 200$ GeV]

Mass $m > 2.260 \times 10^3$ GeV, CL = 95% [R-Parity Violating]
[$\geq 4\ell$, $\lambda_{12k} \neq 0$, $m_{\widetilde{\chi}_1^0} > 1000$ GeV]

Technicolor

The limits for technicolor (and top-color) particles are quite varied depending on assumptions. See the Technicolor section of the full *Review* (the data listings).

Quark and Lepton Compositeness, Searches for

Scale Limits Λ for Contact Interactions
(the lowest dimensional interactions with four fermions)

If the Lagrangian has the form
$$\pm \frac{g^2}{2\Lambda^2}\,\overline{\psi}_L\gamma_\mu\psi_L\,\overline{\psi}_L\gamma^\mu\psi_L$$
(with $g^2/4\pi$ set equal to 1), then we define $\Lambda \equiv \Lambda^{\pm}_{LL}$. For the full definitions and for other forms, see the Note in the Listings on Searches for Quark and Lepton Compositeness in the full *Review* and the original literature.

Excited Leptons

The limits from $\ell^{*+}\ell^{*-}$ do not depend on λ (where λ is the $\ell\ell^*$ transition coupling). The λ-dependent limits assume chiral coupling.

$e^{*\pm}$ — excited electron
Mass $m >$ 103.2 GeV, CL = 95% (from e^*e^*)
Mass $m >$ 5.600×10^3 GeV, CL = 95% (from ee^*)
Mass $m >$ 356 GeV, CL = 95% (if $\lambda_\gamma = 1$)

$\mu^{*\pm}$ — excited muon
Mass $m >$ 103.2 GeV, CL = 95% (from $\mu^*\mu^*$)
Mass $m >$ 5.700×10^3 GeV, CL = 95% (from $\mu\mu^*$)

$\tau^{*\pm}$ — excited tau
Mass $m >$ 103.2 GeV, CL = 95% (from $\tau^*\tau^*$)
Mass $m >$ 4.600×10^3 GeV, CL = 95% (from $\tau\tau^*$)

ν^* — excited neutrino
Mass $m >$ 1.600×10^3 GeV, CL = 95% (from $\nu^*\nu^*$)
Mass $m >$ 213 GeV, CL = 95% (from ν^*X)

q^* — excited quark
Mass $m >$ 338 GeV, CL = 95% (from q^*q^*)
Mass $m >$ 6700 GeV, CL = 95% (from q^*X)

Color Sextet and Octet Particles

Color Sextet Quarks (q_6)
Mass $m >$ 84 GeV, CL = 95% (Stable q_6)

Color Octet Charged Leptons (ℓ_8)
Mass $m >$ 86 GeV, CL = 95% (Stable ℓ_8)

Color Octet Neutrinos (ν_8)
Mass $m >$ 110 GeV, CL = 90% ($\nu_8 \to \nu g$)

Extra Dimensions

Please refer to the Extra Dimensions section of the full *Review* for a discussion of the model-dependence of these bounds, and further constraints.

Constraints on the radius of the extra dimensions, for the case of two-flat dimensions of equal radii
(direct tests of Newton's law)
$R <$ 3.8 μm, CL = 95% ($pp \to jG$)
$R <$ 0.16–916 nm (astrophysics; limits depend on technique and assumptions)

Constraints on the fundamental gravity scale
$M_{TT} >$ 9.02 TeV, CL = 95% ($pp \to$ dijet, angular distribution)
$M_c >$ 4.16 TeV, CL = 95% ($pp \to \ell\overline{\ell}$)

Constraints on the Kaluza-Klein graviton in warped extra dimensions
$M_G >$ 4.78 TeV, CL = 95% ($pp \to e^+e^-,\ \mu^+\mu^-$)

Constraints on the Kaluza-Klein gluon in warped extra dimensions
$M_{g_{KK}} >$ 3.8 TeV, CL = 95% ($g_{KK} \to t\overline{t}$)

WIMP and Dark Matter Searches

No confirmed evidence found for galactic WIMPs from the GeV to the TeV mass scales and down to 1×10^{-10} pb spin independent cross section at M = 100 GeV.

Tests of Conservation Laws

Revised April 2024 by A. Pich (IFIC, Valencia) and M. Ramsey-Musolf (Tsung-Dao Lee Inst.; SJTU; U. Massachusetts).

In keeping with the current interest in tests of conservation laws, we collect together a Table of experimental limits on all weak and electromagnetic decays, mass differences, and moments, and on a few reactions, whose observation would violate conservation laws. The Table is given only in the full Review of Particle Physics (RPP), not in the Particle Physics Booklet, and organizes the data in two main sections: "Discrete Space-Time Symmetries", *i.e.*, C, P, T, CP and CPT; and "Number Conservation Laws", *i.e.*, lepton, baryon, flavor and charge conservation. The references for these data can be found in the Particle Listings. The following text discusses the best limits among those included in the Table and gives a brief overview of the current status. For some topics, a more extensive discussion of the framework for theoretical interpretation is provided, particularly where the analogous discussion does not appear elsewhere in the RPP. References to more extensive review articles are also included where appropriate. Unless otherwise specified, all limits quoted in this review are given at a C.L. of 90%.

DISCRETE SPACE-TIME SYMMETRIES

Charge conjugation (C), parity (P) and time reversal (T) are empirically exact symmetries of the electromagnetic (QED) and strong (QCD) interactions, but they are violated by the weak forces. Owing to the left-handed nature of the $SU(2)_L \otimes U(1)_Y$ electroweak theory, C and P are maximally violated in the fermionic couplings of the $W^\pm$ and (up to $\sin^2\theta_W$ corrections) the Z. However, their product CP is still an exact symmetry when only one or two fermion families are considered. With three generations of fermions, CP is violated through the single complex phase present in the Cabibbo-Kobayashi-Maskawa (CKM) quark mixing matrix. An analogous CP-violating (CPV) phase appears in the lepton sector when non-vanishing neutrino masses are taken into account (plus two additional phases if neutrinos are Majorana particles). The product of the three discrete symmetries, CPT, is an exact symmetry of any local and Lorentz-invariant quantum field theory with a positive-definite hermitian Hamiltonian that preserves micro-causality [1, 2]. Therefore, the breaking of CP implies a corresponding violation of T.

Violations of charge-conjugation symmetry have never been observed in electromagnetic and strong phenomena. The most stringent limits are extracted from C-violating transitions of neutral (self-conjugate) particles such as $\mathrm{Br}(\pi^0 \to 3\gamma) < 3.1 \times 10^{-8}$ [3] and $\mathrm{Br}(J/\psi \to 2\gamma) < 2.7 \times 10^{-7}$ [4]. P (and CP) conservation has been also precisely tested through forbidden decays such as $\mathrm{Br}(\eta \to 4\pi^0) < 6.9 \times 10^{-7}$ [5], but the best limits on P and T are set by the non-observation of electric dipole moments (see section 2). Obviously, the interplay of the weak interaction puts a lower bound in sensitivity for this type of tests, beyond which violations of the corresponding conservation laws should be detected.

1 Violations of CP and T

The first evidence of CP non-invariance in particle physics was the observation in 1964 of $K_L^0 \to \pi^+\pi^-$ decays [6]. For many years afterwards, the non-zero ratio

$$\begin{aligned} |\eta_{+-}| &\equiv |\mathcal{M}(K_L^0 \to \pi^+\pi^-)/\mathcal{M}(K_S^0 \to \pi^+\pi^-)| \\ &= (2.232 \pm 0.011) \times 10^{-3} \end{aligned} \tag{1}$$

could be explained as a K^0–$\overline{K}^0$ mixing effect, $\eta_{+-} = \epsilon$ (superweak CP violation), which would imply an identical ratio $\eta_{00} \equiv \mathcal{M}(K_L^0 \to \pi^0\pi^0)/\mathcal{M}(K_S^0 \to \pi^0\pi^0)$ in the neutral decay mode and successfully predicts the observed CPV semileptonic asymmetry ($A_L(e) \approx 2\,\mathrm{Re}\,\epsilon$)

$$\begin{aligned} A_L(e) &\equiv \frac{\Gamma(K_L^0 \to \pi^- e^+ \nu_e) - \Gamma(K_L^0 \to \pi^+ e^- \bar{\nu}_e)}{\Gamma(K_L^0 \to \pi^- e^+ \nu_e) + \Gamma(K_L^0 \to \pi^+ e^- \bar{\nu}_e)} \\ &= (3.34 \pm 0.07) \times 10^{-3}\,. \end{aligned} \tag{2}$$

A tiny difference between η_{+-} and η_{00} was reported for the first time in 1988 by the CERN NA31 collaboration [7], and later established at the 7.2σ level with the full data samples from the NA31 [8], E731 [9], NA48 [10] and KTeV [11] experiments:

$$\mathrm{Re}(\epsilon'/\epsilon) = \frac{1}{3}\,(1 - |\eta_{00}/\eta_{+-}|) = (1.66 \pm 0.23) \times 10^{-3}\,. \tag{3}$$

This important measurement confirmed that CP violation is associated with a $\Delta S = 1$ transition, as predicted by the CKM mechanism. The Standard Model (SM) prediction, $\mathrm{Re}(\epsilon'/\epsilon) = (1.4 \pm 0.5) \times 10^{-3}$ [12–14], is in good agreement with the measured ratio, although the theoretical uncertainty is unfortunately large.

Much larger CP asymmetries have been later measured in B meson decays, many of them involving the interference between B^0–$\overline{B}^0$ mixing and the decay amplitude. They provide many successful tests of the CKM unitarity structure, validating the SM mechanism of CP violation (see the review on CP violation in the quark sector). Prominent signals of direct CP violation in the decay amplitudes have been also clearly established in several $B^\pm$, B_d^0 and B_s^0 decays, and, very recently, in charm decays [15, 16]:

$$\begin{aligned} \Delta a_{CP}^{\mathrm{dir}} &\equiv a_{CP}^{\mathrm{dir}}(D^0 \to K^+K^-) - a_{CP}^{\mathrm{dir}}(D^0 \to \pi^+\pi^-) \\ &= (-15.7 \pm 2.9) \times 10^{-4}\,. \end{aligned} \tag{4a}$$

$$a_{CP}^{\mathrm{dir}}(D^0 \to \pi^+\pi^-) = (23.2 \pm 6.1) \times 10^{-4}\,. \tag{4b}$$

These direct CP asymmetries necessarily involve the presence of a strong phase-shift difference between (at least) two interfering amplitudes, which makes very challenging to perform reliable SM predictions for heavy-flavored mesons.

Global fits to neutrino oscillation data provide some hints of a non-zero mixing phase [17, 18]. Although the statistical significance is not yet compelling, they suggest that CP-violation effects in neutrino oscillations could be large (see the review on neutrino masses, mixings and oscillations). The future DUNE and Hyper-Kamiokande experiments are expected to confirm the presence of CP violation in the lepton sector or constrain the phase in the leptonic mixing matrix to be smaller than $O(10^\circ)$.

While CP violation implies a breaking of time-reversal symmetry, direct tests of T violation are much more difficult. The CPLEAR experiment observed longtime ago a non-zero difference between the oscillation probabilities of $K^0 \to \overline{K}^0$ and $\overline{K}^0 \to K^0$ [19]. Initial neutral kaons with defined strangeness were produced from proton-antiproton annihilations at rest, $p\bar{p} \to K^-\pi^+K^0, K^+\pi^-\overline{K}^0$, and tagged by the accompanying charged kaon, while the strangeness of the final neutral kaon was identified through its semileptonic decay: $K^0 \to e^+\pi^-\nu_e$, $\overline{K}^0 \to e^-\pi^+\bar{\nu}_e$. The average asymmetry over the time interval from 1 to 20 K_S^0 lifetimes was found to be different from zero at 4σ [19]:

$$\begin{aligned} &\frac{R[\overline{K}^0\,(t=0) \to e^+\pi^-\nu_e\,(t)] - R[K^0\,(t=0) \to e^-\pi^+\bar{\nu}_e\,(t)]}{R[\overline{K}^0\,(t=0) \to e^+\pi^-\nu_e\,(t)] + R[K^0\,(t=0) \to e^-\pi^+\bar{\nu}_e\,(t)]} = \\ &= (6.6 \pm 1.3 \pm 1.0) \times 10^{-3}\,. \end{aligned} \tag{5}$$

Since this asymmetry violates also CP, its interpretation as direct evidence of T violation requires a detailed analysis of the underlying K^0–$\overline{K}^0$ mixing process [20–22].

More recently, the exchange of initial and final states has been made possible in B decays, taking advantage of the entanglement of the two daughter mesons produced in the decay $\Upsilon(4S) \to B\bar{B}$ which allows for both flavor ($B^0 \to \ell^+X$, $\overline{B}^0 \to \ell^-X$) and CP ($B_+ \to J/\psi K_L^0$, $B_- \to J/\psi K_S^0$) tagging. Selecting events where one B candidate is reconstructed in a CP eigenstate and the flavor of the other B is identified, one can compare the rates of the $\overline{B}^0 \to B_\pm$ and $B^0 \to B_\pm$ transitions with their T-reversed $B_\pm \to \overline{B}^0$ and $B_\pm \to B^0$ processes, as a function of the time difference Δt between the two B decays [23–25]. Neglecting the small width difference between the two B_d^0 mass eigenstates, each of these eight transitions has a time-dependent decay rate of the form $\mathrm{e}^{-\Gamma_d\Delta t}\,\{1 + S_{\alpha,\beta}^\pm \sin(\Delta m_d \Delta t) + C_{\alpha,\beta}^\pm \cos(\Delta m_d \Delta t)\}$, where Γ_d is the average decay width, Δm_d the B_d^0 mass difference, the

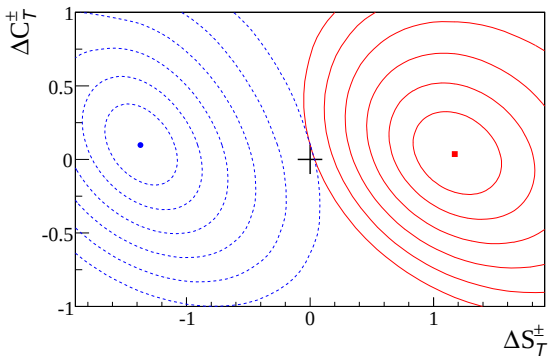

Figure 1: Measured values of ΔS_T^+, ΔC_T^+ (blue point, dashed lines) and ΔS_T^-, ΔC_T^- (red square, solid lines) [26]. The two-dimensional contours correspond to $1 - \mathrm{CL} = 0.317$, 4.55×10^{-2}, 2.70×10^{-3}, 6.33×10^{-5}, 5.73×10^{-7}, and 1.97×10^{-9}. The + sign indicates the T-invariant point.

subindices $\alpha = \ell^+, \ell^-$ and $\beta = K_S^0, K_L^0$ stand for the reconstructed final states of the two B mesons and the superindex + or − indicates whether the decay to the flavor final state α occurs before or after the decay to the CP final state β. Figure 1 shows confidence-level contours for the T-asymmetry parameters $\Delta S_T^{\pm} \equiv S^{\mp}_{\ell^-,K_L^0} - S^{\pm}_{\ell^+,K_S^0}$ and $\Delta C_T^{\pm} \equiv C^{\mp}_{\ell^-,K_L^0} - C^{\pm}_{\ell^+,K_S^0}$, reported by the BABAR experiment [26], which clearly demonstrate a violation of T in $\Delta S_T^{\pm}$, with a significance of 14σ.

2 Electric dipole moments

Among the most powerful tests of CP invariance is the search for a permanent electric dipole moment (EDM) of an elementary fermion or non-degenerate quantum system. The EDM of an elementary spin-1/2 fermion f is defined by the effective, non-renormalizable interaction

$$\mathcal{L}_{\mathrm{EDM}} = -\frac{i}{2} d_f \, \bar{f} \sigma_{\mu\nu} \gamma_5 f \, F^{\mu\nu} \tag{6}$$

where $F^{\mu\nu}$ is the QED field strength tensor. The values for d_f are conventionally expressed in units of $e\,$cm. The interaction (6) is separately odd under T and P. In the non-relativistic limit, Eq. (6) reduces to

$$\mathcal{L}_{\mathrm{EDM}} \to d_f \, \chi_f^{\dagger} \vec{\sigma} \chi_f \cdot \vec{E} \tag{7}$$

where χ is a two-component Pauli spinor and $\vec{E}$ is the electric field. Note the interaction (7) is manifestly T-odd and carries no direct information on CP. The observation of a non-zero EDM of a non-relativistic (and non-degenerate) quantum system, such as the mercury atom (see below) would imply CP violation under the assumption of CPT invariance.

To date, no experimental observation of an EDM of an elementary particle or non-degenerate bound quantum system has been observed. The most stringent limits have been obtained for the EDMs of the electron, mercury atom, and neutron. A selection of the representative, most stringent limits is given in Table 1. The limits on the electron EDM are inferred from experiments involving polar molecules, paramagnetic systems with an unpaired electron spin. In contrast, the neutron and ^{199}Hg atom are diamagnetic. A variety of experimental efforts aimed at improved sensitivities are underway. For reviews of the experimental and theoretical situation, see, *e.g.* [27–30].

EDMs in the Standard Model

The SM provides two sources of d_f: the CPV phase in the CKM matrix and the P- and T-odd 'θ term' in the QCD Lagrangian. The former is characterized by the Jarlskog invariant [37]

$$\mathcal{J} = \mathrm{Im}(V_{us} V_{cs}^* V_{cb} V_{ub}^*) \sim A^2 \lambda^6 \eta < 10^{-4} \,, \tag{8}$$

Table 1: Most stringent limits on electric dipole moments.

EDM	Limit ($e\,$cm)		Source
Electron	1.1×10^{-29}	(90% C.L.)	ThO [31]
	4.1×10^{-30}	(90% C.L.)	HfF^+ [32]
Muon	1.8×10^{-19}	(95% C.L.)	[33]
Neutron	1.8×10^{-26}	(90% C.L.)	[34]
^{199}Hg Atom	7.4×10^{-30}	(95% C.L.)	[35]
^{129}Xe Atom	1.5×10^{-27}	(95% C.L.)	[36]

while the latter is given by

$$\mathcal{L}_{\bar{\theta}} = -\frac{g_3^2}{16\pi^2} \, \bar{\theta} \, \mathrm{Tr} \left(G^{\mu\nu} \tilde{G}_{\mu\nu} \right) , \tag{9}$$

where $G_{\mu\nu}$ ($\tilde{G}_{\mu\nu} = \epsilon_{\mu\nu\alpha\beta} \, G^{\alpha\beta}/2$) is the QCD field strength tensor (dual).

The CKM-induced EDMs of quarks and charged leptons arise at three- and four-loop orders, respectively [38–41]. The resulting numerical impact for the experimental observables (see below) falls well below present and prospective experimental sensitivities. The most important impact of $\mathcal{J}$ for the EDMs of the neutron and diamagnetic atoms arise via induced hadronic interactions. The resulting theoretical expectations for the electron, neutron and ^{199}Hg EDMs are

$$|d_e|_{\mathrm{CKM}} \approx 10^{-44} \; e\,\mathrm{cm} \quad [41], \tag{10a}$$

$$|d_n|_{\mathrm{CKM}} \approx (1-6) \times 10^{-32} \; e\,\mathrm{cm} \quad [42], \tag{10b}$$

$$|d_A(^{199}\mathrm{Hg})|_{\mathrm{CKM}} \lesssim 4 \times 10^{-34} \; e\,\mathrm{cm} \quad [27]. \tag{10c}$$

For d_n and $d_A(^{199}\mathrm{Hg})$, the dominant CKM contributions arise from four-quark operators (generated after integrating out the electroweak gauge bosons) rather than from the EDMs of the individual quarks. The corresponding sensitivities to the QCD $\bar{\theta}$ parameter are given by

$$|d_n|_{\bar{\theta}} \approx (0.9 - 1.2) \times 10^{-16} \; \bar{\theta} \; e\,\mathrm{cm} \quad [42], \tag{11a}$$

$$|d_A(^{199}\mathrm{Hg})|_{\bar{\theta}} \approx (0.07 - 8) \times 10^{-20} \; \bar{\theta} \; e\,\mathrm{cm} \quad [27,28], \tag{11b}$$

where the ranges quoted include the impacts of hadronic, nuclear, and atomic theory uncertainties. The neutron EDM puts then a stringent limit on 'strong' CP violation: $\bar{\theta} \lesssim 2 \times 10^{-10}$. The corresponding limit from $d_A(^{199}\mathrm{Hg})$ is weaker due to the large theoretical uncertainty.

EDMs Beyond the Standard Model

It is possible that the next generation of EDM searches will yield a non-zero result, arising from the $\bar{\theta}$-term interaction and/or physics beyond the SM (BSM). Most of the considered BSM scenarios involve new particles with masses well above the electroweak scale. At energies much lower than the BSM mass scale Λ, the dynamics can be described through an effective field theory (SMEFT) involving an infinite set of non-renormalizable operators $\mathcal{O}_k^{(d)}$, with dimensions $d > 4$, that are invariant under the SM gauge group:

$$\mathcal{L}_{\mathrm{SMEFT}} = \mathcal{L}_{\mathrm{SM}} + \sum_{k,d} \alpha_k^{(d)} \left(\frac{1}{\Lambda} \right)^{d-4} \mathcal{O}_k^{(d)} \, . \tag{12}$$

The operators contain only SM fields, while all short-distance information on the BSM physics is encoded in their Wilson coefficients $\alpha_k^{(d)}$. The $d = 4$ term corresponds to the SM Lagrangian.

For the systems of Table 1 and for many BSM scenarios of recent interest, it suffices to consider the leading contributions from $d = 6$ operators. Considering only the first-generation SM fermions, there exist 12 independent CPV pertinent operators. For a complete listing, see *e.g.*, Refs. [28, 43]. For a given elementary fermion f, two of these operators reduce to the EDM interaction in Eq. (6). Of the remaining, the most relevant include the chromo-electric dipole moments (cEDMs) of the quarks;

Table 2: Pertinent dimension-six EDM and cEDM sources (first generation fermions only).

System	$d=6$ Source	Wilson Coefficient
Paramagnetic	Electron EDM	Im $C_{e\gamma}$
	Electron-quark	$C_{eq}^{(\pm)}$
Diamagnetic	Quark EDM	Im $C_{q\gamma}$
	Quark cEDM	Im C_{qG}
	Three gluon	$C_{\tilde{G}}$
	Four quark	Im $C_{quqd}^{(1,8)}$
	Quark-Higgs	Im $C_{\varphi ud}$
	Electron-quark tensor*	Im $C_{\ell equ}^{(3)}$

*Applicable only to atoms.

a CP-odd three gluon operator; three semileptonic, four-fermion operators; two four-quark operators; and a CPV interaction involving two Higgs fields and a right-handed quark current. For the dipole operators, it is useful to define a rescaled Wilson coefficient $\alpha_{fV_j}^{(6)} \equiv g_j\, C_{fV_j}$, where V_j ($j=1,2,3$) denote the gauge bosons for the three SM gauge groups with corresponding couplings g_j; for all other $d=6$ operators we correspondingly identify $\alpha_k^{(6)} \equiv C_k$. In this case, one has for the EDM (d_f) and cEDM ($\tilde{d}_q$)

$$d_f = -(1.13\times 10^{-16}\ e\ \text{cm})\left(\frac{v}{\Lambda}\right)^2 \text{Im}\, C_{f\gamma}\,, \qquad (13a)$$

$$\tilde{d}_q = -(1.13\times 10^{-16}\ \text{cm})\left(\frac{v}{\Lambda}\right)^2 \text{Im}\, C_{qG}\,, \qquad (13b)$$

with $\text{Im}\ C_{f\gamma} = \text{Im}\ C_{fB} + 3I_3^f\, \text{Im}\ C_{fW}$. As the expressions (13a,13b) illustrate, the magnitude of the BSM contributions scales with two inverse powers of the scale Λ. A similar conclusion holds for the contributions from the other $d=6$ operators to the EDMs of Table 1.

It is important to emphasize that if the BSM mediators are light, with masses below the weak scale, the effective field theory description of Eq. (12) does not apply. For recent studies along these lines, see, *e.g.* [44, 45].

EDM Interpretation: From Short Distances to the Atomic Scale

The EDM limits in Table 1 are obtained using composite quantum systems, wherein the relevant dynamics involve physics at the hadronic, nuclear, atomic and molecular scales. The manifestation of a given CPV source (CKM, $\bar{\theta}$ term, BSM) involves an interplay of these dynamics. In all cases, one must first evolve the Wilson coefficients from the weak scale to the hadronic scale, then match onto the relevant low-energy degrees of freedom (electrons, nucleons, pions, *etc.*). At this level, the most straightforward interpretation involves the paramagnetic systems, for which two sources dominate: the electron EDM and the electron spin-dependent semileptonic interaction $\bar{e}\gamma_5 e\,\bar{q}q$. The latter gives rise to an spin-independent Hamiltonian, for an atom with Z electrons/protons and N neutrons,

$$\hat{H}_S = \frac{iG_F}{\sqrt{2}}\,\delta(\vec{r})\left[(Z+N)\,C_S^{(0)} + (Z-N)\,C_S^{(1)}\right]\gamma_0\gamma_5\,, \qquad (14)$$

where $C_S^{(0)}$ ($C_S^{(1)}$) is proportional to $C_{eq}^{(+)}$ ($C_{eq}^{(-)}$). The computation of $C_S^{(0,1)}$ is relatively free from theoretical uncertainty since the operator $\bar{q}q$ essentially counts the number of quarks of flavor q in the nucleus. Experimental results for paramagnetic systems, thus, often quote bounds on

$$C_S \equiv C_S^{(0)} + \left(\frac{Z-N}{Z+N}\right) C_S^{(1)} \qquad (15)$$

as well as on d_e, assuming only one of these two sources is non-vanishing. Combining results from ThO and HfF^+ (see Figure 2) allows one to obtain the global, 90% C.L. bounds

$$|d_e| < 2.1\times 10^{-29}\ e\ \text{cm}\,, \qquad |C_S| < 1.9\times 10^{-9}\,. \qquad (16)$$

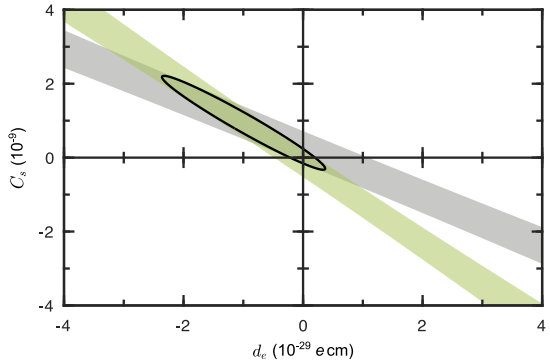

Figure 2: Constraints on d_e and C_S from EDM searches using polar molecules [32]. The green and grey bands are the 90% confidence regions from HfF+ and ThO, while the ellipse shows the 90% CL limits from the global fit. Parameters used in fits are from Ref. [46].

Note that the limits on d_e given in Table 1 have been obtained assuming $C_S = 0$.

For the diamagnetic systems, the situation is considerably more involved. For the neutron, a variety of approaches – including lattice QCD, chiral perturbation theory, QCD sum rules, and the quark model – have been employed to compute the relevant hadronic matrix elements of the CPV sources (see, *e.g.*, [28,29,47,48]). For diamagnetic atoms, the non-leptonic sources of Table 2 give rise to the EDM of the nucleus as well as other P- and T-odd nuclear moments, as allowed by the nuclear spin. However, according to a theorem by Schiff [49], the nuclear EDM generates no contribution to the neutral-atom EDM due to screening by atomic electrons. The leading contribution from these sources, instead, arises via the nuclear Schiff moment, $\vec{S}$, an r^3-weighted moment of the T- and P-odd component of the nuclear charge density. The resulting effective atomic Hamiltonian is

$$\hat{H}_{\text{Schiff}} = -4\pi\,\vec{\nabla}\rho_e(0)\cdot\vec{S}\,, \qquad (17)$$

where $\vec{\nabla}\rho_e(0)$ is the gradient of the electron density at the nucleus. To date, computations of the nuclear Schiff moment have assumed that the leading contribution arises from a pion-exchange induced nuclear force, with the P- and T-odd πN interaction given by

$$\mathcal{L}_{\pi N}^{T,P} = \bar{N}\left[\bar{g}_\pi^{(0)}\vec{\tau}\cdot\vec{\pi} + \bar{g}_\pi^{(1)}\pi^0 + \bar{g}_\pi^{(2)}(3\tau_3\pi^0 - \vec{\tau}\cdot\vec{\pi})\right]N\,. \qquad (18)$$

Chiral effective field theory power counting implies that in general the magnitude of $\bar{g}_\pi^{(2)}$ is suppressed with respect to the isoscalar and isovector couplings. The CPV sources then generate a diamagnetic atom EDM d_A via the sequence

$$\text{CPV source} \longrightarrow \bar{g}_\pi^{(i)} \longrightarrow \vec{S} \longrightarrow d_A\,. \qquad (19)$$

The steps in this sequence involve dynamics at the hadronic, nuclear, and atomic scales, respectively. In addition, d_A may receive contributions from the nuclear spin-dependent interaction generated by the semileptonic tensor interaction listed in Table 2, with the corresponding atomic Hamiltonian

$$\hat{H}_T = \frac{2iG_F}{\sqrt{2}}\,\delta(\vec{r})\sum_N\left[C_T^{(0)} + C_T^{(1)}\tau_3\right]\vec{\sigma}_N\cdot\vec{\gamma}\,, \qquad (20)$$

where σ_N is the nucleon spin Pauli matrix and $C_T^{(0,1)} \propto \text{Im}\, C_{\ell equ}^{(3)}$.

Given the large number of CPV sources and existing diagmagnetic EDM limits, it is not possible to obtain a set of global constraints on the former. One may, however, do so for the low-energy effective parameters $\bar{g}_\pi^{(0,1)}$, $C_T^{(0,1)}$ and $\tilde{d}_n^{\text{sr}}$, where the latter denotes a 'short-range' contribution to the neutron EDM [27, 50]. In this context, the dominant source of theoretical uncertainty involves computations of the nuclear Schiff moment. From the

bounds on the low-energy parameters, one may then derive constraints on the CPV sources by utilizing computations of the hadronic matrix elements. Reducing the degree of theoretical hadronic and nuclear physics uncertainty is an area of active effort.

3 Tests of *CPT*

CPT symmetry implies the equality of the masses and widths of a particle and its antiparticle. The most constraining limits are extracted from the neutral kaons [51, 52]:

$$\begin{aligned} 2\,\frac{|m_{K^0} - m_{\overline{K}^0}|}{(m_{K^0} + m_{\overline{K}^0})} &< 6\times 10^{-19}\,, \\ 2\,\frac{|\Gamma_{K^0} - \Gamma_{\overline{K}^0}|}{(\Gamma_{K^0} + \Gamma_{\overline{K}^0})} &= (8\pm 8)\times 10^{-18}\,. \end{aligned} \tag{21}$$

The limit on the K^0–$\overline{K}^0$ mass difference assumes that there is no other source of *CPT* violation. An upper bound on *CPT* breaking in $K_L^0 \to 2\pi$ has been also set through the measured phase difference of the *CPV* ratios η_{00} and η_{+-}, $\phi_{00} - \phi_{+-} = (0.34 \pm 0.32)^\circ$, thanks to the small value of $(1 - |\eta_{00}/\eta_{+-}|)$ (see the review on *CP* violation in K_L^0 decays).

The measured masses and electric charges of the electron, the proton and their antiparticles provide also strong limits on *CPT* violation [53–56]:

$$\begin{aligned} &2\,\frac{|m_{e^+} - m_{e^-}|}{m_{e^+} + m_{e^-}} < 8\times 10^{-9}\,, \qquad \frac{|q_{e^+} + q_{e^-}|}{e} < 4\times 10^{-8}\,, \\ &\left|\frac{q_{\bar{p}}/m_{\bar{p}}}{q_p/m_p}\right| - 1 = (0.3\pm 1.6)\times 10^{-11}\,. \end{aligned} \tag{22}$$

Worth mentioning are also the tight constraints derived from the lepton and antilepton magnetic moments [57, 58],

$$\begin{aligned} 2\,\frac{g_{e^+} - g_{e^-}}{g_{e^+} + g_{e^-}} &= (-0.5\pm 2.1)\times 10^{-12}\,, \\ 2\,\frac{g_{\mu^+} - g_{\mu^-}}{g_{\mu^+} + g_{\mu^-}} &= (-0.11\pm 0.12)\times 10^{-8}\,, \end{aligned} \tag{23}$$

those of the proton and antiproton [59],

$$(\mu_p + \mu_{\bar{p}})/\mu_p = (2\pm 4)\times 10^{-9}\,, \tag{24}$$

and the measurement of the 1S-2S atomic transition in antihydrogen which agrees with the corresponding frequency spectral line in hydrogen at a relative precision of 2×10^{-12} [60].

A violation of *CPT* in an interacting local quantum field theory would imply that Lorentz symmetry is also violated [61]. Signatures of Lorentz-invariance violation have been searched for with atomic clocks, penning traps, matter and antimatter spectroscopy, colliders and astroparticle experiments, with so far negative results [62]. A compilation of experimental bounds is given in Ref. [63], parametrized through the coefficients of the so-called Standard Model Extension (SME) Lagrangian which contains all possible Lorentz- and *CPT*-violating operators preserving gauge invariance, renormalizability, locality and observer causality [64].

QUANTUM-NUMBER CONSERVATION LAWS

Conservation laws of several quantum numbers have been empirically established with a very high degree of confidence. They are usually associated with some global phase symmetry. However, while some of them are deeply rooted in basic principles such as gauge invariance (charge conservation; local symmetry implies global symmetry) or Lorentz symmetry (fermion number conservation), others appear to be accidental symmetries of the SM Lagrangian and could be broken by new physics interactions.

In fact, if one only assumes the SM gauge symmetries and particle content, the most general dynamics at energies below the BSM mass scale is described by the SMEFT Lagrangian in Eq. (12). All $d = 4$ operators (*i.e.*, the SM) happen to preserve the B and L quantum numbers, but this is no-longer true for the gauge-invariant structures of higher dimensionality. There is only one operator with $d = 5$ (up to hermitian conjugation and flavor assignments), and it violates lepton number by two units [65], giving rise to Majorana neutrino masses after the electroweak spontaneous symmetry breaking. With $d = 6$, there are five operators that violate B and L [66, 67]. Thus, violations of these quantum numbers can be generically expected, unless there is an explicit symmetry protecting them.

4 Electric charge

The conservation of electric charges is associated with the QED gauge symmetry. The most precise tests are the non-observation of the decays $e \to \nu_e\gamma$ (lifetime larger than 6.6×10^{28} yr [68]) and $n \to p\nu_e\bar{\nu}_e$ (Br $< 8\times 10^{-27}$, 68% C.L. [69]). The neutrality of matter can be also interpreted as a test of electric charge conservation. Worth mentioning are the experimental limits on the electric charge of the neutron, $q_n/e = (-0.2\pm 0.8)\times 10^{-21}$, and on the sum of the proton and electron charges, $|q_p + q_e|/e < 1\times 10^{-21}$ [70].

The isotropy of the cosmic microwave background has been used to set stringent limits on a possible charge asymmetry of the Universe [71]. Assuming that charge asymmetries produced by different particles are not anticorrelated, this implies upper bounds on the photon ($|q_\gamma|/e < 1\times 10^{-35}$) and neutrino ($|q_\nu|/e < 4\times 10^{-35}$) electric charges. A much stronger upper bound on the photon charge ($|q_\gamma|/e < 1\times 10^{-46}$) has been derived from the non-observation of Aharonov-Bohm phase differences in interferometric experiments with photons that have traversed cosmological distances, under the assumption that both positive and negative charged photons exist [72].

5 Lepton family numbers

In the SM with massless left-handed neutrinos there is a separate conservation number for each lepton family. However, neutrino oscillations show that neutrinos have tiny masses and there are sizable mixings among the different lepton flavors. Compelling evidence from solar, atmospheric, accelerator and reactor neutrino experiments has established a quite solid pattern of neutrino mass differences and mixing angles [17, 18]. (see the review on neutrino masses, mixings and oscillations). Nevertheless, flavor mixing among the different charged leptons has never been observed.

If neutrino masses and mixings among the three active neutrinos were the only sources of lepton-flavor violation (LFV), neutrinoless transitions from one charged lepton flavor to another would be heavily suppressed by powers of m_{ν_i} (GIM mechanism), leading to un-observably small rates; for instance [75–80],

$$\mathrm{Br}(\mu \to e\gamma) = \frac{3\alpha}{32\pi}\left|\sum_i U^*_{\mu i}U_{ei}\,\frac{m^2_{\nu_i} - m^2_{\nu_1}}{M^2_W}\right|^2 < 10^{-54}\,, \tag{25}$$

where U_{ia} are the relevant elements of the PMNS mixing matrix. This contribution is clearly too small to be observed in any realistic experiment, so any experimentally accessible effect would arise from BSM physics with sources of LFV not related to m_{ν_i}. The search for charged LFV (CLFV) remains an area of active interest, which has the potential to probe physics at scales much higher than the TeV.

Among the most sensitive probes are searches for the CLFV decays of the muon, $\mu \to e\gamma$ and $\mu \to 3e$, as well as the conversion process $\mu^- + A(N,Z) \to e^- + A(N,Z)$, where $A(N,Z)$ denotes a nucleus with N neutrons and Z protons. Searches for rare τ decays such as $\tau \to \ell\gamma$ ($\ell = e, \mu$) also provide interesting probes of CLFV. A variety of BSM scenarios predict that rates for these CLFV processes could be sufficiently large to be observed in the present or planned searches. To date, no observation has been reported, and the resulting null results place strong constraints on BSM scenarios. For extensive reviews of the experimental and theoretical status and prospects, see Refs. [74, 81, 82].

A detailed set of upper bounds on CLFV branching rations is given in the listings for the muon and tau leptons. Here we

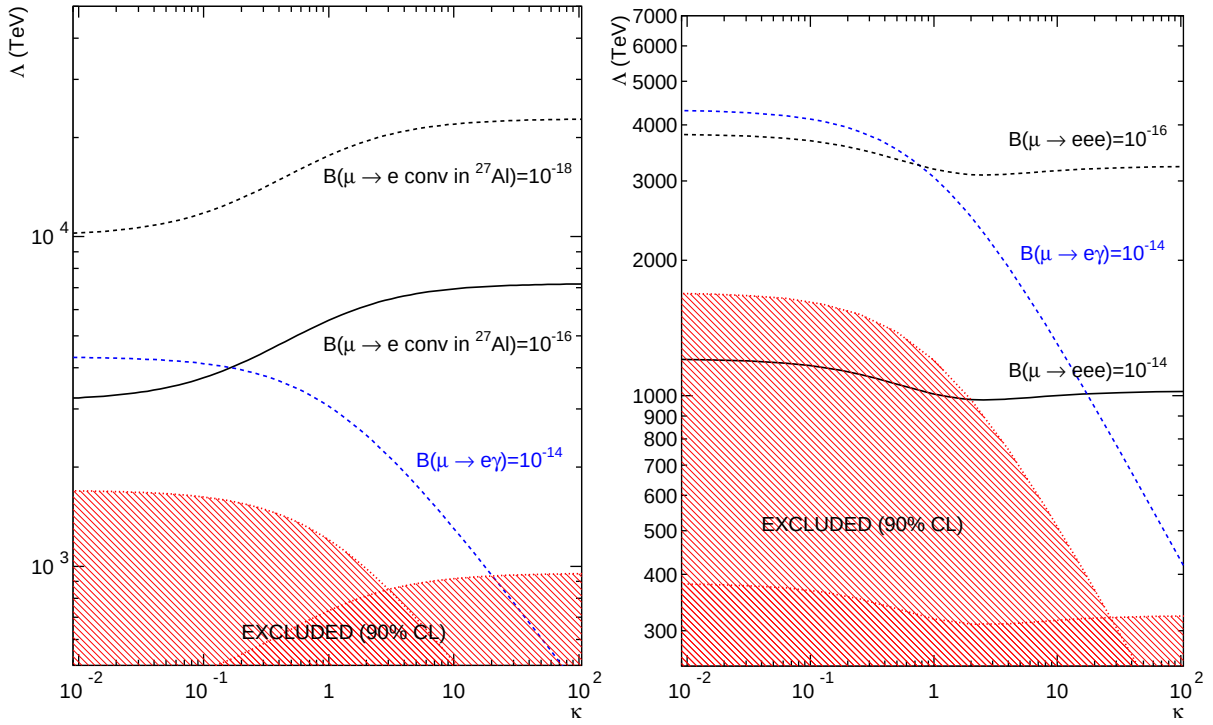

Figure 3: Model-independent CLFV sensitivities based on Eq (31). Left panel shows the comparison of present constraints with prospective future sensitivities for $\mu \to e\gamma$ and $\mu \to e$ conversion. Right panel gives analogous comparison for $\mu \to e\gamma$ and $\mu \to 3e$. Updated by [73] from Ref. [74].

emphasize those with the strongest limits:

$$\begin{aligned} &\mathrm{Br}(\mu \to e\gamma) < 4.2 \times 10^{-13} \quad [83], \\ &\mathrm{Br}(\mu \to 3e) < 1.0 \times 10^{-12} \quad [84] \end{aligned} \tag{26}$$

and

$$B_{\mu\to e} \equiv \frac{\Gamma(\mu^- + A(N,Z) \to e^- + A(N,Z)}{\Gamma(\mu^- + A(N,Z) \to \nu + A(N+1, Z-1)} \tag{27}$$

with the best limit so far, $B_{\mu\to e} < 7 \times 10^{-13}$ [85], obtained with gold. Several proposed experiments aim to improve these limits by several orders of magnitude with different atoms.

One may interpret both $\mu \to e\gamma$ and $\mu \to e$ conversion in terms of the amplitudes to emit a real or virtual photon:

$$\begin{aligned} \mathcal{M}_{\mu\to e\gamma^{(*)}} = eG_\mu \varepsilon^{\alpha *} \bar{e}(p-q) \Big[\left(q^2\gamma_\alpha - \not{q} q_\alpha\right) \left(\tilde{A}_1^R P_R + \tilde{A}_1^L P_L\right) \\ + i m_\mu \sigma_{\alpha\beta} q^\beta \left(\tilde{A}_2^R P_R + \tilde{A}_2^L P_L\right) \Big] \mu(p) \,, \end{aligned} \tag{28}$$

where it is conventional to normalize the amplitude to the Fermi constant. One then has

$$\mathrm{Br}(\mu \to e\gamma) = 48\pi^3 \alpha \left(|\tilde{A}_2^R|^2 + |\tilde{A}_2^L|^2 \right) . \tag{29}$$

For the conversion process, the virtual photon is absorbed by the quarks in the nucleus, yielding an effective four-fermion operator. In general, the exchange of other particles could lead to similar or alternate Lorentz structures, and it is not possible to distinguish between the exchange of a virtual photon or other particle. It is conventional to write the most general four-fermion amplitude, valid for energies below the electroweak scale as (adapted from Ref. [90])

$$\mathcal{M}_{\mu\to e} = G_\mu \sum_{n,a,q} a_{a,q}^{(n)} \, \bar{e} \Gamma^n P_a \mu \, \bar{q} \Gamma_n q \,, \tag{30}$$

where P_a $(a = L, R)$ denote the left and right-handed projectors and Γ^n denotes 1, γ_5, γ^μ, $\gamma^\mu\gamma_5$, and $\sigma_{\mu\nu}$. If any of the coefficients $a_{a,q}^{(n)}$ are generated by physics at a scale $\Lambda > v$, then their effects would be encoded in the SMEFT Lagrangian (12). For scenarios in which the leading CLFV operators occur at $d = 6$, the $a_{a,q}^{(n)}$ will scale as $(v/\Lambda)^2$. The corresponding decay and conversion rates will then scale as $(v/\Lambda)^4$. Note that the scalar and time component of the vector interactions are coherent over the nucleus, essentially counting the number of quarks. Consequently, these interactions typically yield the greatest sensitivities to high BSM mass scales.

It is sometimes convenient to compare the relative sensitivities of the decay and conversion processes using the following simplified effective Lagrangian [74]:

$$\begin{aligned} \mathcal{L}_{\mathrm{eff}}^{\mathrm{CLFV}} = &\frac{m_\mu}{(\kappa+1)\Lambda^2} \, \bar{\mu}_R \sigma_{\mu\nu} e_L \, F^{\mu\nu} \\ &+ \frac{\kappa}{(\kappa+1)\Lambda^2} \, \bar{\mu}\gamma_\mu e \sum_q \bar{q}\gamma^\mu q + \mathrm{h.c.} \,. \end{aligned} \tag{31}$$

Note that one may replace the second term in Eq. (31) by any one of the other four-fermion interactions given in Eq. (30). An analogous expression applies to the process $\mu \to 3e$ when replacing the sum over quarks by the corresponding electron bilinear. A comparison of the present and prospective sensitivities for various muon CLFV searches in this framework is shown in Figure 3.

Stringent limits have been also set on the LFV decay modes of the τ lepton [91]. As shown in Figure 4, the large τ data samples collected at the B factories have made possible to reach a 10^{-8} sensitivity for many of its leptonic ($\tau \to \ell\gamma$, $\tau \to \ell'\ell^+\ell^-$) and semileptonic ($\tau \to \ell P^0$, $\tau \to \ell V^0$, $\tau \to \ell P^0 P^0$, $\tau \to \ell P^+ P'^-$) neutrinoless LFV decays, and BELLE-II is expected to push these limits beyond the 10^{-9} level [87]. Being a third generation lepton, the τ could be more sensitive to heavier new-physics scales, which makes his LFV decays particularly interesting. Compared to the muon, the τ decay amplitudes could be enhanced by a chirality ratio $(m_\tau/m_\mu)^2 \sim 280$ and/or by lepton-mixing factors such as $|U_{\tau 3}/U_{e3}|^2 \sim 20$, but the exact relation is model dependent. In any case, the τ LFV decays provide a rich data set that is very

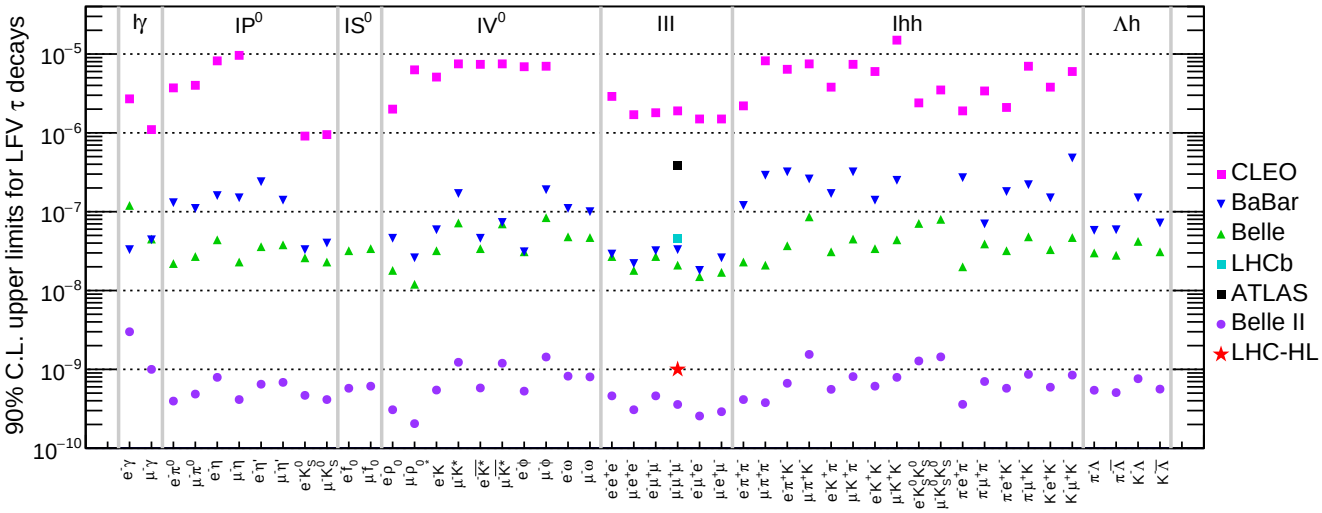

Figure 4: Current experimental limits on neutrinoless LFV τ decays [86]. Also shown are the future projections at Belle-II [87] and at the HL-LHC [88].

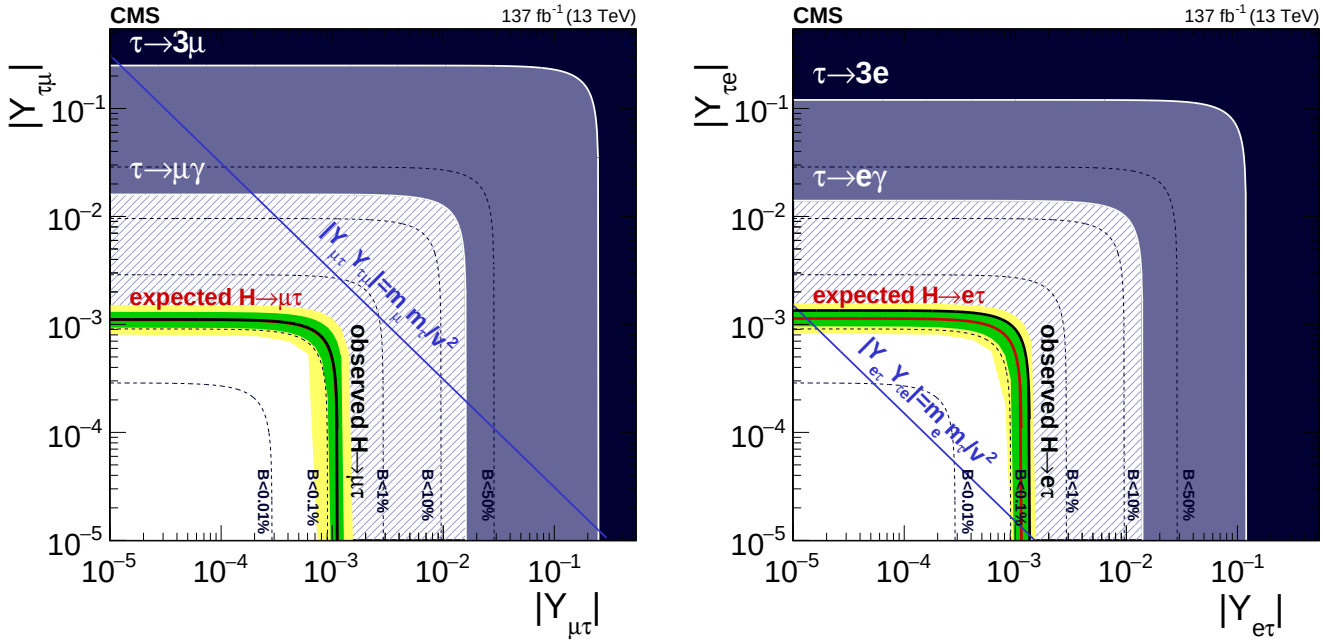

Figure 5: Current limits on the Higgs LFV τ Yukawas from direct $H^0 \to \ell^\pm\tau^\mp$ decays ($\ell = e, \mu$), and indirect constraints from τ decays [89].

complementary to the μ bounds. If LFV is finally observed, the correlations between μ and τ data, and among different LFV τ decays will allow to probe the underlying mechanism of lepton flavor breaking.

Interesting limits on LFV are also obtained in meson decays. The best bounds come from kaon experiments, e.g., $\mathrm{Br}(K_L^0 \to e^\pm\mu^\mp) < 4.7 \times 10^{-12}$ [92], $\mathrm{Br}(K^+ \to \pi^+\mu^+e^-) < 1.3 \times 10^{-11}$ [93]. Quite strong limits have also been set in decays of B and D mesons, the best upper bounds being $\mathrm{Br}(B^0 \to e^\pm\mu^\mp) < 1.0 \times 10^{-9}$ [94] and $\mathrm{Br}(D^0 \to e^\pm\mu^\mp) < 1.3 \times 10^{-8}$ [95].

The LFV decays of the Z boson were probed at LEP at the 10^{-5} to 10^{-6} level. Stronger (95% C.L.) limits have been set recently by the LHC ATLAS collaboration [96, 97]:

$$\mathrm{Br}(Z \to e^\pm\mu^\mp) < 2.62 \times 10^{-7}\,, \qquad \mathrm{Br}(Z \to e^\pm\tau^\mp) < 5.0 \times 10^{-6}\,, \qquad \mathrm{Br}(Z \to \mu^\pm\tau^\mp) < 6.5 \times 10^{-6}\,. \tag{32}$$

LHC is now testing LFV in Higgs decays, within the available statistics. From the current (95% C.L.) experimental upper bounds [89, 98–102],

$$\mathrm{Br}(H^0 \to e^\pm\mu^\mp) < 4.4 \times 10^{-5}\,, \qquad \mathrm{Br}(H^0 \to e^\pm\tau^\mp) < 0.20\%\,, \qquad \mathrm{Br}(H^0 \to \mu^\pm\tau^\mp) < 0.15\%\,, \tag{33}$$

one can derive direct limits on the LFV Yukawa couplings of the Higgs boson,

$$\mathcal{L}_Y = -H^0 \sum_{i \neq j} \left(Y_{\ell_i\ell_j}\, \bar{\ell}_L^i \ell_R^j + \mathrm{h.c.} \right)\,. \tag{34}$$

From $H^0 \to e^\pm\mu^\mp$, one obtains $\sqrt{Y_{\mu e}^2 + Y_{e\mu}^2} < 1.9 \times 10^{-4}$, which is not yet competitive with the indirect limit set by $\mu \to e\gamma$ through a (one-loop) virtual Higgs exchange:

$$\sqrt{Y_{\mu e}^2 + Y_{e\mu}^2} < 3.6 \times 10^{-6}\,. \tag{35}$$

However, the LHC data provide at present the strongest bounds on the LFV τ Yukawas [89, 101]:

$$\sqrt{Y_{e\tau}^2 + Y_{\tau e}^2} < 1.3 \times 10^{-3}\,, \qquad \sqrt{Y_{\mu\tau}^2 + Y_{\tau\mu}^2} < 1.11 \times 10^{-3}\,. \tag{36}$$

Figure 5 compares the Higgs exclusion limits on the τ Yukawas with the current indirect constraints from LFV τ decays.

6 Baryon and Lepton Number

The transitions discussed in the previous section preserve the total lepton number $L = L_e + L_\mu + L_\tau$. In the SM, conservation of $B - L$ is an accidental symmetry of the Lagrangian. At the classical level, $B + L$ is also conserved, though it is violated at the loop level by the anomaly. The latter is a topological effect that is highly suppressed at zero temperature and, moreover, does not contribute to the processes discussed in the review. Going beyond renormalizable interactions, there exists a tower of operators in the SMEFT Lagrangian (12), containing only SM fields, that break one or both of these symmetries. We briefly review these possibilities in turn.

Lepton Number

The lowest-dimension operator containing only SM fields that breaks baryon or lepton number is the $d = 5$, lepton-number-violating (LNV) 'Weinberg' neutrino-mass operator [65]:

$$\mathcal{L}^{\rm LNV} = \frac{y}{\Lambda}\, \bar{L}^C H H^T L\,. \tag{37}$$

When the neutral component of the Higgs field obtains its vacuum expectation value, this $\Delta L = 2$ interaction yields a Majorana mass for the light, active neutrinos. The most comprehensive approach for probing this effect is the search for neutrinoless double-beta decay ($0\nu\beta\beta$) of atomic nuclei, $(Z, A) \to (Z + 2, A) + e^- + e^-$ [103, 104] (see the review on neutrinoless double-β decay). The detection of a non-zero $0\nu\beta\beta$ signal could represent a spectacular evidence of Majorana neutrinos. The current best limit, $\tau_{1/2} > 1.07 \times 10^{26}$ yr, was obtained by the KamLAND-Zen experiment with ^{136}Xe [105].

Theoretically, the interaction (37) can arise from BSM interactions in the well-known see-saw mechanism for neutrino mass (for a review, see [106]). In this context, the conventional choice for the scale Λ is of order the GUT scale, yielding light neutrino masses of order eV and below when the couplings y are of order the charged elementary fermion Yukawa couplings. BSM theories may also give rise to LNV observables in other contexts. In these scenarios, if the LNV scale is of order 1 TeV, one may observe signatures of LNV not only in $0\nu\beta\beta$ but also in collider searches for final states containing same sign dileptons. Searches for same sign dileptons plus a di-jet pair at the LHC have placed constraints on TeV-scale LNV [107, 108] that in some cases complement those obtained from $0\nu\beta\beta$.

Stringent constraints on violations of L have been also set in $\mu^- \to e^+$ conversion in muonic atoms, the best limit being $\sigma(\mu^-\mathrm{Ti} \to e^+\mathrm{Ca})/\sigma(\mu^-\mathrm{Ti} \to \mathrm{all}) < 3.6 \times 10^{-11}$ [109], and at the flavor factories through L-violating decays of the τ lepton and K, D and B mesons. Some representative examples are $\mathrm{Br}(\tau^- \to e^+\pi^-\pi^-) < 2.0 \times 10^{-8}$ [110], $\mathrm{Br}(K^+ \to \pi^-\mu^+\mu^+) < 4.2 \times 10^{-11}$ [111], $\mathrm{Br}(D^+ \to \pi^-\mu^+\mu^+) < 1.4 \times 10^{-8}$ [112] and $\mathrm{Br}(B^- \to \pi^+\mu^-\mu^-) < 4.0 \times 10^{-9}$ (95% CL) [113]. All these $|\Delta L| = 2$ processes could be mediated by a massive Majorana neutrino. They provide useful bounds on the effective Majorana neutrino mass matrix $m_{\ell\ell'} \sim \sum_i U_{\ell i} U_{\ell' i} m_{\nu_i}$ [114], although not as strong as the $0\nu\beta\beta$ constraint on m_{ee}.

Baryon Number

Grand Unified Theories (GUTs) combine leptons and quarks in the same symmetry multiplets and, therefore, predict the violation of the baryon and lepton quantum numbers. Many experiments have searched for B-violating transitions, but no positive signal has been identified so far. Proton decay would be the most relevant violation of B, as it would imply the unstability of matter. The current lower bound on the proton lifetime is 9×10^{29} yr [115]. Stronger limits have been set for particular decay modes, such as $\tau(p \to e^+\pi^0) > 2.4 \times 10^{34}$ yr [116]. For a discussion of proton decay in the context of GUTs, see the review on Grand Unified Theories.

Another spectacular signal would be neutron-antineutron oscillations. Searches have been performed for quasi-free n–$\bar{n}$ oscillations and for $n\bar{n}$ annihilation products in a nucleus. The latter would arise when the $\bar{n}$ produced through oscillations annihilates with another neutron in the nuclear medium. The corresponding best limits, expressed in terms of the free and bound oscillation times, $\tau_{n\bar{n}}$ and τ_m, respectively, are:

$$\tau_{n\bar{n}} > 0.86 \times 10^8 \text{ s} \quad [117], \tag{38a}$$

$$\tau_m > 3.6 \times 10^{32} \text{ yr} \quad [118] \tag{38b}$$

From the latter, one may infer a bound $\tau_{n\bar{n}} > 4.7 \times 10^8$ s, as discussed below. See Ref. [119] for a recent review.

The theoretical interpretation of these bounds starts with an assumed, effective Hamiltonian for the free (anti-)neutron, $\mathcal{H}_{\rm eff}$ that contains a B-violating part, yielding matrix elements

$$\langle n|\mathcal{H}_{\rm eff}|n\rangle = \langle \bar{n}|\mathcal{H}_{\rm eff}|\bar{n}\rangle = m - i\frac{\lambda}{2}\,, \tag{39a}$$

$$\langle n|\mathcal{H}_{\rm eff}|\bar{n}\rangle = \langle \bar{n}|\mathcal{H}_{\rm eff}|n\rangle \equiv \delta m\,, \tag{39b}$$

where CPT is assumed to be conserved, the neutron lifetime $\tau_n = 1/\lambda$ and $\tau_{n\bar{n}} = 1/|\delta m|$. The rate for a neutron to oscillate into an antineutron after a time t is given by

$$\mathcal{P}_{n\bar{n}}(t) = \sin^2\left(\frac{t}{\tau_{n\bar{n}}}\right) e^{-\lambda t}\,. \tag{40}$$

For $t << \tau_n << \tau_{n\bar{n}}$, one has

$$\mathcal{P}_{n\bar{n}}(t) \to (t/\tau_{n\bar{n}})^2\,. \tag{41}$$

In realistic experiments, there exist effects, such as background magnetic fields, that split the energies of the neutron and antineutron. One must ensure that the observation time is sufficiently short so that these effects do not overwhelm the small B-violating term δm and that Eq. (40) applies.

In nuclei, the interactions of neutrons and antineutrons with the surrounding medium are sufficiently distinct that one must take the corresponding matter potentials into account. In particular, the matrix elements in Eq. (39a) become

$$\langle n|\mathcal{H}_{\rm eff}|n\rangle = m + V_n\,, \qquad \langle \bar{n}|\mathcal{H}_{\rm eff}|\bar{n}\rangle = m + V_{\bar{n}}\,, \tag{42}$$

with V_n being essentially real ($V_n \equiv V_{nR}$) and $V_{\bar{n}} = V_{\bar{n}R} - iV_{\bar{n}I}$. The imaginary part $V_{\bar{n}I}$ characterizes the annihilation of the antineutron with bound nucleons into secondary hadrons. The rate for a bound neutron to disappear is given by

$$\Gamma_m = \frac{2(\delta m)^2 |V_{\bar{n}I}|}{(V_{nR} - V_{\bar{n}R})^2 + V_{\bar{n}I}^2} \equiv \left(R\,\tau_{n\bar{n}}^2\right)^{-1}\,. \tag{43}$$

For the nuclei of experimental interest, nuclear theory computations yield $R \sim 10^{23} s^{-1}$. Null results of bound n-$\bar{n}$ oscillation searches thus allow one to infer a bound on $\tau_{n\bar{n}}$ via Eq. (43).

From an elementary particle standpoint, n-$\bar{n}$ oscillations involve the conversion of three quarks into three antiquarks (and vice-versa). The lowest-dimension operators mediating such process arise at dimension nine in the SMEFT:

$$\mathcal{L}_{n\text{-}\bar{n}} = \frac{1}{\Lambda^5} \sum_j \alpha_j^{(9)}\, \mathcal{O}_j^{\rm BNV}\,. \tag{44}$$

Consequently, one expects

$$\delta m \sim \alpha_j^{(9)}\, \frac{\Lambda_{\rm HAD}^6}{\Lambda^5}\,, \tag{45}$$

where $\Lambda_{\rm HAD}$ is a hadronic scale set by the n-$\bar{n}$ matrix elements in Eq. (39b). Taking $\Lambda_{\rm HAD}$ to be of order the QCD scale and using the present bounds on $\tau_{n\bar{n}}$ yields a lower bound on the B-violating mass scale of ~ 100 TeV.

The search for B-violating decays of short-lived particles such as Z bosons, τ leptons and B mesons provides also relevant constraints. The best limits are $\mathrm{Br}(Z \to pe, p\mu) < 1.8 \times 10^{-6}$ (95% C.L.) [120], $\mathrm{Br}(\tau^- \to \bar{p}\mu^-\mu^+) < 1.8 \times 10^{-8}$ [121] and $\mathrm{Br}(B^0 \to p\mu^-) < 2.6 \times 10^{-9}$ [122]

7 Quark flavors

While strong and electromagnetic forces preserve the quark flavor, the charged-current weak interactions generate transitions among the different quark species (see the review on the CKM quark-mixing matrix). Since the SM flavor-changing mechanism is associated with the $W^\pm$ fermionic vertices, the tree-level transitions satisfy a $\Delta F = \Delta Q$ rule where ΔQ denotes the change in charge of the relevant hadrons. Remember that the flavor quantum number F is defined to be $+1$ for positively charged quarks ($F = U, C, T$) and -1 for quarks with negative charges ($F = D, S, B$). The strongest tests on this conservation law have been obtained in kaon decays such as $\mathrm{Br}(K^+ \to \pi^+\pi^+e^-\bar{\nu}_e) < 1.3 \times 10^{-8}$ [123], and $(\mathrm{Re}\, x, \mathrm{Im}\, x) = (-0.002 \pm 0.006, 0.0012 \pm 0.0021)$ [124, 125] where $x \equiv \mathcal{M}(\overline{K}^0 \to \pi^-\ell^+\nu)/\mathcal{M}(K^0 \to \pi^-\ell^+\nu)$.

The $\Delta F = \Delta Q$ rule can be violated through quantum loop contributions giving rise to flavor-changing neutral-current transitions (FCNCs). Owing to the GIM mechanism, processes of this type are very suppressed in the SM, which makes them a superb tool in the search for new physics associated with the flavor dynamics. Within the SM itself, these transitions are also sensitive to the heavy-quark mass scales and have played a crucial role identifying the size of the charm (K^0–$\overline{K}^0$ mixing) and top (B^0–$\overline{B}^0$ mixing) masses before the discovery of those quarks. In addition to the well-established $\Delta F = 2$ mixings in neutral K and B mesons, $\Delta M_{K^0} \equiv M_{K^0_L} - M_{K^0_S} = (0.5293 \pm 0.0009) \times 10^{10}\ \mathrm{s}^{-1}$, $\Delta M_{B^0} \equiv M_{B^0_H} - M_{B^0_L} = (0.5069 \pm 0.0019) \times 10^{12}\ \mathrm{s}^{-1}$ and $\Delta M_{B^0_s} \equiv M_{B^0_{sH}} - M_{B^0_{sL}} = (17.765 \pm 0.006) \times 10^{12}\ \mathrm{s}^{-1}$, the mixing of the D^0 meson and its antiparticle has been recently observed with a significance of more than seven standard deviations [126], showing that there is a nonzero mass difference between the two neutral charm-meson eigenstates, of the expected size:

$$M_{D^0_H} - M_{D^0_L} = (0.997 \pm 0.116) \times 10^{10}\ \mathrm{s}^{-1}. \qquad (46)$$

The SM prediction of the D^0_H–D^0_L mass difference is dominated by long-distance physics, because it involves virtual loops with down-type light quarks, and has unfortunately quite large uncertainties [127].

The FCNC kaon decays into lepton-antilepton pairs put stringent constraints on new flavor-changing interactions. The measured $K^0_L \to \mu^+\mu^-$ rate, $\mathrm{Br}(K^0_L \to \mu^+\mu^-) = (6.84 \pm 0.11) \times 10^{-9}$, is completely dominated by the known 2γ absorptive contribution, leaving very little room for new-physics, and $\mathrm{Br}(K^0_L \to e^+e^-) = (9^{+6}_{-4}) \times 10^{-12}$ [128] (the tiniest branching ratio ever measured) also agrees with the SM expectation [129]. The experimental K^0_S upper bounds on the electron, $\mathrm{Br}(K^0_S \to e^+e^-) < 9 \times 10^{-9}$ [130], and muon, $\mathrm{Br}(K^0_S \to \mu^+\mu^-) < 2.1 \times 10^{-10}$ [131], modes are still five and two orders of magnitude, respectively, larger than their SM predictions [129]. Another very clean test of FCNCs is provided by the decay $K^+ \to \pi^+\nu\bar{\nu}$. The CERN NA62 experiment has already observed 20 signal candidates, providing the first evidence of this decay [132]. This leads to $\mathrm{Br}(K^+ \to \pi^+\nu\bar{\nu}) = (1.14^{+0.40}_{-0.33}) \times 10^{-10}$, in agreement with the predicted SM branching fraction of $(7.73 \pm 0.61) \times 10^{-11}$ [133, 134]. Even more interesting is the CP-violating neutral mode $K^0_L \to \pi^0\nu\bar{\nu}$, expected at a rate of $(2.59 \pm 0.29) \times 10^{-11}$ [133, 134] that is still far away from the current upper bound of 3.0×10^{-9} [135]. The KOTO experiment at KEK is expected to substantially increase the sensitivity to this mode.

The strongest bound on FCNC transitions in charm decays is $\mathrm{Br}(D^0 \to \mu^+\mu^-) < 3.1 \times 10^{-9}$ [136], while in B decays the LHC experiments have recently reached the SM sensitivity: $\mathrm{Br}(B^0_d \to \mu^+\mu^-) < 1.5 \times 10^{-10}$ [137] and $\mathrm{Br}(B^0_s \to \mu^+\mu^-) = (3.34 \pm 0.27) \times 10^{-9}$.

NOTES

In this Summary Table:

When a quantity has "(S = ...)" to its right, the error on the quantity has been enlarged by the "scale factor" S, defined as $S = \sqrt{\chi^2/(N-1)}$, where N is the number of measurements used in calculating the quantity. We do this when $S > 1$, which often indicates that the measurements are inconsistent. When $S > 1.25$, we also show in the Particle Listings an ideogram of the measurements. For more about S, see the Introduction.

[a] Forbidden by angular momentum conservation.

[b] C parity forbids this to occur as a single-photon process.

[c] See the Particle Listings for the (complicated) definition of this quantity.

[d] Time-reversal invariance requires this to be 0° or 180°.

[e] This coefficient is zero if time invariance is not violated.

[f] Allowed by higher-order electroweak interactions.

[g] Violates CP in leading order. Test of direct CP violation since the indirect CP-violating and CP-conserving contributions are expected to be suppressed.

[h] In the 2010 *Review*, the values for these quantities were given using a measure of the asymmetry that was inconsistent with the usual definition.

[i] $\mathrm{Re}(\epsilon'/\epsilon) = \epsilon'/\epsilon$ to a very good approximation provided the phases satisfy CPT invariance.

[j] This mode includes gammas from inner bremsstrahlung but not the direct emission mode $K_L^0 \to \pi^+\pi^-\gamma$(DE).

[k] Neglecting photon channels. See, *e.g.*, A. Pais and S.B. Treiman, Phys. Rev. **D12**, 2744 (1975).

[l] Derived from measured values of ϕ_{+-}, ϕ_{00}, $|\eta|$, $|m_{K_L^0} - m_{K_S^0}|$, and $\tau_{K_S^0}$, as described in the introduction to "Tests of Conservation Laws."

[n] The $|m_p - m_{\overline{p}}|/m_p$ and $|q_p + q_{\overline{p}}|/e$ are not independent, and both use the more precise measurement of $|q_{\overline{p}}/m_{\overline{p}}|/(q_p/m_p)$.

[o] The value is for the sum of the charge states or particle/antiparticle states indicated.

[p] A test of additive vs. multiplicative lepton family number conservation.

[q] Derived from an analysis of neutrino-oscillation experiments.

[r] There is some controversy about whether nuclear physics and model dependence complicate the analysis for bound neutrons (from which the best limit comes). The first limit here is from reactor experiments with free neutrons.

[s] This is the best limit for the mode $e^- \to \nu\gamma$.

[t] The limit is from neutrality-of-matter experiments; it assumes $q_n = q_p + q_e$. See also the charge of the neutron.

[u] See the K_S^0 Particle Listings for the energy limits used in this measurement.

[v] See the K_L^0 Particle Listings for the energy limits used in this measurement.

[x] An ℓ indicates an e or a μ mode, not a sum over these modes.

[y] Here S and P are the hypothetical scalar and pseudoscalar particles with masses of 2.5 GeV/c^2 and 214.3 MeV/c^2, respectively.

[z] This limit is for $\Gamma(t \to Zq)/\Gamma(t \to Wb)$.

REVIEWS, TABLES, AND PLOTS

Constants, Units, Atomic and Nuclear Properties

1. Physical Constants

Table 1.1: Revised 2024 by D. Robinson (LBNL) and P.A. Zyla (LBNL). Mainly from "CODATA Recommended Values of the Fundamental Physical Constants: 2018," E. Tiesinga, D.B. Newell, P.J. Mohr, and B.N. Taylor, NIST SP961 (May 2019) [1].[a] The electron charge magnitude e, and the Planck, Boltzmann, and Avogadro constants h, k, and N_A, now join c as having defined values; the free-space permittivity and permeability constants ϵ_0 and μ_0 are no longer exact. These changes affect practically everything else in the Table. Figures in parentheses after the values are the 1-standard-deviation uncertainties in the last digits; the fractional uncertainties in parts per 10^9 (ppb) are in the last column. The full 2018 CODATA Committee on Data for Science and Technology set of constants are found at `https://physics.nist.gov/cuu/Constants/archive2018.html`. The last set of constants (beginning with the Fermi coupling constant) comes from the Particle Data Group. See also "The International System of Units (SI)," 9th ed. (2019) of the International Bureau of Weights and Measures (BIPM), `https://www.bipm.org/utils/common/pdf/si-brochure/SI-Brochure-9-EN.pdf`.

[a] Updated values reflecting the "2022 CODATA recommended values", released online in May 2024, will be incorporated in future editions of the *Review*.

[§] CODATA recommends that the unit be J/Hz to stress that in $h = E/\nu$ the frequency ν is in cycles/sec (Hz), not radians/sec.

* These are calculated from exact values and are exact to the number of places given (*i.e.* no rounding).

** The molar mass of ^{12}C is 11.999 999 9958(36) g.

[†] CODATA recommended value at $Q^2 = 0$. At $Q^2 \approx m_W^2$ the value is $\sim 1/128$. A world average of the latest data yields $\alpha^{-1} = 137.035999178(8)$. [‡‡]

[‡] Absolute laboratory measurements of G_N have been made only on scales of about 1 cm to 1 m.

[‡‡] See the discussion in "Electroweak model and constraints on new physics" review.

[††] The corresponding $\sin^2\theta$ for the effective angle is $\bar{s}^2_\ell = 0.23161(4)$. The value for the collider average is $\bar{s}^2_\ell = 0.23149(13)$.

[¶] See the "Mass and width of the W boson" and "Electroweak model and constraints on new physics" reviews.

[‖] See the "Z boson" and "Electroweak model and constraints on new physics" reviews.

2. Astrophysical Constants and Parameters

Table 2.1: Revised August 2023 by D.E. Groom (LBNL) and D. Scott (U. of British Columbia). The figures in parentheses after some values give the 1-σ uncertainties in the last digit(s). Physical constants are from Ref. [1]. While every effort has been made to obtain the most accurate current values of the listed quantities, this table does not represent a critical review or adjustment of the constants, and is not intended as a primary reference. The values and uncertainties for the cosmological parameters depend on the exact data sets, priors, and basis parameters used in the fit. Many of the derived parameters reported in this table have non-Gaussian likelihoods and parameters may be highly correlated, so care must be taken in propagating errors. Unless otherwise specified, cosmological parameters are derived from a 6-parameter ΛCDM cosmology fit to *Planck* cosmic microwave background 2018 temperature (TT) + polarization (TE,EE+lowE) + lensing data [2]. For more information see [3] and the original papers.

Quantity	Symbol, equation	Value	Reference, footnote
Newtonian constant of gravitation	G_N	$6.674\,30(15) \times 10^{-11}\ \mathrm{m^3\,kg^{-1}\,s^{-2}}$	[1]
Planck mass	$M_P = \sqrt{\hbar c/G_N}$	$1.220\,890(14) \times 10^{19}\ \mathrm{GeV}/c^2 = 2.176\,434(24) \times 10^{-8}\ \mathrm{kg}$	[1]
Planck length	$l_P = \sqrt{\hbar G_N/c^3}$	$1.616\,255(18) \times 10^{-35}\ \mathrm{m}$	[1]
tropical year (equinox to equinox, 2020)	yr	$31\,556\,925.1\ \mathrm{s} = 365.242\,189\ \mathrm{days}$	[4]
sidereal year (period of Earth around Sun relative to stars)		$31\,558\,149.8\ \mathrm{s} \approx \pi \times 10^7\ \mathrm{s}$	[4]

[40] Planck Collab. Interm. Results XLVI, Astron. Astrophys. **596**, A107 (2016), [arXiv:1605.02985]; the range can be extended by $\Delta z \approx 1$, depending on the reionization model.

[41] Summary Tables in this *Review* list $N_\nu = 2.984(8)$ (Standard Model fits to LEP-SLC data). Because neutrinos are not completely decoupled at $e^\pm$ annihilation, the effective number of massless neutrino species is 3.044, rather than 3.

[42] J. Lesgourgues and L. Verde, "Neutrinos in Cosmology," Sec. 26 in this *Review*.

[43] The sum is over all neutrino mass eigenstates, the lower limit following from neutrino mixing results reported in this *Review* combined with the assumptions that there are three light neutrinos and that the lightest neutrino is substantially less massive than the others.

[44] Astrophysical determinations of Σm_ν, reported in the Full Listings of this *Review* under "Sum of the neutrino masses," range from < 0.17 eV to < 2.3 eV in papers published since 2003.

Table 4.1. Revised March 2024 by D.E. Groom (LBNL). The atomic number (top left) is the number of protons in the nucleus. The atomic masses (bottom) of stable elements are weighted by isotopic abundances in the Earth's surface. Atomic masses are relative to the mass of ^{12}C, defined to be exactly 12 unified atomic mass units (u). The exceptions are Th, Pa, and U, which have no stable isotopes but do have characteristic terrestrial compositions. Relative isotopic abundances often vary considerably, both in natural and commercial samples; this is reflected in the number of significant figures given for the mass. Masses may be found at `https://physics.nist.gov/cgi-bin/Compositions/stand_alone.pl`. If there is no stable isotope, the atomic mass of the most stable isotope known as of June 2019 is given in parentheses.

IUPAC announced verification of the discoveries of elements 113, 115, 117, and 118 in December 2015. The names were approved November 2016. The 7th period of the periodic table is now complete. Attempts to synthesize elements with $Z > 118$ are under way, but as of March 2024 no discoveries have been announced.

PERIODIC TABLE OF THE ELEMENTS

5. Electronic Structure of the Elements

Table 5.1: Reviewed 2022 by A. Kramida (NIST). The electronic configurations, ground state levels, and ionization energies are from A. Kramida, Yu. Ralchenko, J. Reader, and NIST ASD Team (2022), "NIST Atomic Spectra Database" (ver. 5.10), [Online], Available: `https://physics.nist.gov/asd` [2023, Sept 5]. National Institute of Standards and Technology, Gaithersburg, MD. DOI: `https://doi.org/10.18434/T4W30F`. The electron configuration for, say, iron indicates an argon electronic core (see argon) plus six $3d$ electrons and two $4s$ electrons.

		Element	Electron configuration ($3d^5$ = five $3d$ electrons, *etc.*)	Ground state $^{2S+1}L_J$	Ionization energy (eV)
1	H	Hydrogen	$1s$	$^2S_{1/2}$	13.5984
2	He	Helium	$1s^2$	$^1S_0$	24.5874
3	Li	Lithium	(He) 2s	$^2S_{1/2}$	5.3917
4	Be	Beryllium	(He) $2s^2$	$^1S_0$	9.3227
5	B	Boron	(He) $2s^2$ $2p$	$^2P^\circ_{1/2}$	8.2980
6	C	Carbon	(He) $2s^2$ $2p^2$	$^3P_0$	11.2603
7	N	Nitrogen	(He) $2s^2$ $2p^3$	$^4S^\circ_{3/2}$	14.5341
8	O	Oxygen	(He) $2s^2$ $2p^4$	$^3P_2$	13.6181
9	F	Fluorine	(He) $2s^2$ $2p^5$	$^2P^\circ_{3/2}$	17.4228
10	Ne	Neon	(He) $2s^2$ $2p^6$	$^1S_0$	21.5645
11	Na	Sodium	(Ne) 3s	$^2S_{1/2}$	5.1391
12	Mg	Magnesium	(Ne) $3s^2$	$^1S_0$	7.6462
13	Al	Aluminum	(Ne) $3s^2$ $3p$	$^2P^\circ_{1/2}$	5.9858
14	Si	Silicon	(Ne) $3s^2$ $3p^2$	$^3P_0$	8.1517

* The usual *LS* coupling scheme does not apply for these three elements.

See the introductory note to the NIST table at `https://www.nist.gov/pml/data/ion_energy.cfm`.

6. Atomic and Nuclear Properties of Materials

Table 6.1: Abridged from `https://pdg.lbl.gov/current/AtomicNuclearProperties` by D.E. Groom (2023). See web pages for more detail about entries in this table and for several hundred others. Parentheses in the dE/dx and density columns indicate gases at 20° C and 1 atm. Boiling points are at 1 atm. Refractive indices n are evaluated at the sodium D line blend (589.2 nm); values $\gg 1$ in brackets indicate $(n-1) \times 10^6$ for gases at 0° C and 1 atm.

Material	Z	A	$\langle Z/A \rangle$	Nucl.coll. length λ_T {g cm^{-2}}	Nucl.inter. length λ_I {g cm^{-2}}	Rad.len. X_0 {g cm^{-2}}	$dE/dx\|_{\rm min}$ {MeV g^{-1}cm^2}	Density {g cm^{-3}} ({g ℓ^{-1}})	Melting point (K)	Boiling point (K)	Refract. index @ Na D

7.1 Impedances (SI units)

ρ = resistivity at room temperature in $10^{-8}\,\Omega$ m:
~ 1.7 for Cu ~ 5.5 for W
~ 2.4 for Au ~ 73 for SS 304
~ 2.8 for Al ~ 100 for Nichrome
(Al alloys may have double the Al value.)

For alternating currents, instantaneous current I, voltage V, angular frequency ω:

$$V = V_0\, e^{j\omega t} = ZI\ . \tag{7.1}$$

Impedance of self-inductance L: $Z = j\omega L$.

Impedance of capacitance C: $Z = 1/j\omega C$.

Impedance of free space: $Z = \sqrt{\mu_0/\epsilon_0} = 376.7\ \Omega$.

High-frequency surface impedance of a good conductor:

$$Z = \frac{(1+j)\,\rho}{\delta}\ , \quad \text{where } \delta = \text{skin depth}\ ; \tag{7.2}$$

$$\delta = \sqrt{\frac{\rho}{\pi\nu\mu}} \approx \frac{6.6\text{ cm}}{\sqrt{\nu\,(\text{Hz})}} \quad \text{for Cu}\ . \tag{7.3}$$

7.2 Capacitors, inductors, and transmission Lines

The capacitance between two parallel plates of area A spaced by the distance d and enclosing a medium with the dielectric constant ε is

$$C = K\varepsilon A/d\,, \tag{7.4}$$

where the correction factor K depends on the extent of the fringing field. If the dielectric fills the capacitor volume without extending beyond the electrodes. The correction factor $K \approx 0.8$ for capacitors of typical geometry.

The inductance at high frequencies of a straight wire whose length ℓ is much greater than the wire diameter d is

$$L \approx 2.0\left[\frac{\text{nH}}{\text{cm}}\right]\cdot\ell\,\left(\ln\left(\frac{4\ell}{d}\right) - 1\right)\ . \tag{7.5}$$

For very short wires, representative of vias in a printed circuit board, the inductance is

$$L(\text{in nH}) \approx \ell/d\,. \tag{7.6}$$

A transmission line is a pair of conductors with inductance L and capacitance C. The characteristic impedance $Z = \sqrt{L/C}$ and the phase velocity $v_p = 1/\sqrt{LC} = 1/\sqrt{\mu\varepsilon}$, which decreases with the inverse square root of the dielectric constant of the medium. Typical coaxial and ribbon cables have a propagation delay of about 5 ns/cm.

The impedance of a coaxial cable with outer diameter D and inner diameter d is

$$Z = 60\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln \frac{D}{d}\,, \tag{7.7}$$

where the relative dielectric constant $\varepsilon_r = \varepsilon/\varepsilon_0$. A pair of parallel wires of diameter d and spacing $a > 2.5\,d$ has the impedance

$$Z = 120\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln \frac{2a}{d}\,. \tag{7.8}$$

This yields the impedance of a wire at a spacing h above a ground plane,

$$Z = 60\,\Omega \cdot \frac{1}{\sqrt{\varepsilon_r}} \ln \frac{4h}{d}\,. \tag{7.9}$$

A common configuration utilizes a thin rectangular conductor above a ground plane with an intermediate dielectric (microstrip). Detailed calculations for this and other transmission line configurations are given by Gunston [1].

7.3 Synchrotron radiation (CGS units)

For a particle of charge e, velocity $v = \beta c$, and energy $E = \gamma mc^2$, traveling in a circular orbit of radius R, the classical energy loss per revolution δE is

$$\delta E = \frac{4\pi}{3}\,\frac{e^2}{R}\,\beta^3\,\gamma^4\,. \tag{7.10}$$

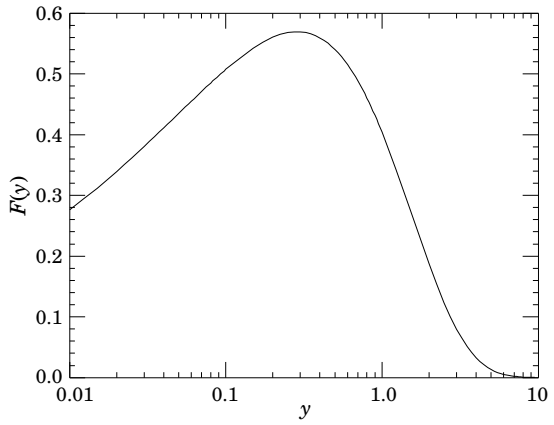

Figure 7.1: The normalized synchrotron radiation spectrum $F(y)$.

For high-energy electrons or positrons ($\beta \approx 1$), this becomes

$$\delta E\ (\text{in MeV}) \approx 0.0885\ [E(\text{in GeV})]^4/R(\text{in m})\,. \tag{7.11}$$

For $\gamma \gg 1$, the energy radiated per revolution into the photon energy interval $d(\hbar\omega)$ is

$$dI = \frac{8\pi}{9}\alpha\,\gamma\,F(\omega/\omega_c)\,d(\hbar\omega)\,, \tag{7.12}$$

where $\alpha = e^2/\hbar c$ is the fine-structure constant and

$$\omega_c = \frac{3\gamma^3 c}{2R} \tag{7.13}$$

is the critical frequency. The normalized function $F(y)$ is

$$F(y) = \frac{9}{8\pi}\sqrt{3}\,y\int_y^\infty K_{5/3}\,(x)\ \,dx\,, \tag{7.14}$$

where $K_{5/3}\,(x)$ is a modified Bessel function of the third kind. For electrons or positrons,

$$\hbar\omega_c\,(\text{in keV}) \approx 2.22\ [E(\text{in GeV})]^3/R(\text{in m})\,. \tag{7.15}$$

For $\gamma \gg 1$ and $\omega \ll \omega_c$,

$$\frac{dI}{d(\hbar\omega)} \approx 3.3\alpha\,(\omega R/c)^{1/3}\ \,, \tag{7.16}$$

whereas for

$$\gamma \gg 1 \text{ and } \omega \gtrsim 3\omega_c\,,$$

$$\frac{dI}{d(\hbar\omega)} \approx \sqrt{\frac{3\pi}{2}}\,\alpha\,\gamma\left(\frac{\omega}{\omega_c}\right)^{1/2} e^{-\omega/\omega_c}\left[1 + \frac{55}{72}\frac{\omega_c}{\omega} + \ldots\right]\,. \tag{7.17}$$

The radiation is confined to angles $\lesssim 1/\gamma$ relative to the instantaneous direction of motion. For $\gamma \gg 1$, where Eq. (7.12) applies, the mean number of photons emitted per revolution is

$$N_\gamma = \frac{5\pi}{\sqrt{3}}\alpha\gamma\,, \tag{7.18}$$

and the mean energy per photon is

$$\langle\hbar\omega\rangle = \frac{8}{15\sqrt{3}}\hbar\omega_c\,. \tag{7.19}$$

When $\langle\hbar\omega\rangle \gtrsim \mathrm{O}(E)$, quantum corrections are important [2].[1]

8. Naming Scheme for Hadrons

Revised August 2023 by C. Amsler (Stefan Meyer Inst.), E. Pianori (LBNL), D.J. Robinson (LBNL) and R.L. Workman (George Washington U.).

In the 1986 edition [1], the Particle Data Group introduced an extended and systematized naming scheme for mesons and baryons. The extensions were necessary in order to name the new particles containing c or b quarks that were then rapidly being discovered. The 1986 naming scheme has been retained in all subsequent editions, including this one. However, a number of particles were since discovered that could not be accommodated in the 1986 scheme. These include, for example the meson state originally named $Z_c(3900)^+$ (now $T_{c\bar{c}1}(3900)^+$) containing $c\bar{c}$ but with isospin $I = 1$ [2,3]. Because of such discoveries, in the 2017 edition [4] the 1986 naming scheme was extended to cover $c\bar{c}$ and $b\bar{b}$ states with $I = 1$, including the Z_c and Z_b states.

The further discovery of various exotic hadron states—including in particular tetraquarks and pentaquarks containing $qq\bar{q}\bar{q}$ and $q\bar{q}qqq$ minimal quark content, respectively—has rendered the 2017 extension insufficient. These include, for example: the meson state $T_{cc}(3875)^+$ containing two charm quarks and with unknown isospin [5]; and the baryon state originally named $P_c(4312)^+$ (now $P_{c\bar{c}}(4312)^+$) containing minimal quark content $c\bar{c}uud$ [6]. In this edition, the 2017 scheme is revised and extended to cover all experimentally known states.

The naming scheme as a whole provides a name for each hadron, driven primarily by consideration of its quantum numbers, its minimal quark content—the smallest combination of quarks required to produce a color singlet with the required isospin, parities, strangeness, and open or hidden-heavy flavor—and its mass. While much of the naming scheme has been developed within the context of the naive quark model, a hadron name does *not* designate the internal structure of a state per se: we make no attempt, for example, to distinguish meson states that are "mostly gluonium" from those that are "mostly $q\bar{q}$." (Other reviews within the RPP discuss our current understanding of the nature of various hadron states). While the naming scheme conventions aim to be comprehensive, exceptions to the scheme are occasionally made for historical reasons (e.g. J/ψ, p, or n) or in cases where the spectroscopic identity of a state is considered established (e.g. $\Upsilon(1S)$). Note also the mass label used in particle names is chosen using the best information available when a name is assigned. A more accurate value of a particle mass may become available at a later time. PDG decides on a case-by-case basis whether to revise the mass label, taking into account the updated information.

8.1 Light unflavored, $c\bar{c}$, and $b\bar{b}$ mesons

Unflavored mesons—also referred to as "neutral-flavor" mesons—have zero strangeness and all heavy-flavor quantum numbers are equal to zero. Their minimal quark content is denoted $q\bar{q}$, with the understanding that for $q = u$ or d, such states may carry unit isospin: the "light unflavored" nomenclature is understood to encompass all states furnishing an isospin-1 multiplet that contains a $q\bar{q}$ neutral meson. Mesons composed of $c\bar{c}$ or $b\bar{b}$ are said to have hidden-heavy flavor.

Within the naive quark model, a neutral $q\bar{q}$ bound state has quantum numbers $P = (-1)^{L+1}$ and $C = (-1)^{L+S}$, where $S(= 0, 1)$ and L are the spin and orbital angular momentum of the $q\bar{q}$ system, respectively. The total angular momentum J satisfies $|L-S| \leq J \leq L+S$ as usual. There is thus a selection rule between the angular-momentum state $^{2S+1}L_J$ and the PC configuration, such that

$$PC = -+, \quad +-, \quad --, \quad ++, \tag{8.1}$$

corresponds to

$$^{2S+1}L_J = {}^1(L \text{ even})_L\,, \quad {}^1(L \text{ odd})_L\,, \quad {}^3(L \text{ even})_{|L-1|\leq J\leq L+1}\,, \quad {}^3(L \text{ odd})_{L-1,L,L+1}\,. \tag{8.2}$$

Table 8.1 describes the naming scheme for unflavored mesons. The scheme is categorized by isospin and hidden-heavy flavor (rows) and parity/charge-conjugation configurations (columns); the first few allowed J^{PC} combinations for each column are shown in the header. Note C-parity is only well-defined for neutral unflavored mesons; the states furnishing an isospin-1 multiplet instead have a well-defined G-parity= $(-1)^{L+S+I}$; see the review on the quark model. The angular momentum J is included as a subscript to the base symbol for most unflavored mesons, but is omitted for various pseudoscalar, vector, and axial vector mesons whenever disambiguation by the J subscript is deemed superfluous. The mass is added in parentheses for mesons that decay strongly. However, for some of the familiar mesons (e.g. η', ϕ, ω), we omit the mass.

For light unflavored mesons—i.e. those unflavored mesons formed from u, d, and s quarks—there can be two isospin-0 mesons: a prime is used to distinguish one from the other (e.g. η and η'), with the exception that vector mesons comprised of $u\bar{u} + d\bar{d}$ and $s\bar{s}$ (ideal mixing) are labeled ω and ϕ, respectively. As usual, we assign the spectroscopic name (e.g. $\Upsilon(1S)$) as the primary name to most of those ψ, Υ, and χ states whose spectroscopic identity is known. We use the form $\Upsilon(9460)$ as an alternative, and as the primary name when the spectroscopic identity is not known.

Determination of the quark content (where relevant) and the quantum numbers I, J, P, and C (or G) of an unflavored meson thus determine its symbol. For example, the light unflavored isospin-1 2^{--} meson would be the ρ_2. Conversely, these properties may be inferred unambiguously from the symbol. The name X is used for states with still unknown quantum numbers. In some cases names are assigned when quantum numbers have not been strictly measured but have instead been inferred from a broader context. These cases typically include an explanation in the header, such as "Quantum numbers shown are quark-model predictions." One example is the $\psi_2(3823)$, for which the $I^G(J^{PC}) = 0^-(2^{--})$ assignment needs confirmation. Since the top quark is so heavy that it decays too rapidly to form bound states, no name is assigned to structures like $t\bar{t}$.

The selection rules in Eq. (8.2) impose restrictions on the J^{PC} quantum numbers that are allowed for $q\bar{q}$ states. These do not apply to more complicated structures such as tetraquarks, hybrid mesons, or glueballs. In particular, unflavored mesons with quantum numbers $J^{PC} = 0^{--}$, 0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, ... cannot

Table 8.1: Base symbols for unflavored mesons (zero strangeness and heavy-flavor quantum numbers equal to zero). Each base symbol is uniquely determined by the isospin/hidden-heavy flavor and PC configuration.

$J^{PC} = \left\{ \begin{array}{cccc} 0^{-+} & 1^{+-} & 1^{--} & 0^{++} \\ 2^{-+} & 3^{+-} & 2^{--} & 1^{++} \\ \vdots & \vdots & \vdots & \vdots \end{array} \right.$				
Minimal quark content				
$u\bar{d}, u\bar{u} - d\bar{d}, d\bar{u}$ $(I = 1)$	π	b	ρ	a
$d\bar{d} + u\bar{u}$, $s\bar{s}$ and/or gluons $(I = 0)$	η,η'	h,h'	ω,ϕ	f,f'
$c\bar{c}$ $(I = 0)$	η_c	h_c	ψ *	χ_c
$b\bar{b}$ $(I = 0)$	η_b	h_b	Υ	χ_b

*With the exception of the J/ψ.

be $q\bar{q}$ bound states, but might be glueballs or $q\bar{q}g$ etc. (This is distinct from light unflavored mesons with $I \geq 2$ or hidden-heavy flavor mesons with $I \geq 1$, which could be interpreted as tetraquarks). For such a "manifestly exotic" unflavored meson, the naming scheme nonetheless assigns the same base symbol as solely determined by the isospin/hidden-heavy flavor and PC in Tab. 8.1. For example, an isospin-0 light unflavored 1^{-+} meson would be denoted η_1 while an isospin-1 0^{--} light unflavored meson would be denoted ρ_0. The exotic nature of the meson can be inferred from its PC quantum numbers—given by the symbol—and the spin J—given by the subscript.

8.2 Remarks on "neutral-flavor" mesons with hidden charm or bottom not classified as $q\bar{q}$

In the heavy-quark sector, there are several states with properties – such as masses, decay patterns, and widths – that are in disagreement with predictions from the naive quark model. For example, the vector state at 4230 MeV (the $\psi(4230)$) apparently does not decay into $D\overline{D}$, although within the naive quark model its quantum numbers would call for this decay channel to be dominant. These states were originally named X, Y, or Z, with their masses added in parentheses. This nomenclature differs from the conventions outlined in the previous section, since the meson names are not related to their quantum numbers. However, these states have properties in conflict with the naive quark model and therefore deserve some special labeling.

Since their original discovery, the properties of some of these states have become better understood and it has become possible to include them in the Listings as well as Summary Tables using the name assigned according to this review. The X-, Y-, or Z-based names used at the time of the discovery are also reported in the Listings and Summary Tables from the 2018 edition onwards as a sub-header (listed are only some examples of the particles that appear in the Summary Tables),

- the state originally named $X(3872)$ appears as '$\chi_{c1}(3872)$ also known as $X(3872)$';
- the state originally named $Z_c(3900)$ appears[1] as '$T_{c\bar{c}1}(3900)$ also known as $Z_c(3900)$';
- the state originally named $Y(4260)$ appears[2] as '$\psi(4230)$ also known as $Y(4230)$';

In addition, states with quantum numbers allowed by the naive quark model but showing some peculiarities, such as an unusual decay pattern, will have the following information in the header:

> This state shows properties different from a conventional $q\bar{q}$ state. A candidate for an exotic structure. See the review on ⟨name of the proper review⟩.

8.3 Mesons with nonzero S, C and/or B

Mesons with nonzero strangeness S or heavy flavor C and/or B are not eigenstates of charge conjugation, and in each of them one of the quarks is heavier than the other (as above, states containing top quarks are not considered). The rules have been and remain:

1. The main symbol is an upper-case italic letter indicating the heavier quark as follows:

   $$s \to \overline{K} \qquad c \to D \qquad b \to \overline{B},$$

   We use the convention that *the flavor quantum number and the charge of a quark have the same sign.* Thus the strangeness of the s quark is negative, the charm of the c quark is positive, and the bottomness of the b quark is negative. The effect of this convention is as follows: *any flavor carried by a charged meson has the same sign as its charge.* Thus the K^+, D^+, and B^+ have positive strangeness, charm, and bottomness, respectively, and all have positive I_3. The D_s^+ has positive charm *and* strangeness. Furthermore, the $\Delta(\text{flavor}) = \Delta Q$ rule, best known for the strange kaons, applies to every flavor.
2. If the lighter quark is not a u or a d quark, its identity is given by a subscript. The D_s^+ is an example.
3. When the spin-parity is in the natural series, $J^P = 0^+, 1^-, 2^+, \cdots$, a superscript "$*$" is added.
4. The spin is added as a subscript except for pseudoscalar or vector mesons.

8.4 Baryons with ordinary quantum numbers

All baryons having quantum numbers consistent with a minimal quark content of three quarks are denoted by the symbols N, Δ, Λ, Σ, Ξ, and Ω introduced more than 50 years ago. These symbols are followed by J^P signifying their spin J and parity P. For those where the minimal content involves one or more heavier quarks than the light (u, d, and s) quarks, subscripts are added to their symbols, (c and b) as appropriate. The rules are:

1. Baryons with minimal content of *three* u and/or d quarks are N's (isospin 1/2) or Δ's (isospin 3/2).
2. Baryons with *two* u and/or d quarks are Λ's (isospin 0) or Σ's (isospin 1). If the third quark is a c or b quark, its identity is given by a subscript.
3. Baryons with *one* u or d quark are Ξ's (isospin 1/2). One or two subscripts are used if one or both of the remaining quarks are heavy: thus Ξ_c, Ξ_{cc}, Ξ_b, etc.[3]
4. Baryons with *no* u or d quarks are Ω's (isospin 0), and subscripts indicate any heavy-quark content.
5. A baryon that decays strongly has its mass in parentheses. Examples are the $\Delta(1232)$ $3/2^+$, $\Sigma(1385)$ $3/2^+$, $N(1440)$ $1/2^+$, $\Xi_c(2645)$ $3/2^+$.
6. If individual states of isospin multiplets are addressed, the electric charge is specified as a superscript. The electric charge is not necessary for isospin-0 states (Λ and Ω), as there is no ambiguity, but may still be included.
7. Antibaryons are labeled by an overline (bar) on the base symbol. For example, $\bar{p}$ for the antiproton, or $\overline{\Lambda}_c^-$ for the antiparticle of Λ_c^+. Alternatively, particle and antiparticle can be distinguished by including only a charge-label superscript, so long as the flavor structure of the baryon is defined solely by the base symbol (and subscripts). Thus one may also write Λ_c^- or p^- for the antiparticles of the Λ_c^+ and p^+, but the Σ^- is not the antiparticle of Σ^+, which is called $\bar{\Sigma}^-$.

In short, the minimal number of u plus d quarks together with the isospin determine the main symbol, and subscripts indicate any content of heavy quarks. A Σ always has isospin 1, an Ω always has isospin 0, etc.

8.5 Hadrons with a minimal quark content of $qq\bar{q}\bar{q}$ or $q\bar{q}qq$

The naming scheme described above does not accommodate various $qq\bar{q}\bar{q}$ mesons and $q\bar{q}qq$ baryons. In such cases, the 1986 naming scheme must be extended. Following discussion initiated by the proposal made by the LHCb collaboration [7], we adopt the notation

$$T^{(*)}_{\text{quarks}J}(\text{mass})^q \qquad \text{for tetraquarks,} \tag{8.3a}$$

$$P_{\text{quarks}}(\text{mass})^q\ J^P \qquad \text{for pentaquarks,} \tag{8.3b}$$

according to the following rules:

1. The basename T or P is chosen in cases where the minimal quark content of a state is $qq\bar{q}\bar{q}$ (tetraquark) or $q\bar{q}qq$ (pentaquark), respectively.
2. The bottom, charm, and strange quark content (b, $\bar{b}$, c, $\bar{c}$, s, $\bar{s}$) is explicitly listed as a subscript, in order from the heaviest quarks and antiquarks to the lightest and listing quarks before antiquarks. The hidden-flavor $c\bar{c}$ and $b\bar{b}$ combinations

[1] The name $T_{c\bar{c}1}(3900)$ derives from the scheme outlined in a later section.

[2] This is one example where the mass label needed to be shifted given improved experimental information.

[3] See the "Charmed and Bottom Baryons" section of the "Quark Model" review.

Table 8.2: Names used from the 2024 edition onward compared to those in the 2022 edition. Whenever the C-parity of a charged tetraquark is specified in the Particle Listings, it refers to the C-parity of the prospective/observed neutral isospin partner. Only one member per isospin multiplet is shown (see the Listings for more information).

2024 Name	minimal quark content	$I^{(G)}(J^{P(C)})$	2022 Name	2024 Name	minimal quark content	$I^{(G)}(J^{P(C)})$	2022 Name

$T_{c\bar{c}}(4055)^+$	$c\bar{c}u\bar{d}$	$1^+(?^{?-})$	$X(4055)^+$	$P_{c\bar{c}}(4312)^+$	$c\bar{c}uud$	$1/2(?^?)$	$P_c(4312)^+$
$T_{c\bar{c}}(4100)^+$	$c\bar{c}u\bar{d}$	$1^-(?^{?+})$	$X(4100)^+$	$P_{c\bar{c}}(4380)^+$	$c\bar{c}uud$	$1/2(?^?)$	$P_c(4380)^+$
$T_{c\bar{c}1}(4200)^+$	$c\bar{c}u\bar{d}$	$1^+(1^{+-})$	$Z_c(4200)^+$	$P_{c\bar{c}}(4440)^+$	$c\bar{c}uud$	$1/2(?^?)$	$P_c(4440)^+$
$T_{c\bar{c}0}(4240)^+$	$c\bar{c}u\bar{d}$	$1^+(0^{--})$	$R_{c0}(4240)^+$	$P_{c\bar{c}}(4457)^+$	$c\bar{c}uud$	$1/2(?^?)$	$P_c(4457)^+$
$T_{c\bar{c}}(4250)^+$	$c\bar{c}u\bar{d}$	$1^-(?^{?+})$	$X(4250)^+$	$P_{c\bar{c}s}(4459)^0$	$c\bar{c}uds$	$0(?^?)$	

are listed explicitly when their presence can be inferred from production or decay patterns.

3. The approximate mass of a state, in MeV/c^2, is given in parentheses.
4. The electric charge (q) can be specified as a superscript after the mass, for example when referring to a specific member of an isospin multiplet.
5. Antibaryons are marked with an overline ($\overline{P}$). The antiparticle of a meson can be specified either with an overline or by the quark content label (e.g. the charge conjugate of $T_{cc}(3875)^+$ is $\overline{T}_{cc}(3875)^-$, which is equivalent to $T_{\bar{c}\bar{c}}(3875)^-$).
6. For pentaquarks, as in the case of ordinary baryons, when known the spin-parity, J^P, of the state is included as a suffix.
7. For tetraquarks, similarly to the naming scheme for mesons, the spin J is appended as a subscript after the quark content. When the spin-parity is in the natural series, $J^P = 0^+, 1^-, 2^+, \cdots$, a superscript "*" is added.

Table 8.2 summarizes PDG name changes with respect to the 2022 edition [8]. We acknowledge that experiments might choose to add $I^{(G)}J^{P(C)}$ information to hadron names using experiment-specific conventions that differ from the one utilized by the PDG.

Standard Model and Related Topics

9. Quantum Chromodynamics

Revised August 2023 by J. Huston (Michigan State U.), K. Rabbertz (KIT) and G. Zanderighi (MPP, Garching; München Tech. U.).

9.1 Basics

Quantum Chromodynamics (QCD), the gauge field theory that describes the strong interactions of colored quarks and gluons, is the SU(3) component of the SU(3)×SU(2)×U(1) Standard Model of Particle Physics. The Lagrangian of QCD is given by

$$\mathcal{L} = \sum_q \bar{\psi}_{q,a}(i\gamma^\mu \partial_\mu \delta_{ab} - g_s \gamma^\mu t^C_{ab} \mathcal{A}^C_\mu - m_q \delta_{ab})\psi_{q,b} - \frac{1}{4} F^A_{\mu\nu} F^{A\,\mu\nu}\,, \tag{9.1}$$

where repeated indices are summed over. The γ^μ are the Dirac γ-matrices. The $\psi_{q,a}$ are quark-field spinors for a quark of flavor q and mass m_q, with a color-index a that runs from $a = 1$ to $N_c = 3$, *i.e.* quarks come in three "colors." Quarks are said to be in the fundamental representation of the SU(3) color group.

The $\mathcal{A}^C_\mu$ correspond to the gluon fields, with C running from 1 to $N_c^2 - 1 = 8$, *i.e.* there are eight kinds of gluon. Gluons transform under the adjoint representation of the SU(3) color group. The t^C_{ab} correspond to eight 3×3 matrices and are the generators of the SU(3) group (*cf.* the section on "SU(3) isoscalar factors and representation matrices" in this *Review*, with $t^C_{ab} \equiv \lambda^C_{ab}/2$). They encode the fact that a gluon's interaction with a quark rotates the quark's color in SU(3) space. The quantity g_s (or $\alpha_s = \frac{g_s^2}{4\pi}$) is the QCD coupling constant. Besides quark masses, which have electroweak origin, it is the only fundamental parameter of QCD. Finally, the field tensor $F^A_{\mu\nu}$ is given by

$$\begin{aligned} F^A_{\mu\nu} &= \partial_\mu \mathcal{A}^A_\nu - \partial_\nu \mathcal{A}^A_\mu - g_s\, f_{ABC} \mathcal{A}^B_\mu \mathcal{A}^C_\nu\,, \\ [t^A, t^B] &= i f_{ABC} t^C\,, \end{aligned} \tag{9.2}$$

where the f_{ABC} are the structure constants of the SU(3) group.

Neither quarks nor gluons are observed as free particles. Hadrons are color-singlet (*i.e.* color-neutral) combinations of quarks, anti-quarks, and gluons.

Ab-initio predictive methods for QCD include lattice gauge theory and perturbative expansions in the coupling. The Feynman rules of QCD involve a quark-antiquark-gluon ($q\bar{q}g$) vertex, a 3-gluon vertex (both proportional to g_s), and a 4-gluon vertex (proportional to g_s^2). A full set of Feynman rules is to be found for example in Refs. [1, 2].

Adopting a standard notation where repeated indices are summed over, useful color-algebra relations include: $t^A_{ab} t^A_{bc} = C_F \delta_{ac}$, where $C_F \equiv (N_c^2 - 1)/(2N_c) = 4/3$ is the color factor ("Casimir") associated with gluon emission from a quark; $f_{ACD} f_{BCD} = C_A \delta_{AB}$, where $C_A \equiv N_c = 3$ is the color factor associated with gluon emission from a gluon; $t^A_{ab} t^B_{ab} = T_R \delta_{AB}$, where $T_R = 1/2$ is the color factor for a gluon to split to a $q\bar{q}$ pair.

There is freedom for an additional CP-violating term to be present in the QCD Lagrangian, $\theta \frac{\alpha_s}{8\pi} F^{A\,\mu\nu} \tilde{F}^A_{\mu\nu}$, where θ is an additional free parameter, and $\tilde{F}^A_{\mu\nu}$ is the dual of the gluon field tensor, $\frac{1}{2}\epsilon_{\mu\nu\sigma\rho} F^{A\,\sigma\rho}$, with $\epsilon_{\mu\nu\sigma\rho}$ being the fully antisymmetric Levi-Civita symbol. Experimental limits on the electric dipole moment (EDM) of ultracold neutrons [3,4] and atomic mercury [5] constrain the QCD vacuum angle to satisfy $|\theta| \lesssim 10^{-10}$. For an overview of current and future experiments measuring EDMs see [6]. Further discussion is to be found in Ref. [7] and in the Axions section in the Listings of this *Review*.

This section will concentrate mainly on perturbative aspects of QCD as they relate to collider physics. Related textbooks and lecture notes include Refs. [1, 2, 8–11]. Aspects specific to Monte Carlo event generators are reviewed in the dedicated section 43. Lattice QCD is also reviewed in a section of its own, Sec. 17, with further discussion of perturbative and non-perturbative aspects to be found in the sections on "Quark Masses", "The CKM quark-mixing matrix", "Structure functions", "Fragmentation Functions", "High Energy Soft QCD and Diffraction", "Passage of Particles Through Matter" and "Heavy-Quark and Soft-Collinear Effective Theory" in this *Review*.

9.1.1 *Running coupling*

In the framework of perturbative QCD (pQCD), predictions for observables are expressed in terms of the renormalized coupling $\alpha_s(\mu_R^2)$, a function of an (unphysical) renormalization scale μ_R. When one takes μ_R close to the scale of the momentum transfer Q in a given process, then $\alpha_s(\mu_R^2 \simeq Q^2)$ is indicative of the effective strength of the strong interaction in that process.

The coupling satisfies the following renormalization group equation (RGE):

$$\mu_R^2 \frac{d\alpha_s}{d\mu_R^2} = \beta(\alpha_s) = -(b_0 \alpha_s^2 + b_1 \alpha_s^3 + b_2 \alpha_s^4 + \cdots)\,, \tag{9.3}$$

where $b_0 = (11C_A - 4n_f T_R)/(12\pi) = (33 - 2n_f)/(12\pi)$ is referred to as the 1-loop β-function coefficient, the 2-loop coefficient is $b_1 = (17C_A^2 - n_f T_R(10C_A + 6C_F))/(24\pi^2) = (153 - 19n_f)/(24\pi^2)$, and the 3-loop coefficient is $b_2 = (2857 - \frac{5033}{9} n_f + \frac{325}{27} n_f^2)/(128\pi^3)$ for the SU(3) values of C_A and C_F. Here n_f is the number of quark flavors. The 4-loop coefficient, b_3, is to be found in Refs. [12, 13], while the 5-loop coefficient, b_4, is in Refs. [14–18]. The coefficients b_2 and b_3 (and beyond) are renormalization-scheme-dependent and given here in the modified minimal subtraction scheme ($\overline{\rm MS}$) [19], by far the most widely used scheme in QCD and the one adopted in the following.

The minus sign in Eq. (9.3) is the origin of "asymptotic freedom" [20, 21], *i.e.* the fact that the strong coupling becomes weak for processes involving large momentum transfers ("hard processes"). For momentum transfers in the 0.1–1 TeV range, $\alpha_s \sim 0.1$, while the theory is strongly interacting for scales around and below 1 GeV.

The β-function coefficients, the b_i, are given for the coupling of an *effective theory* in which n_f of the quark flavors are considered light ($m_q \ll \mu_R$), and in which the remaining heavier quark flavors decouple from the theory. One may relate the coupling for the theory with $n_f + 1$ light flavors to that with n_f flavors through an equation of the form

$$\begin{aligned} \alpha_s^{(n_f+1)}(\mu_R^2) =& \alpha_s^{(n_f)}(\mu_R^2) \times \\ & \times \left(1 + \sum_{n=1}^{\infty} \sum_{\ell=0}^{n} c_{n\ell} \left[\alpha_s^{(n_f)}(\mu_R^2)\right]^n \ln^\ell \frac{\mu_R^2}{m_h^2}\right)\,, \end{aligned} \tag{9.4}$$

where m_h is the mass of the $(n_f+1)^{\rm th}$ flavor, and the first few $c_{n\ell}$ coefficients are $c_{11} = \frac{1}{6\pi}$, $c_{10} = 0$, $c_{22} = c_{11}^2$, $c_{21} = \frac{11}{24\pi^2}$, and $c_{20} = -\frac{11}{72\pi^2}$ when m_h is the $\overline{\rm MS}$ mass at scale m_h, while

$c_{20} = \frac{7}{24\pi^2}$ when m_h is the pole mass (mass definitions are discussed below in Sec. (9.1.2) and in the review on "Quark Masses"). Terms up to $c_{4\ell}$ with $0 \le \ell \le 4$ are to be found in Refs. [22, 23]. Numerically, when one chooses $\mu_R = m_h$, the matching is a modest effect, owing to the zero value for the c_{10} coefficient. Relations between n_f and (n_f+2) flavors where the two heavy flavors are close in mass are given to three loops in Ref. [24].

Working in an energy range where the number of flavors is taken constant, a simple exact analytic solution exists for Eq. (9.3) only if one neglects all but the b_0 term, giving $\alpha_s(\mu_R^2) = (b_0 \ln(\mu_R^2/\Lambda^2))^{-1}$. Here Λ is a constant of integration, which corresponds to the scale where the perturbatively-defined coupling would diverge. Its value is indicative of the energy range where non-perturbative dynamics dominates. A convenient approximate analytic solution to the RGE that includes terms up to b_4 is given by solving iteratively Eq. (9.3)

$$\alpha_s(\mu_R^2) \simeq \frac{1}{b_0 t}\left(1 - \frac{b_1}{b_0^2}\frac{\ell}{t} + \frac{b_1^2(\ell^2-\ell-1)+b_0 b_2}{b_0^4 t^2} + \right.$$
$$+ \frac{b_1^3\left(-2\ell^3+5\ell^2+4\ell-1\right) - 6b_0 b_2 b_1 \ell + b_0^2 b_3}{2b_0^6 t^3} +$$
$$+ \frac{18 b_0 b_2 b_1^2\left(2\ell^2-\ell-1\right) + b_1^4\left(6\ell^4-26\ell^3-9\ell^2+24\ell+7\right)}{6b_0^8 t^4}$$
$$\left. + \frac{-b_0^2 b_3 b_1(12\ell+1) + 2b_0^2\left(5b_2^2+b_0 b_4\right)}{6b_0^8 t^4}\right), \qquad (9.5)$$

with $t \equiv \ln\frac{\mu_R^2}{\Lambda^2}$ and $\ell = \ln t$, again parameterized in terms of a constant Λ. Note that Eq. (9.5) is one of several possible approximate 4-loop solutions for $\alpha_s(\mu_R^2)$, and that a value for Λ only defines $\alpha_s(\mu_R^2)$ once one knows which particular approximation is being used. An alternative to the use of formulas such as Eq. (9.5) is to solve the RGE exactly, numerically (including the discontinuities, Eq. (9.4), at flavor thresholds). In such cases the quantity Λ does not directly arise (though it can be defined, *cf.* Eqs. (1–3) of Ref. [25]). For these reasons, in determinations of the coupling, it has become standard practice to quote the value of α_s at a given scale (typically the mass of the Z boson, m_Z) rather than to quote a value for Λ.

A discussion of determinations of the coupling and a graph illustrating its scale dependence ("running") are to be found in Section 9.4.

9.1.2 *Quark masses*

Free quarks have never been observed, which is understood as a result of a long-distance, confining property of the strong QCD force: up, down, strange, charm, and bottom quarks all *hadronize*, *i.e.* become part of a meson or baryon, on a timescale $\sim 1/\Lambda$; the top quark instead decays before it has time to hadronize. This means that the question of what one means by the quark mass is a complex one, which requires one to adopt a specific prescription. A perturbatively defined prescription is the pole mass, m_q, which corresponds to the position of the divergence of the quark propagator. This is close to one's physical picture of mass. However, when relating it to observable quantities, it suffers from a badly behaved perturbative series which makes it ambiguous to an amount related to Λ (see *e.g.* Ref. [26–28]). An alternative is the $\overline{\rm MS}$ mass, $\overline{m}_q(\mu_R^2)$, which depends on the renormalization scale μ_R.

Results for the masses of heavier quarks are often quoted either as the pole mass or as the $\overline{\rm MS}$ mass evaluated at a scale equal to the mass, $\overline{m}_q(\overline{m}_q^2)$; light quark masses are often quoted in the $\overline{\rm MS}$ scheme at a scale $\mu_R \sim 2\,\text{GeV}$. The pole and $\overline{\rm MS}$ masses are related by a series that starts as $m_q = \overline{m}_q(\overline{m}_q^2)(1 + \frac{4\alpha_s(\overline{m}_q^2)}{3\pi} + \mathcal{O}(\alpha_s^2))$, while the scale-dependence of $\overline{\rm MS}$ masses is given at lowest order by

$$\mu_R^2 \frac{d\overline{m}_q(\mu_R^2)}{d\mu_R^2} = \left[-\frac{\alpha_s(\mu_R^2)}{\pi} + \mathcal{O}(\alpha_s^2)\right]\overline{m}_q(\mu_R^2)\,. \qquad (9.6)$$

A more detailed discussion is to be found in a dedicated section of the *Review*, "Quark Masses", with detailed formulas also in Ref. [29] and references therein.

In perturbative QCD calculations of scattering processes, it is customary to employ an approximation where the masses of all quarks, whose magnitudes are much smaller than the momentum transfer involved in the process, are neglected or set to zero.

9.2 Structure of QCD predictions

9.2.1 *Fully inclusive cross sections*

The simplest observables in perturbative QCD are those that do not depend on the initial-state hadrons and are fully inclusive, disregarding specific details of the final state. An example of such an observable is the total cross section for the process $e^+e^- \to$ hadrons at a center-of-mass energy Q. It can be expressed as follows:

$$\frac{\sigma(e^+e^- \to \text{hadrons}, Q)}{\sigma(e^+e^- \to \mu^+\mu^-, Q)} \equiv R(Q) = R_{\rm EW}(Q)(1 + \delta_{\rm QCD}(Q))\,, \qquad (9.7)$$

where $R_{\rm EW}(Q)$ is the purely electroweak prediction for the ratio and $\delta_{\rm QCD}(Q)$ is the correction due to QCD effects.

For the sake of simplicity, we can focus on energies where $Q \ll m_Z$, where the primary contribution to the process comes from photon exchange (while disregarding electroweak and finite-quark-mass corrections) denoted as $R_{\rm EW} = N_c \sum_q e_q^2$, with e_q representing the electric charges of the quarks. The QCD correction reads

$$\delta_{\rm QCD}(Q) = \sum_{n=1}^{\infty} c_n \cdot \left(\frac{\alpha_s(Q^2)}{\pi}\right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right)\,. \qquad (9.8)$$

The first four terms in the α_s series expansion are [30]

$$c_1 = 1\,, \qquad c_2 = 1.9857 - 0.1152 n_f\,, \qquad (9.9a)$$
$$c_3 = -6.63694 - 1.20013 n_f - 0.00518 n_f^2 - 1.240\eta\,, \qquad (9.9b)$$
$$c_4 = -156.61 + 18.775 n_f - 0.7974 n_f^2 + 0.0215 n_f^3 - (17.828 - 0.575 n_f)\eta\,, \qquad (9.9c)$$

with $\eta = (\sum e_q)^2/(N_c \sum e_q^2)$ and $N_c = 3$. For corresponding expressions including also Z exchange and finite-quark-mass effects, see Refs. [31–33].

A related series holds also for the QCD corrections to the hadronic decay width of the τ lepton, which essentially involves an integral of $R(Q)$ over the allowed range of invariant masses of the hadronic part of the τ decay (see *e.g.* Ref. [34]). The series expansions for QCD corrections to Higgs-boson hadronic (partial) decay widths in the limit of heavy top quark and massless light flavors at N^{4}LO are given in Ref. [35].

One characteristic feature of Eqs. (9.8) and (9.9) is that the coefficients of α_s^n increase order by order: calculations in perturbative QCD tend to converge more slowly than would be expected based just on the size of α_s. The situation is significantly worse near thresholds or in the presence of tight kinematic cuts. Another feature is the existence of an extra "power-correction" term $\mathcal{O}(\Lambda^4/Q^4)$ in Eq. (9.8), which accounts for contributions that are fundamentally non-perturbative. All high-energy QCD predictions involve power corrections $(\Lambda/Q)^p$, although typically the suppression of these corrections with Q is smaller than given in Eq. (9.8), where $p = 4$. The exact power p depends on the observable and, for many processes and observables, it is possible to introduce an operator product expansion and associate power-suppressed terms with specific higher-dimension (non-perturbative) operators [36].

Scale dependence. In Eq. (9.8) the renormalization scale for α_s has been chosen equal to Q. The result can also be expressed in terms of the coupling at an arbitrary renormalization scale μ_R,

$$\delta_{\rm QCD}(Q) = \sum_{n=1}^{\infty} \bar{c}_n\left(\frac{\mu_R^2}{Q^2}\right) \cdot \left(\frac{\alpha_s(\mu_R^2)}{\pi}\right)^n + \mathcal{O}\left(\frac{\Lambda^4}{Q^4}\right)\,, \qquad (9.10)$$

where $\bar{c}_1(\mu_R^2/Q^2) \equiv c_1$, $\bar{c}_2(\mu_R^2/Q^2) = c_2 + \pi b_0 c_1 \ln(\mu_R^2/Q^2)$, $\bar{c}_3(\mu_R^2/Q^2) = c_3 + (2b_0c_2\pi + b_1c_1\pi^2) \times \ln(\mu_R^2/Q^2) + b_0^2c_1\pi^2 \ln^2(\mu_R^2/Q^2)$, *etc.* Given an infinite number of terms in the α_s expansion, the μ_R dependence of the $\bar{c}_n(\mu_R^2/Q^2)$ coefficients will exactly cancel that of $\alpha_s(\mu_R^2)$, and the final result will be independent of the choice of μ_R: physical observables do not depend on unphysical scales.[1]

With just terms up to some finite $n = N$, a residual μ_R dependence will remain, which implies an uncertainty on the prediction of $R(Q)$ due to the arbitrariness of the scale choice. This uncertainty will be $\mathcal{O}(\alpha_s^{N+1})$, *i.e.* of the same order as the neglected higher-order terms. For this reason it is customary to use the scale dependence of QCD predictions as an estimate of the uncertainties due to neglected terms. One usually takes a central value for $\mu_R \sim Q$, in order to avoid the poor convergence of the perturbative series that results from the large $\ln^{n-1}(\mu_R^2/Q^2)$ terms in the $\bar{c}_n$ coefficients when $\mu_R \ll Q$ or $\mu_R \gg Q$. Uncertainties are then commonly determined by varying μ_R by a factor of two up and down around the central scale choice. This is not a rigorous prescription for determining the uncertainty, but is motivated by the requirement that there should not be large logarithms introduced into a calculation by large ratios of scales. A more detailed discussion on the accuracy of theoretical predictions and on ways to estimate the theoretical uncertainties can be found in Section 9.2.4.

9.2.2 *Processes with initial-state hadrons*

Deep-Inelastic Scattering. To illustrate the key features of QCD cross sections in processes with initial-state hadrons, let us consider deep-inelastic scattering (DIS), $e + p \to e + X$, where an electron e with four-momentum k emits a highly off-shell photon (momentum q) that interacts with the proton (momentum p). For photon virtualities $Q^2 \equiv -q^2$ far above the squared proton mass (but far below the squared Z mass), the differential cross section in terms of the kinematic variables Q^2, $x = Q^2/(2p \cdot q)$ and $y = (q \cdot p)/(k \cdot p)$ is

$$\frac{d^2\sigma}{dxdQ^2} = \frac{4\pi\alpha^2}{2xQ^4}\left[(1 + (1-y)^2)F_2(x,Q^2) - y^2F_L(x,Q^2)\right], \tag{9.11}$$

where α is the electromagnetic coupling and $F_2(x,Q^2)$ and $F_L(x,Q^2)$ are proton structure functions, which encode the interaction between the photon and the proton. In the presence of parity-violating interactions (*e.g.* νp scattering) an additional F_3 structure function is present. For an extended review, including equations for the full electroweak and polarized cases, see Sec. 18 of this *Review*.

Structure functions are not calculable in perturbative QCD, nor is any other cross section that involves QCD interactions and initial-state hadrons. To zeroth order in α_s, the structure functions are given directly in terms of non-perturbative parton (quark or gluon) distribution functions (PDFs),

$$F_2(x,Q^2) = x\sum_q e_q^2 f_{q/p}(x), \qquad F_L(x,Q^2) = 0, \tag{9.12}$$

where $f_{q/p}(x)$ is the non-perturbative PDF for quarks of type q inside the proton, *i.e.* the number density of quarks of type q inside a fast-moving proton that carry a fraction x of its longitudinal momentum.

PDFs are primarily determined from data in global fits. PDF sets are available at different orders in perturbation theory (LO, NLO and NNLO) based on the order at which cross sections used in the fits are calculated. The evolution equations for the PDFs from one scale to another matches the perturbative accuracy of the cross sections. In modern global PDF fits, data are included from DIS, Drell-Yan (DY), jets and $t\bar{t}$ processes, and more LHC collider data, with the global PDF fits using 3000-4000 data points. There is a large change in the PDFs from LO to NLO, with a much smaller change from NLO to NNLO. LO PDFs can be unreliable for collider predictions, especially at low and high x. The uncertainties for the resulting PDFs are determined primarily from the experimental uncertainties of the data that serve as input to the global PDF fits. There is also a component due to the limitations of the parameterizations used, as discussed *e.g.* in Ref. [37], although this may be reduced with the use of more flexible forms. The PDF uncertainties can either be determined through a Hessian approach or through the use of Monte Carlo replicas. It is now relatively straightforward to convert results from one approach to the other. There has been a recent combination (PDF4LHC21) of the CT18, MSHT20 and NNPDF3.1 PDFs, each produced from a global PDF fit, that serves to provide a more comprehensive view of both the central PDFs and of their uncertainties [38]. Recently, theoretical uncertainties related to missing higher orders have been included in global PDF determinations but so far only at NLO [39–42]. By tying renormalization scales for related processes, and factorization scales for all processes, together in the global fit, an estimate of the higher order uncertainties can be added to the PDF fit. An alternative approach [43] is to attempt to deal with cross sections rather than PDFs themselves.

Another approach is to use as much available information as possible from N^{3}LO to examine the impact of such information on the resultant PDFs [44]. The result, of course, is sensitive to the higher order information that is still missing, for example from an incomplete knowledge of the splitting functions and the N^{3}LO matrix elements.

Since the original work of Ref. [45], one of the intriguing questions is whether lattice calculations can provide valuable insights for extracting PDFs. Despite initial debates surrounding the underlying methodologies [46, 47], it is now understood that lattice data in Euclidean space can be connected to light-cone PDFs through factorization theorems, once lattice observables have been renormalized and extrapolated to the continuum limit [48]. Initial determinations based on lattice data have begun to emerge [48–61], and the comparisons with determinations based on conventional data show great promise. However, the uncertainties in lattice-based determinations are still quite large, therefore, for practical applications, PDFs are currently derived from global fits of experimental data (*cf.* Sec. 18 of this *Review* and also Refs. [62, 63]). It is likely that lattice simulations for light-cone PDFs will have an impact in the short-medium term if they focus on flavor components (strange and charm) and on the kinematic regions that are poorly covered by the experimental data [64]. Similarly, lattice determinations of transverse momentum dependent PDF (TMDs) and generalized parton distributions (GPDs) will be more relevant for phenomenology since the experimental data for these quantities are much less abundant and precise.

The result in Eq.(9.12), with PDFs $f_{q/p}(x)$ that are independent of the scale Q, corresponds to the "quark-parton model" picture, in which the photon interacts with point-like free quarks, or equivalently, one has incoherent elastic scattering between the electron and individual constituents of the proton. As a consequence, in this picture also F_2 and F_L are independent of Q [65]. When including higher orders in pQCD, one has

$$F_2(x,Q^2) = x\sum_{n=0}^{\infty}\frac{\alpha_s^n(\mu_R^2)}{(2\pi)^n}\times$$
$$\times\sum_{i=q,g}\int_x^1\frac{dz}{z}C_{2,i}^{(n)}(z,Q^2,\mu_R^2,\mu_F^2)f_{i/p}\left(\frac{x}{z},\mu_F^2\right) + \mathcal{O}\left(\frac{\Lambda^2}{Q^2}\right). \tag{9.13}$$

Just as in Eq. (9.10), we have a series in powers of $\alpha_s(\mu_R^2)$, each term involving a coefficient $C_{2,i}^{(n)}$ that can be calculated using Feynman diagrams. At variance with the parton model, the PDFs in pQCD depend on an additional scale, the factorization scale μ_F, whose significance will be discussed in the following. Another important difference is the additional integral over z.

[1] With respect to pQCD there is an important caveat to this statement: at sufficiently high orders, perturbative series generally suffer from "renormalon" divergences $\alpha_s^n n!$ (reviewed in Ref. [26]). This phenomenon is not usually visible with the limited number of perturbative terms available today. However, it is closely connected with non-perturbative contributions and sets a limit on the possible precision of perturbative predictions. The cancellation of scale dependence will also ultimately be affected by this renormalon-induced breakdown of perturbation theory.

The parton that comes from the proton can undergo a splitting before it enters the hard scattering. As a result, the $C_{2,i}^{(n)}$ coefficients are functions that depend on the ratio, z, of the parton's momentum before and after radiation, and one must integrate over that ratio. For the electromagnetic component of DIS with light quarks and gluons, the zeroth order coefficient functions are $C_{2,q}^{(0)} = e_q^2\delta(1-z)$ and $C_{2,g}^{(0)} = 0$. Corrections are known up to $\mathcal{O}(\alpha_s^3)$ (next-to-next-to-next-to-leading order, N^{3}LO) for both electromagnetic [66] and weak currents [67,68]. For heavy-quark production they are known to $\mathcal{O}(\alpha_s^2)$ [69,70] (next-to-leading order, NLO, insofar as the series starts at $\mathcal{O}(\alpha_s)$). The current status of the theoretical description of unpolarized and polarized DIS is summarized in Ref. [71]. For precise comparisons of LHC cross sections with theoretical predictions, the photon PDF of the proton is also needed. It has been computed precisely in Ref. [72,73] and has now been implemented in most global PDF fits. More recently, the PDF for leptons has also been computed [74]. The photon PDF has an elastic and an inelastic component, where the photon is generated from the intact proton or from the splitting of quarks inside the proton, respectively, while the lepton PDF is generated by photons splitting to collinear leptons.

The majority of the emissions that modify a parton's momentum are collinear (parallel) to that parton, and do not depend on whether the parton will interact with a photon. It is natural to view these emissions as modifying the proton's structure rather than being part of the coefficient function for the parton's interaction with the photon. Technically, one uses a procedure known as *collinear factorization* to give a well-defined meaning to this distinction, most commonly through the $\overline{\text{MS}}$ factorization scheme, defined in the context of dimensional regularization. The $\overline{\text{MS}}$ factorization scheme involves an arbitrary choice of *factorization scale*, μ_F, whose meaning can be understood roughly as follows: emissions with transverse momenta above μ_F are included in the $C_{2,q}^{(n)}(z, Q^2, \mu_R^2, \mu_F^2)$; emissions with transverse momenta below μ_F are accounted for within the PDFs, $f_{i/p}(x, \mu_F^2)$. While collinear factorization is generally believed to be valid for suitable (sufficiently inclusive) observables in processes with hard scales, Ref. [75], which reviews the factorization proofs in detail, is cautious in the statements it makes about their exhaustivity, notably for the hadron-collider processes which we shall discuss below. Interesting considerations on the current status of our understanding of factorization can be found in Refs. [76,77]. While the transverse degrees of freedom have been integrated over for collinear PDFs, it is also possible to produce transverse-momentum dependent (or unintegrated) PDFs where these degrees of freedom remain. For a recent comprehensive review of transverse-momentum-dependent parton distribution functions and fragmentation functions see Ref. [78].

For collinear PDFs, the resulting dependence on μ_F is described by the Dokshitzer-Gribov-Lipatov-Altarelli-Parisi (DGLAP) equations [79], which to leading order (LO) read[2]

$$\mu_F^2 \frac{\partial f_{i/p}(x,\mu_F^2)}{\partial \mu_F^2} = \sum_j \frac{\alpha_s(\mu_F^2)}{2\pi} \int_x^1 \frac{dz}{z} P_{i\leftarrow j}^{(1)}(z) f_{j/p}\left(\frac{x}{z}, \mu_F^2\right), \tag{9.14}$$

with, for example, $P_{q\leftarrow g}^{(1)}(z) = T_R(z^2 + (1-z)^2)$. The other LO splitting functions are listed in Sec. 18 of this *Review*, while results up to NLO, α_s^2, and NNLO, α_s^3, are given in Refs. [80] and [81] respectively. At N^{3}LO accuracy, only partial results are currently available in Refs. [82–86]. Splitting functions for PDFs in the helicity dependent case are given in Ref. [87].

Beyond LO, the coefficient functions are also μ_F dependent, for example $C_{2,i}^{(1)}(x, Q^2, \mu_R^2, \mu_F^2) = C_{2,i}^{(1)}(x, Q^2, \mu_R^2, Q^2) - \ln\left(\frac{\mu_F^2}{Q^2}\right) \sum_j \int_x^1 \frac{dz}{z} \times C_{2,j}^{(0)}(\frac{x}{z}) P_{j\leftarrow i}^{(1)}(z)$. Progress in higher-order QED and mixed QED-QCD corrections to the splitting functions can be found in refs. [88,89].

As with the renormalization scale, the choice of factorization scale is arbitrary, but if one has an infinite number of terms in the perturbative series, the μ_F-dependencies of the coefficient functions and PDFs will compensate each other fully. Given only N terms of the series, a residual $\mathcal{O}(\alpha_s^{N+1})$ uncertainty is associated with the ambiguity in the choice of μ_F. As with μ_R, varying μ_F provides an input in estimating uncertainties on predictions. In inclusive DIS predictions, the default choice for the scales is usually $\mu_R = \mu_F = Q$.

As is the case for the running coupling, in DGLAP evolution one can introduce flavor thresholds near the heavy quark masses: below a given heavy quark's mass, that quark is not considered to be part of the proton's structure, while above it is considered to be part of the proton's structure and evolves with massless DGLAP splitting kernels. With appropriate parton distribution matching terms at threshold, such a variable flavor number scheme (VFNS), when used with massless coefficient functions, gives the full heavy-quark contributions at high Q^2 scales. For scales near the threshold, it is instead necessary to appropriately adapt the standard massive coefficient functions to account for the heavy-quark contribution already included in the PDFs [90–92].

At sufficiently small x and Q^2 in inclusive DIS, resummation of small x logarithms may be necessary [93,94]. This may in fact have been observed in Refs. [95] based on HERA data [96], in a kinematic region where useful information for PDFs for collider predictions is present.

In situations, in which the center-of-mass energy $\sqrt{s}$ is much larger than all other momentum-transfer scales in the problem (*e.g.* Q in DIS, m_b for $b\bar{b}$ production in pp collisions, *etc.*), each power of α_s beyond LO can be accompanied by a power of $\ln(s/Q^2)$ (or $\ln(s/m_b^2)$, *etc.*). This is variously referred to as the high-energy, small-x or Balitsky-Fadin-Kuraev-Lipatov (BFKL) limit [94,97,98]. Currently it is possible to account for the dominant and first sub-dominant [99,100] power of such logarithms at each order of α_s, and also to estimate further sub-dominant contributions that are numerically large (see Refs. [101–104] and references therein). Progress towards NNLO is discussed in Ref. [105].

Physically, the summation of all orders in α_s can be understood as leading to a growth with s of the gluon density in the proton. At sufficiently high energies this implies non-linear effects (commonly referred to as parton saturation), whose treatment has been the subject of intense study (see for example Refs. [106–108] and references thereto).

Hadron-hadron collisions.

The extension to processes with two initial-state hadrons can be illustrated with the example of the total (inclusive) cross section for W boson production in collisions of hadrons h_1 and h_2, which can be written as

$$\begin{aligned}\sigma(h_1h_2 \to W + X) = \sum_{n=0}^{\infty} \alpha_s^n(\mu_R^2) \\ \times \sum_{i,j} \int dx_1 dx_2\, f_{i/h_1}\left(x_1, \mu_F^2\right) f_{j/h_2}\left(x_2, \mu_F^2\right) \\ \times \hat{\sigma}_{ij\to W+X}^{(n)}\left(x_1x_2s, \mu_R^2, \mu_F^2\right) + \mathcal{O}\left(\frac{\Lambda^2}{m_W^4}\right),\end{aligned} \tag{9.15}$$

where s is the squared center-of-mass energy of the collision. At LO, $n = 0$, the hard (partonic) cross section $\hat{\sigma}_{ij\to W+X}^{(0)}(x_1x_2s, \mu_R^2, \mu_F^2)$ is simply proportional to $\delta(x_1x_2s - m_W^2)$, in the narrow W-boson width approximation (see Sec. 51 of this *Review* for detailed expressions for this and other hard scattering cross sections). It is non-zero only for choices of i, j that can directly give a W, such as $i = u$, $j = \bar{d}$. At higher orders, $n \geq 1$, new partonic channels contribute, such as gq, and $x_1x_2s \geq m_W^2$ in the narrow W-boson width approximation.

Equation (9.15) involves a collinear factorization between the hard cross section and the PDFs, just like Eq. (9.13). As long as the same factorization scheme is used in DIS and pp or $p\bar{p}$ (usually the $\overline{\text{MS}}$ scheme), then PDFs extracted in DIS can be directly used in pp and $p\bar{p}$ predictions [75,109] (with the anti-quark distributions

[2] LO is generally taken to mean the lowest order at which a quantity is non-zero.

in an anti-proton being the same as the quark distributions in a proton).

A number of fully inclusive cross-sections have been computed up to N^{3}LO, *i.e.* including corrections up to relative order α_s^3, in recent years. These include inclusive Higgs production through gluon fusion in the large m_t limit, calculated at N^{3}LO in Refs. [110, 111]. Higgs boson pair production via gluon fusion in the same approximation was computed at N^{3}LO in Ref. [112]. Calculations at this order, differential in the Higgs rapidity [113, 114] and fully differential [115] have been presented recently. Bottom-induced Higgs boson production has also been computed at N^{3}LO [116]. Vector-boson fusion single- [117] and double-pair [118] production is also known to N^{3}LO [117] in the factorized approximation. Neutral [119, 120] and charged [121] Drell-Yan processes, as well as associated Higgs production [116] have also been computed at N^{3}LO. Differential rapidity distributions are available, but not yet with fiducial cuts. A number of public codes are now available which allow for phenomenological studies at N^{3}LO [116, 117, 122–124]. The uncertainty band derived by varying the renormalization and factorization scales in the perturbative predictions is not always contained within the corresponding uncertainty band of the previous order, as might be expected from a well-behaved process. This has been ascribed to cancellations between channels at NNLO that lead to underestimates of the uncertainty at that order. This effect does not seem to be present in other processes, such as Higgs boson production through gluon-gluon fusion. Note that there is currently a mis-match in N^{3}LO calculations in that PDFs at the same order are not yet available. Preliminary approximated N^{3}LO PDFs [44] suggest that N^{3}LO effects can be large, especially as far as heavy-quark distributions and low scales are concerned, as well as the gluon distribution in a region important for Higgs boson production through gluon-gluon fusion. The fully inclusive hard cross sections for several other processes are known to NNLO,[3] for instance, Higgs-boson production in association with a vector boson [125], Higgs-pair production in the large m_t approximation [126], and with full m_t dependence [127], top-antitop production [128, 129], bottom-anti-bottom production [130] and vector-boson pair production [131–133]. For a comprehensive overview on other recent NNLO $2 \to 2$ calculations see Ref. [134, 135]. Other NNLO calculations with fiducial cuts will be discussed in Sec. 9.2.3.

Photoproduction.

γp (and $\gamma\gamma$) collisions are similar to pp collisions, with the subtlety that the photon can behave in two ways: there is "direct" photoproduction, in which the photon behaves as a point-like particle and takes part directly in the hard collision, with hard subprocesses such as $\gamma g \to q\bar{q}$; there is also resolved photoproduction, in which the photon behaves like a hadron, with non-perturbative partonic substructure and a corresponding PDF for its quark and gluon content, $f_{i/\gamma}(x, Q^2)$. While useful to understand the general structure of γp collisions, the distinction between direct and resolved photoproduction is not well defined beyond leading order, as discussed for example in Ref. [136].

9.2.3 *Cross sections with phase-space restrictions*

QCD final states always consist of hadrons, while perturbative QCD calculations deal with partons. Physically, an energetic parton fragments ("showers") into many further partons, which then, on later timescales, undergo a transition to hadrons ("hadronization"). Fixed-order perturbation theory captures only a small part of these dynamics. This does not matter for the fully inclusive cross sections discussed above: the showering and hadronization stages are approximately unitary, *i.e.* they do not substantially change the overall probability of hard scattering, because they occur long after it has taken place (they introduce at most a correction proportional to a power of the ratio of timescales involved, *i.e.* a power of Λ/Q, where Q is the hard scattering scale).

Less inclusive measurements, in contrast, may be affected by the extra dynamics. For those sensitive just to the main directions of energy flow (jet rates, event shapes, *cf.* Sec. 9.3.1) fixed-order perturbation theory is often still adequate, because showering and hadronization do not substantially change the overall energy flow. This means that one can make a prediction using just a small number of partons, which should correspond well to a measurement of the same observable carried out on hadrons. For observables that instead depend on distributions of individual hadrons (which, *e.g.*, are the inputs to detector simulations), it is mandatory to account for showering and hadronization. The range of predictive techniques available for QCD final states reflects this diversity of needs of different measurements.

While illustrating the different methods, we shall for simplicity mainly use expressions that hold for e^+e^- scattering. The extension to cases with initial-state partons will be mostly straightforward (space constraints unfortunately prevent us from addressing diffraction and exclusive hadron-production processes; extensive discussion is to be found in Sec. 20 of this *Review* and in Refs. [137, 138]).

9.2.3.1 *Soft and collinear limits*

Before examining specific predictive methods, it is useful to be aware of a general property of QCD matrix elements in the soft and collinear limits. Consider a squared tree-level matrix element $|M_n^2(p_1, \ldots, p_n)|$ for the process $e^+e^- \to n$ partons with momenta $p_1, \ldots, p_n$, and a corresponding phase-space integration measure $d\Phi_n$. If particle n is a gluon, which becomes collinear (parallel) to another particle i and additionally its momentum tends to zero (is "soft"), the matrix element simplifies as follows,

$$\lim_{\theta_{in}\to 0,\, E_n \to 0} d\Phi_n |M_n^2(p_1, \ldots, p_n)| = d\Phi_{n-1} |M_{n-1}^2(p_1, \ldots, p_{n-1})| \frac{\alpha_s C_i}{\pi} \frac{d\theta_{in}^2}{\theta_{in}^2} \frac{dE_n}{E_n}\,, \qquad (9.16)$$

where $C_i = C_F$ (C_A) if i is a quark (gluon). This formula has non-integrable divergences both for the inter-parton angle $\theta_{in} \to 0$ and for the gluon energy $E_n \to 0$, which are mirrored also in the structure of divergences in loop diagrams. These divergences are important for at least two reasons: firstly, they govern the typical structure of events (inducing many emissions either with low energy or at small angle with respect to hard partons); secondly, they will determine which observables can be calculated within fixed-order perturbative QCD.

9.2.3.2 *Fixed-order predictions*

Let us consider an observable $\mathcal{O}$ that is a function $\mathcal{O}_n(p_1, \ldots, p_n)$ of the four-momenta of the n final-state particles in an event (either partons or hadrons). In what follows, we shall consider the cross section for events weighted with the value of the observable, $\sigma_{\mathcal{O}}$. As examples, if $\mathcal{O}_n \equiv 1$ for all n, then $\sigma_{\mathcal{O}}$ is just the total cross section; if $\mathcal{O}_n \equiv \hat{\tau}(p_1, \ldots, p_n)$ where $\hat{\tau}$ is the value of the thrust for that event (see Eq. (9.22) in Sec. 9.3.1.2), then the average value of the thrust is $\langle\tau\rangle = \sigma_{\mathcal{O}}/\sigma_{\rm tot}$; if $\mathcal{O}_n \equiv \delta(\tau - \hat{\tau}(p_1, \ldots, p_n))$ then one gets the differential cross section as a function of the thrust, $\sigma_{\mathcal{O}} \equiv d\sigma/d\tau$.

In the expressions below, we shall omit to write the non-perturbative power correction term, which for most common observables is proportional to a single power of Λ/Q.

Leading Order. If the observable $\mathcal{O}$ is non-zero only for events with at least n final-state particles, then the LO QCD prediction for the weighted cross section in e^+e^- annihilation is

$$\sigma_{\mathcal{O}}^{\rm LO} = \alpha_s^{n-2}(\mu_R^2) \int d\Phi_n |M_n^2(p_1, \ldots, p_n)|\, \mathcal{O}_n(p_1, \ldots, p_n)\,, \qquad (9.17)$$

where the squared tree-level matrix element, $|M_n^2(p_1, \ldots, p_n)|$, including relevant symmetry factors, has been summed over all subprocesses (*e.g.* $e^+e^- \to q\bar{q}q\bar{q}$, $e^+e^- \to q\bar{q}gg$) and has had all factors of α_s extracted in front. In processes other than e^+e^- collisions, the center-of-mass energy of the LO process is generally not fixed, and so the powers of the coupling are often brought inside the integrals, with the scale μ_R chosen event by event, as a function of the event kinematics.

[3] Processes with jets or photons in the final state have divergent cross sections unless one places a cut on the jet or (dressed) photon momentum. Accordingly, they are discussed below in Section 9.2.3.2.

Other than in the simplest cases (see the review on Cross Sections in this *Review*), the matrix elements in Eq. (9.17) are usually calculated automatically with programs such as CompHEP [139], MadGraph [140], Alpgen [141], Comix/Sherpa [142], and Helac/Phegas [143]. Some of these (CompHEP, MadGraph) use formulas obtained from direct evaluations of Feynman diagrams. Others (Alpgen, Helac/Phegas and Comix/Sherpa) use methods designed to be particularly efficient at high multiplicities, such as Berends-Giele recursion [144], which builds up amplitudes for complex processes from simpler ones (see also Refs. [145–147] for other tree-level calculational methods).

The phase-space integration is usually carried out by Monte Carlo sampling, because of the high dimensionality of the integration and in order to deal with the possibly involved kinematic cuts that are used in the corresponding experimental measurements. Perturbatively calculable observables should be insensitive to the emission of soft and collinear radiation. Because of the divergences in the matrix element, Eq. (9.16), at lowest order the integral converges only if the observable vanishes for kinematic configurations in which one of the n particles is arbitrarily soft or it is collinear to another particle. As an example, the cross section for producing any configuration of n partons will lead to an infinite integral, whereas a finite result will be obtained for the cross section for producing n deposits of energy (or jets, see Sec. 9.3.1.1), each above some energy threshold and well separated from each other in angle.

At a practical level, LO calculations can be carried out for $2 \to n$ processes with $n \lesssim 6 - 10$. The exact upper limit depends on the process, the method used to evaluate the matrix elements (recursive methods are more efficient), and the extent to which the phase-space integration can be optimized to work around the large variations in the values of the matrix elements.

NLO. Given an observable that is non-zero starting from n final-state particles, its prediction at NLO involves supplementing the LO result, Eq. (9.17), with the $2 \to (n+1)$-particle squared tree-level matrix element ($|M^2_{n+1}|$), and the interference of a $2 \to n$ tree-level and $2 \to n$ 1-loop amplitude ($2\mathrm{Re}(M_n M^*_{n,1-\mathrm{loop}})$),

$$\begin{aligned}\sigma^{\mathrm{NLO}}_{\mathcal{O}} = \sigma^{\mathrm{LO}}_{\mathcal{O}} + \alpha_s^{n-1}(\mu_R^2) \int d\Phi_{n+1} |M^2_{n+1}(p_1,\ldots,p_{n+1})| \\ \times \mathcal{O}_{n+1}(p_1,\ldots,p_{n+1}) \;+\; \alpha_s^{n-1}(\mu_R^2) \\ \times \int d\Phi_n \, 2\mathrm{Re}\left[\, M_n(p_1,\ldots,p_n)\, M^*_{n,1-\mathrm{loop}}(p_1,\ldots,p_n) \,\right] \\ \times \mathcal{O}_n(p_1,\ldots,p_n)\;. \end{aligned} \tag{9.18}$$

Relative to LO calculations, two important issues appear in the NLO calculations. Firstly, the extra complexity of loop-calculations relative to tree-level calculations means that automated calculations started to appear only about fifteen years ago (see below). Secondly, loop amplitudes are infinite in four dimensions, while tree-level amplitudes are finite, but their *integrals over the phase space* are infinite, due to the divergences of Eq. (9.16). These two sources of infinities have the same soft and collinear origins and cancel after the integration only if the observable $\mathcal{O}$ satisfies the property of infrared and collinear safety, which means that the observable is non-sensitive to soft emissions or to collinear splittings, *i.e.*

$$\begin{aligned} \mathcal{O}_{n+1}(p_1,\ldots,p_s,\ldots,p_n) &\to \mathcal{O}_n(p_1,\ldots,p_{s-1},p_{s+1},\ldots,p_n) \\ &\quad \text{if } p_s \to 0 \\ \mathcal{O}_{n+1}(p_1,\ldots,p_a,p_b,\ldots,p_n) &\to \mathcal{O}_n(p_1,\ldots,p_a+p_b,\ldots,p_n) \\ &\quad \text{if } p_a \,||\, p_b\,. \end{aligned} \tag{9.19}$$

Examples of infrared-safe quantities include event-shape distributions and jet cross sections (with appropriate jet algorithms, see below). Unsafe quantities include the distribution of the momentum of the hardest QCD particle (which is not conserved under collinear splitting), observables that require the complete absence of radiation in some region of phase space (*e.g.* rapidity gaps or 100% isolation cuts, which are affected by soft emissions), or the particle multiplicity (affected by both soft and collinear emissions). The non-cancellation of divergences at NLO due to infrared or collinear unsafety compromises the usefulness not only of the NLO calculation, but also that of a LO calculation, since LO is only an acceptable approximation if one can prove that higher-order terms are smaller. Infrared and collinear unsafety usually also implies large non-perturbative effects.

As with LO calculations, the phase-space integrals in Eq. (9.18) are usually carried out by Monte Carlo integration, so as to facilitate the study of arbitrary observables. Various methods exist to obtain numerically efficient cancellation among the different infinities. These include notably dipole [148], FKS [149] and antenna [150] subtraction.

Thanks to new ideas like the OPP method [151], generalized [152] and D-dimensional [153] unitarity, on-shell methods [154], and on-the-fly reduction algorithms [155], recent years have seen a breakthrough in the calculation of one-loop matrix elements (for reviews on unitarity based method see Ref. [156, 157]). Thanks to these innovative methods, automated tools for NLO calculations have been developed and a number of programs are available publicly: MadGraph5_aMC@NLO [140] and Helac-NLO [158] provide full frameworks for NLO calculations; GoSam [159], Njet [160], OpenLoops [161] and Recola [162] calculate just the 1-loop part and are typically interfaced with an external tool for a combination with the appropriate tree-level amplitudes. Other tools such as NLOJet++ [163], MCFM [164], VBFNLO [165], the Phox family [166] or BlackHat [167] implement analytic calculations and provide full frameworks to compute NLO cross sections for selected classes of processes. Recently, a lot of attention has also been paid to the calculation of NLO electroweak corrections. Electroweak corrections are especially important for transverse momenta significantly above the W and Z masses, because they are enhanced by two powers of $\ln p_t/m_W$ for each power of the electroweak coupling, and close to Sudakov peaks[4], where most of the data lie and the best experimental precision can be achieved. In some cases the above programs can be used to calculate also NLO electroweak or beyond-standard-model corrections [168–174].

Given the progress in QCD and EW fixed-order computations, the largest unknown from fixed-order corrections is often given by the mixed QCD-electroweak corrections of $\mathcal{O}(\alpha_s\alpha)$. These mixed two-loop corrections are often available in an approximate form [175–188]. The first complete computation of the mixed QCD–EW corrections to the neutral-current Drell–Yan process appeared recently [189–191]. For a review on EW corrections to collider processes see Ref. [192].

NNLO. NNLO is considerably more complicated than NLO as it involves a further order in α_s, consisting of: the squared $(n+2)$-parton tree-level amplitude, the interference of the $(n+1)$-parton tree-level and 1-loop amplitudes, the interference of the n-parton tree-level and 2-loop amplitudes, and the squared n-parton 1-loop amplitude.

Each of these elements involves large numbers of soft and collinear divergences, satisfying relations analogous to Eq. (9.16) which now involve multiple collinear or soft particles and higher loop orders (see *e.g.* Refs. [193–195]). Arranging for the cancellation of the divergences after numerical Monte Carlo integration has been one of the significant challenges of NNLO calculations, as has been the determination of the relevant 2-loop amplitudes. For the cancellations of divergences a wide range of methods has been developed. Some of them [196–205] retain the approach, inherent in NLO methods, of directly combining the separate loop and tree-level amplitudes. Others combine a suitably chosen, partially inclusive $2 \to n$ NNLO calculation with a fully differential $2 \to n+1$ NLO calculation [206–212]. The q_T-subtraction method was extended to deal with mixed QCD–QED corrections at NNLO [213]. For an overview of NNLO subtraction methods see Ref [214].

Quite a number of processes have been calculated differentially at NNLO so far. The state of the art for e^+e^- collisions is $e^+e^- \to$

[4] For the definition of Sudakov form factors or Sudakov peaks see e.g. Refs. [1, 2, 11].

3 jets [215–218].

For DIS, dijet production is known at NNLO [219, 220] and the description jet production has been recently pushed even to N^{3}LO using the Projection-to-Born method [221, 222]. For hadron colliders, all $2 \to 1$ processes are known, specifically vector boson [223, 224] and Higgs boson production in the large m_t limit [206, 225]. The finite top-mass corrections at this order have also been computed [226]. This calculation eliminates one important source of theoretical uncertainty to inclusive Higgs production at the LHC. Substantial progress has been made in the years for hadron-collider $2 \to 2$ processes, with calculations having been performed for nearly all relevant processes: ZZ [132] WW [131] and WZ [227], $\gamma\gamma$ [228, 229], $Z\gamma$ [230] and $W\gamma$ [231] (many of these color singlet processes are available also in MCFM [232, 233] or MATRIX [133]), inclusive photon [234, 235], $\gamma+$jet [235, 236], $W+$jet [208, 237], $Z+$jet [236, 238, 239] $H+$jet [240–243], WH [244] and ZH [245], s-channel [246] and t-channel single-top [247–250], $t\bar{t}$ production [251, 252], dijet production [253, 254], W production in association with a c-jet [255, 256] and HH [126] (in large-top-mass approximation, see also the exact (two-loop) NLO result [127]). Recently, also the NNLO corrections to identified B-hadron hadro-production have been computed [257]. The frontier of NNLO calculation has now reached the complexity of $2 \to 3$ processes. The first $2 \to 3$ process known at NNLO has been Higgs production through vector-boson fusion, using an approximation in which the two underlying DIS-like $q \to qV$ scatterings are factorized, the so-called structure function approximation [211, 258]. Corrections beyond the structure function approximation are expected to be small, on the order of a percent or less [259]. More recently, first genuine $2 \to 3$ LHC processes have been described at NNLO accuracy, including three photon [260, 261], two photons and one jet [262], two jets and one photon [263], three-jets [264] and $Wb\bar{b}$ production [265]. The calculation of three-jet production might be relevant for future extractions of $\alpha_s(m_Z^2)$ from three-jet observables at the LHC [266].

Cross sections at the LHC are most often measured with fiducial cuts, for example on the transverse momenta and rapidities of the measured objects, restricting the measurement to regions where the objects have a good efficiency to be detected and are well-reconstructed. Ideally, the theoretical predictions should also be constructed at the same fiducial level; the other possibility is to extrapolate the experimental fiducial results to the full phase space. Such an extrapolation, however, requires the extrapolation (typically using a parton shower Monte Carlo) to be accurate over the full phase space.

Comparisons of fixed order predictions to fiducial measurements can sometimes result in the presence of large logarithms which degrade the accuracy of the prediction. Such is the case, for example, in the calculation of the Higgs rapidity distribution, in the diphoton final state. The imposition of transverse momenta and rapidity cuts on the two photons leads to an uncertainty notably greater at N^{3}LO then at NNLO, due to the presence of these logs. One possible solution is to change the form of the kinematic cut on the photons, to a product of the two photon transverse momenta [267], reducing the impact of the logs; another solution is to perform a resummation of the logs, restoring the expected precision [268].

The Les Houches precision wishlist compiles predictions needed to fully exploit the data that will be taken at the High Luminosity LHC [269]. Most of the needed calculations require accuracy of at least NNLO QCD and NLO EW, and many require the prediction of $2 \to 3$ processes, such as $W/Z+ \geq 2$ jets, $H+ \geq 2$ jets, and ttH to NNLO. The latter process has been computed at NNLO in Ref. [270] in the approximation where the Higgs boson in the double-virtual contribution is soft. This calculation considerably reduces the theory uncertainty on this process.

As discussed in this section, calculations at NLO can now be relatively easily generated by non-experts using the programs mentioned above. By now there are also a number of publicly available tools to compute a range of processes at NNLO accuracy in QCD, such as EERAD3 [216] (for e^+e^- collisions), [206], DYNNLO [224], DYTURBO [271], FEHIP [225], FEWZ [272], HTURBO [273], MATRIX [133], MCFM [233] or SUSHI [124, 274]. However, in some cases NNLO calculations can be too complex and CPU-intensive to allow such an approach. In these cases, the relevant matrix element information for a specific observable can be stored by means of interpolation grids developed originally for cross sections at NLO [275–277] and recently extended to include electroweak corrections [278]. The application to NNLO has been demonstrated for $t\bar{t}$ and for DIS jet cross sections in Refs. [279, 280]. Each such interpolation grid corresponds to one fixed observable with specific selection criteria and binning, but is flexible with respect to the renormalization or factorization scale, the PDF, or the α_s evolution chosen for the cross-section computation. An even more flexible method, at the cost of requiring large amounts of storage space, saves huge numbers of partonic events in the form of ROOT n-tuples, which allow predictions to be generated on-the-fly for many observables of a particular process [281, 282]. Recent developments of both techniques for pp collisions at NNLO are described in Ref. [269].

9.2.3.3 *Resummation*

Many experimental measurements place tight constraints on emissions in the final state. For example, in e^+e^- events, that (one minus) the thrust should be less than some value $\tau \ll 1$, or, in $pp \to Z$, events that the Z-boson transverse momentum or the transverse momentum of the accompanying jet should be much smaller than the Z-boson mass. A further example is the production of heavy particles or jets near threshold (so that little energy is left over for real emissions) in DIS and pp collisions.

In such cases, the constraint vetoes a significant part of the integral over the soft and collinear divergence of Eq. (9.16). As a result, there is only a partial cancellation between real emission terms (subject to the constraint) and loop (virtual) contributions (not subject to the constraint), causing each order of α_s to be accompanied by a large coefficient $\sim L^2$, where *e.g.* $L = \ln\tau$ or $L = \ln(m_Z/p_t^Z)$. One ends up with a perturbative series, whose terms go as $\sim (\alpha_s L^2)^n$. It is not uncommon that $\alpha_s L^2 \gg 1$, so that the perturbative series converges very poorly if at all.[5] In such cases one may carry out a "resummation", which accounts for the dominant logarithmically enhanced terms to all orders in α_s, by making use of known properties of matrix elements for multiple soft and collinear emissions, and of the all-orders properties of the divergent parts of virtual corrections, following original works such as Refs. [283–292] and also through soft-collinear effective theory [293, 294] (*cf.* also the section on "Heavy-Quark and Soft-Collinear Effective Theory" in this *Review*, as well as Ref. [295]).

For cases with double logarithmic enhancements (two powers of logarithm per power of α_s), there are two classification schemes for resummation accuracy. Writing the cross section including the constraint as $\sigma(L)$ and the unconstrained (total) cross section as $\sigma_{\rm tot}$, the series expansion takes the form

$$\sigma(L) \simeq \sigma_{\rm tot} \sum_{n=0}^{\infty} \sum_{k=0}^{2n} R_{nk} \alpha_s^n(\mu_R^2) L^k, \qquad L \gg 1\,, \tag{9.20}$$

and leading log (LL) resummation means that one accounts for all terms with $k = 2n$, next-to-leading-log (NLL) includes additionally all terms with $k = 2n-1$, *etc.* Often $\sigma(L)$ (or its Fourier or Mellin transform) *exponentiates*,[6]

$$\sigma(L) \simeq \sigma_{\rm tot} \exp\left[\sum_{n=1}^{\infty} \sum_{k=0}^{n+1} G_{nk} \alpha_s^n(\mu_R^2) L^k\right], \qquad L \gg 1\,, \tag{9.21}$$

where one notes the different upper limit on k ($\leq n+1$) compared to Eq. (9.20). This is a more powerful form of resummation: the

[5] To be precise one should be aware of two causes of the divergence of perturbative series. That which interests us here is associated with the presence of a new large parameter (*e.g.* ratio of scales). It is distinct from the "renormalon" induced factorial divergences of perturbation theory discussed above.

[6] Whether or not this happens depends on the quantity being resummed. A classic example involves two-jet rate in e^+e^- collisions as a function of a jet-resolution parameter $y_{\rm cut}$. The logarithms of $1/y_{\rm cut}$ exponentiate for the k_t (Durham) jet algorithm [296], but not [297] for the JADE algorithm [298] (both are discussed below in Sec. 9.3.1.1).

G_{12} term alone reproduces the full LL series in Eq. (9.20). With the form Eq. (9.21) one still uses the nomenclature LL, but this now means that all terms with $k = n + 1$ are included, and NLL implies all terms with $k = n$, *etc.*

For a large number of observables, NLL resummations are available in the sense of Eq. (9.21) (see Refs. [299–301] and references therein). NNLL has been achieved for the DY and Higgs-boson p_t distributions [302–305] (also available in the CuTe [306], HRes [307] and ResBos [308] families of programs and also differentially in vector-boson decay products [309]) and related variables [310], for the p_t of vector-boson pairs [311, 312], for the back-to-back energy-energy correlation in e^+e^- [313], the jet broadening in e^+e^- collisions [314], the jet-veto survival probability in Higgs and Z boson production in pp collisions [315–317],[7] an event-shape type observable known as the beam thrust [318], hadron-collider jet masses in specific limits [319] (see also Ref. [320]), the production of top anti-top pairs near threshold [321–323] (and references therein), and high-p_t W and Z production [324]. Automation of NNLL jet-veto resummations for different processes has been achieved in Ref. [325] (*cf.* also the NLL automation in Ref. [326]), while automation for a certain class of e^+e^- observables has been achieved in Ref. [327]. N^{3}LL resummations are available for the thrust variable, C-parameter and heavy-jet mass in e^+e^- annihilations [328–330], for p_t distribution of the Higgs boson [331, 332] and weak gauge bosons [333–335] and for Higgs- and vector-boson production near threshold [336]. In order to make better contact with experimental measurements, recent years have seen an increasing interest in resummations in exclusive phase-space regions and joint resummations [337–346]. Finally, there has also been considerable progress in resummed calculations for jet substructure, whose observables involve more complicated definitions than is the case for standard resummations, see *e.g.* Refs. [347–351] and references therein (see also Sec. 9.3.1.3).

9.2.3.4 *Fragmentation functions*

Since the parton-hadron transition is non-perturbative, it is not possible to perturbatively calculate quantities such as the energy-spectra of specific hadrons in high-energy collisions. However, one can factorize perturbative and non-perturbative contributions via the concept of fragmentation functions. These are the final-state analogue of the parton distribution functions which are used for initial-state hadrons. Like parton distribution functions, they depend on a (fragmentation) factorization scale and satisfy a DGLAP evolution equation.

It should be added that if one ignores the non-perturbative difficulties and just calculates the energy and angular spectrum of partons in perturbative QCD with some low cutoff scale $\sim \Lambda$ (using resummation to sum large logarithms of $\sqrt{s}/\Lambda$), then this reproduces many features of the corresponding hadron spectra [352]. This is often taken to suggest that hadronization is "local", in this sense it mainly involves partons that are close both in position and in momentum.

Section 19 of this *Review* provides further information and references on these topics, including also the question of heavy-quark fragmentation.

9.2.3.5 *Parton-shower Monte Carlo event generators*

Parton-shower Monte Carlo (MC) event generators like Pythia [353–355], Herwig [356–358], and Sherpa [359][8] provide fully exclusive simulations of QCD events at the level of measurable particles, the so-called "particle level" or "hadron level". Here, "measurable" refers to color-neutral particles with mean lifetimes τ long enough to be associated with tracks or decay vertices in particle detectors. Usually, this requires mean decay lengths $c\tau$ of around 10 mm. As such MC event generators are a crucial tool for all applications that involve simulating the response of detectors to QCD events. Here we give only a brief outline of how they work and refer the reader to Sec. 43 and Ref. [361] for a full overview.

In general, we expect parton-shower matched predictions to differ from the underlying fixed-order results in regions where (1) there is a large sensitivity to jet shapes (for instance small R jets), (2) there is a restriction in phase space such that soft gluon resummation effects become important, (3) the observable contains multiple disparate scales, (4) there are perturbative instabilities at fixed order, *e.g.* related to kinematical cuts, and (5) the observable is sensitive to higher multiplicity states than those described by the fixed-order calculation (for an explicit study of some of these effects see *e.g.* [362]).

The MC generation of an event involves several stages. It starts with the random generation of the kinematics and partonic channels of whatever *hard scattering process* the user has requested at some high scale Q_0 (for complex processes, this may be carried out by an external program). This is followed by a *parton shower*, usually based on the successive random generation of gluon emissions (and $g \to q\bar{q}$ splittings). Leading contributions to the shower have emissions that are ordered according to some ordering variable. Common choices of scale for the ordering of emissions are virtuality, transverse momentum or angle. Each emission is generated at a scale lower than the previous emission, following a (soft and collinear resummed) perturbative QCD distribution, which depends on the momenta of all previous emissions. Parton showering stops at a scale of order 1 GeV, at which point a *hadronization model* is used to convert the resulting partons into hadrons. One widely-used model involves stretching a color "string" across quarks and gluons, and breaking it up into hadrons [363, 364]. Another breaks each gluon into a $q\bar{q}$ pair and then groups quarks and anti-quarks into colorless "clusters", which then give the hadrons [356]. As both models are tuned primarily to LEP data, the cluster and string models provide similar results for most observables sensitive to hadronization [362]. For pp and γp processes, modeling is also needed to treat the collision between the two hadron remnants, which generates an *underlying event* (UE), usually implemented via additional $2 \to 2$ scatterings ("multiple parton interactions", MPI) at a scale of a few GeV, following Ref. [365]. The parameter values for the MPI models must be determined from fits to minimum-bias and/or underlying-event observables of LHC collision data. As the different MC event generators are adapted to essentially the same measurements, ideally the respective MPI implementations should lead to similar predictions for each program. One complication, however, is some non-universality of the underlying event among different physics processes.

A deficiency of the soft and collinear approximations that underlie parton showers is that they may fail to reproduce the full pattern of hard wide-angle emissions, important, for example, in many new physics searches. It is therefore common to use LO multi-parton matrix elements to generate hard high-multiplicity partonic configurations as additional starting points for the showering, supplemented with some prescription (CKKW [366], MLM [367]) for consistently merging samples with different initial multiplicities. Monte Carlo generators, as described above, compute cross sections for the requested hard process that are correct at LO.

A wide variety of processes are available in MC implementations that are correct to NLO, using the MC@NLO [368] or Powheg [369] prescriptions, through the MadGraph5_aMC@NLO [140], Powheg-Box [370] and Sherpa [142] programs. Techniques have also been developed to combine NLO plus parton shower accuracy for different multiplicities of final-state jets [371]. While NLO+PS accurate predictions can now be implemented in the above tools rather easily and are available for a range of processes, given the advances in NNLO calculations it is natural to seek for NNLO+PS accurate Monte Carlos as well. The two main approaches today are the MiNNLO [372] and Geneva [373] ones. NNLO plus shower accuracy was achieved first for Drell-Yan and Higgs production [374, 375] and is now available for several $2 \to 2$ color singlet processes [376–390], as well as for heavy-quark pair-production [391–393].

It is important to understand/verify the accuracy of the par-

[7] A veto on the jet phase space can be severe, for example by requiring exactly zero jets above a given transverse momentum cut accompanying a Higgs boson, or relatively mild, for example by placing a transverse momentum cut of 30 GeV on the measurement of the production of a Higgs boson with one or more jets. In general, inclusive cross sections are preferable, as uncertainties on both the theoretical and experimental sides are smaller.

[8] The program ARIADNE [360] has also been widely used for simulating e^+e^- and DIS collisions.

ton shower predictions in the Monte Carlo programs. A general framework for assessing the logarithmic accuracy of parton-shower algorithms has been formulated, based on their ability to reproduce the singularity structure of multi-parton matrix elements, and their ability to reproduce logarithmic resummation results [394]. The dominant contributions relevant for the extension of parton showers to higher logarithmic accuracy have been computed [395–399] and included in some algorithms.

There exist ways to improve on current parton-shower algorithms [400, 401] and to demonstrate the parton shower accuracy through a comparison to analytic next-to-leading logarithmic calculations for a range of observables [401]. Considerable progress has been achieved in recent years [400–412]. References [401, 404, 405, 408, 409] introduced the first shower implementations towards NLL, but these implementations did not include spin-correlation effects and lacked full color dependence at LL level. Ref. [402] incorporated full color effects at the NLL level, while spin correlations at NLL were included in Refs. [406, 407], resulting in an NLL accurate parton shower for proton-proton collisions [410, 411]. The modifications necessary for processes such as Deep Inelastic Scattering (DIS) and Vector Boson Fusion (VBF) are addressed in [412]. The next steps involve incorporating non-perturbative effects, accounting for quark masses, and tuning NLL parton shower on experimental data.

9.2.4 *Accuracy of predictions*

Estimating the accuracy of perturbative QCD predictions is not an exact science. It is often said that LO calculations are accurate to within a factor of two. This is based on experience with NLO corrections in the cases where these are available. In processes involving new partonic scattering channels at NLO and/or large ratios of scales (such as jet observables in processes with vector bosons, or the production of high-p_t jets containing B-hadrons), the ratio of the NLO to LO predictions, commonly called the "K factor", can be substantially larger than two. NLO corrections tend to be large for processes for which there is a great deal of color annihilation in the interaction. In addition, NLO corrections tend to decrease as more final state legs are added.

For calculations beyond LO, one approach to estimate the perturbative uncertainty is to base it on the last known perturbative correction; this may lead to misleading results if new sub-processes are present at the next-higher order. A more widely used method is to estimate it from the change in the prediction when varying the renormalization and factorization scales around a central value Q that is taken close to the physical scale of the process. A conventional range of variation is $Q/2 < \mu_R, \mu_F < 2Q$, varying the two scales independently with the restriction $\frac{1}{2}\mu_R < \mu_F < 2\mu_R$ [413]. This constraint limits the risk of misleadingly small uncertainties due to fortuitous cancellations between the μ_F and μ_R dependence when both are varied together, while avoiding the appearance of large logarithms of μ_R^2/μ_F^2 when both are varied completely independently. Where possible, it can be instructive to examine the two-dimensional scale distributions (μ_R *vs.* μ_F) to obtain a better understanding of the interplay between μ_R and μ_F. This procedure should not be assumed to always estimate the full uncertainty from missing higher orders, but it does indicate the size of one important known source of higher-order ambiguity.[9]

Most $2 \to 2$ processes at the LHC are now known to NNLO. This typically results in a large reduction in the uncertainty from that obtained at NLO. However, care must be taken in the estimate of the uncertainty in processes containing jets, as accidental cancellations of the scale uncertainties may result an artificial reduction of the scale uncertainty; for some jet R values, the uncertainty may even be zero. There are several possibilities for providing a more realistic estimate of the scale uncertainty for such processes [362], but none have been widely adopted at the LHC.

Calculations that involve resummations usually have an additional source of uncertainty associated with the choice of argument of the logarithms being resummed, *e.g.* $\ln(2\frac{p_t^Z}{m_Z})$ as opposed to $\ln(\frac{1}{2}\frac{p_t^Z}{m_Z})$, as well as a prescription to switch off resummation effects when the logarithm is not large. In addition to varying renormalization and factorization scales, it is common practice to vary the argument of the logarithm by a suitable factor in either direction with respect to the default argument.

The accuracy of QCD predictions is limited also by non-perturbative (or hadronization) corrections, which typically scale as a power of Λ/Q.[10] For measurements that are directly sensitive to the structure of the hadronic final state, the corrections are usually linear in Λ/Q. The non-perturbative corrections are further enhanced in processes with a significant underlying event (*i.e.* in pp and $p\bar{p}$ collisions) and the impact of non-perturbative corrections is larger in cases where the perturbative cross sections fall steeply as a function of p_t or some other kinematic variable, for example in inclusive jet p_t or dijet mass spectra. Under high-luminosity running conditions, such as 13 TeV at the LHC, there can be on the order of 50 minimum-bias interactions occurring at each beam-beam crossing. This additional energy needs to be subtracted, and is typically removed by means of a rapidity-dependent transverse energy density determined on an event-by-event basis [419]. This subtraction, of necessity, also removes the underlying event, which must be added back in by means of MC event generator modelling if one wants to restore the measured event to the particle level.

Non-perturbative corrections are commonly estimated from the difference between Monte Carlo events at the "parton level" and at particle level. Parton level refers to the stage of the parton shower, where the evolution is stopped at an energy scale of typical hadron masses of a few GeV. An issue to be aware of is that "parton level" is not a uniquely defined concept. For example, in a MC event generator such a procedure depends on an arbitrary and tunable internal cutoff scale that separates the parton showering from the hadronization. In contrast, no such cutoff scale exists in an NLO or NNLO partonic calculation. The uncertainties in these corrections are often estimated by comparing different tunes of the various MC event generators. It should be noted that such estimates are not guaranteed to fully cover the true uncertainties.

Alternative methods exist for estimating hadronization corrections, that attempt to analytically deduce non-perturbative effects in one observable based on measurements of other observables (see the reviews [26, 420]). While they directly address the problem of different possible definitions of parton level, it should also be said that they are far less flexible than Monte Carlo programs and not always able to provide equally good descriptions of the data.

One of the main issues is whether the fixed-order partonic final state of a NLO or NNLO prediction can match the parton shower in its ability to describe the experimental jet shape (minus any underlying event). Calculations at NNLO provide a better match to the parton shower predictions than do NLO ones, as might be expected from the additional gluon available to describe the jet shape. The hadronization predictions appear to work for both orders, but at an unknown accuracy.

9.3 Experimental studies of QCD

Since we are not able to directly measure partons (quarks or gluons), but only hadrons and their decay products, a central issue for every experimental study of perturbative QCD is establishing a correspondence between observables obtained at the parton and the hadron level. The only theoretically sound correspondence is achieved by means of *infrared and collinear safe* quantities, which allow one to obtain finite predictions at any order of perturbative QCD.

As stated above, the simplest case of infrared- and collinear-safe observables are inclusive cross sections. More generally, when measuring fully inclusive observables, the final state is not analyzed at all regarding its (topological, kinematical) structure or its composition. Basically the relevant information consists in the rate of a process ending up in a partonic or hadronic final state. In e^+e^- annihilation, widely used examples are the ratios of partial widths or branching ratios for the electroweak decay of particles into hadrons or leptons, such as Z or τ decays, (*cf.* Sec. 9.2.1).

[9] Various studies have been carried out on how to estimate uncertainties from missing higher orders that go beyond scale variations [414–418].

[10] In some circumstances, the scale in the denominator could be a smaller kinematic or physical scale that depends on the observable.

Such ratios are often favored over absolute cross sections or partial widths because of large cancellations of experimental and theoretical systematic uncertainties. The strong suppression of non-perturbative effects, $\mathcal{O}(\Lambda^4/Q^4)$, is one of the attractive features of such observables, however, at the same time, the sensitivity to radiative QCD corrections is small, which for example leads to a larger statistical uncertainty when using them for the determination of the strong coupling constant. In the case of τ decays not only the hadronic branching ratio is of interest, but also moments of the spectral functions of hadronic τ decays, which sample different parts of the decay spectrum and thus provide additional information. Other examples of fully inclusive observables are structure functions (and related sum rules) in DIS. These are extensively discussed in Sec. 18 of this *Review*.

On the other hand, often the structure or composition of the final state are analyzed, and cross sections differential in one or more variables characterizing this structure are of interest. Examples are jet rates, jet substructure, event shapes or transverse momentum distributions of jets or vector bosons in hadron collisions. The case of fragmentation functions, *i.e.* the measurement of hadron production as a function of the hadron momentum relative to some hard scattering scale, is discussed in Sec. 19 of this *Review*.

It is worth mentioning that, besides the correspondence between the parton and hadron level, also a correspondence between the hadron level and the actually measured quantities in the detector has to be established. The simplest examples are corrections for finite experimental acceptance and efficiencies. Whereas acceptance corrections essentially are of theoretical nature, since they involve extrapolations from the measurable (partial) to the full phase space, other corrections such as for efficiency, resolution and response are of experimental nature. For example, measurements of differential cross sections such as jet rates require corrections in order to relate, *e.g.*, the energy deposits in a calorimeter to the jets at the hadron level. Typically detector simulations and/or data-driven methods are used in order to obtain these corrections. Care should be taken here in order to have a clear separation between the parton-to-hadron level and hadron-to-detector level corrections. Finally, for the sake of an easy comparison to the results of other experiments and/or theoretical calculations, it is suggested to provide, whenever possible, measurements corrected for detector effects and/or all necessary information related to the detector response (*e.g.*, the detector response matrix). Any fiducial phase space for measurements should be defined as close as possible to the detector-level selection in order to minimize model-dependent extrapolations. A versatile repository for storing such information is the use of Rivet routines [421].

9.3.1 *Hadronic final-state observables*

9.3.1.1 *Jets*

In hard interactions, final-state partons and hadrons appear predominantly in collimated bunches, which are generically called *jets*. To a first approximation, a jet can be thought of as a hard parton that has undergone soft and collinear showering and then hadronization. Jets are used both for testing our understanding and predictions of high-energy QCD processes, and also for identifying the hard partonic structure of decays of massive particles such as top quarks and W, Z and Higgs bosons.

In order to map observed hadrons onto a set of jets, one uses a *jet definition*. The mapping involves explicit choices: for example when a gluon is radiated from a quark, for what range of kinematics should the gluon be part of the quark jet, or instead form a separate jet? Good jet definitions are infrared and collinear safe, simple to use in theoretical and experimental contexts, applicable to any type of inputs (parton or hadron momenta, charged particle tracks, and/or energy deposits in the detectors) and lead to jets that are not too sensitive to non-perturbative effects.

An extensive treatment of the topic of jet definitions is given in Ref. [422] (for e^+e^- collisions) and Refs. [423–425]. Here we briefly review the two main classes: cone algorithms, extensively used at hadron colliders before the LHC, and sequential recombination algorithms, more widespread in e^+e^- and ep colliders and at the LHC.

Very generically, most (iterative) cone algorithms start with some seed particle i, sum the momenta of all particles j within a cone of opening-angle R, typically defined in terms of differences in rapidity and azimuthal angle. They then take the direction of this sum as a new seed and repeat until the direction of the cone is stable, and call the contents of the resulting stable cone a jet if its transverse momentum is above some threshold $p_{t,\min}$. The parameters R and $p_{t,\min}$ should be chosen according to the needs of a given analysis.

There are many variants of the cone algorithm, and they differ in the set of seeds they use and the manner in which they ensure a one-to-one mapping of particles to jets, given that two stable cones may share particles ("overlap"). The use of seed particles is a problem w.r.t. infrared and collinear safety. Seeded algorithms are generally not compatible with higher-order (or sometimes even leading-order) QCD calculations, especially in multi-jet contexts, as well as potentially subject to large non-perturbative corrections and instabilities. Seeded algorithms (JetCLU, MidPoint, and various other experiment-specific iterative cone algorithms) are therefore to be deprecated. Such algorithms are not used at the LHC, but were at the Fermilab Tevatron, where data still provide useful information, for example for global PDF fits.[11] A modern alternative is to use a seedless variant, SISCone [427].

Sequential recombination algorithms at hadron colliders (and in DIS) are characterized by a distance $d_{ij} = \min(k_{t,i}^{2p}, k_{t,j}^{2p})\Delta_{ij}^2/R^2$ between all pairs of particles i, j, where Δ_{ij} is their separation in the rapidity-azimuthal plane, $k_{t,i}$ is the transverse momentum w.r.t. the incoming beams, and R is a free parameter. At the LHC, R is typically in the range from 0.4 to 0.8, although analyses can also use jet sizes up to 1.0-1.2. They also involve a "beam" distance $d_{iB} = k_{t,i}^{2p}$. One identifies the smallest of all the d_{ij} and d_{iB}, and if it is a d_{ij}, then i and j are merged into a new pseudo-particle (with some prescription, a recombination scheme, for the definition of the merged four-momentum). If the smallest distance is a d_{iB}, then i is removed from the list of particles and called a jet. As with cone algorithms, one usually considers only jets above some transverse-momentum threshold $p_{t,\min}$. The parameter p determines the kind of algorithm: $p = 1$ corresponds to the (*inclusive-*)k_t algorithm [296, 428, 429], $p = 0$ defines the *Cambridge-Aachen* algorithm [430, 431], while for the *anti-*k_t algorithm $p = -1$ [432]. All these variants are infrared and collinear safe. Whereas the former two lead to irregularly shaped jet boundaries, the latter results in cone-like boundaries, except in situations where there are nearby jets. The *anti-*k_t algorithm has become the de-facto standard for the LHC experiments.

In e^+e^- annihilation the k_t algorithm [296] uses $y_{ij} = 2\min(E_i^2, E_j^2)(1-\cos\theta_{ij})/Q^2$ as distance measure between two particles/partons i and j and repeatedly merges the pair with smallest y_{ij}, until all y_{ij} distances are above some threshold $y_{\rm cut}$, the jet resolution parameter. Q is a measure of the overall hardness of the event. The (pseudo)-particles that remain at this point are called the jets. Here it is $y_{\rm cut}$ (rather than R and $p_{t,\min}$) that should be chosen according to the needs of the analysis. The two-jet rate in the k_t algorithm has the property that logarithms $\ln(1/y_{\rm cut})$ exponentiate. This is one reason why it is preferred over the earlier JADE algorithm [298], which uses the distance measure $y_{ij} = 2\,E_i\,E_j\,(1-\cos\theta_{ij})/Q^2$. Note that other variants of sequential recombination algorithms for e^+e^- annihilations, using different definitions of the resolution measure y_{ij}, exhibit much larger sensitivities to fragmentation and hadronization effects than the k_t and JADE algorithms [433]. Efficient implementations of the above algorithms are available through the *FastJet* package [434].

While building infrared (IR) safe jets is generally considered a solved problem, this is not quite the case when one also wishes to assign a flavor to a jet. In fact, the general experimental definition considers a flavored-jet to be a jet that contains at least one flavor tag (such as a B or D meson) above a given transverse momentum threshold. Because of collinear or soft wide-angle $g \to q\bar{q}$ splittings, it is easy to see that such a definition is neither collinear nor infrared safe. This problem was addressed

[11] In the data, the difference between the use of the Midpoint algorithm and the use of the SISCone algorithm is small [426], allowing the use of the SISCone algorithm for any theory comparisons at higher order in QCD.

in Ref. [435, 436] in the context of heavy-flavor production at the Tevatron. However, the jet-algorithm proposed in that work was impractical to implement experimentally because it was based on the k_t-algorithm. Furthermore, it required tagging two nearby flavored hadrons and involved a rather complex beam-distance measure. Since most experimental studies instead rely on the anti-k_t algorithm, recent investigations have focused on developing algorithms that preserve the anti-k_t kinematics of the jets while assigning jet flavors in an infrared safe way [437–439]. It turns out that the problem is more involved than anticipated, and a formulation of infrared-safe anti-k_t-like jets could only be achieved by introducing an interleaved flavor neutralization procedure [440]. An unfolding procedure will be necessary to convert experimental measurements of flavor-k_t jets to a form that can be directly compared to theoretical predictions.

9.3.1.2 *Event Shapes*

Event-shape variables are functions of the four momenta of the particles in the final state and characterize the topology of an event's energy flow. They are sensitive to QCD radiation (and correspondingly to the strong coupling) insofar as gluon emission changes the shape of the energy flow.

The classic example of an event shape is the *thrust* [441, 442] in e^+e^- annihilations, defined as

$$\hat{\tau} = \max_{\vec{n}_\tau} \frac{\sum_i |\vec{p}_i \cdot \vec{n}_\tau|}{\sum_i |\vec{p}_i|} \,, \tag{9.22}$$

where $\vec{p}_i$ are the momenta of the particles or the jets in the final-state and the maximum is obtained for the thrust axis $\vec{n}_\tau$. In the Born limit of the production of a perfect back-to-back $q\bar{q}$ pair, the limit $\hat{\tau} \to 1$ is obtained, whereas a perfectly spherical many-particle configuration leads to $\hat{\tau} \to 1/2$. Further event shapes of similar nature have been extensively measured at LEP and at HERA, and for their definitions and reviews we refer to Refs. [1, 8, 420, 443, 444]. The energy-energy correlation function [445], namely the energy-weighted angular distribution of produced hadron pairs, and its associated asymmetry are further shape variables which have been studied in detail at e^+e^- colliders. For hadron colliders the appropriate modification consists in only taking the transverse momentum component [446]. The event shape variable *N-jettiness* has been proposed [447], that measures the degree to which the hadrons in the final state are aligned along N jet axes or the beam direction. It vanishes in the limit of exactly N infinitely narrow jets.

Phenomenological discussions of event shapes at hadron colliders can be found in Refs. [447–451]. Measurements of hadronic event-shape distributions have been published by CDF [452], ATLAS [453–459] and CMS [460–463].

Event shapes are used for many purposes. These include measuring the strong coupling (see *e.g.* Ref. [459]), tuning the parameters of Monte Carlo programs, investigating analytical models of hadronization and distinguishing QCD events from events that might involve decays of new particles (giving event-shape values closer to the spherical limit).

9.3.1.3 *Jet substructure, quark vs. gluon jets*

Jet substructure, which can be resolved by finding subjets or by measuring jet shapes, is sensitive to the details of QCD radiation in the shower development inside a jet and has been extensively used to study differences in the properties of quark and gluon induced jets, strongly related to their different color charges. There is clear experimental evidence that gluon jets have a softer particle spectrum and are "broader" than (light-) quark jets (as expected from perturbative QCD) when looking at observables such as the jet shape $\Psi(r/R)$ (see *e.g.* Ref. [464]). This is the fraction of transverse momentum contained within a sub-cone of cone-size r for jets of cone-size R. It is sensitive to the relative fractions of quark and gluon jets in an inclusive jet sample and receives contributions from soft-gluon initial-state radiation and the underlying event. Therefore, it has been widely employed for validation and tuning of Monte Carlo parton-shower models. Furthermore, this quantity turns out to be sensitive to the modification of the gluon radiation pattern in heavy ion collisions (see *e.g.* Ref. [465]).

Jet shape measurements using proton-proton collision data have been presented for inclusive jet samples [466–468] and for top-quark production [469]. Further discussions, references and summaries can be found in Refs. [444,470–472] and Sec. 4 of Ref. [473].

The use of jet substructure has also been investigated in order to distinguish QCD jets from jets that originate from hadronic decays of boosted massive particles (high-p_t electroweak bosons, top quarks and hypothesized new particles). A considerable number of experimental studies have been carried out with Tevatron and LHC data, in order to investigate the performance of the proposed algorithms for resolving jet substructure and to apply them to searches for new physics, as well as to the reconstruction of boosted top quarks, vector bosons and the Higgs boson. For reviews of this rapidly growing field, see Sec. 5.3 of Ref. [423], Refs. [350, 351, 473–479] and references thereto. One convenient representation for visualizing jet substructure is through the Lund plane [480]. From a theoretical perspective, the Lund plane would be constructed using quarks and gluons, but similar observables can be constructed through the use of jets, as described in detail in Ref. [481].

Neural network techniques and deep learning methods have also been applied to jet and top physics and jet substructure, see *e.g.* Refs. [482–485]. Perhaps no other sub-field has benefited as much from machine learning techniques as the study of jet substructure. As a jet can have O(100) constituents each with kinematic and other information, jet substructure analysis is naturally a highly multivariate problem. Deep learning techniques can use all of the available information to study jets in their natural high dimensionality. Such techniques have not only improved discrimination between different final states/types of jets, but have also improved our understanding of perturbative QCD. See for example the review in Ref. [349].

9.3.2 *QCD measurements at colliders*

There exists a wealth of data on QCD-related measurements in e^+e^-, ep, pp, and $p\bar{p}$ collisions, to which a short overview like this would not be able to do any justice. Reviews of the subject have been published in Refs. [443, 444] for e^+e^- colliders and in Ref. [486] for ep scattering, whereas for hadron colliders overviews are given in, *e.g.*, Refs. [424, 471] and Refs. [2, 11, 487–489].

Below we concentrate our discussion on measurements that are most sensitive to hard QCD processes with focus on jet production.

9.3.2.1 e^+e^- *colliders*

Analyses of jet production in e^+e^- collisions are mostly based on data from the JADE experiment at center-of-mass energies between 14 and 44 GeV, as well as on LEP collider data at the Z resonance and up to 209 GeV. The analyses cover the measurements of (differential or exclusive) jet rates (with multiplicities typically up to 4, 5 or 6 jets), the study of three-jet events and particle production between the jets, as well as four-jet production and angular correlations in four-jet events.

Event-shape distributions from e^+e^- data have been an important input to the tuning of parton shower MC models, typically matched to matrix elements for three-jet production. In general these models provide good descriptions of the available, highly precise data. Especially for the large LEP data sample at the Z peak, the statistical uncertainties are mostly negligible and the experimental systematic uncertainties are at the percent level or even below. These are usually dominated by the uncertainties related to the MC model dependence of the efficiency and acceptance corrections (often referred to as "detector corrections").

Observables measured in e^+e^- collisions have been used for determinations of the strong coupling constant (*cf.* Section 9.4 below) and for putting constraints on the QCD color factors (*cf.* Sec. 9.1 for their definitions), thus probing the non-Abelian nature of QCD. Angular correlations in four-jet events are sensitive at leading order. Some sensitivity to these color factors, although only at NLO, is also obtained from event-shape distributions. Scaling violations of fragmentation functions and the different subjet structure in quark and gluon induced jets also give access to these color factors. A compilation of results [444] quotes world average values of $C_A = 2.89 \pm 0.03\,(\text{stat}) \pm 0.21\,(\text{syst})$

and $C_F = 1.30 \pm 0.01\,(\text{stat}) \pm 0.09\,(\text{syst})$, with a correlation coefficient of 82%. These results are in perfect agreement with the expectations from SU(3) of $C_A = 3$ and $C_F = 4/3$.

9.3.2.2 *DIS and photoproduction*

Jet measurements in *ep* collisions, both in the DIS and photoproduction regimes, allow for tests of QCD factorization (as they involve only one initial state proton and thus one PDF function), and provide sensitivity to both the gluon PDF and to the strong coupling constant. Calculations are available at NNLO in both regimes [219, 220]. An N^{3}LO calculation using the Projection-to-Born method was also presented in Ref. [221, 222]. Experimental uncertainties of the order of 5–10% have been achieved, whereas statistical uncertainties are negligible to a large extent. For comparison to theoretical predictions, at large jet p_t the PDF uncertainty dominates the theoretical uncertainty (typically of order 5–10%, in some regions of phase space up to 20%), therefore jet observables become useful inputs for PDF fits.

In general, the data are well described by the NLO and NNLO matrix-element calculations, combined with DGLAP evolution equations, in particular at large Q^2 and central values of jet pseudo-rapidity. At low values of Q^2 and x, in particular for large jet pseudo-rapidities, certain features of the data have been interpreted as requiring BFKL-type evolution, though the predictions for such schemes are still limited. It is worth noting that there is no indication that the BKFL approximation is needed within the currently probed phase space in the x, Q^2 plane, and an alternative approach [490], which implements the merging of LO matrix-element based event generation with a parton shower (using the SHERPA framework), successfully describes the data in all kinematical regions, including the low Q^2, low x domain. At moderately small x values, it should perhaps not be surprising that the BFKL approach and fixed-order matrix-element merging with parton showers may both provide adequate descriptions of the data, because some part of the multi-parton phase space that they model is common to both approaches.

In the case of photoproduction, a wealth of measurements with low p_t jets were performed in order to constrain the photon content of the proton (which is by now determined with percent accuracy thanks to the LUX approach [72, 73]). A few examples of measurements can be found in Refs. [491–495] for photoproduction and in Refs. [496–505] for DIS.

9.3.2.3 *Hadron-hadron colliders*

The spectrum of observables and the number of measurements performed at hadron colliders is enormous, probing many regions of phase space and covering a huge range of cross sections, as exemplified in Fig. 9.1 for a wide class of processes by the ATLAS experiment, and specialised to top-quark related processes by the CMS experiment at the LHC. In general, the theory agreement with data is excellent for a wide variety of processes, indicating the success of perturbative QCD with the PDF and the strong coupling as inputs. For the sake of brevity, in the following only certain classes of those measurements will be discussed, which permit various aspects of the QCD studies to be addressed. Most of our discussion will focus on LHC results, which are available for center-of-mass energies of 2.76, 5, 7, 8 and 13 TeV with integrated luminosities of up to 140 fb^{-1}. As of writing of this update, new results at 13.6 TeV are starting to appear. Generally speaking, besides representing precision tests of the Standard Model and QCD in particular, these measurements serve several purposes, such as: (i) probing pQCD and its various approximations and implementations in MC models to quantify the order of magnitude of not yet calculated contributions and to gauge their precision when used as background predictions to searches for new physics, or (ii) extracting/constraining model parameters such as the strong coupling constant or PDFs.

The final states measured at the LHC include single, double and triple gauge boson production, top production (single top, top pair and four top production), Higgs boson production, alone and in conjunction with a W or Z boson, and with a top quark pair. Many/most of these events are accompanied by additional jets. So far only limits have been placed on double Higgs production. The volume of LHC results prohibits a comprehensive description in this *Review*; hence, only a few highlights will be presented.

Among the most important cross sections measured, and the one with the largest dynamic range, is the inclusive jet spectrum as a function of the jet transverse momentum (p_t), for several rapidity regions and for p_t up to 700 GeV at the Tevatron and ~ 3.5 TeV at the LHC. It is worth noting that this latter upper limit in p_t corresponds to a distance scale of $\sim 10^{-19}$ m: no other experiment so far is able to directly probe smaller distance scales of nature than this measurement. The Tevatron inclusive jet measurements in Run 2 (Refs. [508–511]) were carried out with the MidPoint jet clustering algorithm (or its equivalent) and, in a few cases, with the k_t jet clustering algorithm. Most of the LHC measurements use the *anti-k_t* algorithm, with a variety of jet radii. The use of multiple jet radii in the same analysis allows a better understanding of the underlying QCD dynamics. Measurements by ALICE, ATLAS and CMS have been published in Refs. [512–522].

In general, we observe a good description of the data by the NLO and NNLO QCD predictions over about 11 orders of magnitude in cross section, as long as care is taken for the functional form of the central scale choice [523]. The experimental systematic uncertainties are dominated by the jet energy scale uncertainty, quoted to be in the range of a few percent (see for instance the review in Ref. [524]), leading to uncertainties of $\sim 5-30\%$ on the cross section, increasing with p_t and rapidity. The PDF uncertainties dominate the theoretical uncertainty at large p_t and rapidity. In fact, inclusive jet data are one of the most important inputs to global PDF fits, in particular for constraining the high-x gluon PDF [525–527]. Constraints on the PDFs can also be obtained from ratios of inclusive cross sections at different center-of-mass energies [513, 518]. Ratios of jet cross sections are a means to (at least partially) cancel the jet energy scale uncertainties and thus provide jet observables with significantly improved precision.

Dijet events are typically analyzed in terms of their invariant mass or average dijet p_t and angular distributions, which allows for tests of NLO and NNLO QCD predictions (see *e.g.* Refs. [517, 528, 529] for recent LHC results), and for setting stringent limits on deviations from the Standard Model, such as quark compositeness or contact interactions (some examples can be found in Refs. [520, 530–536]). Furthermore, dijet azimuthal correlations between the two leading jets, normalized to the total dijet cross section, are an extremely valuable tool for studying the spectrum of gluon radiation in the event. The azimuthal separation of the two leading jets is sensitive to multi-jet production, avoiding at the same time large systematic uncertainties from the jet energy calibration. For example, results from the Tevatron [537, 538] and the LHC [458, 539–543] show that the LO (non-trivial) prediction for this observable, with at most three partons in the final state, is not able to describe the data for an azimuthal separation below $2\pi/3$, where NLO contributions (with 4 partons) restore the agreement with data. In addition, this observable can be employed to tune Monte Carlo predictions of soft gluon radiation. Further examples of dijet observables that probe special corners of phase space are those that involve forward (large rapidity) jets and where a large rapidity separation, possibly also a rapidity gap, is required between the two jets. Reviews of such measurements can be found in Ref. [471], showing that no single prediction is capable of describing the data in all phase-space regions. In particular, no conclusive evidence for BFKL effects in these observables has been established so far.

Beyond dijet final states, measurements of the production of three or more jets, including cross section ratios, have been performed (see Refs. [471, 544] for recent reviews), as a means of testing perturbative QCD predictions, determining the strong coupling constant, and probing/tuning MC models, in particular those combining multi-parton matrix elements with parton showers [459, 545]. The calculation of three-jet production to NNLO [264] will allow more precise predictions of the three-jet to two-jet ratio, and thus the extraction of $\alpha_s(m_Z^2)$ from this observable. This calculation also allows for the use of transverse energy-energy correlations (TEEC) for the determination of $\alpha_s(m_Z^2)$ [459].

W and Z production serve as benchmark cross sections at the

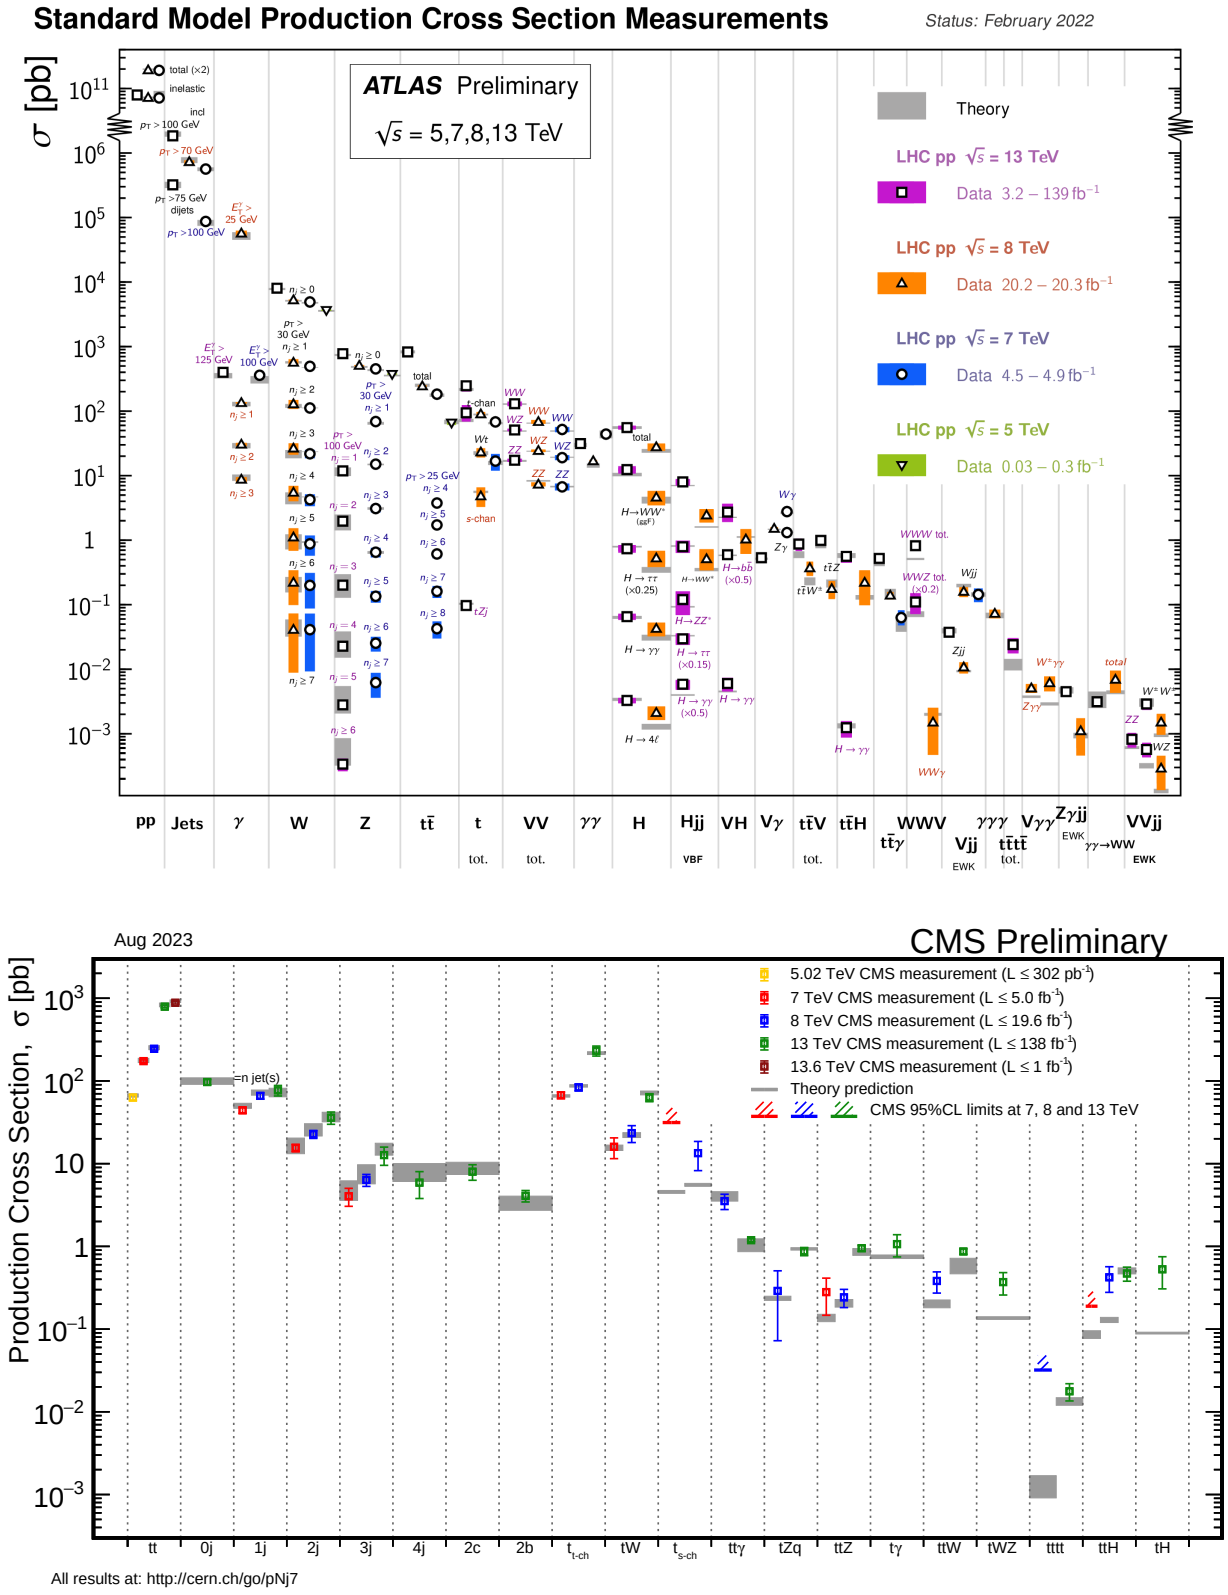

Figure 9.1: Overview of cross section measurements for a wide class of processes by the ATLAS [506] experiment, and specialised to top-quark related processes by the CMS [507] experiment at the LHC, for center-of-mass energies of 5, 7, 8, 13, and 13.6 TeV. Also shown are the theoretical predictions and their uncertainties.

LHC. The large boson mass stabilizes perturbative predictions, which results in better theoretical accuracy. In terms of experimental precision, measurements of inclusive vector boson (W, Z) production provide the most precisely determined observables at hadron colliders so far. This is because the experimental signatures are based on charged leptons which are measured much more accurately than jets or photons. At the LHC [546–553], the dominant uncertainty stems from the luminosity determination ($\leq$2–4%), while other uncertainties (*e.g.* statistical or from lepton efficiencies) are controlled at the $\sim$0.5–3% level. The uncertainty from the acceptance correction of about $\sim$1–2% can be reduced by measuring so-called fiducial cross sections, *i.e.* by applying kinematic cuts also to the particle level of the theoretical predictions. Measurements combining the electron and muon final states were able to achieve a precision a few per mille level in the dilepton final state for the normalized cross section for p_T^{ll} less than 30 GeV [554, 555]. This level of precision can also be achieved by measuring cross section ratios (W/Z or W^+/W^-). On the theory side, as discussed earlier in this *Review*, the production of these color-singlet states has been calculated to N^{3}LO [119–121]. Since the dominant theoretical uncertainty is related to the choice of PDFs, these high-precision data provide useful handles for PDF determinations.

Further insights are obtained from measurements of differential vector boson production, as a function of the invariant dilepton mass, the boson's rapidity or its transverse momentum. For example, the dilepton invariant mass distribution has been measured [556–561] for masses between 15 and 3000 GeV, covering more than 8 orders of magnitude in cross section. NNLO QCD predictions, together with modern PDF sets and including higher-order electroweak and QED final-state radiation corrections, describe the data to within 5–10% over this large range, whereas NLO predictions show larger deviations, unless matched to a parton shower.

Similar conclusions can be drawn from the observed rapidity distribution of the dilepton system (see *e.g.* Refs. [546, 557, 562]) or, in the case of W production, from the observed charged lepton rapidity distribution and its charge asymmetry. The latter is particularly sensitive to differences among PDF sets [546, 563–565], also thanks to the high precision achieved by the ATLAS and CMS experiments for central rapidity ranges. These measurements are extended to the very forward region, up to 4.5 in lepton rapidity, by the LHCb experiment [552, 553, 566].

An overview of these kinds of measurement can be found in Ref. [471]. There one can also find a discussion of and references to LHC results from studies of the vector boson's transverse momentum distribution, p_t^V (see also Refs. [567–569]). This observable covers a wide kinematic range and probes different aspects of higher-order QCD effects. It is sensitive to jet production in association with the vector boson, without suffering from the large jet energy scale uncertainties. In the p_t^V region of several tens of GeV to over 1 TeV, the NNLO predictions for V+jet can be used to predict the high-p_t boson production cross section.[12] The NNLO predictions agree with the data to within about 10%, and agree somewhat better at high transverse momentum than do the NLO predictions [570]. At transverse momenta below $\sim$20 GeV, the fixed-order predictions fail and soft-gluon resummation is needed to restore the agreement with data. The soft gluon resummation can either be performed analytically, or effectively using parton showering implemented in Monte Carlo programs. While analytic approaches reach a higher perturbative precision, they typically refer to inclusive measurements without fiducial cuts.

The addition of further jets to the final state extends the kinematic range as well as increasing the complexity of the calculation/measurements. The number of results obtained both at the Tevatron and at the LHC is extensive, summaries can be found in Refs. [471, 571], and more recent results can be found in Refs. [570, 572–575]. The measurements cover a very large phase space, *e.g.* with jet transverse momenta between 30 GeV and $\sim$ 1.5 TeV and jet rapidities up to $|y| < 4.4$ [570, 576]. Jet multiplicities as high as seven jets accompanying the vector boson have already been probed at the LHC, together with a substantial number of other kinematical observables, such as angular correlations among the various jets or among the jets and the vector boson, or the sum of jet transverse momenta, H_T. Whereas the jet p_t and H_T distributions are dominated by jet energy scale uncertainties at levels similar to those discussed above for inclusive jet production, angular correlations and jet multiplicity ratios have been measured with a precision of $\sim$ 10%, see *e.g.* Refs. [461,577].

NLO calculations for up to five jets [578] in addition to the vector boson are in good agreement with the data over that phase space, where the calculations are applicable. Predictions for V+jet at NNLO improve the description of the data for distributions involving the vector boson or the leading jet. MC models that implement parton shower matching to matrix elements (either at LO or NLO) have mixed results.

The challenges get even more severe in the case of vector boson plus heavy quark (b, c) production: on the theory side because an additional scale is introduced by the heavy quark mass, and different schemes exist for the handling of heavy quarks and their mass effects in the initial and/or final state; and on the experimental side because additional uncertainties related to the heavy-flavor tagging must be considered [579] (see also the discussion regarding flavor-jet definition in Sec. 9.3.1.1). A review of heavy quark production at the LHC is presented in Ref. [580], where the di-b-jet p_t and mass spectra are found to be well modeled within uncertainties by most generators for b-jet production with or without associated W and Z bosons. However, sizable differences between data and predictions are seen in the modeling of events with single b jets, particularly at large b-jet p_t, where gluon splitting processes become dominant, as also confirmed by studies of b-hadron and b-jet angular correlations.

The precision reached in photon measurements is in between that for lepton and jet measurements. The photon energy and angles can be measured at about the same precision as the lepton energy and angles in Drell-Yan production, but there are greater challenges encountered in photon reconstruction (for example isolation) and in purity determination. Note, though, that the photon purity approaches unity as the photon p_t increases. At high p_t, it becomes increasingly difficult for a jet to fragment into an isolated neutral electromagnetic cluster which mimics the photon signature. The inclusive photon cross section can be measured [528, 581–584], as well as the production of a photon accompanied by one or more jets [584–586, 586–590]. The kinematic range for photon production is less than that for jet production because of the presence of the electromagnetic coupling, but still reaches about 2 TeV. Better agreement is obtained with NNLO predictions for photon production than for NLO predictions, except when the latter are matched to matrix element plus parton shower predictions. Photon production in association with a heavy-flavor jet is a useful input for the determination of the b and c quark PDFs [591].

Electroweak corrections are expected to become more and more relevant now that the TeV energy range starts to be explored, and EW corrections can now also be computed automatically [171]. For a comprehensive review on electroweak corrections see Ref. [192]. For example, such corrections were found [592, 593] to be sizable (tens of percent) when studying the ratio $(d\sigma^\gamma/dp_t)/(d\sigma^Z/dp_t)$ in $\gamma\,(Z)$+jet production, p_t being the boson's transverse momentum, and might account for (some of) the differences observed in a CMS measurement [594] of this quantity.

A number of interesting developments, in terms of probing higher-order QCD effects, have occurred in the sector of diboson production, in particular for the WW and $\gamma\gamma$ cases. Regarding the former, an early disagreement of about 10% between the LHC measurements and the NLO predictions had led to a number of speculations of possible new physics effects in this channel. However, more recent ATLAS and CMS measurements [595–598] are in agreement with the NNLO prediction [131]. The statistical reach of the LHC has resulted in the discovery of triple massive gauge boson production [599–601].

In the case of diphoton production, ATLAS [602–604] and CMS [605] have provided accurate measurements, in particular

[12] For these calculations, there is a requirement of the presence of a jet, but the p_t cut is typically small (30 GeV) compared to the high p_t region being discussed here.

for phase-space regions that are sensitive to radiative QCD corrections (multi-jet production), such as small azimuthal photon separation. While there are large deviations between data and NLO predictions in this region, a calculation [228] at NNLO accuracy manages to mostly fill this gap. This is an interesting example where scale variations can not provide a reliable estimate of missing contributions beyond NLO, since at NNLO new channels appear in the initial state (gluon fusion in this case). These missing channels can be included in a matrix element plus parton shower calculation in which two additional jets are included at NLO. The result exhibits a similar level of agreement as that obtained at NNLO. Three-photon production has also been measured [606] and is in good agreement with NNLO theory predictions [260, 261].

In terms of heaviest particle involved, top-quark production at the LHC has become an important tool for probing higher-order QCD calculations, thanks to very impressive achievements both on the experimental and theoretical side, as extensively summarized in Ref. [607]. Regarding $t\bar{t}$ production, the most precise inclusive cross section measurements are achieved using the dilepton ($e\,\mu$) final state, with a total uncertainty of 4% [608–612]. This is of about the same size as the uncertainty on the most advanced theoretical predictions [128, 129, 613, 614], obtained at NNLO with additional soft-gluon resummation at NNLL accuracy [615]. There is excellent agreement between data and the QCD predictions.

The $t\bar{t}$ final state allows multiple observables to be measured. A large number of differential cross section measurements have been performed at 7, 8 and 13 TeV center-of-mass energy, studying distributions such as the top-quark p_t and rapidity, the transverse momentum and invariant mass of the $t\bar{t}$ system (probing the TeV range), or the number of additional jets. These measurements have been compared to a wide range of predictions, at fixed order up to NNLO as well as using LO or NLO matrix elements matched to parton showers. Each of the observables provides information on the high x gluon. However, there are tensions among the multiple observables that can lead to difficulties in PDF fits. Four top production has been measured in multi-lepton final states [616] by the ATLAS and CMS collaboration, with results consistent with the standard model prediction [617].

Thanks to both the precise measurements of, and predictions for, the inclusive top-pair cross section, which is sensitive to the strong coupling constant and the top-quark mass, this observable has been used to measure the strong coupling constant at NNLO accuracy from hadron collider data [618, 619] (*cf.* Section 9.4 below), as well as to obtain a measurement of the top-quark's pole mass without employing direct reconstruction methods [618, 620, 621].

The Higgs boson provides a tool for QCD studies, especially as the dominant production mechanism is gg fusion, which is subject to very large QCD corrections. Higgs boson production has been measured in the ZZ, $\gamma\gamma$, $b\bar{b}$, WW and $\tau\tau$ decay channels. A measurement of the cross section in the ZZ and $\gamma\gamma$ channels is one of the first measurements at 13.6 TeV to be published [622]. The experimental cross section is now known with a precision approaching 10% [623, 624], similar to the size of the theoretical uncertainty [625], of which the PDF+α_s uncertainty is the largest component. Part of this systematic is the mis-match in orders between the PDF determination (NNLO) and the cross section evaluation (N^{3}LO), as discussed earlier. The experimental precision has allowed detailed fiducial and differential cross section measurements. For example, with the diphoton final state, the transverse momentum of the Higgs boson can be measured out to the order of 650 GeV [626–629], where top quark mass effects become important. The production of a Higgs boson with up to 4 jets has been measured [624, 626]. The experimental cross sections have been compared to NNLO predictions (for $H+\geq 1$ jet), NLO for 2 and 3 jets, and NNLO+NNLL for the transverse momentum distribution. In addition, finite top quark mass effects have been taken into account at NLO. The use of the boosted $H \to b\bar{b}$ topology allows probes of Higgs boson transverse momenta on the order of 600 GeV and greater [624]. So far the agreement with the perturbative QCD corrections is good.

9.4 Determinations of the strong coupling constant

Beside the quark masses, the only free parameter in the QCD Lagrangian is the strong coupling constant α_s. The coupling constant in itself is not a physical observable, but rather a quantity defined in the context of perturbation theory, which enters predictions for experimentally measurable observables, such as R in Eq. (9.7). The value of the strong coupling constant must be inferred from such measurements and is subject to experimental and theoretical uncertainties. The incomplete knowledge of α_s propagates into uncertainties in numerous precision tests of the Standard Model. Here, we present an update of the 2022 PDG average value of $\alpha_s(m_Z^2)$ and its uncertainty [630].

Many experimental observables are used to determine α_s. A number of recent determinations are collected in Refs. [631, 632]. Further discussions and considerations on determinations of α_s can also be found in Refs. [633–635]. Such considerations include:

- The observable's sensitivity to α_s as compared to the experimental precision. For example, for the e^+e^- cross section to hadrons (*cf.* R in Sec. 9.2.1), QCD effects are only a small correction, since the perturbative series starts at order α_s^0; three-jet production or event shapes in e^+e^- annihilations are directly sensitive to α_s since they start at order α_s; the hadronic decay width of heavy quarkonia, $\Gamma(\Upsilon \to \text{hadrons})$, is very sensitive to α_s since its leading order term is $\propto \alpha_s^3$.
- The accuracy of the perturbative prediction, or equivalently of the relation between α_s and the value of the observable. Several observables have been known to NNLO for quite some time. These include, for instance, inclusive observables, as well as three-jet rates and event shapes in e^+e^- collisions, inclusive jet and dijet production in DIS, and inclusive jet, dijet, $t\bar{t}$, W/Z+jet and three-jet production cross sections in pp or $p\bar{p}$ collisions. The e^+e^- hadronic cross section and τ, W and Z branching fractions to hadrons are even known to N^{3}LO, if one denotes the LO as the first non-trivial term. In certain cases, fixed-order predictions are supplemented with resummation. The precise magnitude of the associated theory uncertainties usually is estimated as discussed in Sec. 9.2.4.
- The size of non-perturbative effects. Sufficiently inclusive quantities, like the e^+e^- cross section to hadrons, have small non-perturbative contributions $\sim \Lambda^4/Q^4$. Others, such as event-shape distributions, have typically contributions $\sim \Lambda/Q$.
- The scale at which the measurement is performed. An uncertainty δ on a measurement of $\alpha_s(Q^2)$, at a scale Q, translates to an uncertainty $\delta' = (\alpha_s^2(m_Z^2)/\alpha_s^2(Q^2)) \cdot \delta$ on $\alpha_s(m_Z^2)$. For example, this enhances the already important impact of precise low-Q measurements, such as from τ decays, in combinations performed at the m_Z scale.

The selection of results from which to determine the world average value of $\alpha_s(m_Z^2)$ is restricted to those that are

- published in a peer-reviewed journal at the time of writing this report,
- based on the most complete perturbative QCD predictions of at least NNLO accuracy,
- accompanied by reliable estimates of all experimental and theoretical uncertainties.

Numerous measurements from jet production in DIS and at hadron colliders are still excluded from the average presented here, because the determination of $\alpha_s(m_Z^2)$ from those data sets has not yet been upgraded to NNLO. A few new results did appear comparing to theory at NNLO and are included in the corresponding section. NLO analyses will still be discussed in this *Review*, as they are important ingredients for the experimental evidence of the energy dependence of α_s, *i.e.* for asymptotic freedom, one of the key features of QCD.

In order to calculate the world average value of $\alpha_s(m_Z^2)$, we apply, as in earlier editions, an intermediate step of pre-averaging results within the sub-fields now labeled "Hadronic τ decays and low Q^2 continuum" (τ decays and low Q^2), "Heavy quarkonia decays"

($Q\bar{Q}$ bound states), "PDF fits" (PDF fits), "Hadronic final states of e^+e^- annihilations" (e^+e^- jets & shapes), "Observables from hadron-induced collisions" (hadron colliders), and "Electroweak precision fit" (electroweak) as explained in the following sections. For each sub-field, the *unweighted average* of all selected results is taken as the pre-average value of $\alpha_s(m_Z^2)$, and the *unweighted average* of the quoted total uncertainties is assigned to be the respective overall error of this pre-average. Asymmetric total uncertainties are symmetrised beforehand by adopting the larger of the two values as the ($\pm$) uncertainty. For the "Lattice QCD" (lattice) sub-field we do not perform a pre-averaging; instead, we adopt for this sub-field the $\alpha_s(m_Z^2)$ estimate and uncertainty derived by the Flavour Lattice Averaging Group (FLAG) in Ref. [636].

Assuming that the six sub-fields (excluding lattice) are largely independent of each other, we determine a non-lattice world average value using a 'χ^2 *averaging*' method. In a last step we perform an unweighted average of the values and uncertainties of $\alpha_s(m_Z^2)$ from our non-lattice result and the lattice result presented in the FLAG 2021 report [636].

9.4.1 *Hadronic τ decays and low Q^2 continuum:*

Based on complete N^{3}LO predictions [34], analyses of the τ hadronic decay width and spectral functions have been performed, *e.g.* in Refs. [34,637–642], and lead to precise determinations of α_s at the energy scale of m_τ^2. They are based on different approaches to treat perturbative and non-perturbative contributions, the impacts of which have been a matter of intense discussions for a long time, see *e.g.* Refs. [641–644]. In particular, in τ decays there is a significant difference between results obtained using fixed-order (FOPT) or contour-improved perturbation theory (CIPT), such that analyses based on CIPT generally arrive at larger values of $\alpha_s(m_\tau^2)$ than those based on FOPT.

In addition, some results show discrepancies in $\alpha_s(m_\tau^2)$ among groups of authors using the same data sets and perturbative calculations, most likely due to different treatments of the non-perturbative contributions, *cf.* Ref. [642] with Refs. [641, 645]. References [646, 647] question the validity of using a truncated operator product expansion (OPE) at $Q^2 = m_\tau^2$ based on the disagreement found between experimental values of the spectral moments and the theory representations based on the truncated OPE fits at $Q^2 > m_\tau^2$.

Recent developments now have shed light on the disagreement between FOPT- and CIPT-based analyses. References [648–650] argue that CIPT-based calculations require a dedicated estimation of non-perturbative effects instead of "standard" ones used so far. Otherwise an asymptotic separation between results using the two perturbative approaches would remain. Potential ways forward are suggested in Refs. [651, 652]. As a consequence we remove for the time being determinations of the strong coupling constant based on CIPT from the derivation of the central value and the uncertainty of $\alpha_s(m_Z^2)$.

We determine the pre-average value of $\alpha_s(m_Z^2)$ for this sub-field only from studies that employ FOPT expansions and remove any eventual averaging with CIPT central values or increased uncertainties due to the differences in CIPT vs. FOPT. As the results from Refs. [34, 644, 645] are not totally independent, we pre-averaged as a first step these three results in the previous edition of this *Review*. Lacking, however, an estimate of the theory uncertainty for the FOPT method, Ref. [645] had to be left out, such that the first entry to this category of α_s determinations is pre-averaged from $\alpha_s(m_Z^2) = 0.1183 \pm 0.0026$ [34] and $\alpha_s(m_Z^2) = 0.1181 \pm 0.0015$ [644] to $\alpha_s(m_Z^2) = 0.1182 \pm 0.0021$ (summarized as BP 2008-16 FO in Fig. 9.2).

Subsequently, this is combined with $\alpha_s(m_Z^2) = 0.1158 \pm 0.0022$ [653] and $\alpha_s(m_Z^2) = 0.1171 \pm 0.0010$ [654], which replaces the previous result from Ref. [642]. We also include the result from τ decay and lifetime measurements, obtained in Sec. *Electroweak Model and constraints on New Physics* of the 2022 edition of this *Review* [630], $\alpha_s(m_Z^2) = 0.1171 \pm 0.0018$. The latter result, being a global fit of τ data, involves some correlations with the other extractions of this category. However, since we perform an unweighted average of the central value and uncertainty, the effects of the potential correlations are reduced. Finally, a new determination reported in Ref. [655] is added to this category: $\alpha_s(m_Z^2) = 0.1183^{+0.0009}_{-0.0012}$. A recent publication evaluating data on $R_{\rm had}$ in the continuum below the charm threshold exhibits huge experimental uncertainties and therefore has not been considered [656].

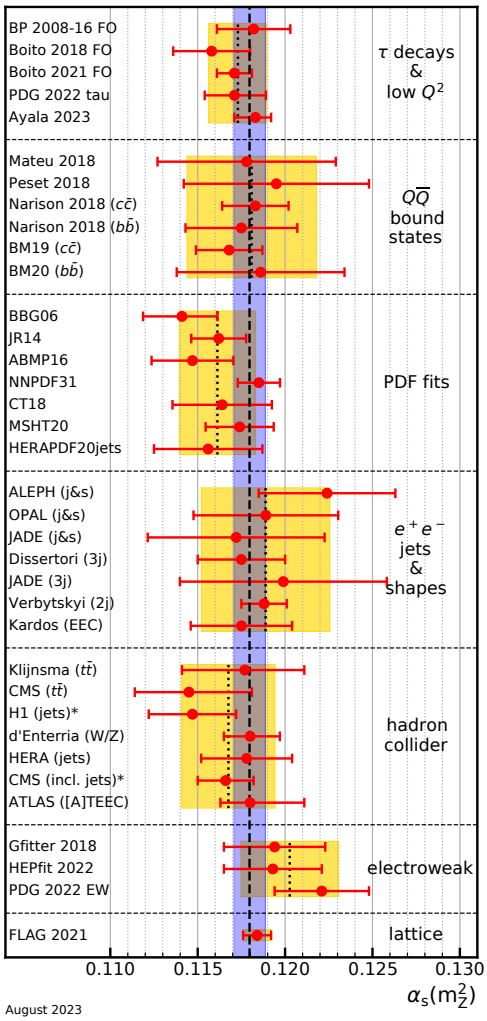

Figure 9.2: Summary of determinations of $\alpha_s(m_Z^2)$ with uncertainty in the seven sub-fields as discussed in the text. The yellow (light shaded) bands and dotted lines indicate the pre-average values of each sub-field. The dashed line and blue (dark shaded) band represent the final world average value of $\alpha_s(m_Z^2)$. The "*" symbol within the "hadron colliders" sub-field indicates a determination including a simultaneous fit of PDFs.

All these results are summarized in Fig. 9.2. Determining the unweighted average of the central values and their overall uncertainties, we arrive at $\alpha_s(m_Z^2) = 0.1173 \pm 0.0017$, which we will use as the first input for determining the world average value of $\alpha_s(m_Z^2)$. This corresponds to $\alpha_s(m_\tau^2) = 0.314 \pm 0.014$.

9.4.2 *Heavy quarkonia decays:*

Two determinations of $\alpha_s(m_Z^2)$ have been performed [657, 658] that are based on N^{3}LO accurate predictions. Reference [657] performs a simultaneous fit of the strong coupling and the bottom mass $\overline{m_b}$, including states with principal quantum number up to $n \leq 2$ in order to break the degeneracy between α_s and $\overline{m_b}$, finding $\alpha_s(m_Z^2) = 0.1178 \pm 0.0051$. Reference [658] instead uses as input of the fit the renormalon-free combination of masses of the meson B_c, the bottomonium η_b and the charmonium η_c, $M_{B_c} - M_{\eta_b}/2 - M_{\eta_c}/2$, which is weakly dependent on the heavy quark masses, but shows a good dependence on α_s. Using this observable, they obtain $\alpha_s(m_Z^2) = 0.1195 \pm 0.0053$.

Two further values are derived at NNLO in Ref. [659, 660] from mass splittings and sum rules giving $\alpha_s(m_Z^2) = 0.1183 \pm 0.0019$ and $\alpha_s(m_Z^2) = 0.1175 \pm 0.0032$ when evolved from the relevant charmonium respectively bottomonium mass scales to m_Z^2. Finally, by means of quarkonium sum rules, Refs. [661, 662] quote $\alpha_s(m_Z^2) = 0.1168 \pm 0.0019$ and $\alpha_s(m_Z^2) = 0.1186 \pm 0.0048$ for charmonium and bottomonium respectively. These six determinations satisfy our criteria to be included in the heavy-quarkonia category of the world average. Their unweighted combination leads to the pre-average for this category of $\alpha_s(m_Z^2) = 0.1181 \pm 0.0037$.

9.4.3 *PDF fits:*

Another class of studies, analyzing structure functions at NNLO QCD (and partly beyond), provide results that serve as relevant inputs for the world average of α_s. Some of these studies do *not*, however, explicitly include estimates of theoretical uncertainties when quoting fit results of α_s. In such cases we add, in quadrature, half of the difference between the results obtained in NNLO and NLO to the quoted errors.

A combined analysis of non-singlet structure functions from DIS [663], based on QCD predictions up to N^{3}LO in some of its parts, results in $\alpha_s(m_Z^2) = 0.1141 \pm 0.0022$ (BBG). Studies of singlet and non-singlet structure functions, based on NNLO predictions, result in $\alpha_s(m_Z^2) = 0.1162 \pm 0.0017$ [664] (JR14). The AMBP group [665, 666] determined a set of parton distribution functions using data from HERA, NOMAD, CHORUS, from the Tevatron and the LHC using the Drell-Yan process and the hadro-production of single-top and top-quark pairs, and determined $\alpha_s(m_Z^2) = 0.1147 \pm 0.0024$ [665].

The MSHT group [667], also including hadron collider data, determined a set of parton density functions (MSHT20) together with $\alpha_s(m_Z^2) = 0.1174 \pm 0.0013$. Similarly, the CT group [37] determined the CT18 parton density set together with $\alpha_s(m_Z^2) = 0.1164 \pm 0.0026$. The NNPDF group [668] presented NNPDF3.1 parton distribution functions together with $\alpha_s(m_Z^2) = 0.1185 \pm 0.0012$. New in this category is the result of $\alpha_s(m_Z^2) = 0.1156 \pm 0.0031$ reported as HERAPDF2.0Jets in Ref. [669]. In addition to DIS data from HERA also jet cross sections are considered in the fit to theory at NNLO.

We note that criticism has been expressed on some of the above extractions. Among the issues raised, we mention the neglect of singlet contributions at $x \geq 0.3$ in pure non-singlet fits [670], the impact and detailed treatment of particular classes of data in the fits [670, 671], possible biases due to insufficiently flexible parameterizations of the PDFs [672] and the use of a fixed-flavor number scheme [673, 674]. For recent more extensive discussions see *e.g.* Ref. [38].

Summarizing the results from world data on structure functions, taking the *unweighted average* of the central values and errors of all selected results, leads to a pre-average value of $\alpha_s(m_Z^2) = 0.1161 \pm 0.0022$, see also Fig. 9.2.

9.4.4 *Hadronic final states of e^+e^- annihilations:*

Re-analyses of jets and event shapes in e^+e^- annihilation (j&s), measured around the Z peak and at LEP2 center-of-mass energies up to 209 GeV, using NNLO predictions matched to NLL resummation and Monte Carlo models to correct for hadronization effects, resulted in $\alpha_s(m_Z^2) = 0.1224 \pm 0.0039$ (ALEPH) [675], and in $\alpha_s(m_Z^2) = 0.1189 \pm 0.0043$ (OPAL) [676]. Similarly, an analysis of JADE data [677] at center-of-mass energies between 14 and 46 GeV gives $\alpha_s(m_Z^2) = 0.1172 \pm 0.0051$, with contributions from the hadronization model and from perturbative QCD uncertainties of 0.0035 and 0.0030, respectively. Precise determinations of α_s from three-jet production alone (3j), at NNLO, resulted in $\alpha_s(m_Z^2) = 0.1175 \pm 0.0025$ [678] from ALEPH data and in $\alpha_s(m_Z^2) = 0.1199 \pm 0.0059$ [679] from JADE. A recent determination is based on an NNLO+NNLL accurate calculation that allows to fit the region of lower three-jet rate (2j) using data collected at LEP and PETRA at different energies. This fit gives $\alpha_s(m_Z^2) = 0.1188 \pm 0.0013$ [680], where the dominant uncertainty is the hadronization uncertainty, which is estimated from Monte Carlo simulations. A fit of energy-energy-correlation (EEC), also based on an NNLO+NNLL calculation, together with a Monte Carlo based modeling of hadronization corrections gives $\alpha_s(m_Z^2) = 0.1175 \pm 0.0029$ [681]. These results are summarized in the e^+e^- sector of Fig. 9.2.

Another class of α_s determinations is based on analytic modeling of non-perturbative and hadronization effects, rather than on Monte Carlo models [682–685], using methods like power corrections, factorization of soft-collinear effective field theory, dispersive models and low scale QCD effective couplings. In these studies, the world data on thrust distributions (T), or the C-parameter distributions (C), are analyzed and fitted to perturbative QCD predictions at NNLO matched with resummation of leading logs up to N^{3}LL accuracy, see Sec. 9.2.3.3. The results are $\alpha_s(m_Z^2) = 0.1135 \pm 0.0011$ [683] and $\alpha_s(m_Z^2) = 0.1134^{+0.0031}_{-0.0025}$ [684] from thrust, and $\alpha_s(m_Z^2) = 0.1123 \pm 0.0015$ [685] from C-parameter.

A long-standing question was why this latter class of determinations led systematically to rather small values of $\alpha_s(m_Z^2)$ as compared to the former one based on Monte Carlo models to correct for hadronization effects. New insights have now been gained in this regard. In a recent calculation of the leading non-perturbative contribution to the C-parameter in the three-jet symmetric limit based on an effective coupling approach it was found that it differs by a factor of two from the one in the two-jet limit [686]. Subsequently, using the same effective coupling approach, the leading $1/Q$ power correction was computed for thrust and the C-parameter in the full three-jet region under the assumption of a large (negative) n_f limit [687]. Expanding on this approach, Ref. [688] extended the calculation of non-perturbative corrections to include the heavy-jet mass, the difference of jet masses, wide broadening, and, with some caveat, the three-jet resolution variable in the Durham algorithm. The key finding in Ref. [688] is that non-perturbative corrections computed in the three-jet region significantly deviate from those computed in the two-jet limit and hence the aforementioned fits based on power corrections in the two-jet limit result in smaller values of $\alpha_s(m_Z^2)$. Another important observation is that the inclusion of resummation effects introduces a relatively substantial ambiguity outside the two-jet limit. Additionally, other factors such as the choice of mass-scheme used to extend the definition of event shapes to massive hadrons can have significant effects.

These findings are inconsistent with the very small experimental, hadronization, and theoretical uncertainties of only 2, 5, and 9 per-mille, respectively, as reported in Refs. [683, 685]. For these reasons, we exclude the results of Refs. [683–685] from the average. Determinations based on corrections for non-perturbative hadronization effects using QCD-inspired Monte Carlo generators have also faced criticism due to the differing nature of parton-level simulations compared to fixed-order calculations. However, these determinations typically exhibit a more conservative theoretical uncertainty.

Not included in the computation of the world average but worth mentioning are a computation of the NLO corrections to 5-jet production and comparison to the measured 5-jet rates at LEP [689], giving $\alpha_s(m_Z^2) = 0.1156^{+0.0041}_{-0.0034}$, and a computation of non-perturbative and perturbative QCD contributions to the scale evolution of quark and gluon jet multiplicities, including resummation, resulting in $\alpha_s(m_Z^2) = 0.1199 \pm 0.0026$ [690].

The unweighted average of the considered determinations as shown in the e^+e^- sector of Fig. 9.2 yields $\alpha_s(m_Z^2) = 0.1189 \pm 0.0037$.

9.4.5 *Observables from hadron-induced collisions:*

Until recently, determinations of α_s using hadron collider data, mostly from jet or $t\bar{t}$ production processes, could be performed at NLO only. NNLO calculations have now become available for $t\bar{t}$ [128, 613, 614] and for inclusive jet, dijet, and three-jet production [253, 264, 266, 691, 692]. For $t\bar{t}$ production, in addition, logarithms to NNLL have been resummed [615]. Both should be supplemented by electroweak corrections [693–696], which become important for high-p_T collisions at the LHC. Z+jet production, studied with respect to an α_s determination at NLO from multi-jet events in Ref. [697], is also known at NNLO for the 1-jet case [239, 698].

Determinations of α_s from production cross sections at hadron colliders also require a knowledge of the relevant PDFs for those α_s values. Two strategies are pursued for the extraction of α_s, one using pre-determined PDFs as input and a second strategy fitting the proton PDFs together with the strong coupling constant. Each global PDF group produces PDF sets not only for a value of 0.118 that is close to the world average, but also for a wide range above and below in increments of 0.001, which can be used in such determinations. The latter technique of simultaneously fitting α_s and the PDFs is technically more accurate, given that the new data used in the determination of α_s may modify the PDFs in a manner not taken into account by the α_s-variation PDFs provided by the fitting collaborations. The former technique may result in a bias of unknown magnitude [699]. As the LHC experiments have the ability to combine a PDF fit with the α_s determination, for example with tools like described in Ref. [700], we expect more experimental joint determinations of PDFs and of α_s for future iterations of this review.

The first determination of α_s at NNLO accuracy in QCD has been reported by CMS from the $t\bar{t}$ production cross section at $\sqrt{s} = 7$ TeV [618]. In former *Reviews* this opened up a new subfield on its own. In the meantime, multiple datasets on $t\bar{t}$ production from Tevatron at $\sqrt{s} = 1.96$ TeV and from LHC at $\sqrt{s} = 7$, 8, and 13 TeV have been analyzed simultaneously to determine α_s [619] to $\alpha_s(m_Z^2) = 0.1177^{+0.0034}_{-0.0036}$, where the largest uncertainties are associated with missing higher orders and with PDFs, and where an additional complication arises from the top-mass dependence. Since this combined analysis contains among other things an updated measurement as compared to the dataset used by CMS, the latter is replaced in the averaging by this combined result. A second entry into this sub-field is given by an analysis of $t\bar{t}$ production data at $\sqrt{s} = 13$ TeV from the CMS Collaboration [610]. From the four values derived for different PDF sets, the unweighted average is taken: $\alpha_s(m_Z^2) = 0.1145^{+0.0036}_{-0.0031}$. A second analysis by CMS using differential distributions of $t\bar{t}$ production [611] has been performed at NLO only and is not further considered.

From collisions at HERA the α_s determination at NNLO using inclusive jet and dijet measurements in addition to DIS data of the H1 Collaboration [505] has been corrected for an issue with the theory prediction reported in Ref. [220]. We choose the result $\alpha_s(m_Z^2) = 0.1147 \pm 0.0025$ that is derived from a simultaneous fit of the strong coupling constant together with proton PDFs. We note that results of this section derived from such a simultaneous fit will be marked with a "*" in the corresponding figures. A second determination [280] combines multiple datasets on inclusive jet production of the H1 and ZEUS collaborations into one fit using interpolation grids at NNLO. The result of $\alpha_s(m_Z^2) = 0.1178 \pm 0.0026$ has been updated for the same issue reported above [220] and is included in the unweighted average, although some of the inclusive jet data have already been used in the previous analysis. We note that the ZEUS Collaboration has presented preliminary results from a new inclusive jet measurement [701].

A first new determination of $\alpha_s(m_Z^2)$ at NNLO from inclusive jet production at the LHC has been presented by the CMS Collaboration [522]. A simultaneous fit of the strong coupling constant and the proton PDFs to the HERA DIS and the new LHC jet data gives: $\alpha_s(m_Z^2) = 0.1166 \pm 0.0016$. The ATLAS Collaboration has published an extraction of $\alpha_s(m_Z^2)$ at NNLO from the transverse energy-energy correlation (TEEC) and its asymmetry (ATEEC) [459]. The results of this first derivation from an event shape observable requiring three-jet predictions at NNLO are $\alpha_s(m_Z^2) = 0.1175^{+0.0035}_{-0.0018}$ for the TEEC and $\alpha_s(m_Z^2) = 0.1185^{+0.0027}_{-0.0015}$ for the ATEEC, respectively. We include the unweighted average of the two numbers $\alpha_s(m_Z^2) = 0.1180^{+0.0031}_{-0.0017}$ as a new result in this category. Very recently, two preliminary determinations of the strong coupling constant, albeit at NLO, have been reported by CMS from energy correlators inside jets and from azimuthal correlations among jets [702, 703].

Finally, Ref. [704] extracts the strong coupling constant from a fit at NNLO to measurements of inclusive Z and W boson production by experiments at the LHC and Tevatron colliders. From the four values quoted for different PDF sets we include the unweighted average for the CT14 and MMHT14 PDFs $\alpha_s(m_Z^2) = 0.1180^{+0.0017}_{-0.0015}$. The other results suffer from either a bad fit quality or $\alpha_s(m_Z^2)$ values outside the range of validity for the PDF set. Furthermore, two determinations using measurements of the Z boson's recoil at low p_T have been submitted using data of the CDF respectively ATLAS experiments [705,706]. The very small size of the estimated uncertainties has stimulated some discussion.

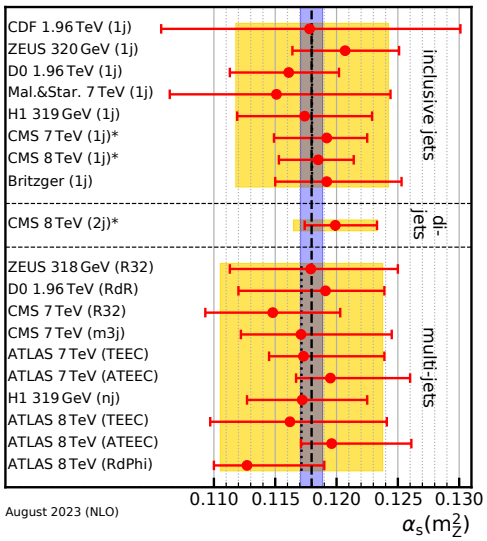

Figure 9.3: Summary of determinations of $\alpha_s(m_Z^2)$ at NLO from inclusive jet, dijet, and multi-jet measurements at hadron colliders. The uncertainty is dominated by estimates of the impact of missing higher orders. The yellow (light shaded) bands and dotted lines indicate average values for each sub-field. The dashed line and blue (dark shaded) band represent the final world average value of $\alpha_s(m_Z^2)$. The "*" symbol indicates determinations including a simultaneous fit of PDFs.

As unweighted pre-average for this sub-field we now obtain $\alpha_s(m_Z^2) = 0.1168 \pm 0.0027$. If the stricter requirement of simultaneous fits with PDFs is imposed, then only the H1 and CMS results are left giving $\alpha_s(m_Z^2) = 0.1157 \pm 0.0021$ for this sub-field. In sect. 9.4.8 below, we will also report the outcome for this choice.

Many further α_s determinations from jet measurements have not yet been advanced to NNLO accuracy. A selection of results from inclusive jet [504, 518, 707–712], dijet [529], and multi-jet measurements [455,457,458,504,713–717] is presented in Fig. 9.3, where the uncertainty in most cases is dominated by the impact of missing higher orders estimated through scale variations. From the CMS Collaboration we quote for the inclusive jet production at $\sqrt{s} = 7$ and 8 TeV, and for dijet production at 8 TeV the values that have been derived in a simultaneous fit with the PDFs and marked with "*" in the figure. The last point of the inclusive jet sub-field from Ref. [712] is derived from a simultaneous fit to six datasets from different experiments and partially includes data used already for the other data points, *e.g.* the CMS result at 7 TeV.

The multi-jet α_s determinations are based on three-jet cross sections (m3j), three- to two-jet cross-section ratios (R32), dijet angular decorrelations (RdR, RdPhi), and the aforementioned transverse energy-energy-correlations, but at $\sqrt{s} = 7$ and 8 TeV only. The H1 result is extracted from a fit to inclusive one-, two-, and three-jet cross sections (nj) simultaneously.

All NLO results are within their large uncertainties in agreement with the world average and the associated analyses provide valuable new values for the scale dependence of α_s at energy scales now extending beyond 2.0 TeV as shown in Fig. 9.5.

9.4.6 *Electroweak precision fit:*

For this category, we take the global electroweak fit of Ref. [718], which includes kinematic top quark and W boson mass measurements from the LHC, determinations of the effective leptonic electroweak mixing angles from the Tevatron, a Higgs mass measurement from ATLAS and CMS, and an evaluation of the hadronic contribution to the running of the electromagnetic coupling at the Z-boson mass. We also consider the fit of $\alpha_s(m_Z^2)$ from the global fit to electroweak data presented in the supplemental material of Ref. [719]. We choose to include the result of their "conservative scenario"[13] in accounting for the uncertainties of m_t and m_W, which avoids a potential bias from inconsistencies between the world average of the W boson mass and the new measurement reported by the CDF Collaboration in Ref. [721]. In addition, we use the newer results of the electroweak fit at the Z mass pole from LEP and SLC data presented in Sec. *Electroweak Model and constraints on New Physics* of the 2022 edition of this *Review*. All three determinations, $\alpha_s(m_Z^2) = 0.1194 \pm 0.0029$ [718], $\alpha_s(m_Z^2) = 0.1193 \pm 0.0028$ [719], and $\alpha_s(m_Z^2) = 0.1221 \pm 0.0027$ [630], are also in perfect agreement with the original result obtained from LEP and SLD data [722]. Our pre-averaging gives $\alpha_s(m_Z^2) = 0.1203 \pm 0.0028$.

We note, however, that results from electroweak precision data strongly depend on the strict validity of Standard Model predictions and the existence of the minimal Higgs mechanism to implement electroweak symmetry breaking. Any - even small - deviation of nature from this model could strongly influence this extraction of α_s.

9.4.7 *Lattice QCD:*

Several methods exist to extract the strong coupling constant from lattice QCD, as reviewed also in Sec. *Lattice QCD* of this *Review* and in Ref. [723]. The Flavour Lattice Averaging Group has considered the most up-to-date determinations and combined them to produce an updated $\alpha_s(m_Z^2)$ estimate [636]. Their final result is obtained by considering a multitude of possible input calculations and by retaining in their final estimate only those that fulfill their predefined quality criteria, detailed in the Sec. 9.2.1 of Ref. [636]. In summary, a determination of α_s needs to satisfy the following requirements:

- The determination of α_s should be based on a comparison of a short-distance quantity $\mathcal{Q}$ at scale μ with a well-defined continuum limit, which does not involve UV or IR divergences, when the quantity is expressed by using an expansion in terms of a short distance definition of the strong coupling (*e.g.* in the $\overline{MS}$ scheme);
- The scale μ, at which the determination is carried out, has to be sufficiently large such that the error associated with the perturbative truncation remains small enough;
- If $\mathcal{Q}$ is defined by physical quantities in infinite volume, one needs to satisfy the constraints $L/a \gg \mu/\Lambda_{\rm QCD}$, where L is the lattice size and a the lattice spacing;
- Only results for $n_f \geq 3$ are considered.
- As is the case for the PDG average, a calculation must be published in a peer-reviewed journal to be eligible for inclusion into the FLAG estimate.

We note that the FLAG criteria applied now are unchanged compared to the FLAG 2019 Review [724] and are considered to be relatively loose. More stringent criteria have already been formulated by FLAG, and it is likely that in future their estimate includes only those results that satisfy these stricter criteria.

Altogether, from a large number of old and new results six from the 2019 Review also enter the final FLAG 2021 estimate [725–729][14] and three new ones qualify for inclusion [730–732]. These determinations, together with their uncertainties, are displayed in Fig. 9.4. The yellow (light shaded) band and dotted line indicate the FLAG 2021 estimate, while the dashed line and blue (dark shaded) band represent the world average (see later). The level of agreement of individual results to the world average, or to the non-lattice world average is very similar.

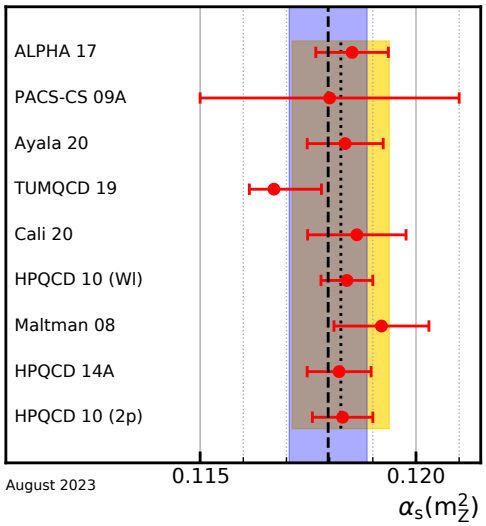

Figure 9.4: Lattice determinations that enter the FLAG 2021 estimate. The yellow (light shaded) band and dotted line indicate the *unweighted average* value for this sub-field. The dashed line and blue (dark shaded) band represent our final world average value of $\alpha_s(m_Z^2)$.

Similarly to what is done here, the FLAG Collaboration built pre-averages of results within the various classes. The five categories that contribute to their final estimate are: step-scaling methods ($\alpha_s(m_Z^2) = 0.11848 \pm 0.00081$), the potential at short distances ($\alpha_s(m_Z^2) = 0.11782 \pm 0.00165$), Wilson loops ($\alpha_s(m_Z^2) = 0.11871 \pm 0.00128$), heavy-quark current two-point functions ($\alpha_s(m_Z^2) = 0.11826 \pm 0.00200$) and, for the first time, light quark vacuum polarization ($\alpha_s(m_Z^2) = 0.11863 \pm 0.00360$). Other categories such as the calculation of QCD vertices, or of the eigenvalue spectrum of the Dirac operator have not yet published results that fulfill all requirements.

We note that, in addition to presenting new results and improvements on previous works, the ALPHA Collaboration [733] has introduced a novel approach to non-perturbative renormalization called decoupling. This strategy shifts the perspective on results involving unphysical flavor numbers, particularly $n_f = 0$. By performing a non-perturbative matching calculation, these results can be non-perturbatively related to results with $n_f > 0$. Consequently, obtaining precise and controlled $n_f = 0$ results becomes of great importance, with significant implications for future FLAG reports.

The final value is obtained by performing a *weighted average* of the pre-averages. The final uncertainty however is not the combined uncertainty of the pre-averages (which is 0.0006), since the errors on almost all determinations are dominated by the perturbative truncation error. Instead, the error on the pre-range for α_s from the step-scaling method is taken, since perturbative truncation errors are sub-dominant in this method. The final FLAG 2021 estimate (rounded to four digits) is

$$\alpha_s(m_Z^2) = 0.1184 \pm 0.0008 \qquad \text{(FLAG 2021 estimate)}\,, \quad (9.23)$$

which is fully compatible with the FLAG 2019 result of $\alpha_s(m_Z^2) = 0.1182 \pm 0.0008$.

We believe that this result expresses to a large extent the consensus of the lattice community and that the imposed criteria and the rigorous assessment of systematic uncertainties qualify for a direct inclusion of this FLAG estimate here. As in the previous review, we therefore adopt the FLAG estimate with its uncertainty as our value of α_s for the lattice category. Moreover, this lattice result will not be directly combined with any other sub-field

[13] We note that this result agrees with the previous fit in the "conservative scenario" of Ref. [720], which precedes the latest CDF W mass determination.

[14] Reference [727] contains two results.

Table 9.1: Unweighted and weighted pre-averages of $\alpha_s(m_Z^2)$ for each sub-field in columns two and three. The bottom line corresponds to the combined result (without lattice gauge theory) using the χ^2 averaging method. The same χ^2 averaging is used for column four combining all unweighted averages except for the sub-field of column one. See text for more details.

averages per sub-field	unweighted	weighted	unweighted without subfield
τ decays & low Q^2	0.1173 ± 0.0017	0.1174 ± 0.0009	0.1177 ± 0.0013
$Q\bar{Q}$ bound states	0.1181 ± 0.0037	0.1177 ± 0.0011	0.1175 ± 0.0011
PDF fits	0.1161 ± 0.0022	0.1168 ± 0.0014	0.1179 ± 0.0011
e^+e^- jets & shapes	0.1189 ± 0.0037	0.1187 ± 0.0017	0.1174 ± 0.0011
hadron colliders	0.1168 ± 0.0027	0.1169 ± 0.0014	0.1177 ± 0.0011
electroweak	0.1203 ± 0.0028	0.1203 ± 0.0016	0.1171 ± 0.0011
PDG 2023 (without lattice)	0.1175 ± 0.0010	0.1178 ± 0.0005	n/a

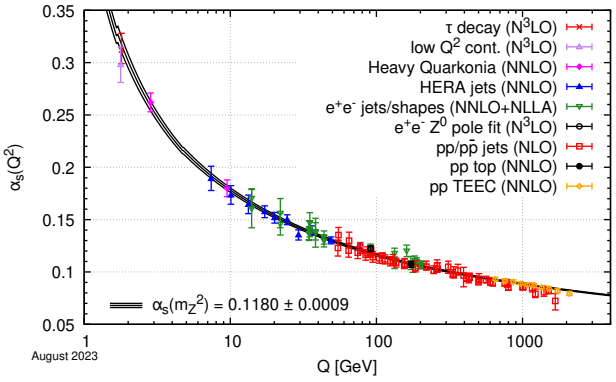

Figure 9.5: Summary of determinations of α_s as a function of the energy scale Q compared to the running of the coupling computed at five loops taking as an input the current PDG average, $\alpha_s(m_Z^2) = 0.1180 \pm 0.0009$. Compared to the previous edition, numerous points have been updated or added.

average, but with our non-lattice average to give our final world average value for α_s.

9.4.8 ***Determination of the world average value of $\alpha_s(m_Z^2)$:*** Obtaining a world average value for $\alpha_s(m_Z^2)$ is a non-trivial exercise. A certain arbitrariness and subjective component is inevitable because of the choice of measurements to be included in the average, the treatment of (non-Gaussian) systematic uncertainties of mostly theoretical nature, as well as the treatment of correlations among the various inputs, of theoretical as well as experimental origin.

We have chosen to determine pre-averages for sub-fields of measurements that are considered to exhibit a maximum degree of independence among each other, considering experimental as well as theoretical issues. The six pre-averages, illustrated also in Fig. 9.2, are listed in column two of Table 9.1. We recall that these are exclusively obtained from extractions that are based on (at least) NNLO QCD predictions, and are published in peer-reviewed journals at the time of completing this *Review*. To obtain our final world average, we first combine these six pre-averages, excluding the lattice result, using a χ^2 *averaging method*. This gives

$$\alpha_s(m_Z^2) = 0.1175 \pm 0.0010 \qquad \text{(PDG 2023 without lattice)}\,. \tag{9.24}$$

This result is fully compatible with the lattice estimate Eq. (9.23) and has a comparable error. To avoid a possible over-reduction, we combine these two numbers using an unweighted average and take as an uncertainty the average between these two uncertainties. This gives our final world average value

$$\alpha_s(m_Z^2) = 0.1180 \pm 0.0009 \qquad \text{(PDG 2023 average)}\,. \tag{9.25}$$

If for the sub-field of hadron colliders we are more restrictive and instead only accept results from a simultaneous fit of PDFs, we arrive at 0.1157 ± 0.0021 for this sub-field leading to 0.1172 ± 0.0010 (without lattice) and $\alpha_s(m_Z^2) = 0.1178 \pm 0.0009$ for the final average. Both the new world average value and the restricted result are compatible with each other and changed only marginally as compared to the values reported in the last edition of this *Review*.

It also stands to question whether the sub-fields of PDF fits and hadron colliders still are as independent as originally assumed. To test the potential impact, the fit has been repeated while grouping all $\alpha_s(m_Z^2)$ determinations of both sub-fields into a common one. We obtain 0.1164 ± 0.0024 for the new larger sub-field and 0.1178 ± 0.0011 for the combination with all other sub-fields except lattice, which is well within the estimated uncertainties. Moreover, we present in column four of Table 9.1 the combined result for $\alpha_s(m_Z^2)$ when the respective sub-field is omitted from the combination. The variation in values obtained for $\alpha_s(m_Z^2)$ is ± 0.0004, which is less than half our estimated uncertainty.

Since two long-standing issues causing offsets among determinations of $\alpha_s(m_Z^2)$ in the sub-fields of τ decays and low Q^2 and e^+e^- jets & shapes have been resolved, it may be argued that a weighted fit among the non-lattice sub-fields may be warranted. We compare the outcome of weighted fits with our standard procedure in columns two and three of Table 9.1. We observe that the weighted averages are rather close to the unweighted ones. However, the uncertainties become significantly smaller. This approach may be too aggressive as it ignores the correlations among the data, methods, and theory ingredients of the various determinations. We feel that the uncertainty of ± 0.0005 is an underestimation of the true error. We also note that in the unweighted combination the estimated uncertainty for each sub-field is larger than the spread of the results as given by the standard deviation. In the weighted fit this crosscheck fails in four out of six cases.

The last several years have seen clarification of some persistent concerns and a wealth of new results at NNLO, providing not only a rather precise and reasonably stable world average value of $\alpha_s(m_Z^2)$, but also a clear signature and proof of the energy dependence of α_s in full agreement with the QCD prediction of asymptotic freedom. This is demonstrated in Fig. 9.5, where results of $\alpha_s(Q^2)$ obtained at discrete energy scales Q are summarized, which now mostly include those based on NNLO QCD.[15] Thanks to the results from the LHC, the energy scales, at which α_s is determined, now extend even beyond 2 TeV.[16] The points in this plot are extracted from Refs. [280, 458, 459, 518, 619, 630, 653, 660, 675–677, 679, 709, 715, 716].

In this combination, as in past combinations, we have considered lattice QCD calculations of α_s independently of experimental/phenomenological determinations. In the future, when the lattice continuum extrapolations are under better control, it may be useful to group lattice QCD determinations of α_s with experimental determinations of α_s that have systematics of similar

[15] The uncertainties of the HERA jets points were, by mistake, shown at only half their size. The uncertainties of the ALEPH points of the e^+e^- jets/shapes sub-field now correspond to the total uncertainty.

[16] We note, however, that the relevant energy scale of a measurement is not uniquely defined. In addition to being multiplied by factors of *e.g.* 1/2 or 2, for instance in studies of the ratio of three- to two-jet cross sections at the LHC, the relevant scale can be taken to be the average of the transverse momenta of the two leading jets [714], or alternatively might be chosen to be the transverse momentum of the 3^{rd} jet.

origin, in a similar manner as we currently group, for example, hadron collider results together [723].

10. Electroweak Model and Constraints on New Physics

Revised April 2024 by J. Erler (KPH, JGU Mainz) and A. Freitas (Pittsburgh U.).

10.1 Introduction

The standard model of the electroweak interactions (SM) [1–4] is based on the gauge group SU(2) × U(1), with gauge bosons W^i_μ, $i = 1, 2, 3$, and B_μ for the SU(2) and U(1) factors, respectively, and the corresponding gauge coupling constants g and g'. The left-handed fermion fields of the $i^{\rm th}$ fermion family transform as doublets $\Psi_i = \begin{pmatrix} \nu_i \\ \ell_i^- \end{pmatrix}$ and $\begin{pmatrix} u_i \\ d'_i \end{pmatrix}$ under SU(2), where $d'_i \equiv \sum_j V_{ij}\, d_j$, and V is the Cabibbo-Kobayashi-Maskawa mixing [5,6] matrix. The right-handed fields are SU(2) singlets. From Higgs and electroweak precision data it is known that there are precisely three sequential fermion families. Constraints on V and tests of universality are discussed in Ref. [7] and in Section 12 on the "CKM Quark-Mixing Matrix" in this *Review*. The extension of the formalism to allow an analogous leptonic mixing matrix is discussed in Section 14 on "Neutrino Masses, Mixing, and Oscillations" in this *Review*.

A complex scalar Higgs doublet, ϕ, is added to the model for mass generation through spontaneous symmetry breaking with potential[1] given by,

$$V(\phi) = \mu^2 \phi^\dagger \phi + \frac{\lambda^2}{2} (\phi^\dagger \phi)^2 \ , \qquad \phi \equiv \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} \ . \tag{10.1}$$

For μ^2 negative, ϕ develops a vacuum expectation value, $v/\sqrt{2} = |\mu|/\lambda$, where $v = 246.22$ GeV, breaking part of the electroweak (EW) gauge symmetry, after which only one neutral Higgs scalar, H, remains in the physical particle spectrum. In non-minimal models there are additional charged and neutral scalar Higgs particles. Higgs boson physics is reviewed in Section 11 on the "Status of Higgs Boson Physics" in this *Review*.

After symmetry breaking the Lagrangian for the fermion fields, ψ_i, is

$$\begin{aligned} \mathscr{L}_F = & \sum_i \bar\psi_i \left(i \,\partial\!\!\!/ - m_i - \frac{m_i H}{v} \right) \psi_i \\ & - \frac{g}{2\sqrt{2}} \sum_i \overline{\Psi}_i \, \gamma^\mu \, (1 - \gamma^5) (T^+ \, W^+_\mu + T^- \, W^-_\mu) \, \Psi_i \\ & - e \sum_i Q_i \, \bar\psi_i \, \gamma^\mu \, \psi_i \, A_\mu \\ & - \frac{g}{2 \cos\theta_W} \sum_i \bar\psi_i \, \gamma^\mu (g^i_V - g^i_A \gamma^5) \, \psi_i \, Z_\mu \ . \end{aligned} \tag{10.2}$$

Here $\theta_W \equiv \tan^{-1}(g'/g)$ is the weak mixing angle and $e = g \sin\theta_W$ is the positron electric charge. Furthermore,

$$A_\mu \equiv B_\mu \cos\theta_W + W^3_\mu \sin\theta_W \ , \tag{10.3a}$$

$$W^\pm_\mu \equiv \frac{W^1_\mu \mp i W^2_\mu}{\sqrt{2}} \ , \tag{10.3b}$$

$$Z_\mu \equiv -B_\mu \sin\theta_W + W^3_\mu \cos\theta_W \ , \tag{10.3c}$$

are the photon field (γ) and the charged ($W^\pm$) and neutral (Z) weak boson fields, respectively.

The Yukawa coupling of H to ψ_i in the first term in $\mathscr{L}_F$, which is flavor diagonal in the minimal model, is $g m_i / 2 M_W$. From the bosonic interaction Lagrangian,

$$\begin{aligned} \mathscr{L}_{HV} = & \frac{1}{2}(v + H)^2 \left[\frac{g^2}{2} W^+_\mu W^{\mu -} + \frac{g^2 + g'^2}{4} Z_\mu Z^\mu \right] \\ & - V\left(\frac{v + H}{\sqrt{2}} \right) , \end{aligned} \tag{10.4}$$

one obtains the EW boson masses (at tree level, *i.e.*, to lowest order in perturbation theory)

$$M_H = \lambda \, v \ , \tag{10.5a}$$

$$M_W = \frac{g v}{2} = \frac{e v}{2 \sin\theta_W} \ , \tag{10.5b}$$

$$M_Z = \sqrt{g^2 + g'^2} \ \frac{v}{2} = \frac{e v}{2 \sin\theta_W \cos\theta_W} \ , \tag{10.5c}$$

$$M_\gamma = 0 \ . \tag{10.5d}$$

The second term in $\mathscr{L}_F$ represents the charged-current weak interaction [8–10], where T^+ and T^- are the weak isospin raising and lowering operators. For example, the coupling of a W to an electron and a neutrino is

$$- \frac{e}{2\sqrt{2} \sin\theta_W} \left[W^-_\mu \, \bar e \, \gamma^\mu (1 - \gamma^5) \nu + W^+_\mu \, \bar\nu \, \gamma^\mu \, (1 - \gamma^5) e \right] \ . \tag{10.6}$$

For momenta small compared to M_W, this term gives rise to the effective four-fermion interaction with the Fermi constant given by $G_F/\sqrt{2} = 1/2v^2 = g^2/8M^2_W$. CP violation is incorporated into the EW model by a single observable phase in V_{ij}.

The third term in $\mathscr{L}_F$ describes electromagnetic interactions (QED) [11, 12], and the last is the weak neutral-current interaction [9, 10, 13]. The vector and axial-vector couplings are

$$g^i_V \equiv t_{3L}(i) - 2 Q_i \sin^2\theta_W \ , \tag{10.7a}$$

$$g^i_A \equiv t_{3L}(i) \ , \tag{10.7b}$$

where $t_{3L}(i)$ is the weak isospin of fermion i ($+1/2$ for u_i and ν_i; $-1/2$ for d_i and e_i) and Q_i is the charge of ψ_i in units of e.

The first term in Eq. (10.2) also gives rise to fermion masses, and in the presence of right-handed neutrinos to Dirac neutrino masses. The possibility of Majorana masses is discussed in Section 14 on "Neutrino Mass, Mixing, and Oscillations" in this *Review*.

10.2 Renormalization and radiative corrections

In addition to the Higgs boson mass, M_H, the fermion masses and mixings, and the strong coupling constant, α_s, the SM has three parameters. The set with the smallest experimental errors contains the Z mass[2], the Fermi constant, and the fine structure constant. The latter two will be discussed in more detail in

[1] There is no generally accepted convention to write the quartic term. Our numerical coefficient simplifies Eq. (10.5a) below and the squared coupling preserves the relation between the number of external legs and the power counting of couplings at a given loop order. This structure also naturally emerges from physics beyond the SM, such as Supersymmetry.

[2] We emphasize that in the fits described in Sec. 10.6 and Sec. 10.7 the values of the SM parameters are affected by all observables that depend on

the next two subsections. (The numerical values quoted in Sections 10.2–10.4 correspond to the main fit result in Table 10.7.)

10.2.1 *The Fermi constant*

The Fermi constant,

$$G_F = 1.1663788(6) \times 10^{-5}\ \text{GeV}^{-2}\ , \tag{10.8}$$

is derived from the μ lifetime formula[3],

$$\frac{\hbar}{\tau_\mu} = \frac{G_F^2 m_\mu^5}{192\pi^3}\, F(\rho)\Big[1 + H_1(\rho)\frac{\widehat{\alpha}(m_\mu)}{\pi} + H_2(\rho)\frac{\widehat{\alpha}^2(m_\mu)}{\pi^2} + H_3\frac{\widehat{\alpha}^3(m_\mu)}{\pi^3}\Big]\ , \tag{10.9}$$

where $\rho = m_e^2/m_\mu^2$, and where

$$F(\rho) = 1 - 8\rho + 8\rho^3 - \rho^4 - 12\rho^2 \ln\rho = 0.99981295\ , \tag{10.10a}$$

$$H_1(\rho) = \frac{25}{8} - \frac{\pi^2}{2} - \left(9 + 4\pi^2 + 12\ln\rho\right)\rho + 16\pi^2\rho^{3/2} + \mathcal{O}(\rho^2) = -1.80793\ , \tag{10.10b}$$

$$H_2(\rho) = \frac{156815}{5184} - \frac{518}{81}\pi^2 - \frac{895}{36}\zeta(3) + \frac{67}{720}\pi^4 + \frac{53}{6}\pi^2\ln 2 - (0.042 \pm 0.002)_{\text{had}} - \frac{5}{4}\pi^2\sqrt{\rho} + \mathcal{O}(\rho) = 6.64\ , \tag{10.10c}$$

$$\widehat{\alpha}(m_\mu)^{-1} = \alpha^{-1} + \frac{1}{3\pi}\ln\rho + \mathcal{O}(\alpha) = 135.901\ . \tag{10.10d}$$

H_1 and H_2 capture the QED corrections within the Fermi model. The results for $\rho = 0$ have been obtained in Refs. [16] and [17,18] for H_1 and H_2, respectively, where the term in parentheses is from the hadronic vacuum polarization [17]. The mass corrections to H_1 have been known for some time [19], while those to H_2 are more recent [20]. Notice the term linear in m_e in H_2 whose appearance was unforeseen and can be traced to the use of the muon pole mass in the prefactor [20]. The coefficient $H_3 = -15.3 \pm 2.3$ has been estimated in Refs. [21–23]. The remaining uncertainty in G_F is mostly experimental and has been reduced by an order of magnitude by the MuLan collaboration [15] at the PSI.

10.2.2 *The electromagnetic coupling*

The fine structure constant, α, can be extracted from the anomalous magnetic moment of the electron, $a_e = (1159652180.59 \pm 0.13) \times 10^{-12}$ [24]. Application of QED corrections up to five loop order [25–27] allows to extract the value $\alpha^{-1} = 137.035999166(15)$. (Here the number in paratheses denotes the uncertainty in the last digits shown.) Another approach combines measurements of the Rydberg constant and atomic masses with interferometry of atomic recoil kinematics. Applied to ^{87}Rb [28] and ^{133}Cs [29], this method implies the results $\alpha^{-1} = 137.035999206(11)$ and $\alpha^{-1} = 137.035999046(27)$, respectively, which differ by 5.5 σ from each other, and when combined would give $\alpha^{-1} = 137.035999183(10)$. Finally, combining the anomalous magnetic moment and atomic interferometry methods, which unlike in the past are now in agreement, leads to the world average,

$$\alpha^{-1} = 137.035999178(8)\ . \tag{10.11}$$

This combination differs from the value in Section 1 ("Physical Constants") in this *Review*, which does not use the latest experimental inputs.

In most EW renormalization schemes it is convenient to define a running α dependent on the energy scale of the process, with $\alpha^{-1} \approx 137.036$ appropriate at very low energy, *i.e.* close to the Thomson limit. The OPAL [30] and L3 [31] collaborations at LEP could also observe the running directly in small and large angle Bhabha scattering, respectively. For scales above a few hundred MeV the low energy hadronic contribution to vacuum polarization introduces a theoretical uncertainty in α. In the modified minimal subtraction ($\overline{\text{MS}}$) scheme[4] [32] (used for this *Review*), and with $\alpha_s(M_Z) = 0.1187 \pm 0.0017$ we have $\widehat{\alpha}^{(4)}(m_\tau)^{-1} = 133.450 \pm 0.006$ and $\widehat{\alpha}^{(5)}(M_Z)^{-1} = 127.930 \pm 0.008$. The latter corresponds to a quark sector contribution (without the top) to the conventional (on-shell) QED coupling,

$$\alpha(M_Z) = \frac{\alpha}{1 - \Delta\alpha(M_Z)}\ , \tag{10.12}$$

of $\Delta\alpha^{(5)}_{\text{had}}(M_Z) = 0.02783 \pm 0.00006$. These values are updated with respect to Ref. [33] with the uncertainty reduced (partly due to a more precise charm quark mass). Various evaluations of $\Delta\alpha^{(5)}_{\text{had}}(M_Z)$ are summarized in Table 10.1, where the relation[5] between the $\overline{\text{MS}}$ and on-shell definitions (obtained using Refs. [37, 38]) is given by,

$$\begin{aligned}
&\Delta\widehat{\alpha}(M_Z) - \Delta\alpha(M_Z) \\
&= \frac{\alpha}{\pi}\left[\frac{100}{27} - \frac{1}{6} - \frac{7}{4}\ln\frac{M_Z^2}{M_W^2} + \frac{\alpha_s(M_Z)}{\pi}\left(\frac{605}{108} - \frac{44}{9}\zeta(3)\right)\right. \\
&+ \frac{\alpha_s^2}{\pi^2}\left(\frac{976481}{23328} - \frac{253}{36}\zeta(2) - \frac{781}{18}\zeta(3) + \frac{275}{27}\zeta(5)\right) \\
&+ \frac{\alpha_s^3}{\pi^3}\left(\frac{1483517111}{3359232} - \frac{22781}{144}\zeta(2) - \frac{3972649}{7776}\zeta(3) - \frac{31}{81}\zeta(2)^2\right. \\
&\left.\left. + \frac{521255}{7776}\zeta(5) - \frac{7315}{324}\zeta(7) + \frac{5819}{54}\zeta(2)\zeta(3) + \frac{14675}{162}\zeta(3)^2\right)\right] \\
&= 0.007122(2)(5)\ ,
\end{aligned} \tag{10.13}$$

and where the first entry of the lowest order term is from fermions and the other two are from $W^\pm$ loops, which are usually excluded from the on-shell definition. Fermion mass effects and corrections of $\mathcal{O}(\alpha^2)$ contributing to Eq. (10.13) are small, partly cancel each other and are not included here. The first error in Eq. (10.13) is parametric (from α_s) and the second is from the truncation of the perturbative expansion. The most recent results of $\Delta\alpha^{(5)}_{\text{had}}(M_Z)$ [39–42] typically assume the validity of perturbative QCD (PQCD) at scales of ~ 2 GeV and above and are in good agreement with each other. In regions where PQCD is not trusted, one can use $e^+e^- \to$ hadrons cross-section data (for a list of references see, *e.g.*, Ref. [41]) and isospin rotated information derived from τ decay spectral functions [43], where the latter derive from OPAL [44], CLEO [45], ALEPH [46], and Belle [47]. Very recently new results appeared from the CMD-3 experiment [48] at the e^+e^- collider VEPP-2000. There is noticeable spread in the results, with lattice QCD [49] and CMD-3 (KLOE) suggesting stronger (weaker) running. While VEPP-2000 and VEPP-4M scanned center-of-mass (CM) energies up to 2 GeV and between about 3 and 4 GeV, respectively, the BaBar collaboration studied multi-hadron events radiatively returned from the $\Upsilon(4S)$, reconstructing the radiated photon and normalizing to $\mu^\pm\gamma$ final states.

We include all of this information by using as actual input (fit constraint) instead of $\Delta\alpha^{(5)}_{\text{had}}(M_Z)$ the low energy contribution by

them. This is of no practical consequence for α and G_F, however, since they are very precisely known. Also note that other choices for the three SM input parameters (see *e.g.* Ref. [14]) will lead to equivalent fit results within theoretical uncertainties.

[3] In the spirit of the Fermi theory, we incorporated the small propagator correction, 3/5 m_μ^2/M_W^2, into Δr (see below). This is also the convention adopted by the MuLan collaboration [15]. While this breaks with historical consistency, the numerical difference was negligible in the past.

[4] In this Section we denote quantities defined in the $\overline{\text{MS}}$ scheme by a caret; the exception is the strong coupling constant, α_s, which will always correspond to the $\overline{\text{MS}}$ definition and where the caret will be dropped. Furthermore, $\alpha^{(n)}$ and $\alpha_s^{(n)}$ denote the running couplings with n quark flavors.

[5] In practice, $\alpha(M_Z)$ is directly evaluated in the $\overline{\text{MS}}$ scheme using the FORTRAN package GAPP [34], including the QED contributions of both leptons and quarks. The leptonic three-loop [35] and four-loop [36] contributions in the on-shell scheme have also been obtained.

the three light quarks,

$$\Delta\alpha^{(3)}_{\rm had}(2.0\ {\rm GeV}) = (60.30 \pm 0.43) \times 10^{-4}\ , \qquad (10.14)$$

which we obtained relying on the analysis in Ref. [41], with τ decay data and the latest CMD-3 results added following Ref. [50]. Its correlation (86% [51]) with a_μ discussed in Sec. 10.4.2, is included in the fits. The non-linear α_s dependence of $\widehat{\alpha}(M_Z)$ and the resulting correlation with the input variable α_s are fully taken into account by calculating the perturbative and heavy quark contributions to $\widehat{\alpha}(M_Z)$ in each call of the fits according to Ref. [33]. Part of the uncertainty ($\pm 0.37 \times 10^{-4}$) in $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ is from the combination of e^+e^- annihilation data, τ decays into two-pion final states, and constraints from lattice QCD (LQCD), but un-calculated higher order perturbative QCD corrections ($\pm 0.21 \times 10^{-4}$) and the $\overline{\rm MS}$ quark mass values (see below) also contribute.

10.2.3 *Quark masses*

Further free parameters entering into Eq. (10.2) are the quark and lepton masses, where m_i is the mass of the $i^{\rm th}$ fermion ψ_i. For the light quarks, as described in Section 60 on "Quark Masses" in this *Review*, $\widehat{m}_u = 2.16^{+0.49}_{-0.26}$ MeV, $\widehat{m}_d = 4.67^{+0.48}_{-0.17}$ MeV, and $\widehat{m}_s = 93.4^{+8.6}_{-3.4}$ MeV. These are running $\overline{\rm MS}$ masses evaluated at the scale $\mu = 2$ GeV. For the charm mass we use the constraint [58],

$$\widehat{m}_c(\widehat{m}_c) = 1274 \pm 8 + 2616\,[\alpha_s(M_Z) - 0.1182]\ {\rm MeV}\ , \qquad (10.15)$$

which is based on QCD sum rules [59,60], and recalculate $\widehat{m}_c$ in each call of our fits to account for its α_s dependence. Similarly, for the bottom quark mass we use [61],

$$\widehat{m}_b(\widehat{m}_b) = 4180 \pm 8 - 108\,[\alpha_s(M_Z) - 0.1182]\ {\rm MeV}\ , \qquad (10.16)$$

with a theoretical correlation of about 60% arising from the PQCD truncation uncertainty which is similar for $\widehat{m}_c(\widehat{m}_c)$ and $\widehat{m}_b(\widehat{m}_b)$. To improve the precisions in $\widehat{m}_c(\widehat{m}_c)$ and $\widehat{m}_b(\widehat{m}_b)$ in the future it would help to remeasure the threshold regions of the heavy quarks, as well as the electronic decay widths of the narrow $c\bar{c}$ and $b\bar{b}$ resonances. It would also be important to obtain data on the R-ratio in e^+e^- annihilation for center-of-mass energies $\gtrsim 11.2$ GeV, as in this region QCD perturbation theory cannot be sufficiently relied upon for b quarks [61].

The top quark "pole" mass (the quotation marks are a reminder that the experiments do not strictly measure the pole mass and that quarks do not form asymptotic states) has been kinematically reconstructed by the Tevatron collaborations, CDF and DØ, in leptonic, hadronic, and mixed channels with the result [62],

$$m_t = 174.30 \pm 0.35_{\rm\,stat.} \pm 0.54_{\rm\,syst.}\ {\rm GeV\ (Tevatron)}\ . \qquad (10.17)$$

Likewise, using data from CM energies $\sqrt{s} = 7$ and 8 TeV (Run 1), ATLAS and CMS (including alternative technique measurements) at the LHC obtained [63],

$$m_t = 172.52 \pm 0.14_{\rm\,stat.} \pm 0.30_{\rm\,syst.}\ {\rm GeV\ (LHC\ Run\ 1)}\ . \qquad (10.18)$$

In addition, there are results derived from $\sqrt{s} = 13$ TeV data (Run 2). The CMS collaboration obtained $m_t = 171.77 \pm 0.04_{\rm\,stat.} \pm 0.37_{\rm\,syst.}$ GeV [64] in the lepton + jets channel, $m_t = 172.33 \pm 0.14_{\rm\,stat.} \pm 0.69_{\rm\,syst.}$ GeV [65] in the di-lepton channel, $m_t = 172.34 \pm 0.20_{\rm\,mostly\,stat.} \pm 0.70_{\rm\,syst.}$ GeV [66] in the all-jets channel, and $m_t = 172.13 \pm 0.32_{\rm\,stat.} \pm 0.70_{\rm\,syst.}$ GeV [67] in t-channel single top events (leptonic decays). ATLAS quotes $m_t = 174.41 \pm 0.39_{\rm\,stat.} \pm 0.71_{\rm\,syst.}$ GeV [68] from the lepton + jets channel and $m_t = 172.21 \pm 0.20_{\rm\,stat.} \pm 0.78_{\rm\,syst.}$ GeV [69] from the di-lepton channel. Assuming that the correlation matrix for individual channels of the Run 1 combination [63] is approximately applicable also at Run 2 (and that the same applies to the effective 9% correlation between ATLAS and CMS which can also be extracted from Ref. [63]), we arrive at the result,

$$m_t = 172.13 \pm 0.06_{\rm\,stat.} \pm 0.30_{\rm\,syst.}\ {\rm GeV\ (LHC\ Run\ 2)}\ . \qquad (10.19)$$

To combine the two LHC runs, we use the largest correlation coefficient (0.51) between 7 TeV and 8 TeV results from the same experiment and channel in Ref. [63], and obtain,

$$m_t = 172.30 \pm 0.07_{\rm\,stat.} \pm 0.27_{\rm\,syst.}\ {\rm GeV\ (LHC)}\ . \qquad (10.20)$$

This treatment is highly conservative in view of the fact that for their lepton + jets channels novel leptonic invariant mass and profile likelihood approaches were used by ATLAS and CMS, respectively, implying reduced correlations with the more traditional analyzes at Run 1. Note that the statistical uncertainty of the combination (0.07 GeV) is larger than that of the CMS lepton+jets measurement at 13 TeV (0.04 GeV) [64] because the latter has a relatively large systematic uncertainty and thus gets a small weight in the average. See Ref. [70] for a detailed discussion.

The Tevatron and LHC average values, (10.17) with (10.20), differ by 2.8 σ. In the inter-collider combination we treat them as uncorrelated, yielding

$$m_t = 172.61 \pm 0.25_{\rm\,exp.}\ {\rm GeV} + \Delta m_{\rm MC}\ , \qquad (10.21)$$

where $\Delta m_{\rm MC}$ is defined to account for any difference between the top pole mass, m_t, and the mass parameter implemented in the Monte Carlo event generators employed by the experimental groups. $\Delta m_{\rm MC}$ is expected to be of order $\alpha_s(Q_0)Q_0$ with a low scale $Q_0 \sim \mathcal{O}(1\ {\rm GeV})$ [71], but its value is unknown in hadron collider environments so that we will treat it as an uncertainty instead[6], and choose for definiteness $Q_0 = \Gamma_t = 1.42$ GeV to arrive at $\Delta m_{\rm MC} = 0 \pm 0.52$ GeV. We further assume that an uncertainty [74] of ± 0.32 GeV in the relation [75] between m_t and the $\overline{\rm MS}$ definition, $\widehat{m}_t(\widehat{m}_t)$, entering electroweak radiative correction libraries, including the renormalon ambiguity [76], is already included in $\Delta m_{\rm MC}$, as m_t merely serves as an intermediate bookkeeping device in Ref. [71]. A promising future direction to arrive at a competitive independent constraint on m_t is to analyze differential top quark pair production cross-sections at next-to-next-to-leading order (NNLO) [77,78] as m_t extraction based on them are easier to interpret, and experimentally they have become much more precise recently [79–82]. The combination in Eq. (10.21) differs slightly from the average, $m_t = 172.57 \pm 0.29_{\rm\,exp.}$ GeV, which appears in the Top Quark Listings in this *Review*, and which is based exclusively on published results and assumes vanishing correlations. For more details and references, see Section 61 on the "Top Quark" and the Quarks Listings in this *Review*.

10.2.4 *The weak mixing angle*

The observables $\sin^2\theta_W$ and M_W can be calculated from M_Z, $\widehat{\alpha}(M_Z)$, and G_F, when values for m_t and M_H are given, or conversely, M_H can be constrained by $\sin^2\theta_W$ and M_W. The value of $\sin^2\theta_W$ is extracted from neutral-current processes (see Sec. 10.3) and Z pole observables (see Sec. 10.5.4) and depends on the renormalization prescription. There are a number of popular schemes [9] leading to values which differ by small factors depending on m_t and M_H. The notation for these schemes is shown in Table 10.2.

(i) The on-shell scheme [84] promotes the tree-level formula $\sin^2\theta_W = 1 - M_W^2/M_Z^2$ to a definition of the renormalized $\sin^2\theta_W$ to all orders in perturbation theory, *i.e.*,

$$\sin^2\theta_W \to s_W^2 \equiv 1 - \frac{M_W^2}{M_Z^2}\ , \qquad (10.22a)$$

$$M_W = \frac{A_0}{s_W(1-\Delta r)^{1/2}}\ , \qquad M_Z = \frac{M_W}{c_W}\ , \qquad (10.22b)$$

where $c_W \equiv \cos\theta_W$, $A_0 = (\pi\alpha/\sqrt{2}G_F)^{1/2} = 37.28038(1)$ GeV, and Δr includes the radiative corrections relating α, $\alpha(M_Z)$, G_F, M_W, and M_Z. One finds $\Delta r \sim$

[6] However, see Ref. [72, 73] for proposed procedures to calibrate the Monte-Carlo mass parameter at hadron colliders.

Table 10.1: Evaluations of the on-shell $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ by different groups (for a more complete list of evaluations see the 2012 edition of this *Review*). For better comparison we adjusted central values and errors to correspond to a common and fixed value of $\alpha_s(M_Z) = 0.120$, except for Ref. [49], for which α_s is not an explicit input. References quoting results without the top quark decoupled are converted to the five flavor definition. Ref. [52] uses $\Lambda_{\rm QCD} = 380 \pm 60$ MeV; for the conversion we assumed $\alpha_s(M_Z) = 0.118 \pm 0.003$.

Table 10.2: Notations used to indicate the various $\sin^2\theta_W$ schemes discussed in the text. Numerical values and the uncertainties induced by the imperfectly known SM parameters and unknown higher orders [83] are also given for illustration.

Scheme	Notation	Value	Uncertainty
On-shell	s^2_W	0.22348	± 0.00010
$\overline{\rm MS}$	$\widehat{s}^2_Z$	0.23129	± 0.00004
$\overline{\rm MS}$ (ND)	$\widehat{s}^2_{\rm ND}$	0.23147	± 0.00004
$\overline{\rm MS}$	$\widehat{s}^2_0$	0.23873	± 0.00005
Effective angle	$\bar{s}^2_\ell$	0.23161	± 0.00004

$\Delta r_0 - \rho_t \tan^{-2}\theta_W$, where $\Delta r_0 = 1 - \alpha/\widehat{\alpha}(M_Z) = 0.06646(6)$ is due to the running of α, and

$$\rho_t = \frac{3G_F m_t^2}{8\sqrt{2}\pi^2} = 0.00934 \times \frac{m_t^2}{(172.61\ {\rm GeV})^2} \ , \qquad (10.23)$$

represents the dominant (quadratic) m_t dependence. There are additional contributions to Δr from bosonic loops, including those which depend logarithmically on M_H and higher-order corrections[7]. One has $\Delta r = 0.03685 \mp 0.00020 \pm 0.00006$, where the first uncertainty is from m_t (the $\mp$ sign indicates that increasing m_t has the effect of decreasing Δr) and the second is from $\alpha(M_Z)$. Thus the value of s^2_W extracted from M_Z includes an uncertainty (∓ 0.00007) from the currently allowed range of m_t. This scheme is simple conceptually. However, the relatively large ($\sim 3\%$) correction from ρ_t causes large spurious contributions in higher orders. s^2_W depends not only on the gauge couplings but also on the spontaneous-symmetry breaking, and it is awkward in the presence of any extension of the SM which perturbs the value of M_Z (or M_W). Other definitions are motivated by the tree-level coupling constant definition $\theta_W = \tan^{-1}(g'/g)$:

(ii) In particular, the $\overline{\rm MS}$ scheme introduces the quantity,

$$\sin^2\widehat{\theta}_W(\mu) \equiv \frac{\widehat{g}'^2(\mu)}{\widehat{g}^{\,2}(\mu) + \widehat{g}'^2(\mu)} \ , \qquad (10.24)$$

where the couplings $\widehat{g}$ and $\widehat{g}'$ are defined by modified minimal subtraction and the scale μ is conveniently chosen to be M_Z for many EW processes. The value of $\widehat{s}^2_Z \equiv \sin^2\widehat{\theta}_W(M_Z)$ extracted from M_Z is less sensitive than s^2_W to m_t (by a factor of $\tan^2\theta_W$), and is less sensitive to most types of new physics. It is also very useful for comparing with the predictions of grand unification. There are actually several variant definitions of $\sin^2\widehat{\theta}_W(M_Z)$, differing according to whether or how finite $\alpha\ln(m_t/M_Z)$ terms are decoupled (subtracted from the couplings). One cannot entirely decouple the $\alpha\ln(m_t/M_Z)$ terms from all EW quantities because $m_t \gg m_b$ breaks SU(2) symmetry. The scheme that will be adopted here decouples the $\alpha\ln(m_t/M_Z)$ terms from the γ–Z mixing [32, 85], essentially eliminating any $\ln(m_t/M_Z)$ dependence in the formulae for asymmetries at the Z pole when written in terms of $\widehat{s}^2_Z$. (A similar definition is used for $\widehat{\alpha}$.) The on-shell and $\overline{\rm MS}$ definitions are related by

$$\widehat{s}^2_Z = c(m_t, M_H) s^2_W = (1.0349 \pm 0.0003) s^2_W \ . \qquad (10.25)$$

The quadratic m_t dependence is given by $c \sim 1 + \rho_t/\tan^2\theta_W$. The expressions for M_W and M_Z in the $\overline{\rm MS}$ scheme are

$$M_W = \frac{A_0}{\widehat{s}_Z(1 - \Delta\widehat{r}_W)^{1/2}} \ , \quad M_Z = \frac{M_W}{\widehat{\rho}^{\,1/2}\widehat{c}_Z} \ , \qquad (10.26)$$

and one predicts $\Delta\widehat{r}_W = 0.06937 \pm 0.00006$. $\Delta\widehat{r}_W$ has no quadratic m_t dependence, because shifts in M_W are absorbed into the observed G_F, so that the error in $\Delta\widehat{r}_W$ is almost entirely due to $\Delta r_0 = 1 - \alpha/\widehat{\alpha}(M_Z)$. The quadratic m_t dependence has been shifted into $\widehat{\rho} \sim 1 + \rho_t$, where including bosonic loops, $\widehat{\rho} = 1.01016 \pm 0.00009$.

(iii) A variant $\overline{\rm MS}$ quantity $\widehat{s}^2_{\rm ND}$ (used in the 1992 edition of this *Review*) does not decouple the $\alpha\ln(m_t/M_Z)$ terms [86]. It is related to $\widehat{s}^2_Z$ by

$$\widehat{s}^2_Z = \frac{\widehat{s}^2_{\rm ND}}{1 + \frac{\widehat{\alpha}}{\pi}d} \ ,$$
$$d = \frac{1}{3}\left(\frac{1}{\widehat{s}^{\,2}} - \frac{8}{3}\right)\left[\left(1 + \frac{\alpha_s}{\pi}\right)\ln\frac{m_t}{M_Z} - \frac{15\alpha_s}{8\pi}\right] \ . \qquad (10.27)$$

Thus, $\widehat{s}^2_Z - \widehat{s}^2_{\rm ND} = -0.0002$.

(iv) Some of the low-energy experiments discussed in the next section are sensitive to the weak mixing angle at almost van-

[7] All explicit numbers quoted here and below include the two- and three-loop corrections described near the end of Sec. 10.2.

ishing momentum transfer [39,87–89]. Thus, Table 10.2 also includes $\widehat{s}_0^2 \equiv \sin^2\widehat{\theta}_W(0)$.

(v) Yet another definition, the effective angle [90, 91], $\bar{s}_f^2 \equiv \sin\theta_{\rm eff}^f$, for the Z vector coupling to fermion f, is based on Z pole observables and described in Sec. 10.5.

10.2.5 *Radiative corrections*

Experiments are at such level of precision [83] that complete one-loop, dominant two-loop, and partial three and four-loop radiative corrections must be applied. For neutral-current and Z pole processes, these corrections are conveniently divided into two classes:

1. QED diagrams involving the emission of real photons or the exchange of virtual photons in loops, but not including vacuum polarization diagrams. These graphs often yield finite and gauge-invariant contributions to observable processes. However, they are dependent on energies, experimental cuts, *etc.*, and must be calculated individually for each experiment.
2. EW corrections, including $\gamma\gamma$, γZ, ZZ, and WW vacuum polarization diagrams, as well as vertex corrections, box graphs, *etc.*, involving virtual W and Z bosons. One-loop corrections [92] are included for all processes, and many two-loop corrections are also important. In particular, two-loop corrections involving the top quark modify ρ_t in $\widehat{\rho}$, Δr, and elsewhere by

$$\rho_t \to \rho_t \left[1 + R(M_H, m_t)\,\frac{\rho_t}{3}\right] . \qquad (10.28)$$

$R(M_H, m_t)$ can be described as an expansion in M_Z^2/m_t^2, for which the leading m_t^4/M_Z^4 [93, 94] and next-to-leading m_t^2/M_Z^2 [95, 96] terms are known. The complete two-loop calculation of Δr (without further approximation) has been performed in Refs. [97–101]. More recently, Ref. [102] obtained the $\overline{\rm MS}$ quantities $\Delta\widehat{r}_W$ and $\widehat{\rho}$ to two-loop accuracy, confirming the prediction of M_W in the on-shell scheme from Refs. [99, 103] within about 4 MeV. Similarly, the EW two-loop corrections for the relation between $\bar{s}^2_{\ell,b}$ and s^2_W are known [104–109], as well as for the partial decay and total decay widths and the effective couplings of the Z boson [110–113]. For $\bar{s}_{s,c}$ only two-loop corrections from diagrams with closed fermion loops are available [114], but given the experimental precision this is more than adequate.

The mixed QCD-EW contributions to gauge boson self-energies of order $\alpha\alpha_s m_t^2$ [115, 116], $\alpha\alpha_s^2 m_t^2$ [117, 118], and $\alpha\alpha_s^3 m_t^2$ [119–121] increase the predicted value of m_t by 6%. This is, however, almost entirely an artifact of using the pole mass definition for m_t. The equivalent corrections when using the $\overline{\rm MS}$ definition $\widehat{m}_t(\widehat{m}_t)$ increase m_t by less than 0.5%. The sub-leading $\alpha\alpha_s$ corrections [122–125] are also included. Further three-loop corrections of order $\alpha\alpha_s^2$ [126,127], $\alpha^3 m_t^6$, $\alpha^2\alpha_s m_t^4$ [128, 129], α_f^3 and $\alpha_f^2\alpha_s$ [130, 131] are rather small (here α_f denotes electroweak corrections with a closed fermion loop). The same is true for $\alpha^3 M_H^4$ [132] corrections unless M_H approaches 1 TeV. The theoretical uncertainty from unknown higher-order corrections [83] is estimated to amount to 4 MeV for the prediction of M_W [103] and 4.5×10^{-5} for $\bar{s}^2_\ell$ [114].

Throughout this *Review* we utilize EW radiative corrections from the program GAPP [34], which works entirely in the $\overline{\rm MS}$ scheme, and which is independent of the ZFITTER [133] and GRIFFIN [134] packages.

10.3 Low energy electroweak observables

In the following we discuss EW precision observables obtained at low momentum transfers [135], *i.e.*, $Q^2 \ll M_Z^2$. It is convenient to write the four-fermion interactions relevant to ν-hadron, ν-e, as well as parity violating e-hadron and e-e neutral-current processes, in a form that is valid in an arbitrary gauge theory (assuming massless left-handed neutrinos). One has[8],

Table 10.3: SM tree level expressions for the neutral-current parameters for ν-hadron, ν-e, and e^- scattering processes. To obtain the SM values in the last column, the tree level expressions have to be multiplied by the low-energy neutral-current ρ parameter, $\rho_{\rm NC} = 1.00060$, and further vertex and box corrections need to be added as detailed in Ref. [13]. The dominant m_t dependence is again given by $\rho_{\rm NC} \sim 1 + \rho_t$.

Quantity	SM tree level	SM value
$g_{LV}^{\nu_\mu e}$	$-\frac{1}{2} + 2\,\widehat{s}_0^2$	−0.0395
$g_{LA}^{\nu_\mu e}$	$-\frac{1}{2}$	−0.5063
$g_{LL}^{\nu_\mu u}$	$\frac{1}{2} - \frac{2}{3}\,\widehat{s}_0^2$	0.3457
$g_{LL}^{\nu_\mu d}$	$-\frac{1}{2} + \frac{1}{3}\,\widehat{s}_0^2$	−0.4288
$g_{LR}^{\nu_\mu u}$	$-\frac{2}{3}\,\widehat{s}_0^2$	−0.1553
$g_{LR}^{\nu_\mu d}$	$\frac{1}{3}\,\widehat{s}_0^2$	0.0777
g_{AV}^{ee}	$\frac{1}{2} - 2\,\widehat{s}_0^2$	0.0224
g_{AV}^{eu}	$-\frac{1}{2} + \frac{4}{3}\,\widehat{s}_0^2$	−0.1886
g_{AV}^{ed}	$\frac{1}{2} - \frac{2}{3}\,\widehat{s}_0^2$	0.3418
g_{VA}^{eu}	$-\frac{1}{2} + 2\,\widehat{s}_0^2$	−0.0349
g_{VA}^{ed}	$\frac{1}{2} - 2\,\widehat{s}_0^2$	0.0246

$$-\mathscr{L}^{\nu e} = \frac{G_F}{\sqrt{2}}\,\bar{\nu}\gamma_\mu(1-\gamma^5)\nu\;\bar{e}\,\gamma^\mu(g_{LV}^{\nu e} - g_{LA}^{\nu e}\,\gamma^5)e\;, \qquad (10.29a)$$

$$-\mathscr{L}^{\nu h} = \frac{G_F}{\sqrt{2}}\,\bar{\nu}\,\gamma_\mu(1-\gamma^5)\nu\sum_q\Big[g_{LL}^{\nu q}\,\bar{q}\,\gamma^\mu(1-\gamma^5)q + g_{LR}^{\nu q}\,\bar{q}\,\gamma^\mu(1+\gamma^5)q\Big]\,, \qquad (10.29b)$$

$$-\mathscr{L}^{ee} = -\frac{G_F}{\sqrt{2}}\,g_{AV}^{ee}\,\bar{e}\,\gamma_\mu\gamma^5 e\;\bar{e}\,\gamma^\mu e\;, \qquad (10.29c)$$

$$-\mathscr{L}^{eh} = -\frac{G_F}{\sqrt{2}}\sum_q\Big[g_{AV}^{eq}\,\bar{e}\,\gamma_\mu\gamma^5 e\;\bar{q}\,\gamma^\mu q + g_{VA}^{eq}\,\bar{e}\,\gamma_\mu e\;\bar{q}\;\gamma^\mu\gamma^5 q\Big]\;, \qquad (10.29d)$$

where one must include the charged-current contribution for ν_e-e and $\bar{\nu}_e$-e and the parity conserving QED contribution for electron scattering. The SM tree level expressions for the four-Fermi couplings are given in Table 10.3. Note that they differ from the respective products of the gauge couplings in (10.7) in the radiative corrections and in the presence of possible physics beyond the SM.

10.3.1 *Neutrino scattering*

The cross-section in the laboratory system for $\nu_\mu e \to \nu_\mu e$ or $\bar{\nu}_\mu e \to \bar{\nu}_\mu e$ elastic scattering [9,136] is (in this subsection we drop the redundant index L in the effective neutrino couplings),

$$\frac{d\sigma_{\nu,\bar{\nu}}}{dy} = \frac{G_F^2 m_e E_\nu}{2\pi}\Big[(g_V^{\nu e} \pm g_A^{\nu e})^2 + (g_V^{\nu e} \mp g_A^{\nu e})^2(1-y)^2 - (g_V^{\nu e 2} - g_A^{\nu e 2})\frac{y\,m_e}{E_\nu}\Big]\,, \qquad (10.30)$$

where the upper (lower) sign refers to $\nu_\mu(\bar{\nu}_\mu)$, and $y \equiv T_e/E_\nu$ (which runs from 0 to $(1+m_e/2E_\nu)^{-1}$) is the ratio of the kinetic energy of the recoil electron to the incident ν or $\bar{\nu}$ energy. For

[8] We use here slightly different definitions (and to avoid confusion also a different notation) for the coefficients of these four-Fermi operators than we did in previous editions of this *Review*. The new couplings [13] are defined in the static limit, $Q^2 \to 0$, with specific radiative corrections included, while others (more experiment specific ones) are assumed to be removed by the experimentalist. They are convenient in that their determinations from very different types of processes can be straightforwardly combined.

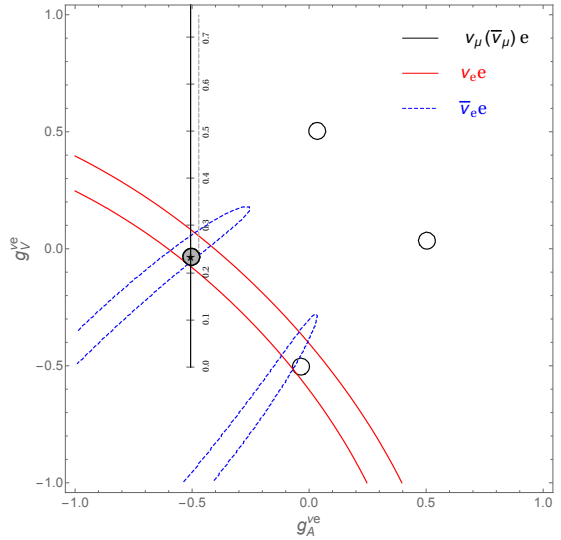

Figure 10.1: Allowed contours in $g_A^{\nu e}$ *vs.* $g_V^{\nu e}$ from neutrino-electron scattering and the SM prediction as a function of $\widehat{s}^2_Z$. (The SM best fit value, $\widehat{s}^2_Z = 0.23129$, is also indicated.) The ν_e-e [140, 141] and $\bar{\nu}_e$-e [142] constraints are at 1 σ, while each of the four equivalent $\nu_\mu(\bar{\nu}_\mu)$-e [137–139] solutions ($g_{V,A} \to -g_{V,A}$ and $g_{V,A} \to g_{A,V}$) are at the 90% CL. The global best fit region (shaded) almost exactly coincides with the corresponding $\nu_\mu(\bar{\nu}_\mu)$-e region. The solution near $g_A = 0$ and $g_V = -0.5$ is eliminated by $e^+e^- \to \ell^+\ell^-$ data under the weak additional assumption that the neutral current is dominated by the exchange of a single Z boson.

$E_\nu \gg m_e$ this yields a total cross-section

$$\sigma = \frac{G_F^2 m_e E_\nu}{2\pi}\left[(g_V^{\nu e} \pm g_A^{\nu e})^2 + \frac{1}{3}(g_V^{\nu e} \mp g_A^{\nu e})^2\right] \ . \qquad (10.31)$$

The most accurate measurements of $\sin^2\theta_W$ from ν-lepton scattering (see Sec. 10.6) are from the ratio $R \equiv \sigma_{\nu_\mu e}/\sigma_{\bar{\nu}_\mu e}$, in which many of the systematic uncertainties cancel. The results are $\sin^2\theta_W = 0.211 \pm 0.037$ [137], $\sin^2\theta_W = 0.195 \pm 0.022$ [138], and $\sin^2\theta_W = 0.2324 \pm 0.0083$ [139], where radiative corrections (other than m_t effects) are small compared to the precision of present experiments and have negligible effect. As shown in Fig. 10.1, one can determine $g_{V,A}^{\nu e}$ from the experimental data as well. The cross-sections for ν_e-e and $\bar{\nu}_e$-e may be obtained from Eq. (10.30) by replacing $g_{V,A}^{\nu e}$ by $g_{V,A}^{\nu e} + 1$, where the 1 is due to the charged-current contribution.

A precise determination of the on-shell s^2_W, which depends only very weakly on m_t and M_H, is obtained from deep inelastic scattering (DIS) of neutrinos [136, 143] from (approximately) isoscalar targets. The ratio $R_\nu \equiv \sigma^{NC}_{\nu N}/\sigma^{CC}_{\nu N}$ of neutral-to-charged-current cross-sections has been measured to 1% accuracy by CDHS [144] and CHARM [145] at CERN. CCFR [146] at Fermilab has obtained an even more precise result, so it is important to obtain theoretical expressions for R_ν and $R_{\bar{\nu}} \equiv \sigma^{NC}_{\bar{\nu}N}/\sigma^{CC}_{\bar{\nu}N}$ to comparable accuracy. Fortunately, many of the uncertainties from the strong interactions and neutrino spectra cancel in the ratio. A large theoretical uncertainty is associated with the c-threshold, which mainly affects σ^{CC}. Using the slow rescaling prescription [147, 148] the central value of $\sin^2\theta_W$ from CCFR varies as $0.0111(m_c/\text{GeV} - 1.31)$, where m_c is the effective mass which is numerically close to the $\overline{\text{MS}}$ mass $\widehat{m}_c(\widehat{m}_c)$, but their exact relation is unknown at higher orders. For $m_c = 1.31 \pm 0.24$ GeV, which was determined from ν-induced di-muon production [149], this contributes ± 0.003 to the total error of $\Delta \sin^2\theta_W = \pm 0.004$ (the experimental uncertainty was also ± 0.003). This uncertainty largely cancels, however, in the Paschos-Wolfenstein ratio [150],

$$R^- = \frac{\sigma^{NC}_{\nu N} - \sigma^{NC}_{\bar{\nu}N}}{\sigma^{CC}_{\nu N} - \sigma^{CC}_{\bar{\nu}N}} \ . \qquad (10.32)$$

It was measured by Fermilab's NuTeV collaboration [151] for the first time, and required a high-intensity and high-energy anti-neutrino beam.

A simple zero$^{\text{th}}$-order approximation is,

$$R_\nu = g_L^2 + g_R^2 r \ , \qquad R_{\bar{\nu}} = g_L^2 + \frac{g_R^2}{r} \ , \qquad (10.33a)$$

$$R^- = g_L^2 - g_R^2 \ , \qquad r \equiv \frac{\sigma^{CC}_{\bar{\nu}N}}{\sigma^{CC}_{\nu N}} \ , \qquad (10.33b)$$

where r is the ratio of $\bar{\nu}$ to ν charged-current cross-sections which can be measured directly[9], and

$$g_L^2 \equiv (g_{LL}^{\nu_\mu u})^2 + (g_{LL}^{\nu_\mu d})^2 \approx \frac{1}{2} - \sin^2\theta_W + \frac{5}{9}\sin^4\theta_W \ , \qquad (10.34a)$$

$$g_R^2 \equiv (g_{LR}^{\nu_\mu u})^2 + (g_{LR}^{\nu_\mu d})^2 \approx \frac{5}{9}\sin^4\theta_W \ . \qquad (10.34b)$$

In practice, Eq. (10.33b) must be corrected for quark mixing, quark sea effects, c quark threshold effects, non-isoscalarity, W–Z propagator differences, the finite muon mass, QED and EW radiative corrections. Details of the neutrino spectra, experimental cuts, x and Q^2 dependence of structure functions, and longitudinal structure functions, enter only at the level of these corrections and therefore lead to very small uncertainties. CCFR quotes $s^2_W = 0.2236 \pm 0.0041$ for the reference values $(m_t, M_H) = (175, 150)$ GeV with very little sensitivity to (m_t, M_H).

The NuTeV collaboration found $s^2_W = 0.2277 \pm 0.0016$ (for the same reference values), which was 3.0 σ higher than the SM prediction [151]. However, since then several groups have raised concerns about the interpretation of the NuTeV result, which could affect the extracted $g^2_{L,R}$ (and thus s^2_W) including their uncertainties and correlation. These include the assumption of symmetric strange and anti-strange sea quark distributions, the electron neutrino contamination from K_{e3} decays, isospin symmetry violation in the parton distribution functions and from QED splitting effects, nuclear shadowing effects, and a more complete treatment of EW and QCD radiative corrections. A more detailed discussion and a list of references can be found in the 2016 edition of this *Review*. The precise impact of these effects would need to be evaluated carefully by the collaboration, but in the absence of such an effort we do not include the νDIS constraints in our default set of fits.

Recently, the COHERENT collaboration was the first to observe the coherent elastic neutrino nucleus scattering (CEνNS) process [152] on a target consisting mostly of ^{133}Cs and ^{127}I, and at the opposite end of the kinematic scale where the momentum transfer is significantly smaller than the inverse of the nuclear radius. Subsequently, COHERENT [153] observed CEνNS using a liquid ^{40}Ar detector, as well. The coherence enhances the process roughly proportional to the square of the number of neutrons in the nuclei, but the process is difficult to observe as the experimental signature is a mere keV scale nuclear recoil.

10.3.2 *Parity violating lepton scattering*

Reviews on weak polarized electron scattering may be found in Refs. [9, 154]. The SLAC polarized electron-deuteron DIS (eDIS) experiment [155] measured the parity violating right-left asymmetry,

$$A_{RL} \equiv \frac{\sigma_R - \sigma_L}{\sigma_R + \sigma_L} \ , \qquad (10.35)$$

where $\sigma_{R,L}$ is the cross-section for the deep-inelastic scattering of a right- or left-handed electron, $e_{R,L}N \to e\text{X}$. In the quark

[9] In the simple parton model, ignoring hadron energy cuts, $r \approx (1 + 3\epsilon)/(3 + \epsilon)$, where $\epsilon \sim 0.125$ is the ratio of the fraction of the nucleon's momentum carried by anti-quarks to that carried by quarks.

parton model,

$$\frac{A_{RL}}{Q^2} = a_1 + a_2\,\frac{1-(1-y)^2}{1+(1-y)^2}\ , \tag{10.36}$$

where $Q^2 > 0$ is the momentum transfer and y is the fractional energy transfer from the electron to the hadrons. For the deuteron or other isoscalar targets, one has, neglecting the s quark and anti-quarks,

$$a_1 = \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(g_{AV}^{eu} - \frac{1}{2}g_{AV}^{ed}\right) \approx \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(-\frac{3}{4} + \frac{5}{3}\widehat{s}_0^2\right)\ , \tag{10.37a}$$

$$a_2 = \frac{3G_F}{5\sqrt{2}\pi\alpha}\left(g_{VA}^{eu} - \frac{1}{2}g_{VA}^{ed}\right) \approx \frac{9G_F}{5\sqrt{2}\pi\alpha}\left(\widehat{s}_0^2 - \frac{1}{4}\right)\ . \tag{10.37b}$$

The Jefferson Lab Hall A collaboration [156, 157] improved on the SLAC result by measuring A_{RL} at $Q^2 = 1.085$ GeV^2 and 1.901 GeV^2, and determined the weak mixing angle to 2% precision, $\widehat{s}_Z^2 = 0.2299 \pm 0.0043$. In another polarized electron scattering experiment on deuterons, but in the quasi-elastic kinematic regime, the SAMPLE experiment [158, 159] at MIT-Bates extracted the combination $g_{VA}^{eu} - g_{VA}^{ed}$ at Q^2 values of 0.038 GeV^2 and 0.091 GeV^2. What was actually determined were nucleon form factors from which the quoted results were obtained by the removal of a multi-quark radiative correction [160]. Other linear combinations of the effective couplings have been determined in polarized lepton scattering at CERN in μ-^{12}C DIS [161] (the observable was the double charge-helicity cross-section asymmetry), at Mainz in e-^{9}Be (quasi-elastic) [162], and at Bates in e-^{12}C (elastic) [163]. More recent polarized electron scattering experiments, *i.e.*, SAMPLE, the PVA4 experiment at Mainz, and the HAPPEX and GØ experiments at Jefferson Lab, have focussed on the strange quark content of the nucleon [164].

A_{RL} can also be measured in fixed target polarized Møller scattering, $e^-e^- \to e^-e^-$, and reads [165],

$$\frac{A_{RL}}{Q^2} = -2\,g_{AV}^{ee}\,\frac{G_F}{\sqrt{2}\pi\alpha}\,\frac{1-y}{1+y^4+(1-y)^4}\ . \tag{10.38}$$

It has been determined at low $Q^2 = 0.026$ GeV^2 in the SLAC E158 experiment [166], with the result, $A_{RL} = (-1.31 \pm 0.14_{\,\text{stat.}} \pm 0.10_{\,\text{syst.}}) \times 10^{-7}$. Expressed in terms of the weak mixing angle in the $\overline{\text{MS}}$ scheme this yields $\widehat{s}^2(161\text{ MeV}) = 0.2403 \pm 0.0013$, and as shown in Fig. 10.2 established the scale dependence of the weak mixing angle at the level of 6.4 σ. One also extracts the model-independent effective coupling, $g_{AV}^{ee} = 0.0190 \pm 0.0027$ [13]. One-loop radiative corrections and implications are discussed in Ref. [87].

In a similar experiment and at about the same $Q^2 = 0.0248$ GeV^2, the Q_{weak} collaboration at Jefferson Lab obtained $A_{RL} = (-2.265 \pm 0.073_{\,\text{stat.}} \pm 0.058_{\,\text{syst.}}) \times 10^{-7}$ [167, 168] in elastic $e^-p \to e^-p$ scattering. To extract the physical quantity of interest, the weak charge of the proton [169], a large ($\approx 30\%$) correction had to be applied to A_{RL} arising from electromagnetic, strange, and axial form factors. This was achieved by performing a global fit [170] including a large number of A_{RL} data points at larger Q^2, dominated by the HAPPEX result at $Q^2 = 0.109$ GeV^2 [171]. Finally, the constraint, $2g_{AV}^{eu} + g_{AV}^{ed} = 0.0356 \pm 0.0023$, which translates into a weak mixing angle measurement of $\widehat{s}^2(157\text{ MeV}) = 0.2382 \pm 0.0011$, could be deduced, after correcting for a relatively large and uncertain contribution from the γZ box diagram [172–175].

10.3.3 *Atomic parity violation*

There are precise measurements of atomic parity violation (APV) [9, 176, 177] in ^{133}Cs [178, 179] (at the 0.4% level [178]), ^{205}Tl [180, 181], ^{208}Pb [182], and ^{209}Bi [183]. The EW physics is contained in the nuclear weak charges $Q_W(Z,N)$, where Z and N are the numbers of protons and neutrons in the nucleus. In terms

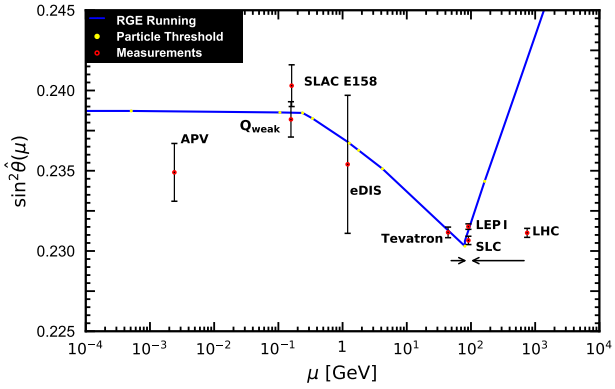

Figure 10.2: Scale dependence of the weak mixing angle defined in the $\overline{\text{MS}}$ scheme [39, 88] (for the scale dependence in a mass-dependent renormalization scheme, see Ref. [87]). The minimum of the curve corresponds to $\mu = M_W$, below which we switch to an effective theory with the $W^\pm$ bosons integrated out, and where the β-function for $\widehat{s}^2(\mu)$ changes sign. At M_W and each fermion mass there are also discontinuities arising from scheme dependent matching terms, which are necessary to ensure that the various effective field theories within a given loop order describe the same physics. However, in the $\overline{\text{MS}}$ scheme these are very small numerically and barely visible in the figure provided one decouples quarks at $\mu = \widehat{m}_q(\widehat{m}_q)$. The width of the curve exceeds the theory uncertainty from strong interaction effects which at low energies is at the level of $\pm 2 \times 10^{-5}$ [39]. The Tevatron and LHC measurements are strongly dominated by invariant masses of the final-state di-lepton pair of $\mathcal{O}(M_Z)$ and can thus be considered as additional Z pole data points. For clarity we displayed the Tevatron and LHC points horizontally to the left and right, respectively.

of the nucleon vector couplings,

$$g_{AV}^{ep} \equiv 2g_{AV}^{eu} + g_{AV}^{ed} \approx -\frac{1}{2} + 2\widehat{s}_0^2\ , \tag{10.39a}$$

$$g_{AV}^{en} \equiv g_{AV}^{eu} + 2g_{AV}^{ed} \approx +\frac{1}{2}\ , \tag{10.39b}$$

one has,

$$Q_W(Z,N) \equiv -2\big[Z(g_{AV}^{ep} + 0.00005) + N(g_{AV}^{en} + 0.00006)\big]\left(1 - \frac{\alpha}{2\pi}\right)\ , \tag{10.40}$$

where the numerically small adjustments are discussed in Ref. [13] and include the result of the γZ-box correction from Ref. [184].

E.g., $Q_W(^{133}_{78}\text{Cs})$ is extracted by measuring experimentally the ratio of the parity violating amplitude, E_{PNC}, to the Stark vector transition polarizability, β, and by calculating theoretically E_{PNC} in terms of Q_W. One can then write,

$$Q_W(^{133}_{78}\text{Cs}) = N\left(\frac{\text{Im}\,E_{\text{PNC}}}{\beta}\right)_{\text{exp.}}\left(\frac{|e|\,a_B}{\text{Im}\,E_{\text{PNC}}}\,\frac{Q_W}{N}\right)_{\text{th.}} \times \left(\frac{\beta}{a_B^3}\right)_{\text{exp.+th.}}\left(\frac{a_B^2}{|e|}\right)\ , \tag{10.41}$$

where a_B is the Bohr radius. There are currently two semi-empirical approaches to β of similar precision. The ratio of the off-diagonal hyperfine amplitude to the vector polarizability was measured directly by the Boulder group [185]. Combined with the hyperfine amplitude, computed precisely in Ref. [186], one finds $\beta = (26.957 \pm 0.044_{\,\text{exp.}} \pm 0.027_{\,\text{th.}})\,a_B^3$. Alternatively, one can combine [187] the measurement of the ratio of scalar to vector transition polarizabilities [188] with the recent calculation of the scalar polarizability [189] to obtain $\beta = (26.887 \pm 0.030_{\,\text{exp.}} \pm 0.021_{\,\text{th.}})\,a_B^3$, in agreement with earlier results [190, 191] based on this approach. The two determinations average to $\beta = (26.911 \pm 0.025_{\,\text{exp.}} \pm 0.017_{\,\text{th.}})\,a_B^3$.

The uncertainties associated with the atomic wave function calculations are relatively small for cesium [9, 192–194]. State-of-the-art many-body atomic structure computations of the parity non-conserving amplitude, $\mathrm{Im}\,E_{\rm PNC} = (0.8977 \pm 0.0040) \times 10^{-11}|e|\,a_B\,Q_W/N$ [195–200], together with the measurements [178,179] which can be combined to give $\mathrm{Im}\,E_{\rm PNC}/\beta = -1.5924 \pm 0.0055$ mV/cm, imply,

$$Q_W(^{133}_{78}\mathrm{Cs}) = -72.41 \pm 0.26_{\,\rm exp.} \pm 0.33_{\,\rm th.}\ , \qquad (10.42)$$

or equivalently the constraint, $55g_{AV}^{ep} + 78g_{AV}^{en} = 36.25 \pm 0.21$. Within the SM this can also be translated into a determination of the weak mixing angle, $\widehat{s}^2(2.4\ \mathrm{MeV}) = 0.2349 \pm 0.0018$, where the scale setting follows the estimate in Ref. [201] for the typical momentum transfer for parity violation experiments in Cs (the corresponding estimate for Tl amounts to 8 MeV). By comparing different hyperfine transitions, the Boulder experiment in cesium also observed the parity violating weak corrections to the nuclear electromagnetic vertex, called the nuclear anapole moment [202–204].

The theoretical atomic structure uncertainties are 3% for thallium [205] and even larger for the other atoms. However, they mostly cancel if one takes ratios of parity violation in different isotopes [206]. The first result of this type of experiment was announced recently by the Mainz group [207], who studied APV in ^{100}Yb, ^{102}Yb, ^{104}Yb, and ^{106}Yb, at the 0.5% level. The resulting three ratios can be interpreted as a measurement of $\widehat{s}_0^2 = 0.258 \pm 0.052$, and represent a very complementary approach to search for BSM physics [208]. If the precision increases in the future, one would ultimately face uncertainties from differences in the neutron charge radii [209, 210]. These can be constrained experimentally [211], *e.g.*, by measuring A_{RL} in heavier nuclei as done by the PREX collaboration at Jefferson Lab on ^{208}Pb [212] and ^{48}Ca [213].

10.4 Precision flavor physics

In addition to cross-sections, asymmetries, parity violation, W, Z, Higgs and other collider physics, there is a large number of experiments and observables testing the flavor structure of the SM. These are addressed elsewhere in this *Review*, and are generally not included in this Section. However, we identify three precision observables with sensitivity to similar types of new physics as the other processes discussed here. The branching fraction of the flavor changing transition $b \to s\gamma$ is of comparatively low precision, but since it is a loop-level process (in the SM) its sensitivity to new physics (and SM parameters, such as heavy quark masses) is enhanced. A discussion can be found in the 2010 edition of this *Review*.

The τ lepton lifetime and leptonic branching ratios are primarily sensitive to α_s and not affected significantly by many types of new physics. However, having an independent and reliable low energy measurement of α_s in a global analysis allows the comparison with the Z lineshape determination of α_s which shifts easily in the presence of new physics contributions. By far the most precise observable discussed here is the anomalous magnetic moment of the muon. Its combined experimental and theoretical uncertainty is smaller than typical electroweak scale contributions. The electron magnetic moment is measured to even greater precision, and as discussed in Sec. 10.2.2 can be used to determine α. Its new physics sensitivity, however, is suppressed by an additional factor of m_e^2/m_μ^2, unless there is a new light degree of freedom such as a dark Z [214] boson.

10.4.1 *The τ lifetime*

The extraction of α_s from the τ lifetime τ_τ [215,216] is standing out from other determinations because of a variety of independent reasons:

(i) The τ-scale is low, so that upon extrapolation to the Z scale (where it can be compared to the theoretically clean Z lineshape determinations) the α_s error shrinks by about an order of magnitude.

(ii) Yet, this scale is high enough that perturbation theory and the operator product expansion (OPE) can be applied.

(iii) These observables are fully inclusive and thus free of fragmentation and hadronization effects that would have to be modeled or measured.

(iv) Duality violation (DV) effects are most problematic near the branch cut but there they are suppressed by a double zero at $s = m_\tau^2$.

(v) There are data [44, 46, 217] to constrain non-perturbative effects both within and breaking the OPE.

(vi) A complete four-loop order QCD calculation is available [218–222] in the massless limit.

(vii) Large effects associated with the QCD β-function can be re-summed [223] in what has become known as contour improved perturbation theory (CIPT).

However, while CIPT certainly shows faster convergence in the lower (calculable) orders, doubts have been cast on the method by the observation of discrepancies in a specific model [224] and the realization that CIPT appears to be incompatible with the OPE [225, 226]. Moreover, it has been found that the construction of a renormalon-free scheme for the gluon condensate brings the CIPT results in agreement with ordinary fixed order perturbation theory (FOPT), without significantly modifying the latter [227, 228]. We therefore use the FOPT expressions [60, 222, 229],

$$\tau_\tau = \hbar \frac{1 - \mathcal{B}_\tau^s}{\Gamma_\tau^e + \Gamma_\tau^\mu + \Gamma_\tau^{ud}} = 290.75 \pm 0.36\ \mathrm{fs}\ , \qquad (10.43)$$

and

$$\Gamma_\tau^{ud} = \frac{G_F^2 m_\tau^5 |V_{ud}|^2}{64\pi^3} S(m_\tau, M_Z) \left(1 + \frac{3}{5}\,\frac{m_\tau^2 - m_\mu^2}{M_W^2}\right) \times \left[1 + \frac{\alpha_s(m_\tau)}{\pi} + 5.202\,\frac{\alpha_s^2}{\pi^2} + 26.37\,\frac{\alpha_s^3}{\pi^3} + 127.1\,\frac{\alpha_s^4}{\pi^4} + \frac{\widehat{\alpha}}{\pi}\left(\frac{85}{24} - \frac{\pi^2}{2}\right) + \delta_{\rm NP}\right]\ , \qquad (10.44)$$

where Γ_τ^e and Γ_τ^μ can be taken from Eq. (10.9) with obvious replacements. The relative fraction of strangeness changing ($\Delta S = -1$) decays, $\mathcal{B}_\tau^s = 0.0292 \pm 0.0004$, is based on experimental data since the value for the strange quark mass, $\widehat{m}_s(m_\tau)$, is not well known and the QCD expansion proportional to $\widehat{m}_s^2$ converges poorly and cannot be trusted. $S(m_\tau, M_Z) = 1.01908 \pm 0.0003$ is a logarithmically enhanced EW correction factor [230] with higher orders re-summed [231].

$\delta_{\rm NP}$ collects non-perturbative and quark-mass suppressed contributions, including the dimension four, six and eight terms in the OPE, as well as DV effects. We use the average $\delta_{\rm NP} = 0.0141 \pm 0.0072$ derived from the τ decay spectral functions provided by OPAL [44] and ALEPH [46,217], which give $\delta_{\rm NP} = 0.000 \pm 0.012$ and $\delta_{\rm NP} = 0.022 \pm 0.009$, respectively. These numbers are based on the original analyses in Refs. [232, 233], but are modified to correspond to a strict FOPT analysis as is appropriate for our purpose[10] (for alternative analyses, see Section 9 on "Quantum Chromodynamics" in this *Review*).

The dominant uncertainty arises from the truncation of the FOPT series and is conservatively taken as the α_s^4 term (this is re-calculated in each call of the fits, leading to an α_s-dependent and thus asymmetric error) until a better understanding of the numerical differences between FOPT and CIPT has been gained. Our perturbative error covers almost the entire range from using CIPT to assuming that the nearly geometric series in Eq. (10.44) continues to higher orders. The experimental uncertainty in Eq. (10.43) is from the combination of the two leptonic branching ratios with the direct τ_τ. Included are also various smaller uncertainties (± 0.16 fs) from other sources. Based on the method of Refs. [60, 234], we obtain in total

$$\alpha_s^{(4)}(m_\tau) = 0.312^{+0.016}_{-0.013}\ , \quad \alpha_s^{(5)}(M_Z) = 0.1171^{+0.0018}_{-0.0017}\ , \qquad (10.45)$$

[10] We are indebted to Diogo Boito, Maarten Golterman, Kim Maltman and Santiago Peris for privately communicating these results to us.

which represents a 1.5% determination of $\alpha_s(M_Z)$. For more details, see Refs. [232,233] where the τ spectral functions themselves and an estimate of the unknown α_s^5 term were used as additional inputs.

10.4.2 *The muon anomalous magnetic moment*

The world average of the muon anomalous magnetic moment[11],

$$a_\mu^{\rm exp} = \frac{g_\mu - 2}{2} = (1165920.59 \pm 0.22) \times 10^{-9} \ , \qquad (10.46)$$

is the combination of the final result of the BNL E821 collaboration [235] and the recent result of the Muon $g-2$ collaboration at Fermilab [236]. The QED contribution has been calculated to five loops [25, 27, 237–239] (fully analytic to three loops [240–244]). The estimated SM EW contribution [245–250], $a_\mu^{\rm EW} = (1.54 \pm 0.01) \times 10^{-9}$, includes two-loop [251–255] and leading three-loop [256,257] corrections and is at the level of more than four times the current total uncertainty.

The limiting factor in the interpretation of the result are the uncertainties from hadronic effects. The most recent evaluations of the leading-order (two-loop) hadronic vacuum polarization contribution using data from $e^+e^- \to$ hadrons obtained $a_\mu^{\rm had,VP}(\alpha^2) = (68.81 \pm 0.41) \times 10^{-9}$ [258], $a_\mu^{\rm had,VP}(\alpha^2) = (69.23 \pm 0.33) \times 10^{-9}$ [259], $a_\mu^{\rm had,VP}(\alpha^2) = (69.40 \pm 0.40) \times 10^{-9}$ [41], and $a_\mu^{\rm had,VP}(\alpha^2) = (69.28 \pm 0.24) \times 10^{-9}$ [42]. Our analysis is based on the e^+e^- data compiled in Ref. [41], where by utilizing the assessment in Ref. [50], we add τ-decay information and the very recent CMD-3 result [48] to estimate the dominant pion form factor contribution. We complement the contributions up to $\sqrt{s} = 2$ GeV, for which we find $a_\mu^{\rm had,VP}(\alpha^2, 2\ {\rm GeV}) = (65.12 \pm 0.30) \times 10^{-9}$, with analytical PQCD expressions for energies beyond 2 GeV and for the c and b quark contributions [244, 260].

By now there are also precise results for $a_\mu^{\rm had,VP}(\alpha^2)$ from lattice QCD calculations [261]. We use the constraint, $a_\mu^{\rm had,VP}(\alpha^2, 2\ {\rm GeV}) = (65.71 \pm 0.55) \times 10^{-9}$, obtained from the result with the smallest quoted uncertainty (by the BMW collaboration [262]), $a_\mu^{\rm had,VP}(\alpha^2) = (70.75 \pm 0.55) \times 10^{-9}$, by subtracting the perturbative QCD contribution including from charm and bottom quarks. It is important to note that there is a strong correlation (estimated to 86% in Ref. [51]) between $a_\mu^{\rm had,VP}(\alpha^2, 1.8\ {\rm GeV})$ and $\Delta\alpha_{\rm had}^{(3)}(1.8\ {\rm GeV})$ discussed in Sec. 10.2.2. As a result, using the lattice calculation from Ref. [49] as a constraint for $\Delta\alpha_{\rm had}$ has an impact on $a_\mu^{\rm had,VP}$ by slightly increasing it[12]. Incorporating this effect together with the BMW result, $a_\mu^{\rm had,VP}(\alpha^2, 2\ {\rm GeV}) = (65.71 \pm 0.55) \times 10^{-9}$, and the data-driven value, $a_\mu^{\rm had,VP}(\alpha^2, 2\ {\rm GeV}) = (65.12 \pm 0.30) \times 10^{-9}$, we obtain

$$a_\mu^{\rm had,VP}(\alpha^2, 2\ {\rm GeV}) = (65.44 \pm 0.25) \times 10^{-9} \ , \qquad (10.47)$$

which we use as an input to our fits. The BMW result is roughly 2 σ higher than the value derived from the KLOE data [263], is slightly lower than that from CMD-3 [48], and agrees well with τ decays. In fact, the discrepancy between KLOE and CMD-3 cross-sections exceeds 5σ locally, and amounts to 3.3σ if one considers the entire overlap region of the two experiments [50]. A more detailed analysis [264, 265] of the difference between BMW and the data-driven evaluation using KLOE input suggests that it originates mostly from hadronic contributions below 2 GeV to the vacuum polarization. The BMW result for this hadronic window is supported by findings from other lattice collaborations [266–272]. Possible explanations for this discrepancy include underestimated systematic uncertainties in the analysis of some of the available experimental data and higher-order initial-state radiation effects [50].

Sub-leading hadronic vacuum polarization effects at three-loop [273] and four-loop order [274] contribute $a_\mu^{\rm had,VP}(\alpha^3) = (-0.983 \pm 0.004) \times 10^{-9}$ [42] and $a_\mu^{\rm had,VP}(\alpha^4) = (0.124 \pm 0.001) \times 10^{-9}$ [274], respectively. To account for the larger vacuum polarization effects suggested by lattice QCD, we increase both $a_\mu^{\rm had,VP}(\alpha^3)$ and $a_\mu^{\rm had,VP}(\alpha^4)$ by 1%. The correlations with the two-loop hadronic contribution and with $\Delta\alpha(M_Z)$ (see Sec. 10.2) were considered in Ref. [244].

The other hadronic uncertainty is induced by the three-loop light-by-light scattering amplitude, where a number of independent model calculations yield results which are in reasonable agreement with each other, $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = (1.36 \pm 0.25) \times 10^{-9}$ [275], $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = 1.37^{+0.15}_{-0.27} \times 10^{-9}$ [276], $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = (1.05 \pm 0.26) \times 10^{-9}$ [277], and $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = (1.03 \pm 0.29) \times 10^{-9}$ [258], but the sign of this effect is opposite [278] to the one quoted in the 2002 edition of this *Review*. There is also an upper bound given by $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) < 1.59 \times 10^{-9}$ [276] but this requires an *ad hoc* assumption, too. Efforts to improve the evaluation by using experimental input where available yield the lower values, $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = (0.87 \pm 0.13) \times 10^{-9}$ [279] and $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = (0.92 \pm 0.19) \times 10^{-9}$ [261]. See also Ref. [280] for a recent discussion of the axial-vector contribution and short-distance constraints. Lattice calculations have reached similar levels of precision, $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = (1.10 \pm 0.15) \times 10^{-9}$ [281, 282] and $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = (1.25 \pm 0.15) \times 10^{-9}$ [283], and are consistent with the model and data-driven calculations. For our fits we average the two lattice results (with the systematic errors considered as fully correlated) and combine them with the data-driven result [261] to obtain,

$$a_\mu^{\rm had,\gamma\times\gamma}(\alpha^3) = (1.11 \pm 0.10) \times 10^{-9} \ , \qquad (10.48)$$

which we have shifted by 1×10^{-11} to account for the perturbative charm quark treatment of Ref. [276]. Higher-order contributions with a hadronic light-by-light scattering subgraph have been estimated in Ref. [284] with the result, $a_\mu^{\rm had,\gamma\times\gamma}(\alpha^4) = (0.02 \pm 0.01) \times 10^{-9}$ [261].

Altogether, the SM prediction is

$$a_\mu^{\rm theory} = (1165919.46 \pm 0.27) \times 10^{-9} \ , \qquad (10.49)$$

where the error is from the hadronic uncertainties excluding parametric ones, such as from α_s and the heavy quark masses. We evaluate the correlation of the total (experimental plus theoretical) uncertainty in a_μ with $\Delta\alpha(M_Z)$ to amount to 43%. The overall 3.2 σ discrepancy between the experimental value (10.46) and the SM prediction,

$$a_\mu^{\rm exp} - a_\mu^{\rm theory} = (1.13 \pm 0.35) \times 10^{-9} \ , \qquad (10.50)$$

could be due to fluctuations ($a_\mu^{\rm exp}$ is statistics dominated) or underestimates of the theoretical uncertainties. On the other hand, the deviation could also arise from physics beyond the SM, such as supersymmetric models with large $\tan\beta$ and moderately light superparticle masses [285], or a dark Z boson [214].

10.5 Physics of the massive electroweak bosons

If the CM energy $\sqrt{s}$ is large compared to the fermion mass m_f, the unpolarized Born cross-section for $e^+e^- \to f\bar{f}$ [286] can be written as,

$$\frac{d\sigma}{d\cos\theta} = \frac{\pi\alpha^2(s)}{2s}\left[F_1(1+\cos^2\theta) + 2F_2\cos\theta\right] + B \ , \qquad (10.51a)$$

$$F_1 = Q_e^2 Q_f^2 - 2\chi Q_e Q_f \bar{g}_V^e \bar{g}_V^f \cos\delta_R + \chi^2(\bar{g}_V^{e2} + \bar{g}_A^{e2})(\bar{g}_V^{f2} + \bar{g}_A^{f2}) \ , \qquad (10.51b)$$

$$F_2 = -2\chi Q_e Q_f \bar{g}_A^e \bar{g}_A^f \cos\delta_R + 4\chi^2 \bar{g}_V^e \bar{g}_A^e \bar{g}_V^f \bar{g}_A^f \ , \qquad (10.51c)$$

[11] In what follows, we summarize the most important aspects of a_μ and give some details on the evaluation in our fits. For more details and references, see Section 56 on the "Muon Anomalous Magnetic Moment" in this *Review*. There are some numerical differences, which are well understood and arise because internal consistency of the fits requires the calculation of all observables from analytical expressions and common inputs and fit parameters, so that an independent evaluation is necessary for this Section.

[12] Conversely, adding the BMW constraint for $a_\mu^{\rm had,VP}$ has the effect of increasing $\Delta\alpha_{\rm had}^{(3)}(2\ {\rm GeV})$.

where

$$\tan\delta_R = \frac{\overline{M}_Z\overline{\Gamma}_Z}{\overline{M}_Z^2 - s} \ , \quad \chi = \frac{G_F}{2\sqrt{2}\pi\alpha(s)} \frac{s\overline{M}_Z^2}{\left[(\overline{M}_Z^2 - s)^2 + \overline{M}_Z^2\overline{\Gamma}_Z^2\right]^{1/2}} \ . \tag{10.52}$$

B accounts for box graphs involving virtual Z and W bosons, and the $\bar{g}^f_{V,A}$ are defined in Eq. (10.53) below. $\overline{M}_Z$ and $\overline{\Gamma}_Z$ correspond to mass and width definitions based on a Breit-Wigner shape with an energy-independent width (see Section 55 on the "Z Boson" in this *Review*). The differential cross-section receives important corrections from QED effects in the initial and final states, and interference between the two [287]. For $q\bar{q}$ production, there are additional final-state QCD corrections, which are relatively large. Note also that the equations above are written in the CM frame of the incident e^+e^- system, which may be boosted due to the initial-state QED radiation.

Some of the leading virtual EW corrections are captured by the running QED coupling $\alpha(s)$ and the Fermi constant G_F. The remaining corrections to the $Zf\bar{f}$ interactions are absorbed by replacing the tree-level couplings in Eq. (10.7) with the s-dependent *effective couplings* [288],

$$\bar{g}^f_V = \sqrt{\rho_f}\left(t^f_{3L} - 2Q_f\kappa_f \sin^2\theta_W\right) \ , \tag{10.53a}$$

$$\bar{g}^f_A = \sqrt{\rho_f}\, t^f_{3L} \ . \tag{10.53b}$$

In these equations, the effective couplings are to be taken at the scale $\sqrt{s}$, but for notational simplicity we do not show this explicitly. At tree-level, $\rho_f = \kappa_f = 1$, but inclusion of EW radiative corrections leads to $\rho_f \neq 1$ and $\kappa_f \neq 1$, which depend on the fermion f and on the renormalization scheme. In the on-shell scheme, the quadratic m_t dependence is given by,

$$\rho_f \sim 1 + \rho_t \ , \qquad \kappa_f \sim 1 + \frac{\rho_t}{\tan^2\theta_W} \ , \tag{10.54}$$

while in $\overline{\rm MS}$, $\widehat{\rho}_f \sim \widehat{\kappa}_f \sim 1$, for $f \neq b$, and

$$\widehat{\rho}_b \sim 1 - \frac{4}{3}\rho_t \ , \qquad \widehat{\kappa}_b \sim 1 + \frac{2}{3}\rho_t \ . \tag{10.55}$$

In the $\overline{\rm MS}$ scheme the normalization is changed according to $G_F M_Z^2/2\sqrt{2}\pi \to \widehat{\alpha}/4\widehat{s}_Z^2\widehat{c}_Z^2$ in the second Eq. (10.52).

As reviewed in Sec. 10.2.5, for the high precision Z pole observables discussed below, many additional bosonic and fermionic loop effects, vertex corrections, and higher order contributions, *etc.*, must be included. For example, in the $\overline{\rm MS}$ scheme one then has $\widehat{\rho}_\ell = 0.9977$, $\widehat{\kappa}_\ell = 1.0014$, $\widehat{\rho}_b = 0.9867$, and $\widehat{\kappa}_b = 1.0068$.

To connect to measured quantities, it is convenient to define an effective angle

$$\bar{s}^2_f \equiv \sin^2\bar{\theta}_{Wf} \equiv \widehat{\kappa}_f\widehat{s}^2_Z = \kappa_f s^2_W \ , \tag{10.56}$$

in terms of which $\bar{g}^f_V$ and $\bar{g}^f_A$ are given by $\sqrt{\rho_f}$ times their tree-level formulae. One finds that the $\widehat{\kappa}_f$ ($f \neq b$) are almost independent of m_t and M_H, and thus one can write,

$$\bar{s}^2_\ell = \widehat{s}^2_Z + 0.00032 \ , \tag{10.57}$$

while the κ_f for the on-shell scheme are m_t dependent.

10.5.1 *The Z boson mass*

The mass of the Z boson, $M_Z = 91.1876 \pm 0.0021$ GeV, has been determined from the Z lineshape scan at LEP 1 [288]. Very recently the CDF collaboration at the Tevatron [289] determined M_Z from fits to the dimuon and dielectron mass distributions. The dimuon channel strongly dominates so that our combination, $M_Z = 91.192 \pm 0.007$ GeV, is insensitive (at the level of the quoted digits) to variations in the assumption concerning possible cross-channel correlations. Combined we find the world average,

$$M_Z = 91.1880 \pm 0.0020 \text{ GeV} \ . \tag{10.58}$$

These values correspond to a definition based on a Breit-Wigner shape with an energy-dependent width, which differs from $\overline{M}_Z$ in eq. (10.52)[13].

10.5.2 *Electroweak physics off the Z pole*

Experiments at PEP, PETRA and TRISTAN have measured the unpolarized forward-backward asymmetry, A_{FB}, and the total cross-section relative to pure QED, R, for $e^+e^- \to \ell^+\ell^-$, $\ell = \mu$ or τ at CM energies $\sqrt{s} < M_Z$. They are defined as

$$A_{FB} \equiv \frac{\sigma_F - \sigma_B}{\sigma_F + \sigma_B} \ , \qquad R = \frac{\sigma}{\mathcal{R}_{\rm ini} \otimes \sigma_{\rm QED}} \ , \tag{10.59}$$

where σ_F (σ_B) is the cross-section for ℓ^- to travel forward (backward) with respect to the e^- direction, $\sigma_{\rm QED}$ is the tree-level cross-section from s-channel photon exchange, and $\mathcal{R}_{\rm ini}\otimes$ denotes convolution with initial-state QED corrections. Neglecting box graph contributions, they are given by,

$$A_{FB} = \frac{3}{4}\frac{F_2}{F_1} \ , \qquad R = F_1 \ . \tag{10.60}$$

For the available data, it is sufficient to approximate the EW corrections through the leading running $\alpha(s)$ and quadratic m_t contributions [290], as described above. Reviews and formulae for $e^+e^- \to$ hadrons may be found in [9, 291, 292].

LEP 2 [294] ran at several energies above the Z pole up to ~ 209 GeV. Measurements were made of a number of observables, including the total production cross-sections of $f\bar{f}$ pairs for $f = \mu, \tau$, and q (hadrons), of four-fermion final states, of $\gamma\gamma$, ZZ, WW and $WW\gamma$. The differential cross-sections for all three lepton flavors, and the leptonic and hadronic W branching ratios were also extracted.

Among the most important LEP 2 results were the measurements [294] of the W boson mass, M_W, which were dominated by kinematic reconstruction, but included the complementary albeit statistics limited and thus much less precise determination from a WW threshold cross-section measurement. The kinematic method was also employed at the Tevatron [301] and by ATLAS [302] and LHCb [296] at the LHC. A recent combination [298] of all available M_W measurements, using a careful calibration of simulation tools and PDFs, obtained the world average,

$$M_W = 80.3946 \pm 0.0115 \text{ GeV} \ . \tag{10.61}$$

However, the χ^2 probability of this combination is 0.5% or less, depending on the chosen PDF set, which is mostly due to the W mass measurement by CDF from Run II at the Tevatron [289], $M_W = 80.432 \pm 0.016$ GeV (adjusted to the common PDF set CT18 [303] in Ref. [298]). It differs by almost 4 σ from the other measurements of M_W, while the latter agree well among each other, with the average [298]

$$M_W = 80.3692 \pm 0.0133 \text{ GeV} \ , \tag{10.62}$$

without CDF II. Subsequently, the ATLAS result has been updated [295], resulting in a significant downward shift of M_W. It also included a measurement of the W boson width, Γ_W, together with a strong 30% anticorrelation with M_W. The new ATLAS Γ_W value differs by about 2 σ from the Tevatron width result [299] and the SM prediction. To include it in the global fit, instead of employing (10.62) *verbatim*, we combine (i) the adjusted results for DØ and LHCb quoted in Ref. [298], (ii) LEP [294], (iii) the new ATLAS results [295], and (iv) the Tevatron width determination [299], keeping the approximate 49% PDF anticorrelation between ATLAS and LHCb. Including further small correlations between DØ and the LHC experiments, this results in the updated overall averages (without M_W from CDF as recommended

[13] Note that $\overline{M}_Z$ is defined through the complex pole of the propagator, which ensures that it is gauge-invariant and theoretically consistent, and which leads to a Breit-Wigner shape with a constant width. The two definitions differ numerically, and this difference has to be accounted for in theoretical calculations.

Table 10.4: Non-Z pole observables, compared with the SM best fit predictions. The SM prediction for Γ_H is without electroweak corrections as in Ref. [293]. The first and second M_W and Γ_W values are from LEP 2 [294] and ATLAS [295], respectively. The remaining M_W values are from LHCb [296], DØ [297], and CDF [289], respectively, adjusted according to Ref. [298], and where the last one [in brackets] is omitted from the fits (see text and Sec. 10.8). The third Γ_W is the Tevatron combination [299], shifted to correspond to the current SM prediction of M_W (what is actually measured is a linear combination containing an M_W term). The hadronic branching ratio for W decays combines LEP 2 [294] and CMS [300] and assumes lepton flavor universality. The world averages for $g^{\nu e}_{V,A}$ are dominated by the CHARM II [139] results, $g^{\nu e}_V = -0.035 \pm 0.017$ and $g^{\nu e}_A = -0.503 \pm 0.017$. The τ_τ value is the τ lifetime world average computed by combining the direct measurements with values derived from the leptonic branching ratios [60]; in this case, the theory error is included in the SM prediction. In all other SM predictions, the uncertainty is parametric from M_Z, M_H, m_t, m_b, m_c, $\widehat{\alpha}(M_Z)$, and α_s, and theoretical from unknown higher orders [83], where correlations due to both types have been accounted for. The column denoted by Pull gives the standard deviations.

Quantity	Value	Standard Model	Pull
m_t [GeV]	172.61 ± 0.58	172.85 ± 0.55	-0.4

$\frac{1}{2}(g_\mu - 2 - \frac{\alpha}{\pi})$	$(4510.86 \pm 0.35) \times 10^{-9}$	$(4509.73 \pm 0.03) \times 10^{-9}$	3.2

by the authors of Ref. [298][14]),

$$M_W = 80.360 \pm 0.012 \text{ GeV} , \quad (10.63)$$
$$\Gamma_W = 2.136 \pm 0.032 \text{ GeV} , \quad (10.64)$$

with a correlation coefficient of close to -0.3. Alternatively, fixing Γ_W to the SM prediction gives

$$M_W = 80.366 \pm 0.012 \text{ GeV} . \quad (10.65)$$

For details and references, see Section 54 on the "Mass and Width of the W Boson" in this *Review*.

Strong constraints on anomalous triple and quartic gauge couplings have been obtained at LEP 2, the Tevatron, and the LHC. These are described in detail in "Extraction of Triple Gauge Couplings (TGCs)", "Anomalous W/Z Quartic Couplings (QGCs)" notes in the W particle listing and in "Anomalous $ZZ\gamma$, $Z\gamma\gamma$, and ZZV Couplings" note in the Z particle listing.

After their discovery of the Higgs boson [304, 305], the LHC experiments are now performing high precision measurements of its mass, M_H. We average the results, $M_H = 125.11 \pm 0.09_{\,\text{stat.}} \pm 0.06_{\,\text{syst.}}$ GeV from ATLAS [306], and $M_H = 125.08 \pm 0.10_{\,\text{stat.}} \pm 0.07_{\,\text{syst.}}$ GeV from CMS [307], by treating the smaller systematic error as common among the two determinations, and arrive at,

$$M_H = 125.10 \pm 0.07_{\,\text{stat.}} \pm 0.06_{\,\text{syst.}} \text{ GeV (LHC)} . \quad (10.66)$$

There are also first measurements of the Higgs boson width, $\Gamma_H = 2.9^{+1.9}_{-1.4}$ MeV from CMS [307] and $\Gamma_H = 4.5^{+3.3}_{-2.5}$ MeV from ATLAS [308]. We perform a simple Gaussian average using the upper error of CMS and the lower error of ATLAS. For further references and more details on Higgs boson properties, see Section 11 on the "Status of Higgs Boson Physics" in this *Review*.

The principal non-Z pole observables discussed here and in Sections 10.2–10.4 are summarized in Table 10.4.

10.5.3 *Z pole physics*

High precision measurements of various Z pole ($\sqrt{s} \approx M_Z$) observables [9, 318, 319] have been performed at LEP 1 and SLC [288, 315, 316, 320, 321], as summarized in Table 10.5. These include the Z mass and total width, Γ_Z, and partial widths $\Gamma_{f\bar{f}}$ for $Z \to f\bar{f}$, where $f = e$, μ, τ, light hadrons, b, and c. It is convenient to use the variables M_Z, Γ_Z,

$$\sigma_{\text{had}} \equiv \frac{12\pi\Gamma_{e^+e^-}\Gamma_{\text{had}}}{M_Z^2\,\Gamma_Z^2} , \quad R_\ell \equiv \frac{\Gamma_{\text{had}}}{\Gamma_{\ell^+\ell^-}} , \quad R_q \equiv \frac{\Gamma_{q\bar{q}}}{\Gamma_{\text{had}}} , \quad (10.67)$$

for $\ell = e, \mu$ or τ, and $q = b$ or c, where Γ_{had} is the partial decay width into hadrons. Most of these are weakly correlated experimentally. The three values for R_ℓ are consistent with lepton universality[15] (although R_τ is somewhat low compared to R_e and R_μ), but we use the general analysis in which the three observables are treated as independent. Similar remarks apply to $A^{0,\ell}_{FB}$ defined through Eq. (10.68) with $P_e = 0$, where $A^{0,\tau}_{FB}$ is somewhat high. Initial-state radiation reduces the peak cross-section by more than 25%, where $\mathcal{O}(\alpha^3)$ QED effects induce a large anti-correlation (-30%) between Γ_Z and σ_{had}. The anti-correlation between R_b and R_c amounts to -18% [288]. The R_ℓ are insensitive to m_t except for the $Z \to b\bar{b}$ vertex, final-state corrections,

[14] See Sec. 10.8 for the impact of including the CDF W mass result.

[15] The ratio of branching fractions for Z bosons decaying into e^+e^- relative to $\mu^+\mu^-$ final states has also been measured by ATLAS [322], obtaining $R_{e/\mu} = 1.0026 \pm 0.0050$, in perfect agreement with lepton universality.

Table 10.5: Principal Z pole observables and their SM predictions (*cf.* Table 10.4). The first M_Z is from LEP 1 [288] and the second from CDF [289]. The first $\bar{s}^2_\ell$ is the effective weak mixing angle extracted from the hadronic charge asymmetry at LEP 1 [288], the second is the combined value from the Tevatron [309], and the third is from the LHC [310–314]. The values of A_e are (i) from A_{LR} for hadronic final states [315]; (ii) from A_{LR} for leptonic final states and from polarized Bhabha scattering [316]; and (iii) from the angular distribution of the τ polarization at LEP 1 [288]. The A_τ values are from SLD [316], the total τ polarization from LEP [288], and from CMS [317], respectively. Note that the SM errors in Γ_Z, the R_ℓ, and $\sigma_{\rm had}$ are largely dominated by the uncertainty in α_s.

Quantity	Value	Standard Model	Pull
M_Z [GeV]	91.1876 ± 0.0021	91.1884 ± 0.0019	-0.4
	91.192 ± 0.007		0.6

$A_{FB}^{(0,b)}$	0.0996 ± 0.0016	0.1026 ± 0.0002	-1.8
$A_{FB}^{(0,c)}$	0.0707 ± 0.0035	0.0732 ± 0.0002	-0.7
$A_{FB}^{(0,s)}$	0.0976 ± 0.0114	0.1027 ± 0.0002	-0.4
$\bar{s}^2_\ell$	0.2324 ± 0.0012	0.23161 ± 0.00004	0.7
	0.23148 ± 0.00033		-0.4
	0.23145 ± 0.00028		-0.6
A_e	0.15138 ± 0.00216	0.1463 ± 0.0003	2.3
	0.1544 ± 0.0060		1.3
	0.1498 ± 0.0049		0.7
A_μ	0.142 ± 0.015		-0.3
A_τ	0.136 ± 0.015		-0.7
	0.1439 ± 0.0043		-0.6
	0.144 ± 0.015		-0.2
A_b	0.923 ± 0.020	0.9347	-0.6
A_c	0.670 ± 0.027	0.6674 ± 0.0001	0.1
A_s	0.895 ± 0.091	0.9356	-0.4

and the implicit dependence through $\sin^2\theta_W$. Thus, they are especially useful for constraining α_s.

Very important constraints follow from measurements of various Z pole asymmetries. These include the forward-backward asymmetry, A_{FB}, and the polarization or left-right asymmetry, A_{LR}, defined analogously to Eq. (10.35). The latter was measured precisely by the SLD collaboration at the SLC [315], and has the advantages of being very sensitive to $\bar{s}^2_\ell$ and that systematic uncertainties largely cancel. After removing initial-state QED corrections and contributions from photon exchange, γ–Z interference, as well as the EW boxes in Eq. (10.51a), one can use the effective tree-level expressions,

$$A_{LR} = A_e P_e \ , \qquad A_{FB} = \frac{3}{4} A_f \, \frac{A_e + P_e}{1 + P_e A_e} \ , \tag{10.68}$$

where,

$$A_f \equiv \frac{2\bar{g}_V^f \bar{g}_A^f}{\bar{g}_V^{f2} + \bar{g}_A^{f2}} = \frac{1 - 4|Q_f|\bar{s}_f^2}{1 - 4|Q_f|\bar{s}_f^2 + 8Q_f^2\bar{s}_f^4} \ . \tag{10.69}$$

P_e is the initial e^- polarization, so that the second equality in Eq. (10.70) is reproduced for $P_e = 1$, and the Z pole forward-backward asymmetries at LEP 1 ($P_e = 0$) are given by $A_{FB}^{(0,f)} = \frac{3}{4} A_e A_f$ for $f = e$, μ, τ, b, c, s [288], and q, and where $A_{FB}^{(0,q)}$ refers to the hadronic charge asymmetry. Corrections for t-channel exchange and s/t-channel interference cause $A_{FB}^{(0,e)}$ to be strongly anti-correlated with R_e (-37%). Recently, the m_b-dependence [323] of the $\mathcal{O}(\alpha_s^2)$ QCD correction [324], affecting the reference axis of the b quark asymmetry [325], increased the extracted[16] $A_{FB}^{(0,b)}$ by about 0.2 σ. The correlation between $A_{FB}^{(0,b)}$ and $A_{FB}^{(0,c)}$ amounts to 15%.

In addition, SLD extracted the final-state couplings A_b, A_c [288], A_s [320], A_τ, and A_μ [316], from left-right forward-backward asymmetries, using

$$A_{LR}^{FB}(f) = \frac{\sigma_{LF}^f - \sigma_{LB}^f - \sigma_{RF}^f + \sigma_{RB}^f}{\sigma_{LF}^f + \sigma_{LB}^f + \sigma_{RF}^f + \sigma_{RB}^f} = \frac{3}{4} A_f \ , \tag{10.70}$$

where, for example, σ_{LF}^f is the cross-section for a left-handed incident electron to produce a fermion f traveling in the forward hemisphere. Similarly, A_τ and A_e were measured at LEP 1 [288] (A_τ also very recently by CMS [317]) through the τ polarization, $\mathcal{P}_\tau$, as a function of the scattering angle θ, which can be written as,

$$\mathcal{P}_\tau = -\frac{A_\tau(1 + \cos^2\theta) + 2A_e\cos\theta}{(1 + \cos^2\theta) + 2A_\tau A_e \cos\theta} \ . \tag{10.71}$$

The average polarization, $\langle \mathcal{P}_\tau \rangle$, obtained by integrating over $\cos\theta$ in the numerator and denominator of Eq. (10.71), yields

[16] We are grateful to Werner Bernreuther and Long Chen for the recalculation of their result employing the more appropriate $\overline{\rm MS}$ mixing angle, $\widehat{s^2_Z}$, instead of the on-shell quantity, s^2_W.

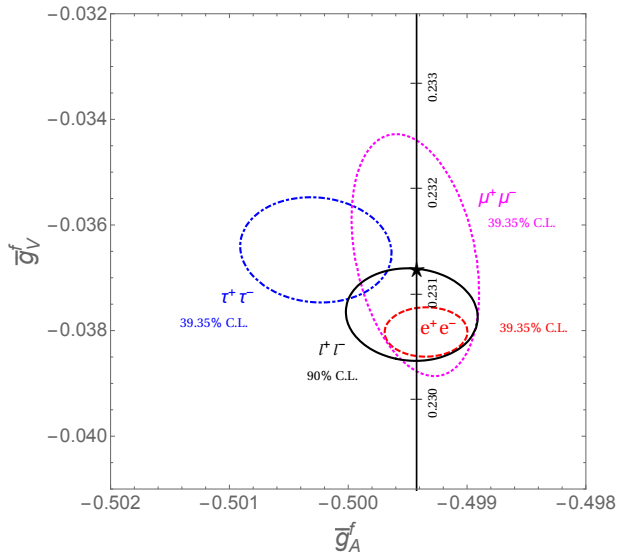

Figure 10.3: 1 σ (39.35% CL) contours of the effective couplings $\bar{g}_A^f$ and $\bar{g}_V^f$ for $f = e, \mu$ and τ from LEP and SLC, compared to the SM expectation as a function of $\widehat{s}_Z^2$. (The SM best fit value $\widehat{s}_Z^2 = 0.23129$ is also indicated.) Also shown is the 90% CL allowed region in $\bar{g}_{A,V}^\ell$ obtained assuming lepton universality.

$\langle \mathcal{P}_\tau \rangle = -A_\tau$, and A_e can be extracted from the $\mathcal{P}_\tau$ angular distribution. The initial-state coupling, A_e, was also determined through the left-right charge asymmetry [321] and in polarized Bhabha scattering [316] at the SLC. Because $\bar{g}_V^\ell$ is very small, not only $A_{LR}^0 = A_e$, $A_{FB}^{(0,\ell)}$, and $\mathcal{P}_\tau$, but also $A_{FB}^{(0,q)}$ for $q = b$, c, and s, as well as the hadronic asymmetries are mainly sensitive to $\bar{s}_\ell^2$. The combination of all LEP and SLC asymmetries (but excluding other observables such as R_ℓ) yields,

$$\bar{s}_\ell^2 = 0.23151 \pm 0.00016 \text{ (LEP + SLC)} . \tag{10.72}$$

As an example of the precision of the Z pole observables, the values of $\bar{g}_A^f$ and $\bar{g}_V^f$ for $f = e, \mu, \tau$, and ℓ, extracted from the LEP and SLC lineshape and asymmetry data, are shown in Fig. 10.3. It may be compared with Fig. 10.1 as the two sets of parameters coincide at the SM at tree-level.

As for hadron colliders, the forward-backward asymmetry, A_{FB}, for e^+e^- and $\mu^+\mu^-$ final states (with invariant masses restricted to or dominated by values around M_Z) in $p\bar{p}$ collisions has been measured by the CDF [326] and DØ [327] collaborations, and the values $\bar{s}_\ell^2 = 0.23221 \pm 0.00046$ and $\bar{s}_\ell^2 = 0.23095 \pm 0.00040$ were extracted, respectively. The combination of these measurements (which differ by more than 2 σ) yields [309],

$$\bar{s}_\ell^2 = 0.23148 \pm 0.00033 \text{ (Tevatron)} . \tag{10.73}$$

By varying the invariant mass and the scattering angle (and assuming the electron couplings), information on the effective Z couplings to light quarks, $\bar{g}_{V,A}^{u,d}$, could also be obtained [328,329], but with large uncertainties, mutual correlations, and not independently of $\bar{s}_\ell^2$ above. Similar analyses have also been reported by the H1 [330] and ZEUS [331] collaborations at HERA and by the LEP collaborations [288]. This kind of measurement is harder in the pp environment due to the difficulty to assign the initial quark and antiquark in the underlying Drell-Yan process to the protons, thus requiring excellent control of uncertainties from parton distribution functions. ATLAS obtained $\bar{s}_\ell^2 = 0.2308 \pm 0.0012$ using 7 TeV data [310] and a preliminary result $\bar{s}_\ell^2 = 0.23140 \pm 0.00036$ at 8 TeV [311], while CMS measured $\bar{s}_\ell^2 = 0.23101 \pm 0.00053$ (8 TeV) [312] and a preliminary result $\bar{s}_\ell^2 = 0.23157 \pm 0.00031$ (13 TeV) [313], and LHCb reported $\bar{s}_\ell^2 = 0.23142 \pm 0.00106$ (from both 7 and 8 TeV data, but only analyzing $\mu^+\mu^-$ final state) [314]. Assuming that the smallest theoretical and PDF uncertainty (± 0.00024 from ATLAS [311]) is fully correlated among the five determinations, they combine to

$$\bar{s}_\ell^2 = 0.23145 \pm 0.00028 \text{ (LHC)} . \tag{10.74}$$

Combining Eqs. (10.72), (10.73), and (10.74) gives,

$$\bar{s}_\ell^2 = 0.23149 \pm 0.00013 \text{ (collider average)} . \tag{10.75}$$

10.5.4 *W and Z decays*

The partial decay widths for gauge bosons to decay into massless fermions $f_1\bar{f}_2$ (the numerical values include the small EW radiative corrections and final-state mass effects) are given by,

$$\Gamma(W^+ \to e^+\nu_e) = \frac{M_W^3}{12\pi v^2} = 226.29 \pm 0.04 \,\text{MeV} , \tag{10.76a}$$

$$\Gamma(W^+ \to u_i\bar{d}_j) = \frac{M_W^3}{12\pi v^2} |V_{ij}|^2 \mathcal{R}_V^q = (705.3 \pm 0.4 \,\text{MeV})|V_{ij}|^2 , \tag{10.76b}$$

$$\Gamma(Z \to f\bar{f}) = \frac{M_Z^3}{12\pi v^2} \left[\mathcal{R}_V^f \bar{g}_V^{f2} + \mathcal{R}_A^f \bar{g}_A^{f2}\right] , \tag{10.76c}$$

where the result for the latter are shown in Table 10.6. Final-state QED and QCD corrections [333] to the vector and axial-vector form factors are given by,

$$\mathcal{R}_{V,A}^f = N_C \left[1 + \frac{3}{4}\left(Q_f^2 \frac{\alpha(s)}{\pi} + \frac{N_C^2 - 1}{2N_C}\frac{\alpha_s(s)}{\pi}\right) + \cdots\right] , \tag{10.77}$$

where $N_C = 3$ (1) is the color factor for quarks (leptons) and the dots indicate finite fermion mass effects proportional to m_f^2/s which are different for $\mathcal{R}_V^f$ and $\mathcal{R}_A^f$, as well as higher-order QCD corrections [334], which are known to $\mathcal{O}(\alpha_s^4)$ [222]. For the Z boson, these include singlet contributions starting from two-loop order which are large, strongly top quark mass dependent, family universal, and flavor non-universal [335–339]. The $\mathcal{O}(\alpha^2)$ self-energy corrections from Ref. [340] are also taken into account.

For the W decay into quarks, Eq. (10.76b), only the universal massless part (non-singlet and $m_q = 0$) of the final-state QCD radiator function in $\mathcal{R}_V$ from Eq. (10.77) is used, and the QED corrections are modified. Expressing the widths in terms of $G_F M_{W,Z}^3$ incorporates the largest radiative corrections from the running QED coupling. EW corrections to the Z widths are then taken into account through the effective couplings $\bar{g}_{V,A}^{i\,2}$. Hence, in the on-shell scheme the Z widths are proportional to $\rho_i \sim 1 + \rho_t$. There is additional (negative) quadratic m_t dependence in the $Z \to b\bar{b}$ vertex corrections [341, 342] which causes $\Gamma_{b\bar{b}}$ to decrease with m_t. The dominant effect is to multiply $\Gamma_{b\bar{b}}$ by the vertex correction $1 + \delta\rho_{b\bar{b}}$, where $\delta\rho_{b\bar{b}} \sim 10^{-2}(-\frac{1}{2}m_t^2/M_Z^2 + \frac{1}{5})$. In practice, the corrections are included in $\widehat{\rho}_b$ and $\widehat{\kappa}_b$, as discussed in Sec. 10.5.

Starting at $\mathcal{O}(\alpha\alpha_s)$, the factorized form indicated in Eq. (10.76) is violated and corrections need to be included [343–345]. They add coherently, resulting in a sizable effect, and shift $\alpha_s(M_Z)$ when extracted from Z lineshape observables by about $+0.0007$. Similar non-factorizable corrections are also known for mixed QED-EW corrections [111, 112, 114, 346].

For three fermion families the total widths of the Z [347–351] and W [352, 353] bosons are predicted to be,

$$\Gamma_Z = 2.4940 \pm 0.0009 \,\text{GeV} , \quad \Gamma_W = 2.0892 \pm 0.0008 \,\text{GeV} . \tag{10.78}$$

The uncertainties in these predictions are almost entirely induced by the parametric error in $\alpha_s(M_Z) = 0.1187 \pm 0.0017$ from the global fit. These predictions can be compared with the experimental results, $\Gamma_Z = 2.4955 \pm 0.0023$ GeV [288, 332] and $\Gamma_W = 2.137 \pm 0.032$ GeV in (10.78). Note regarding the latter that in this Section we include the very recent result from ATLAS [295] and an updated value of the Tevatron result [299],

Table 10.6: Results derived from Table 10.5 and the corresponding covariance matrices [288, 332], and the SM predictions for the partial and total Z decay widths [in MeV]. In the (second) third column lepton universality is (not) assumed.

Quantity	Value	Value (universal)	Standard Model
$\Gamma_{e^+e^-}$	83.87 ± 0.12	83.942 ± 0.085	83.955 ± 0.009
$\Gamma_{\mu^+\mu^-}$	83.95 ± 0.18	83.941 ± 0.085	83.955 ± 0.009
$\Gamma_{\tau^+\tau^-}$	84.03 ± 0.21	83.759 ± 0.085	83.772 ± 0.009
$\Gamma_{\rm inv}$	498.9 ± 2.5	500.5 ± 1.5	501.435 ± 0.045
$\Gamma_{u\bar{u}}$	—	—	299.87 ± 0.20
$\Gamma_{c\bar{c}}$	300.3 ± 5.3	300.0 ± 5.2	299.81 ± 0.20
$\Gamma_{d\bar{d}}, \Gamma_{s\bar{s}}$	—	—	382.75 ± 0.14

which differ from the treatment in the Gauge & Higgs Bosons Particle Listings and Section 54 on the "Mass and Width of the W Boson" in this *Review*. The hadronic branching ratio of the W boson, $\mathcal{B}(W \to \text{hadrons})$ has been measured by both LEP 2 [294] and CMS [300]. The measurements of the total and partial widths are generally in good agreement with the SM. The exceptions are Γ_W, which is 1.5 σ larger than the SM prediction, and the branching ratio $W \to \tau + \nu_\tau$ from LEP 2, which is 2.6 σ larger than the electron-muon average [294][17].

The invisible decay width, $\Gamma_{\rm inv} = \Gamma_Z - \Gamma_{e^+e^-} - \Gamma_{\mu^+\mu^-} - \Gamma_{\tau^+\tau^-} - \Gamma_{\rm had}$, can be used to determine the number of neutrino flavors, N_ν, much lighter than $M_Z/2$. The hadronic peak cross-section, and therefore the extracted $\Gamma_{\rm had}$, depends strongly on the knowledge of the LEP 1 luminosity derived from small-angle Bhabha scattering. However, the prediction for the Bhabha cross-section was recently found to be overestimated, and consequently the luminosity underestimated [332]. The updated analysis involved an improved Z lineshape fit, significantly reducing $\sigma_{\rm had}$, while slightly increasing Γ_Z, with the result, $N_\nu = 2.9963 \pm 0.0074$ [332]. In practice, we determine N_ν by allowing it as an additional fit parameter and obtain,

$$N_\nu = 3.0025 \pm 0.0061 \ , \tag{10.79}$$

which is now in perfect agreement with the observed number of fermion generations and $N_\nu = 3$ (a 1.3 σ deviation was observed in the 2018 edition of this *Review* before including the correction in the luminosity determination).

10.6 Global fit results

In this section, we present the results of global fits, subject to the experimental data and theoretical constraints discussed in Section 10.2−10.5. For earlier analyses, see Refs. [83,288,355–358] and previous editions of this *Review*. Recent global fits by other groups [359–361] find a similar pattern of agreement as discussed below, with some discrepancies beyond the 2σ level for a few quantities entering into the fit. They differ, however, from the fit presented here by (i) not including inputs from low-energy parity-violation data and the muon magnetic moment[18]; (ii) the set of input data; (iii) the implementation of radiative corrections; and (iv) the fitting tools used.

For the results in this *Review*, the values for m_t (see Sec. 10.2.3), M_H [364, 365], Γ_H [308, 366], M_W [295, 298], Γ_W [294, 295, 299], $\mathcal{B}(W \to \text{hadrons})$ [294,300], the weak charges of the electron [166], the proton [167], cesium [178, 179] and thallium [180, 181], the weak mixing angle extracted from eDIS [156], $\nu_\mu(\bar{\nu}_\mu)$-e scattering [137–139], the τ lifetime, and the μ anomalous magnetic moment [367] are listed in Table 10.4. Likewise, Table 10.5 summarizes the principal Z pole observables, where the LEP 1 averages of the ALEPH, DELPHI, L3, and OPAL results include common systematic uncertainties and correlations [288, 332]. The heavy flavor results [288, 323] of LEP 1 and SLD are based on common inputs, and are thus correlated, as well.

Also shown in both tables are the SM predictions for the values of M_Z, $\alpha_s(M_Z)$, $\Delta\alpha^{(3)}_{\rm had}$ and the heavy quark masses shown in Table 10.7. The predictions result from a global least-square (χ^2) fit to all data using the minimization package MINUIT [368] and the EW library GAPP [34]. In most cases, we treat all input errors (the uncertainties of the values) as Gaussian. The reason is not that we assume that theoretical and systematic errors are intrinsically bell-shaped (which they are not) but because in most cases the input errors are either dominated by the statistical components or they are combinations of many different (including statistical) error sources, which should yield approximately Gaussian *combined* errors by the large number theorem. An exception is the theory dominated error on the τ lifetime, which we recalculate in each χ^2-function call since it depends itself on α_s. Sizes and shapes of the output errors (the uncertainties of the predictions and the SM fit parameters) are fully determined by the fit, and 1 σ errors are defined to correspond to $\Delta\chi^2 = \chi^2 - \chi^2_{\rm min} = 1$, and do not necessarily correspond to the 68.3% probability range or the 39.3% probability contour (for 2 parameters).

The agreement is generally very good. Despite the few discrepancies addressed in the following, the global electroweak fit describes the data well, with a very good χ^2/d.o.f. = 49.5/47. The probability of a larger χ^2 is 37%, and only $g_\mu - 2$ is currently showing a larger (3.2 σ) conflict. In addition, A^0_{LR} (SLD) from hadronic final states, $A^{(0,b)}_{FB}$ (LEP 1), Γ_W (ATLAS) and Q_W(Cs) deviate at the 2 σ level. g^2_L from NuTeV is nominally in conflict with the SM, as well, but the precise status is unresolved (see Sec. 10.3.1). Also, there is currently no understanding as to why the M_W value reported by the CDF collaboration is significantly larger than the findings by other groups. In this context, we refer to Sec. 10.8 for a discussion of fits involving alternative data inputs. We also emphasize that there are a number of discrepancies among individual measurements of certain quantities, as discussed in previous sections, but that they are not reflected in the overall χ^2 of the fit as only the corresponding combinations are used as constraints.

A_b can be extracted from $A^{(0,b)}_{FB}$ when $A_e = 0.1501 \pm 0.0016$ is taken from a fit to leptonic asymmetries (using lepton universality). The result, $A_b = 0.885 \pm 0.017$, is 2.9 σ below the SM prediction[19] and also 1.4 σ below $A_b = 0.923 \pm 0.020$ obtained from $A^{FB}_{LR}(b)$ at SLD. Thus, it appears that at least some of the problem in A_b is due to a statistical fluctuation or other experimental effect in one of the asymmetries. Note, however, that the uncertainty in $A^{(0,b)}_{FB}$ is strongly statistics dominated. The combined value, $A_b = 0.901 \pm 0.013$ deviates by 2.6 σ.

[17] W-boson branching ratio measurements from CMS and ATLAS are in good agreement with lepton universality and slightly more precise than LEP-2 [300, 354].

[18] Refs. [51, 362, 363] report on specialized fits to study the impact of a shift of the hadronic vacuum polarization in the running of the electromagnetic coupling, where such shift is motivated by the apparent mismatch of the direct measurement and the data-driven SM prediction of $g_\mu - 2$, but they do not include $g_\mu - 2$ itself in the fit.

[19] Alternatively, one can use $A_\ell = 0.1481 \pm 0.0027$, which is from LEP 1 alone and in excellent agreement with the SM, and obtain $A_b = 0.897 \pm 0.022$ which is 1.7 σ low. This illustrates that some of the discrepancy is related to the one in A_{LR}.

Table 10.7: Principal electroweak SM fit result including mutual correlations.

M_Z [GeV]	91.1884 ± 0.0019	1.00	−0.08	0.00	0.00	0.02	0.02
$\widehat{m}_t(\widehat{m}_t)$ [GeV]	163.18 ± 0.54	−0.08	1.00	0.00	−0.12	−0.23	0.04
$\widehat{m}_b(\widehat{m}_b)$ [GeV]	4.180 ± 0.008	0.00	0.00	1.00	0.19	−0.02	0.01
$\widehat{m}_c(\widehat{m}_c)$ [GeV]	1.274 ± 0.009	0.00	−0.12	0.19	1.00	0.48	0.01
$\alpha_s(M_Z)$	0.1187 ± 0.0017	0.02	−0.23	−0.02	0.48	1.00	−0.04
$\Delta\alpha^{(3)}_{\rm had}(2\ {\rm GeV})$	0.00608 ± 0.00004	0.02	0.04	0.01	0.01	−0.04	1.00

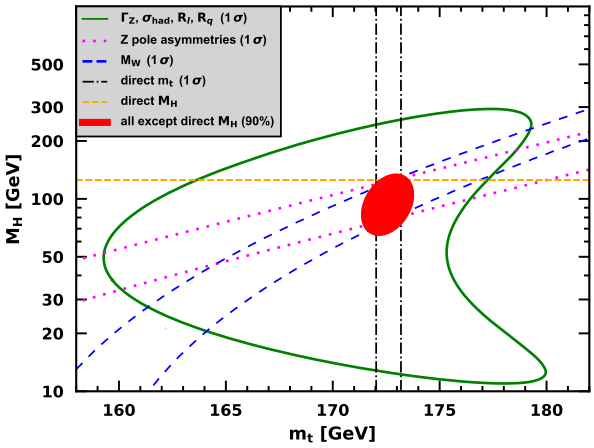

Figure 10.4: Fit result and one-standard-deviation (approximately 39.35% for the closed contours and 68% for the others) uncertainties in M_H as a function of m_t for various inputs, and the 90% CL region ($\Delta\chi^2 = 4.605$) allowed by all data. $\alpha_s(M_Z) = 0.1187$ is assumed except for the fits including the Z lineshape. The width of the horizontal dashed band is not visible on the scale of the plot.

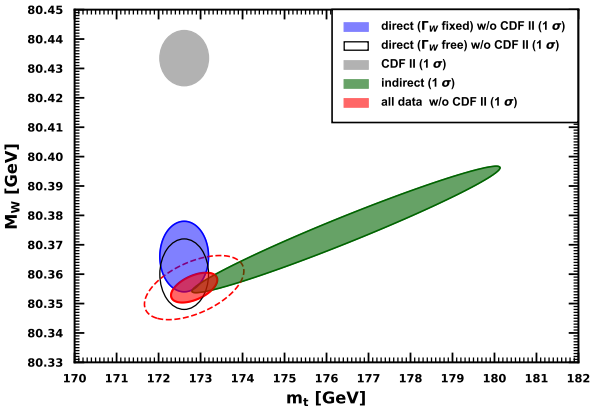

Figure 10.5: One-standard-deviation (39.35%) regions in M_W as a function of m_t for the indirect data from the fit (green), the direct data for m_t and M_W without the CDF II measurement (blue and black contour, respectively, for two differently treatments of the W-boson width), and the combination thereof (red). For the combination, the 90% CL region ($\Delta\chi^2 = 4.605$) is also shown as a red dashed contour. The grey region uses only the M_W value from CDF II. Compared to previous editions of this *Review*, this plot additionally includes theoretical uncertainties and subleading parameter dependencies.

The left-right asymmetry, $A^0_{LR} = 0.15138 \pm 0.00216$ [315], from hadronic decays at SLD, differs by 2.3 σ from the SM expectation of 0.1463 ± 0.0003. The combined value of $A_\ell = 0.1513 \pm 0.0021$ from SLD (using lepton-family universality and including correlations) is also 2.4 σ above the SM prediction; but there is experimental agreement between this SLD value and the LEP 1 value, $A_\ell = 0.1481 \pm 0.0027$, obtained from a fit to $A^{(0,\ell)}_{FB}$, $A_e(\mathcal{P}_\tau)$, and $A_\tau(\mathcal{P}_\tau)$, again assuming universality.

The observables in Table 10.4 and Table 10.5, as well as some other less precise observables, are used in the global fits described below. In all fits, the errors include full statistical, systematic, and theoretical uncertainties. The correlations from the LEP 1 lineshape and τ polarization measurements, the LEP/SLD heavy flavor observables, the SLD lepton asymmetries, and the ν-e scattering observables, are included. The theoretical correlations between $\Delta\alpha^{(5)}_{\rm had}$, $\widehat{s}^2_0$, and $g_\mu - 2$, and between the M_W and Γ_W extractions from the LHC and the Tevatron, are also accounted for.

The electroweak data allow a simultaneous determination of M_Z, m_t, and $\alpha_s(M_Z)$. The direct measurements of M_H at the LHC [364, 365] have reached a precision that the global fit result for M_H coincides with the constraint in Eq. (10.66) with negligible correlations with the other fit parameters. $\widehat{m}_c$, $\widehat{m}_b$, and $\Delta\alpha^{(3)}_{\rm had}$ are also allowed to float in the fits, subject to the theoretical constraints [33, 58] described in Sec. 10.2, and are correlated with α_s, which in turn is determined mainly through R_ℓ, Γ_Z, $\sigma_{\rm had}$, and τ_τ, but Γ_W and $\mathcal{B}(W \to {\rm hadrons})$ also have an impact. The global fit to all data, including the hadron collider m_t average in Eq. (10.21), yields the results in Table 10.7, while those for the weak mixing angle in various schemes are summarized in Table 10.2.

Removing the kinematic constraint on M_H from LHC gives the loop-level determination from the precision data,

$$M_H = 97^{+18}_{-16}\ {\rm GeV}\ , \tag{10.80}$$

which is 1.6 σ below the value in Eq. (10.66). The latter is just inside the 90% central confidence range,

$$71\ {\rm GeV} < M_H < 126\ {\rm GeV}\ . \tag{10.81}$$

It is instructive to study the effect of doubling the uncertainty in Eq. (10.14) on the loop-level determination of the Higgs boson mass. The result, $M_H = 94^{+19}_{-16}$ GeV, reduces the small tension compared to Eq. (10.80) only slightly (1.5 σ) and demonstrates that the uncertainty in $\Delta\alpha_{\rm had}$ is currently of only secondary importance. In fact, even removing $\Delta\alpha^{(3)}_{\rm had}(2\ {\rm GeV})$ altogether as a fit constraint still gives the bound $M_H < 135$ GeV at the 95% CL. The hadronic contribution to $\alpha(M_Z)$ is correlated with $g_\mu - 2$ (see Sec. 10.4). The measurement of the latter is higher than the SM prediction, and its inclusion in the fit favors a larger $\alpha(M_Z)$ and a lower M_H from the precision data (currently by 3.2 GeV).

Alternatively, one can carry out a fit without including the direct constraint from the hadron colliders. One obtains $m_t = 175.2 \pm 1.8$ GeV, which is 1.4 σ higher than the collider average $m_t = 172.61 \pm 0.58$ GeV, and a reflection of the low value in Eq. (10.80). (The indirect prediction is for the $\overline{\rm MS}$ mass definition, $\widehat{m}_t(\widehat{m}_t) = 165.4 \pm 1.7$ GeV, which is in the end converted to the pole mass.) Finally, one can remove the explicit M_W and Γ_W constraints from the global fit and use $M_H = 125.10 \pm 0.09$ GeV to obtain $M_W = 80.353 \pm 0.006$ GeV, in very good agreement with the experimental measurements except the one from CDF II. The situation is summarized in Fig. 10.4 and in Fig. 10.5, showing the m_t dependence of M_H and M_W, respectively.

Table 10.8: Values of $\widehat{s}^2_Z$, s^2_W, α_s, m_t and M_H for various data sets. In the fit to the LHC data, the α_s constraint is from an NNLO analysis of the transverse momentum distribution of Z bosons [369]. For the Tevatron fit we use the α_s result from the inclusive jet cross-section at DØ [370] and add the M_W result from CDF [289] as adjusted in Ref. [298].

data set	$\widehat{s}^2_Z$	s^2_W	$\alpha_s(M_Z)$	m_t [GeV]	M_H [GeV]

$2\, g^{eu}_{VA} - \ g^{ed}_{VA}$	-0.13 ± 0.06	-0.0944		
g^{ee}_{VA}	0.0190 ± 0.0027	0.0224		

The weak mixing angle can be determined from Z pole observables, M_W, and a variety of neutral-current processes spanning a very wide Q^2 range. The results (for older low energy neutral-current data see Refs. [355–358], as well as earlier editions of this *Review*) shown in Table 10.8 are in reasonable agreement with each other, indicating the quantitative success of the SM. One of the largest discrepancies is the value $\widehat{s}^2_Z = 0.23064 \pm 0.00028$ from the SLD asymmetries (combined with M_Z, Γ_Z, and m_t), which is 2.3 σ below the value 0.23129 ± 0.00004 from the global fit to all data. On the other hand, $\widehat{s}^2_Z = 0.23176 \pm 0.00027$ from $A^{(0,b)}_{FB}$ and $A^{(0,c)}_{FB}$ is 1.7 σ high.

The extracted Z pole value of $\alpha_s(M_Z)$ is based on a formula with negligible theoretical uncertainty if one assumes the exact validity of the SM. One should keep in mind, however, that this value, $\alpha_s(M_Z) = 0.1221 \pm 0.0027$, which increased after the updated analysis in Ref. [332], is very sensitive to certain types of new physics such as non-universal vertex corrections. A fit to the wider set of high-energy data, *i.e.*, including W-decays but without τ_τ and $g_\mu - 2$, returns $\alpha_s(M_Z) = 0.1211 \pm 0.0025$. In contrast, the value derived from τ decays, $\alpha_s(M_Z) = 0.1171^{+0.0018}_{-0.0017}$, is theory dominated but less sensitive to new physics. The agreement between these values is only marginal, but the latter does agree well with the averages deduced from heavy quarkonia spectroscopy (0.1181 ± 0.0037), DIS and global PDF fits (0.1161 ± 0.0022), hadronic final states of e^+e^- annihilations (0.1189 ± 0.0037), hadron colliders (0.1168 ± 0.0027), as well as lattice QCD simulations (0.1184 ± 0.0008). For more details, other determinations, and references, see Section 9 on "Quantum Chromodynamics" in this *Review*. We also provide the values, computed with five-loop beta functions and four-loop matching,

$$\alpha^{(4)}_s(m_\tau) = 0.325 \ \ \pm 0.014 \ , \tag{10.82}$$

$$\alpha^{(5)}_s(M_W) = 0.1210 \pm 0.0017 \ , \tag{10.83}$$

$$\alpha^{(5)}_s(M_H) = 0.1132 \pm 0.0015 \ , \tag{10.84}$$

$$\alpha^{(6)}_s(\widehat{m}_t) = 0.1090 \pm 0.0014 \ , \tag{10.85}$$

to be used in precision calculations.

Using $\alpha(M_Z)$ and $\widehat{s}^2_Z$ as inputs, one can predict $\alpha_s(M_Z)$ assuming grand unification. One finds $\alpha_s(M_Z) = 0.13 \pm 0.01$ [371, 372] for the simplest theories based on the minimal supersymmetric extension of the SM, where the uncertainty is from the unknown particle thresholds. This is slightly larger, but consistent with $\alpha_s(M_Z) = 0.1187 \pm 0.0017$ from our fit and most other determinations, while minimal non-supersymmetric theories predict much lower and excluded values (see Section 93 on "Grand Unified Theories" in this *Review*).

Most of the parameters relevant to ν-hadron, ν-e, e-hadron, and e-e processes are determined uniquely and precisely from the data in "model-independent" fits, *i.e.*, fits allowing for an arbitrary EW gauge theory. The values for the parameters defined in Eq. (10.29) are given in Table 10.9 along with the predictions of the SM. The agreement is very good. (The ν-hadron results including NuTeV [151] and other ν-DIS data can be found in the 2006 edition of this *Review*, and fits with modified NuTeV constraints in the 2008 and 2010 editions.)

10.7 Constraints on new physics

The masses and decay properties of the electroweak bosons and low energy data can be used to search for and set limits on deviations from the SM. We will mainly discuss the effects of exotic particles (with heavy masses $M_{\rm new} \gg M_Z$ in an expansion in $M_Z/M_{\rm new}$) on the gauge boson self-energies. (Brief remarks are made on new physics which is not of this type.) Most of the effects on precision measurements can be described by three gauge self-energy parameters S, T, and U. We will define these, as well as

the related parameters ρ_0 and $\widehat{\epsilon}_i$, to arise from new physics only. In other words, they are equal to zero ($\rho_0 = 1$) exactly in the SM, and do not include any (loop induced) contributions that depend on m_t or M_H, which are treated separately. Our treatment differs from most of the original papers.

The dominant effect of many extensions of the SM can be described by the ρ_0 parameter,

$$\rho_0 \equiv \frac{M_W^2}{M_Z^2\,\widehat{c}_Z^2\,\widehat{\rho}}\ , \tag{10.86}$$

which describes new sources of SU(2) breaking that cannot be accounted for by the SM Higgs doublet or by m_t effects. $\widehat{\rho}$ is calculated as in Eq. (10.26) assuming the validity of the SM. In the presence of $\rho_0 \neq 1$, Eq. (10.86) generalizes the second Eq. (10.26) while the first remains unchanged. Provided that the new physics which yields $\rho_0 \neq 1$ is a small perturbation which does not significantly affect other radiative corrections, ρ_0 can be regarded as a phenomenological parameter which multiplies G_F in Eqs. (10.29) and (10.52), as well as Γ_Z in Eq. (10.76c). From the global fit,

$$\rho_0 = 1.00031 \pm 0.00019\ , \tag{10.87a}$$

$$\alpha_s(M_Z) = 0.1189\ \ \pm 0.0017\ , \tag{10.87b}$$

where as before the uncertainty is from the experimental inputs and includes an estimate of the error from unknown higher-order electroweak corrections. The result in Eq. (10.87a) is 1.6 σ above the SM expectation, $\rho_0 = 1$, and not unrelated to the small tension observed in the context with Eq. (10.80). It can be used to constrain higher-dimensional Higgs representations to have vacuum expectation values of less than a few percent of those of the doublets. Indeed, the relation between M_W and M_Z is modified if there are Higgs multiplets with weak isospin $> 1/2$ and significant vacuum expectation values. For a general (charge-conserving) Higgs structure,

$$\rho_0 = \frac{\sum_i [t_i(t_i+1) - t_{3i}^2]|v_i|^2}{2\sum_i t_{3i}^2|v_i|^2}\ , \tag{10.88}$$

where v_i is the expectation value of the neutral component of a Higgs multiplet with weak isospin t_i and third component t_{3i}. In order to calculate to higher orders in such theories one must define a set of four fundamental renormalized parameters which one may conveniently choose to be α, G_F, M_Z, and M_W, since M_W and M_Z are directly measurable. Then $\widehat{s}_Z^2$ and ρ_0 can be considered dependent parameters.

Eq. (10.87a) can also be used to constrain other types of new physics. For example, non-degenerate multiplets of heavy fermions or scalars break the vector part of weak SU(2) and lead to a decrease in the value of M_Z/M_W. Each non-degenerate SU(2) doublet $\binom{f_1}{f_2}$ yields a positive contribution to ρ_0 [373–375] of

$$\frac{N_C\,G_F}{8\sqrt{2}\pi^2}\Delta m^2\ , \tag{10.89}$$

where

$$\Delta m^2 \equiv m_1^2 + m_2^2 - \frac{4m_1^2m_2^2}{m_1^2 - m_2^2}\ln\frac{m_1}{m_2} \geq (m_1 - m_2)^2\ , \tag{10.90}$$

and $N_C = 1$ (3) for color singlets (triplets). Eq. (10.87a) taken together with Eq. (10.89) implies the following constraint on the mass splitting at the 90% CL,

$$(2\ \text{GeV})^2 < \sum_i \frac{N_C^i}{3}\,\Delta m_i^2 < (44\ \text{GeV})^2\ , \tag{10.91}$$

where the sum runs over all new-physics doublets, for example fourth-family quarks or leptons, $\binom{t'}{b'}$ or $\binom{\nu'}{\ell'-}$, vector-like fermion doublets (which contribute to the sum in Eq. (10.91) with an extra factor of 2), and scalar doublets such as $\binom{\tilde{t}}{\tilde{b}}$ in Supersymmetry (in the absence of L–R mixing).

Non-degenerate multiplets usually imply $\rho_0 > 1$. Similarly, heavy Z' bosons decrease the prediction for M_Z due to mixing and generally lead to $\rho_0 > 1$ [376]. On the other hand, extra Higgs doublets participating in spontaneous symmetry breaking [377–379] or heavy lepton doublets involving Majorana neutrinos [380], both of which have more complicated expressions, and the v_i of higher-dimensional Higgs representations can contribute to ρ_0 with either sign.

A number of authors [381–383] have considered the general effects on neutral-current, Z and W boson observables of various types of heavy (*i.e.*, $M_{\rm new} \gg M_Z$) physics which contribute to the W and Z self-energies but which do not have any direct coupling to the ordinary fermions (an alternative formulation is given by Ref. [384]). In addition to non-degenerate multiplets, which break the vector part of weak SU(2), these include heavy degenerate multiplets of chiral fermions which break the axial generators.

Such effects can be described by just three parameters, S, T, and U [385], at the (EW) one-loop level[20]. T is proportional to the difference between the W and Z self-energies at $Q^2 = 0$ (*i.e.*, vector SU(2)-breaking), while S ($S + U$) is associated with the difference between the Z (W) self-energy at $Q^2 = M_{Z,W}^2$ and $Q^2 = 0$ (axial SU(2)-breaking). Denoting the contributions of new physics to the various self-energies by $\Pi_{ij}^{\rm new}$, we have

$$\widehat{\alpha}(M_Z)T \equiv \frac{\Pi_{WW}^{\rm new}(0)}{M_W^2} - \frac{\Pi_{ZZ}^{\rm new}(0)}{M_Z^2}\ , \tag{10.92a}$$

$$\frac{\widehat{\alpha}(M_Z)}{4\widehat{s}_Z^2\widehat{c}_Z^2}S \equiv \frac{\Pi_{ZZ}^{\rm new}(M_Z^2) - \Pi_{ZZ}^{\rm new}(0)}{M_Z^2} - \frac{\widehat{c}_Z^2 - \widehat{s}_Z^2}{\widehat{c}_Z\widehat{s}_Z}\frac{\Pi_{Z\gamma}^{\rm new}(M_Z^2)}{M_Z^2} - \frac{\Pi_{\gamma\gamma}^{\rm new}(M_Z^2)}{M_Z^2}\ , \tag{10.92b}$$

$$\frac{\widehat{\alpha}(M_Z)}{4\widehat{s}_Z^2}(S+U) \equiv \frac{\Pi_{WW}^{\rm new}(M_W^2) - \Pi_{WW}^{\rm new}(0)}{M_W^2} - \frac{\widehat{c}_Z}{\widehat{s}_Z}\frac{\Pi_{Z\gamma}^{\rm new}(M_Z^2)}{M_Z^2} - \frac{\Pi_{\gamma\gamma}^{\rm new}(M_Z^2)}{M_Z^2}\ . \tag{10.92c}$$

S, T, and U are defined with a factor proportional to $\widehat{\alpha}$ removed, so that they are expected to be of order unity in the presence of new physics. In the $\overline{\rm MS}$ scheme as defined in Ref. [85], the last two terms in Eqs. (10.92b) and (10.92c) can be omitted, as was done in some earlier editions of this *Review*. These parameters are related to other parameter sets, S_i [85], $\widehat{\epsilon}_i$ [389], and h_i [390], by

$$T = h_V = \frac{\widehat{\epsilon}_1}{\widehat{\alpha}(M_Z)}\ , \tag{10.93a}$$

$$S = h_{AZ} = S_Z = 4\,\widehat{s}_Z^2\frac{\widehat{\epsilon}_3}{\widehat{\alpha}(M_Z)}\ , \tag{10.93b}$$

$$U = h_{AW} - h_{AZ} = S_W - S_Z = -4\,\widehat{s}_Z^2\frac{\widehat{\epsilon}_2}{\widehat{\alpha}(M_Z)}\ . \tag{10.93c}$$

A heavy non-degenerate multiplet of fermions or scalars contributes positively to T as

$$\rho_0 - 1 = \frac{1}{1 - \widehat{\alpha}(M_Z)T} - 1 \approx \widehat{\alpha}(M_Z)T\ , \tag{10.94}$$

where $\rho_0 - 1$ is given in Eq. (10.89). The effects of non-standard Higgs representations cannot be separated from heavy non-degenerate multiplets unless the new physics has other consequences, such as vertex corrections. Most of the original papers defined T to include the effects of loops only. However, we

[20] Three additional parameters are needed if the new physics scale is comparable to M_Z [386]. Further generalizations, including effects relevant to LEP 2 and Drell-Yan production at the LHC, are described in Refs. [387] and [388], respectively.

will redefine T to include all new sources of SU(2) breaking, including non-standard Higgs, so that T and ρ_0 are equivalent by Eq. (10.94).

A multiplet of heavy degenerate chiral fermions yields

$$S = \frac{N_C}{3\pi} \sum_i \left(t_{3i}^L - t_{3i}^R\right)^2 \ , \tag{10.95}$$

where $t_{3i}^{L,R}$ is the 3rd component of weak isospin of the left-(right-)handed component of fermion i. For example, a heavy degenerate ordinary or mirror family would contribute $2/3\pi$ to S. In models with warped extra dimensions [391], sizeable corrections to the S parameter are generated through mixing between the SM gauge bosons and their Kaluza-Klein (KK) excitations, and one finds $S \approx 30\, v^2 M_{KK}^{-2}$ [392], where M_{KK} is the mass scale of the KK gauge bosons. Large positive values of S can also be generated in models with dynamical electroweak symmetry breaking, where the Higgs boson is composite. In simple composite Higgs models, the dominant contribution stems from heavy spin-1 resonances of the strong dynamics leading to $S \approx 4\pi v^2 (M_V^{-2} + M_A^{-2})$, where $M_{V,A}$ are the masses of the lightest vector and axial-vector resonances, respectively [393].

Negative values of S are possible, for example, in composite Higgs models with larger gauge group representations [394,395], or from loops involving scalars or Majorana particles [396–398]. The simplest origin of $S < 0$ would probably be an additional heavy Z' boson [376]. Supersymmetric extensions of the SM [399, 400] generally give very small effects. For more details and references, see Refs. [401–410] and Sections 88,89 on "Supersymmetry" in this *Review*. Most simple types of new physics yield $U = 0$, although there are counter-examples, such as the effects of anomalous triple gauge vertices [389].

The SM expressions for observables are replaced by,

$$M_Z^2 = M_{Z0}^2 \, \frac{1 - \widehat{\alpha}(M_Z) T}{1 - G_F M_{Z0}^2 S/2\sqrt{2}\pi} \ , \tag{10.96a}$$

$$M_W^2 = M_{W0}^2 \, \frac{1}{1 - G_F M_{W0}^2 (S+U)/2\sqrt{2}\pi} \ , \tag{10.96b}$$

where M_{Z0} and M_{W0} are the SM expressions (as functions of m_t and M_H) in the $\overline{\rm MS}$ scheme. Furthermore,

$$\Gamma_Z = \frac{M_Z^3 \beta_Z}{1 - \widehat{\alpha}(M_Z) T} \ , \tag{10.97a}$$

$$\Gamma_W = M_W^3 \beta_W \ , \tag{10.97b}$$

$$A_i = \frac{A_{i0}}{1 - \widehat{\alpha}(M_Z) T} \ , \tag{10.97c}$$

where $\beta_{Z,W}$ are the SM expressions for the reduced widths Γ_{Z0}/M_{Z0}^3 and Γ_{W0}/M_{W0}^3, M_Z and M_W are the physical masses, and A_i (A_{i0}) is a neutral-current amplitude (in the SM).

The data allows for a simultaneous determination of M_H and m_t (from the hadron colliders), S (from M_Z), T (mainly from Γ_Z), U (from M_W), $\widehat{s}_Z^2 = 0.23113 \pm 0.00013$ (from the Z pole asymmetries), and $\alpha_s(M_Z) = 0.1191 \pm 0.0018$ (mostly from R_ℓ, $\sigma_{\rm had}$, and τ_τ), giving,

$$S = -0.04 \pm 0.10 \ , \tag{10.98a}$$

$$T = \ \ 0.01 \pm 0.12 \ , \tag{10.98b}$$

$$U = -0.01 \pm 0.09 \ , \tag{10.98c}$$

where the correlations among the SM parameters are similar to those in Table 10.7, and where the uncertainties are from unknown higher orders in the SM predictions and the inputs. The parameters in Eq. (10.98), which by definition are due to new physics only, are in excellent agreement with the SM values of zero. Fixing $U = 0$, which is motivated by the fact that U is suppressed by an additional factor $M_{\rm new}^2/M_Z^2$ compared to S and T [411],

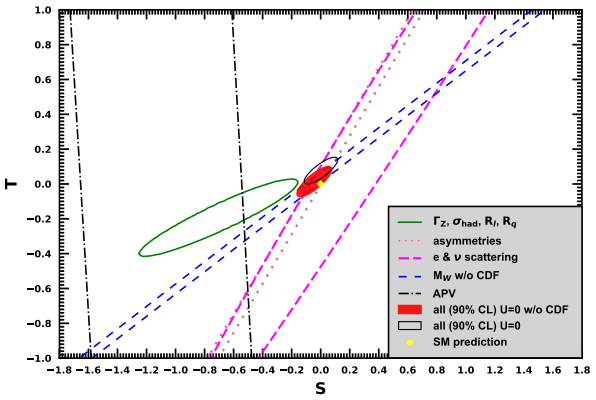

Figure 10.6: 1 σ constraints (39.35% for the closed contours and 68% for the others) on S and T (for $U = 0$) from various inputs combined with M_Z. S and T represent the contributions of new physics only. Data sets not involving M_W or Γ_W are insensitive to U. With the exception of the fit to all data, we fix $\alpha_s = 0.1187$. The yellow dot indicates the Standard Model values $S = T = 0$. The fits to all data are at the 90% CL, with the open black ellipse corresponding to the alternative scenario discussed in Sec. 10.8, *i.e.* including the M_W result from CDF.

greatly improves the precision on S and particularly T,

$$S = -0.05 \pm 0.07 \ , \tag{10.99a}$$

$$T = \ \ 0.00 \pm 0.06 \ . \tag{10.99b}$$

Using Eq. (10.94), the value of ρ_0 corresponding to T in Eq. (10.98b) is 1.0001 ± 0.0009, while the one corresponding to Eq. (10.99b) is 1.0000 ± 0.0005. Thus, the multi-parameter fits are consistent with $\rho_0 = 1$, in contrast to the fit with $S = U = 0$ in Eq. (10.87a). There is a strong correlation (93%) between the S and T parameters. The U parameter is -70% (-87%) anti-correlated with S (T). The allowed regions in S–T (for $U = 0$) are shown in Fig. 10.6. From Eqs. (10.98) one obtains $S \leq 0.11$ and $T \leq 0.20$ at 95% CL, where the former puts the constraint $M_{KK} \gtrsim 4$ TeV on the masses of KK gauge bosons in warped extra dimensions. In minimal composite Higgs models, the bound on S requires $M_V \gtrsim 4.8$ TeV, which is obtained from a one-sided 95% CL bound on $S > 0$ for $T = 0$ and using Weinberg sum rules [412]. However, this constraint can be relaxed, *e.g.*, if the fermionic sector is also allowed to be partially composite [413,414] and in soft-wall models [415].

The S parameter can also be used to constrain the number of fermion families, *under the assumption* that there are no new contributions to T or U and therefore that any new families are degenerate; then an extra generation of SM fermions is excluded with almost 9 σ confidence, corresponding to $N_F = 2.75 \pm 0.14$. This can be compared to the fit to the number of light neutrinos given in Eq. (10.79), $N_\nu = 3.0025 \pm 0.0061$, but the S parameter fits are valid even for a very heavy fourth family neutrino. Allowing T to vary as well, the constraint on a fourth family is weaker [416]. However, a heavy fourth family would increase the Higgs production cross-section through gluon fusion by a factor of about 9 [417], which is in considerable tension with the observed Higgs signal at the LHC [418]. Combining the limits from electroweak precision data with the measured Higgs production rate and limits from direct searches for heavy quarks [419], a fourth family of chiral fermions is now excluded by more than five standard deviations [420,421]. Similar remarks apply to a heavy mirror family [422] involving right-handed SU(2) doublets and left-handed singlets. In contrast, new doublets that receive most of their mass from a different source than the Higgs vacuum expectation value, such as vector-like fermion doublets or scalar doublets in Supersymmetry, give small or no contribution to S, T, U, and the Higgs production cross-section and are therefore still allowed. Partial or complete vector-like fermion families are predicted in

many Grand Unified Theories [423] (see Section 93 on "Grand Unified Theories" in this *Review*), and many other models including supersymmetric and superstring inspired ones [424–427].

As discussed in Sec. 10.6, there is a 3.6% deviation in the asymmetry parameter A_b. Assuming that this is due to new physics affecting preferentially the third generation, we can perform a fit allowing additional $Z \to b\bar{b}$ vertex corrections ρ_b and κ_b as in Eq. (10.53) (here defined to be due to new physics only with the SM contributions removed), as well as S, T, U, and the SM parameters, with the result,

$$\rho_b = 0.057 \pm 0.020 \ , \tag{10.100a}$$

$$\kappa_b = 0.183 \pm 0.067 \ , \tag{10.100b}$$

with an almost perfect correlation of 99% (because R_b is much better determined than A_b). The central values of the oblique parameters are consistent with their SM values of zero (note, however, that $S = -0.10 \pm 0.10$ is slightly outside its 1σ range), and there is little change in the SM parameters, except that the value of $\alpha_s(M_Z)$ is lower by 0.0009 compared to the SM fit. Given that an $\mathcal{O}(20\%)$ correction to κ_b would be necessary, it would be difficult to account for the deviation in A_b by new physics that enters only at the level of radiative corrections. Thus, if it is due to new physics, it is most likely of tree-level type affecting preferentially the third generation. Examples include the decay of a scalar neutrino resonance [428], mixing of the b quark with heavy exotics [429], and a heavy Z' with family non-universal couplings [430,431]. It is difficult, however, to simultaneously account for R_b without tuning, which has been measured on the Z peak and off-peak [432] at LEP 1.

There is no simple parametrization to describe the effects of every type of new physics on every possible observable. The S, T, and U formalism describes many types of heavy physics which affect only the gauge self-energies, and it can be applied to all precision observables. However, new physics which couples directly to ordinary fermions cannot be fully parametrized in this framework. Examples include heavy Z' bosons [376], mixing with exotic fermions [9, 433, 434], leptoquark exchange [294, 435, 436], supersymmetric models, strong EW dynamics [413], Little Higgs models [437, 438], and TeV-scale extra spatial dimensions [439–442] (for more details and references, see Section 85 on "Extra Dimensions" in this *Review*). These types of new physics can be parametrized in a model-independent way by using an effective field theory description [443–446]. Here the SM is extended by a set of higher-dimensional operators, denoted $\mathcal{O}_i$,

$$\mathcal{L} = \mathcal{L}_{\rm SM} + \sum_{d>4} \sum_i \frac{C_i}{\Lambda^{d-4}} \mathcal{O}_i \ , \tag{10.101}$$

where Λ is the characteristic scale of the new physics sector, which is assumed to satisfy $\Lambda \gg v$. For EW precision observables, the leading new operators enter at dimension $d = 6$. Note that S and T can be identified with two of these operators (or linear combinations thereof, depending on the chosen operator basis), while U corresponds to a dimension-8 operator [411, 447]. With current data on M_W and Z pole observables, Λ is constrained to be larger than $\mathcal{O}$(TeV) if the Wilson coefficients C_i are of order unity [448–454].

Limits on new four-Fermi operators and on leptoquarks using LEP 2 and lower energy data are given in Refs. [294, 455–457], while constraints on various types of new physics are addressed in Refs. [9, 169, 319, 458, 459]. For a particularly well motivated and explored type of physics beyond the SM, see Section 87 on "Z'-Boson Searches" in this *Review*.

10.8 Alternative scenarios

For our evaluation of $g_\mu - 2$ and $\Delta\alpha^{(5)}_{\rm had}(M_Z)$ we took the recent vacuum polarization constraints from CMD-3 [48] and LQCD into account. Both have the effect to move the SM prediction of $g_\mu - 2$ closer to the new measurement result in Ref. [236], while reducing the indirect determination of M_H and slightly increasing the small tension with the direct LHC measurements [306, 307]. The discrepancies of CMD-3 and LQCD with some of the older data (especially KLOE) is presently not understood. Thus, it is illustrative to repeat the global fit by replacing $\Delta\alpha^{(3)}_{\rm had}(2\ {\rm GeV}) = (60.30 \pm 0.43) \times 10^{-4}$ and $a_\mu^{\rm had,VP}(\alpha^2) = (65.44 \pm 0.25) \times 10^{-9}$ with the values that we used for the 2022 edition of this *Review*, $\Delta\alpha^{(3)}_{\rm had}(2\ {\rm GeV}) = (58.84 \pm 0.51) \times 10^{-4}$ and $a_\mu^{\rm had,VP}(\alpha^2) = (64.49 \pm 0.33) \times 10^{-9}$. As a result, the discrepancy between the SM prediction and the measurement of a_μ would become 5.1 σ, and Eq. (10.50) would change to

$$a_\mu^{\rm exp} - a_\mu^{\rm theory} = (2.08 \pm 0.41) \times 10^{-9} \ . \tag{10.102}$$

On the other hand, the result for the indirect determination of M_H in Eq. (10.80) would now read

$$M_H = 103^{+18}_{-17}\ {\rm GeV} \ . \tag{10.103}$$

The global fit reported in Sec. 10.6 excluded the recent M_W result by the CDF collaboration [289], because there is a roughly 4 σ discrepancy with other measurements whose origin is currently not understood (Ref. [289] also contains the first high-precision measurement of M_Z at a hadron collider shown in Table 10.5, in perfect agreement with LEP). Here we study the effect of including this measurement as an additional constraint, using $M_W = 80.432 \pm 0.016$ GeV (see Table 10.4), which is the result of the adjustment to the common PDF set CT18 [303] in Ref. [298]. The quality of the global fit deteriorates sharply with a χ^2/d.o.f. = 70.1/48 and a probability of a larger χ^2 of only 2%. The increase in χ^2 amounts to more than 20 for 1 additional degree of freedom. Removing M_H from the LHC as a constraint gives a somewhat improved fit quality with a χ^2/d.o.f. = 60.1/47, but with

$$M_H = 75^{+14}_{-12}\ {\rm GeV} \ , \tag{10.104}$$

driven to very low and excluded values. More acceptable is the ρ_0 fit as in Eq. (10.87a) with a χ^2/d.o.f. = 58.5/47 (12%), and

$$\rho_0 = 1.00059 \pm 0.00016 \ , \tag{10.105}$$

corresponding to $T = 0.08 \pm 0.02$. Thus, if one views the discrepancies in the M_W measurements as statistical fluctuations, then ample parameter space would open up, allowing, *e.g.*, additional non-degenerate SU(2) doublets, as reviewed in Sec. 10.7. In the STU fit,

$$S = -0.04 \pm 0.10 \ , \tag{10.106a}$$

$$T = \ \ 0.01 \pm 0.12 \ , \tag{10.106b}$$

$$U = \ \ 0.05 \pm 0.09 \ , \tag{10.106c}$$

the effect is mostly moved to the U parameter when compared to Eqs. (10.98). S, T and U are highly correlated and despite appearances the probability of all vanishing simultaneously is just 0.3%. Finally, Eq. (10.99) changes only moderately (see also the open black ellipse in Fig. 10.6),

$$S = -0.00 \pm 0.07 \ , \tag{10.107a}$$

$$T = \ \ 0.07 \pm 0.05 \ . \tag{10.107b}$$

Of course, more drastic changes would be observed with the constraint, $M_W = 80.4335 \pm 9.4$ GeV from the original publication [289] with its much smaller quoted uncertainty. For related discussions of this issue, see Refs. [361, 460–463].

Acknowledgments

It is a pleasure to thank Rodolfo Ferro-Hernández for discussions, for performing some of the calculations and checks, and for updating the plots. A.F. is supported in part by the National Science Foundation under grant no. PHY-2112829.

11. Status of Higgs Boson Physics

Revised August 2023 by M. Carena (FNAL; Chicago U.; Chicago U., Kavli Inst.), C. Grojean (DESY, Hamburg; Physik, Humboldt U.), M. Kado (MPP, Garching) and V. Sharma (UC San Diego).

11.1 Introduction

Understanding how the masses of the known elementary particles are generated has been one of the fundamental endeavours in particle physics for several decades. The chiral nature of the weak interactions forbids an intrinsic mass terms for the quarks and leptons at high energy, and their masses can only appear as emergent quantities after the spontaneous symmetry of the electroweak symmetry. The discovery in 2012 by the ATLAS [1] and the CMS [2] collaborations of a new resonance with a mass of approximately 125 GeV and the subsequent studies of its properties with the full data set from Run 1, from 2009 to 2012, with a centre-of-mass energy of 7 TeV and 8 TeV, conclusively provided a first sketch of the Electroweak Symmetry Breaking (EWSB) mechanism. The much larger dataset collected during the LHC Run 2, from 2015 to 2018, with a higher centre-of-mass energy of 13 TeV, demonstrated the compatibility of the measured resonance with the Higgs boson of the Standard Model (SM) [3] and strongly challenged other contenders. The LHC started its Run 3 in 2022 and this data taking phase is expected to comprise of four years of operations until 2026. By then the LHC is expected to deliver proton-proton collision data corresponding to an integrated luminosity of approximately $250\,\text{fb}^{-1}$ per experiment.

In the SM, the electroweak interactions are described by a gauge field theory invariant under the $\text{SU}(2)_L \times \text{U}(1)_Y$ symmetry group. The mechanism of EWSB [4] provides a general framework to keep untouched the structure of these gauge interactions at high energies and still generate the observed masses of the W and Z gauge bosons as well as those of the quarks and charged leptons. The EWSB mechanism posits a self-interacting complex EW doublet scalar field, whose CP-even neutral component acquires a vacuum expectation value (VEV) $v \approx 246\,\text{GeV}$, which sets the scale of the symmetry breaking. Three massless Goldstone bosons are generated and are absorbed to give masses to the W and Z gauge bosons. The remaining component of the complex doublet becomes the Higgs boson – a new, and so far unique, fundamental scalar particle. The masses of all fermions are also a consequence of EWSB since the Higgs doublet is postulated to couple to the fermions through Yukawa interactions in a way consistent with all the gauge symmetries of the SM.

The initial measurements during the LHC Run 1 were accessible mainly through production and decay channels related to the couplings of the Higgs boson to the vector gauge bosons. The outstanding performance of the LHC Run 2, made it possible for the ATLAS and CMS experiments to independently and unambiguously establish the couplings of the Higgs boson to the charged fermions of the third generation (the top quark, the bottom quark, and the tau lepton). In all observed production and decay modes measured so far, the rates and differential measurements are found to be consistent, within experimental and theoretical uncertainties, with the SM predictions. In high mass resolution decay channels, such as the ones with four leptons (electrons or muons) or diphoton final states, the mass of the Higgs boson has been measured at the permill precision level. And, from the search for Higgs boson decays to muons, there are tentalising experimental evidences for Yukawa interactions of the Higgs boson to the second generation of fermions. Nevertheless, several Higgs boson decay channels are very challenging experimentally at the LHC. The couplings of the Higgs boson to the first generation of fermions, at the level expected in the Standard Model, remain so far out of reach at the LHC.

Within the current precision, a more complex Higgs sector with additional states, although significantly constrained, is not ruled out. Nor has it been established whether the Higgs boson is an elementary particle or whether it has an internal structure like any other scalar particle observed before it. Therefore, Higgs physics remains a vivid and intense field of research on the experimental and theoretical fronts.

Without the Higgs boson, the calculability of the SM would have been spoiled. In particular, perturbative unitarity [5] would be lost at high energies since the longitudinal W/Z boson scattering amplitude would grow with the centre-of-mass energy. In addition, the radiative corrections to the gauge boson self-energies would exhibit dangerous logarithmic divergences that would be difficult to reconcile with EW precision data. With the discovery of the Higgs boson, the SM is a spontaneously broken gauge theory and, as such, it could a priori be consistently extrapolated well above the masses of the W and Z bosons. Hence, formally there is no need for new physics at the EW scale. However, as the SM Higgs boson is a scalar particle, it has sensitivity to possible new physics scales. Quite generally, the Higgs boson mass is affected by the presence of heavy particles and it receives large quantum corrections which destabilise the weak scale barring a large fine-tuning of unrelated parameters. This is known as the Higgs naturalness or hierarchy problem [6], and it has been the prime argument for expecting new physics right at the TeV scale. To remedy to his unsatisfactory feature, theoretically motivated paradigms have been explored for several decades, such as a new fermion-boson symmetry called supersymmetry (SUSY) [7] (for recent reviews, see Refs. [8, 9]), or the existence of strong interactions at a scale of the order of a TeV from which the Higgs boson would emerge as a composite state [10] (see Refs. [11, 12]

for recent reviews). Alternatively, new agents stabilising the weak scale could also be light but elusive, like in models of neutral naturalness [13, 14]. And it was recently appreciated [15, 16] that the cosmological evolution of the Universe could drive the Higgs boson mass to a value much smaller than the cutoff of the theory, alleviating the hierarchy problem without the need for TeV scale new physics, even though there might still be interesting and spectacular signatures [15,17]. This new approach spurs a change in perspective invoking our Universe as part of a multiverse that should be treated as a quantum statistical system [18].

The Higgs boson is special and, in the eleven years since its discovery, it became a powerful tool to explore the manifestations of the SM and to probe the physics landscape beyond it.

This review is organised as follows. Section 11.2 is a theoretical introduction to the SM Higgs boson, its properties, production mechanisms and decay rates. The experimental measurements are described in Section 11.3. In Section 11.3.6, the combination of the main Higgs boson production and decay channels is presented. In Section 11.4, measurements of the main quantum numbers and CP properties of the Higgs boson are reported and the bounds on its total width are discussed. In Section 11.5, a general theoretical framework to describe the deviations of the Higgs boson couplings from the SM predictions is introduced and the experimental measurements of these Higgs couplings are reviewed. Measurements of differential cross sections are also outlined. Section 11.6 presents, in detail, some interesting models with an extended Higgs sector, addressing the hierarchy problem or not, and considers their experimental signatures. Section 11.7 provides a short summary and a brief outlook.

11.2 The Standard Model and the mechanism of electroweak symmetry breaking

In the SM [3], electroweak symmetry breaking [4] is responsible for generating a mass for the W and Z gauge bosons rendering the weak interactions short ranged. The SM scalar potential reads:

$$V(\Phi) = m^2 \Phi^\dagger \Phi + \lambda (\Phi^\dagger \Phi)^2 \tag{11.1}$$

with the Higgs field Φ being a self-interacting $\mathrm{SU}(2)_L$ complex doublet (four real degrees of freedom) with weak hypercharge $Y{=}1$ (the hypercharge is normalised such that $Q = T_{3L} + Y/2$, Q being the electric charge and T_{3L} the eigenvalue of the diagonal generator of $\mathrm{SU}(2)_L$):

$$\Phi = \frac{1}{\sqrt{2}} \begin{pmatrix} \sqrt{2}\phi^+ \\ \phi^0 + i a^0 \end{pmatrix}, \tag{11.2}$$

where ϕ^0 and a^0 are the CP-even and CP-odd neutral components, and ϕ^+ is the complex charged component of the Higgs doublet, respectively. $V(\Phi)$ is the most general renormalisable scalar potential invariant under $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$. If the quadratic term is negative, the neutral component of the scalar doublet acquires a non-zero (real) vacuum expectation value (VEV)

$$\langle \Phi \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v \end{pmatrix}, \tag{11.3}$$

with $\phi^0 = H + \langle \phi^0 \rangle$ and $\langle \phi^0 \rangle \equiv v$, inducing the spontaneous breaking of the SM gauge symmetry $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ into $\mathrm{SU}(3)_C \times \mathrm{U}(1)_{\mathrm{em}}$. The global minimum of the theory defines the ground state, and spontaneous symmetry breaking implies that there is a (global and/or local) symmetry of the system that is not respected by the ground state. From the four generators of the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ SM gauge group, three are spontaneously broken, i.e., they do not leave the ground state invariant. This breaking implies the existence of three massless Goldstone bosons identified with three of the four Higgs field degrees of freedom. The Higgs field couples to the W_μ and B_μ gauge fields associated with the $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ local symmetry through the covariant derivative appearing in the kinetic term of the Higgs Lagrangian,

$$\mathcal{L}_{\mathrm{Higgs}} = (D_\mu \Phi)^\dagger (D^\mu \Phi) - V(\Phi), \tag{11.4}$$

where $D_\mu \Phi = (\partial_\mu + i g \sigma^a W_\mu^a/2 + i g' Y B_\mu/2)\Phi$, g and g' are the $\mathrm{SU}(2)_L$ and $\mathrm{U}(1)_Y$ gauge couplings, respectively, and $\sigma^a, a = 1,2,3$ are the usual Pauli matrices. As a result, the neutral and the two charged massless Goldstone degrees of freedom mix with the gauge fields corresponding to the broken generators of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ and become, in the unitarity gauge, the longitudinal components of the Z and W physical gauge bosons, respectively. The Z and W gauge bosons acquire masses,

$$m_W^2 = \frac{g^2 v^2}{4}, \quad m_Z^2 = \frac{(g'^2 + g^2) v^2}{4}. \tag{11.5}$$

The fourth generator remains unbroken since it is the one associated to the conserved $\mathrm{U}(1)_{\mathrm{em}}$ gauge symmetry, and its corresponding gauge field, the photon, remains massless. Similarly, the eight color gauge bosons, the gluons, corresponding to the conserved $\mathrm{SU}(3)_C$ gauge symmetry with 8 unbroken generators, also remain massless (though confined inside hadrons and mesons as the result of the asymptotic freedom behaviour of Quantum ChromoDynamics (QCD)). Hence, from the initial four degrees of freedom of the Higgs field, two are absorbed by the $W^\pm$ gauge bosons, one by the Z gauge boson, and there is one remaining degree of freedom, H, that is the physical Higgs boson — a new scalar particle first imagined by P. Higgs [4]. The Higgs boson is neutral under the electromagnetic interactions and transforms as a singlet under $\mathrm{SU}(3)_C$ and hence does not couple at tree level to the massless photons and gluons.

The fermions of the SM acquire a mass through renormalisable and gauge invariant interactions between the Higgs field and the fermions: the Yukawa interactions,

$$\mathcal{L}_{\mathrm{Yukawa}} = -\hat{h}_{d_{ij}} \bar{q}_{L_i} \Phi \, d_{R_j} - \hat{h}_{u_{ij}} \bar{q}_{L_i} \tilde{\Phi} u_{R_j} - \hat{h}_{l_{ij}} \bar{l}_{L_i} \Phi \, e_{R_j} + h.c., \tag{11.6}$$

which respect the symmetries of the SM but generate fermion masses once EWSB occurs. In the Lagrangian above, $\tilde{\Phi} = i\sigma_2 \Phi^*$ and q_L (l_L) and u_R, d_R (e_R) are the quark (lepton) $\mathrm{SU}(2)_L$ doublets and singlets, respectively, while in each term, $\hat{h}_{f_{ij}}$, $f = u, d, l$ is parametrised by a 3×3 matrix in family space. The mass term for neutrinos is omitted, but could be added in an analogous manner to the up-type quarks when right-handed neutrinos are supplementing the SM particle content (neutrinos can also acquire Majorana masses via non-renormalisable dimension-5 interactions with the Higgs field [19]). Once the Higgs field acquires a VEV, and after rotation to the fermion mass eigenstate basis that also diagonalises the Higgs-fermion interactions, $\hat{h}_{f_{ij}} \to h_{f_i} \delta_{ij}$ (the diagonal Yukawa coupling h_{f_i} is often denoted as y_{f_i}), all fermions acquire a mass given by $m_{f_i} = h_{f_i} v/\sqrt{2}$. The indices $i, j = 1, 2, 3$ refer to the three families in the up-quark, down-quark or charged lepton sectors. Remarkably, if the Yukawa interactions Eq. (11.6) are indeed fully responsible for the fermion masses, the Higgs interactions do not mediate flavour changing neutral currents at tree-level. It should be further noted that the EWSB mechanism provides no additional insight on possible underlying reasons for the large variety of mass values of the fermions, often referred to as the flavour hierarchy. The fermion masses, accounting for a large number of the free parameters of the SM, are simply translated into Yukawa couplings.

11.2.1 *The SM Higgs boson mass, couplings and quantum numbers*

The SM Higgs boson is a CP-even scalar of spin 0. Its mass is given by $m_H = \sqrt{2\lambda}\, v$, where λ is the self-coupling parameter in $V(\Phi)$. The expectation value of the Higgs field, $v = (\sqrt{2} G_F)^{-1/2} \approx 246\,\mathrm{GeV}$, is fixed by the Fermi coupling G_F, which is determined with a precision of 0.6 ppm from muon decay measurements [20]. The quartic coupling λ is a free parameter in the SM, and hence, there is no a priori prediction for the Higgs mass. Moreover the sign of the quadratic coupling, $m^2 = -\lambda v^2$, in the Higgs field potential $V(\Phi)$ has to be negative for the EW symmetry breaking to take place, but there is no a priori understanding of what decides of this sign. The experimentally measured Higgs boson mass, $m_H \simeq 125\,\mathrm{GeV}$ [20], implies that $\lambda \simeq 0.13$ and $|m| \simeq 88.4\,\mathrm{GeV}$.

The Higgs boson couplings to the fundamental particles are set by their masses. This is a new type of interaction; very weak for light particles, such as up and down quarks, and electrons, but strong for heavy particles such as the W and Z bosons and

the top quark. More precisely, the SM Higgs couplings to fundamental fermions are linearly proportional to the fermion masses, whereas the couplings to bosons are proportional to the square of the boson masses. The SM Higgs boson couplings to gauge bosons and fermions, as well as the Higgs boson self coupling, are summarised in the following Lagrangian:

$$\mathcal{L} = -g_{Hf\bar{f}}\bar{f}fH + \frac{g_{HHH}}{6}H^3 + \frac{g_{HHHH}}{24}H^4 + \delta_V V_\mu V^\mu \left(g_{HVV}H + \frac{g_{HHVV}}{2}H^2\right) \quad (11.7)$$

with

$$g_{Hf\bar{f}} = \frac{m_f}{v},\ g_{HVV} = \frac{2m_V^2}{v},\ g_{HHVV} = \frac{2m_V^2}{v^2},\ g_{HHH} = \frac{3m_H^2}{v},\ g_{HHHH} = \frac{3m_H^2}{v^2}, \quad (11.8)$$

where $V = W^\pm$ or Z and $\delta_W = 1, \delta_Z = 1/2$. As a result, the dominant mechanisms for Higgs boson production and decay involve the coupling of H to W, Z and/or the third generation quarks and leptons. The Higgs boson coupling to gluons [21,22] is induced at leading order by a one-loop process in which H couples to a virtual $t\bar{t}$ pair (with minor contributions from the other lighter quarks). Likewise, the Higgs boson coupling to photons is also generated via loops, although in this case the one-loop graph with a virtual W^+W^- pair provides the dominant contribution [23] and it is interfering destructively with the smaller contribution involving a virtual $t\bar{t}$ pair (as such, the Higgs coupling to photons is sensitive to the relative phase of the interactions between bosons and fermions).

11.2.2 *The SM custodial symmetry*

The SM Higgs Lagrangian, $\mathcal{L}_{\text{Higgs}} + \mathcal{L}_{\text{Yukawa}}$ of Eq. (11.4) and Eq. (11.6), is, by construction, $\text{SU}(2)_L \times \text{U}(1)_Y$ gauge invariant, but it also has an approximate global symmetry. In the limit $g' \to 0$ and $h_f \to 0$, a global $\text{SU}(2)_R$ symmetry emerges. This symmetry is preserved for non-vanishing Yukawa couplings provided $\hat{h}_u = \hat{h}_d$. Once the Higgs field acquires a VEV, both the $\text{SU}(2)_L$ and $\text{SU}(2)_R$ symmetry groups are broken but the diagonal subgroup $\text{SU}(2)_{L+R}$ remains unbroken and it is this subgroup that defines the custodial symmetry of the SM [24].

In the limit $g' \to 0$, the $W^\pm$ and Z gauge bosons have equal mass and form a triplet of the $\text{SU}(2)_{L+R}$ unbroken global symmetry. Using the expressions for the W and Z gauge boson masses in term of the gauge couplings, one obtains at tree level

$$\frac{m_W^2}{m_Z^2} = \frac{g^2}{g'^2 + g^2} \equiv \cos^2\theta_W \quad \text{i.e.} \quad \rho \equiv \frac{m_W^2}{m_Z^2 \cos^2\theta_W} = 1. \quad (11.9)$$

The custodial symmetry protects the above relation from large radiative corrections. All corrections to the ρ parameter are therefore proportional to terms that break the custodial symmetry. For instance, radiative corrections involving the Higgs boson are proportional to $\sin^2\theta_W$, $\delta\rho = -11 G_F m_Z^2 \sin^2\theta_W \log(m_H^2/m_Z^2)/(24\sqrt{2}\pi^2)$, and vanish in the limit $g' \to 0$. Since $m_t \neq m_b$, there are also relevant radiative corrections generated by massive fermions. They are proportional to $m_t^2 + m_b^2 - 2(m_t^2 m_b^2)\log(m_t^2/m_b^2)/(m_t^2 - m_b^2)$ and would indeed vanish for $m_t = m_b$ [25].

11.2.3 *Stability of the Higgs potential*

The discovery of the Higgs boson with $m_H \approx 125\,\text{GeV}$ has far reaching consequences within the SM framework. In particular, the precise value of m_H determines the value of the quartic coupling λ at the electroweak scale and makes it possible to study its behavior up to high energy scales. A larger value of m_H would have implied that the self coupling λ would become non-perturbative at some scale Λ that could be well below the Planck scale [26].

However, for the value of Higgs boson mass experimentally measured, the EW vacuum of the Higgs potential is most likely metastable [27]. The high-energy evolution of λ shows that it becomes negative at energies $\Lambda = \mathcal{O}(10^{11})\,\text{GeV}$ (even though λ could remain positive till higher energy, maybe all the way to the Planck scale, if the top quark mass exceeds its current measured value by 3σ). When this occurs, the SM Higgs potential develops an instability and the long term existence of the EW vacuum is challenged. This behaviour may call for new physics at an intermediate scale before the instability develops, i.e., below M_{Planck}, even though new physics at M_{Planck} could influence the stability of the EW vacuum and possibly modify this conclusion [28]. The consequences of the instability of the EW vacuum on high-scale inflation have been discussed in Ref. [29]. It was also noticed that Higgs field fluctuations during inflation could seed the formation of primordial black holes, possibly making up the Dark Matter relic abundance [30] or they could produce a stochastic background of gravitational waves with characteristic structures [31], offering a probe of the EW vacuum near criticality.

The lifetime of the EW metastable vacuum is determined by the rate of quantum tunnelling from this vacuum into the true vacuum of the theory (for the most recent computation of the EW vacuum lifetime within the SM, see Ref. [32]). Within the SM, the running of the Higgs self coupling slows down at high energies with a cancellation of its β-function at energies just one to two orders of magnitude below the Planck scale [33]. This slow evolution of the quartic coupling is responsible for saving the EW vacuum from premature collapse. It might also help the Higgs boson to play the role of an inflaton [34] (see, however, Ref. [35] for potential issues with this Higgs-boson-as-an-inflaton idea).

11.2.4 *Higgs boson production and decay mechanisms*

Comprehensive reviews of the SM Higgs boson properties and phenomenology, with an emphasis on the impact of loop corrections to the Higgs boson decay rates and cross sections, can be found in Refs. [36–40]. The main results are summarised here.

11.2.4.1 *Production mechanisms at hadron colliders*

The main production mechanisms at the Tevatron collider and the LHC are gluon fusion (ggF), weak-boson fusion (VBF), associated production with a gauge boson (VH), and associated production with a $t\bar{t}$ pair ($t\bar{t}H$) or with a single top quark (tHq). Figure 11.1 depicts representative diagrams for these dominant Higgs boson production processes.

The state-of-the-art of the theoretical calculations in the main different production channels is summarised in Table 11.1.

Table 11.1: State-of-the-art of the theoretical calculations in the main Higgs boson production channels in the SM, and, when publicly available, the major MC tools used in the simulations. Furthermore, all the Higgs-boson production modes have been interfaced with parton-shower event generators at NLO QCD like `Poweg-Box, MG5_aMC@NLO or Sherpa` (the entries "—" indicate cases when the results are implemented in codes that are not yet public). For ggF and VH NNLO matched simulations now also exist. Differential NNLO QCD results exist for $t\bar{t}H$ [41] (though the exact 2-loop virtual corrections are still missing) and have been implemented in `MATRIX` [42].

The cross sections for the production of a SM Higgs boson as a function of $\sqrt{s}$, the center of mass energy, for pp collisions, including bands indicating the theoretical uncertainties, are summarised in Fig. 11.2 (left) [43]. A detailed discussion, including uncertainties in the theoretical calculations due to missing higher-order effects and experimental uncertainties on the determination

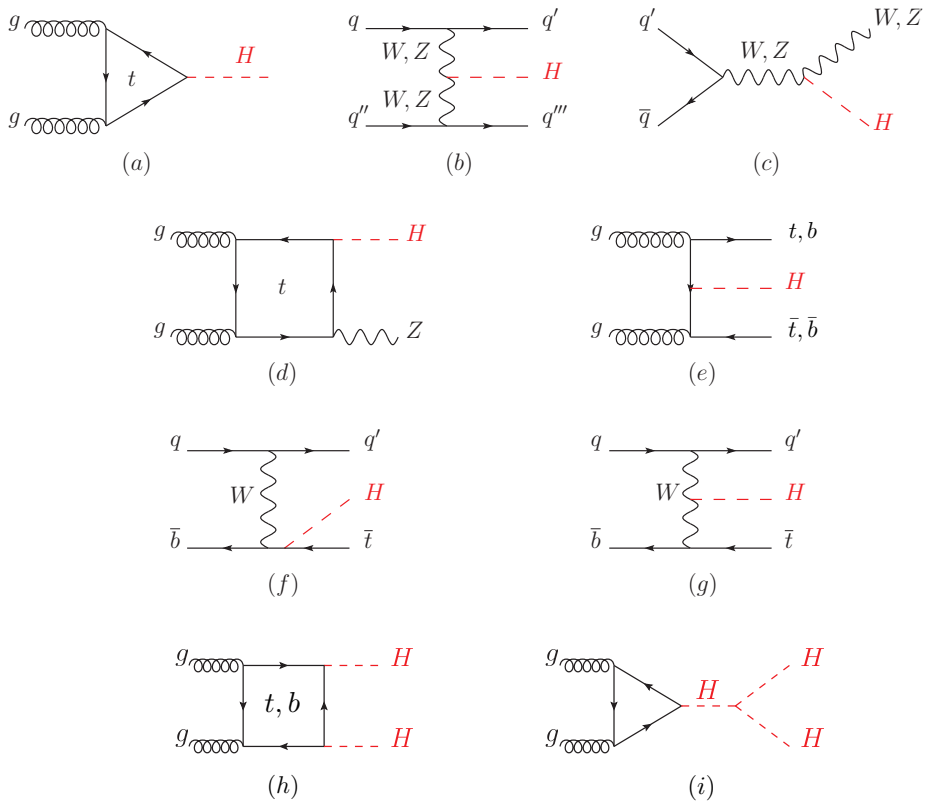

Figure 11.1: Main leading order Feynman diagrams contributing to the single Higgs boson production in (*a*) gluon fusion, (*b*) Vector-boson fusion, (*c*) Higgs-strahlung (or associated production with a gauge boson at tree level from a quark-quark interaction), (*d*) associated production with a gauge boson (at loop level from a gluon-gluon interaction), (*e*) associated production with a pair of top/bottom quarks, (*f*-*g*) production in association with a single top quark, and double Higgs production through (*h*) a top- and bottom-quark loop, (*i*) the self coupling of the Higgs boson.

of SM parameters involved in the calculations, can be found in Refs. [37–40]. These references also contain state-of-the-art discussions on the impact of PDF uncertainties, QCD scale uncertainties and uncertainties due to different procedures for including higher-order corrections matched to parton shower simulations, as well as uncertainties due to hadronisation and parton-shower events.

Table 11.2 summarises the Higgs boson production cross sections and relative uncertainties for a Higgs boson mass of 125 GeV, for $\sqrt{s} = 7$, 8, 13, 13.6 and 14 TeV.

i. *Gluon fusion production mechanism*

At high-energy hadron colliders, the Higgs boson production mechanism with the largest cross section is the gluon-fusion process, $gg \to H + X$, mediated by the exchange of a virtual, heavy top quark [45]. Contributions from lighter quarks propagating in the loop are suppressed proportionally to m_q^2. QCD radiative corrections to the gluon-fusion process are very important and have been studied in detail. Including the full dependence on the (top, bottom, charm) quark and Higgs boson masses, the cross section has been calculated at the next-to-leading order (NLO) in α_s [46, 47]. To a very good approximation, the leading top-quark contribution can be evaluated in the limit $m_t \to \infty$ by matching the SM to an effective theory. The gluon-fusion amplitude is then evaluated from an effective Lagrangian containing a local $HG^a_{\mu\nu}G^{a\,\mu\nu}$ operator [21, 22]. In this approximation, the cross section is known at next-to-next-to-next-to-leading order in α_s expansion (N3LO QCD) [48]. The validity of the effective theory with infinite m_t is greatly enhanced by rescaling the result by the exact LO result: $\sigma = (\sigma^{\rm LO}_{m_t}/\sigma^{\rm LO}_{m_t=\infty})\times\sigma_{m_t=\infty}$ [40]. The large top-quark mass approximation, after this rescaling of the cross section, yields a next-to-next-to-leading order (NNLO) QCD result that has been established to be at the percent level accuracy [49]. Further progress was made to include full top mass dependence at NNLO QCD [50]. And the bottom and light quark contributions to the Higgs production have been reassessed in Refs. [51–53].

The LO contribution and NLO QCD corrections [54] amount to about 80% of the total N3LO QCD cross section. The NNLO QCD corrections [55] further enhance the cross section by approximately 30% of the LO plus NLO result (at $\mu_f = \mu_r = m_H/2$). Electroweak radiative corrections have been computed at NLO and increase the LO cross section by about 5% for $m_H \simeq 125$ GeV [56]. Mixed QCD-EW corrections are now being investigated with encouraging results on the computation of the exact 3-loop amplitude [57] complementing the results obtained in either limit of heavy [58] or massless [59] gauge bosons. The mixed QCD-EW corrections still have to be evaluated at large p_T.

At N3LO QCD, the perturbation series is rather stable with a mere enhancement of 3% of the total cross section, with a central value quite insensitive to threshold resummation effects with the scale choice mentioned above ($\mu_f = \mu_r = m_H/2$) [40, 48, 60, 61]. At the LHC with a center-of-mass energy of 13 TeV, the most up-to-date value for the production cross section of a 125 GeV Higgs boson amounts to [40]

$$\sigma^{\rm N3LO}_{\rm ggF} = 48.6\,^{+2.2\,(4.6\%)}_{-3.3\,(6.7\%)}\,(\text{theory}) \pm 1.6\,(3.2\%)\,(\text{PDF} + \alpha_s)\,\text{pb}. \tag{11.10}$$

This cross-section was first computed in terms of an expansion around the production threshold of the Higgs boson. This approximation was overcome in Ref. [61]. The PDF uncertainty of order 1-2% quoted above has been questioned as the first global analysis of PDFs at approximate N3LO QCD was presented, suggesting an unexpected decrease of the cross-section central value by more than 5% [62].

Besides considering the inclusive Higgs boson production cross section at the LHC, it is important to study differential distri-

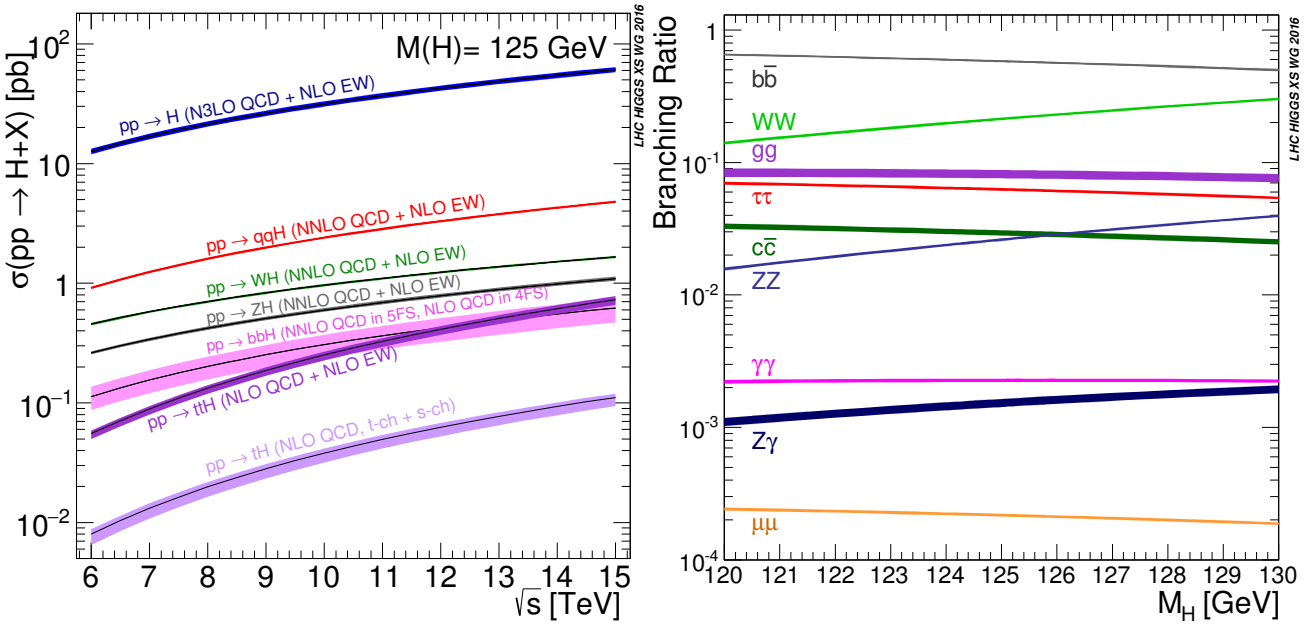

Figure 11.2: (Left) The SM Higgs boson production cross sections as a function of the center of mass energy, $\sqrt{s}$, for pp collisions [43]. The VBF process is indicated here as qqH. (Right) The branching ratios for the main decays of the SM Higgs boson near $m_H = 125\,\text{GeV}$ [39, 40]. The theoretical uncertainties are indicated as bands.

butions in order to probe the properties of the Higgs boson in a detailed way. The Higgs boson rapidity distribution has been computed at the N3LO QCD order in Ref. [63]. And fully differential N3LO QCD predictions for Higgs production in gluon fusion have been obtained by combining N3LO QCD predictions for Higgs rapidity distribution with NNLO QCD predictions for H+jet [64]. A more exclusive account of Higgs boson production is also required because experimental analyses often impose cuts on the final states in order to improve the signal-to-background ratio. Using soft-collinear effective theory, large fiducial power corrections induced by fiducial cuts have been resummed at N3LO+N3LL′ QCD accuracy, i.e. at next-to-next-to-next-leading-log, incorporating the complete $\mathcal{O}(\alpha_s^3)$ singular structure for $q_T \to 0$ allowing one to consistently match to N3LO QCD [65]. This is the most accurate result that can be directly compared with fiducial measurements. Different fiducial cuts are explored to suppress these fiducial effects. In addition, progress has been made to improve the calculation of the Higgs boson production cross section with a jet veto (the "0-jet bin" or in the presence of a veto bounding the transverse momentum of the hardest accompanying jet) [66], reaching NNLL accuracy matched to N3LO QCD. These accurate predictions for the jet-veto cross section are required, e.g., to suppress the $t\bar{t}$ background in the $H \to WW$ channel [67].

ii. *Vector boson fusion production mechanism*

The SM Higgs boson production mode with the second-largest cross section at the LHC is vector boson fusion. At the Tevatron collider, VBF also occurred, but for $m_H = 125\,\text{GeV}$ had a smaller cross section than Higgs boson production in association with a W or Z boson. Higgs boson production via VBF, $qq \to qqH$, proceeds by the scattering of two (anti-)quarks, mediated by t- or u-channel exchange of a W or Z boson, with the Higgs boson radiated off the weak-boson propagator. The scattered quarks give rise to two hard jets in the forward and backward regions of the detector with a large rapidity gap [68]. Because of the color-singlet nature of the weak-gauge boson exchange, gluon radiation from the central-rapidity regions is strongly suppressed. These characteristic features of VBF processes can be exploited to distinguish them from overwhelming QCD backgrounds, including gluon-fusion induced Higgs boson + 2 jet production, and from s-channel WH or ZH production with a hadronically decaying weak gauge boson. After the application of specific selection cuts, the VBF channel provides a clean environment, not only for the Higgs boson searches originally performed, but also for the subsequent determination of Higgs boson couplings at the LHC.

The cross-section is known at N3LO QCD at the inclusive level [69] and at NNLO enforcing the VBF cuts [70] with a residual uncertainty of the order of few permill. However, this result is obtained in the DIS/factorized approximation [71] where the fusing gauge bosons are emitted from the two quark legs independently. While, the exact NNLO QCD VBF calculation will remain out-of-reach in the near future, the leading non-factorisable contributions with two forward jets have been estimated [72] and the impact of non-factorizable effects have been studied in Ref. [73]. They give some corrections, also of the order of few permill, to inclusive quantities, but they are an order of magnitude larger for differential observables. Overall, the residual uncertainty is of the order of a few percent but is quite sensitive to the tagging jet cuts and jet radius modelling [74]. Extensive studies on VBF at fixed order and with parton shower matched computations can be found in Ref. [75]. In addition, EW corrections have been included and the VBF process is known at NLO QCD+EW order for some time [76, 77].

iii. *WH and ZH associated production mechanism*

The next most relevant Higgs boson production mechanisms are associated production with W and Z gauge bosons. The cross sections for the associated production processes, $pp \to VH + X$, with $V = W^{\pm}, Z$ receive contributions at NLO QCD given by NLO QCD corrections to the Drell–Yan cross section [78, 79] and from NLO EW corrections. The latter, unlike the QCD corrections, do not respect the factorisation into Drell–Yan production since there are irreducible box contributions already at one loop [76,80]. At NNLO QCD, the Drell–Yan-like corrections to WH production also give the bulk of the corrections to ZH production [81]. For ZH production there are, however, gluon-gluon induced contributions that do not involve a virtual Z gauge boson but are such that the Z gauge boson and H boson couple to gluons via top-quark loops [82], see diagram (d) in Fig. 11.1. NLO QCD virtual corrections to the partonic cross section for $gg \to ZH$, in the high-energy and large top mass limits are available in Refs. [83]. In addition, WH and ZH production receive non Drell–Yan-like corrections in the $q\bar{q}'$ and $q\bar{q}$ initiated channels, respectively, at the NNLO level in QCD, where the Higgs boson is radiated off

Table 11.2: The SM Higgs boson production cross sections for $m_H = 125\,\text{GeV}$ in pp collisions ($p\bar{p}$ collisions at $\sqrt{s} = 1.96\,\text{TeV}$ for the Tevatron), as a function of the center of mass energy, $\sqrt{s}$. The predictions for the LHC energies are taken from Refs. [37–40, 43], the ones for the Tevatron energy are the ones used in Ref. [44]. The predictions for the ggF channel at the LHC include the latest N3LO QCD + NLO EW results. The uncertainties are estimated assuming no correlation between α_S and PDF uncertainties. The uncertainties on the total cross sections are dominated by the ones on the gluon fusion process.

$\sqrt{s}$ (TeV)	Production cross section (in pb) for $m_H = 125\,\text{GeV}$

top-quark loops [84]. The full QCD corrections up to NNLO order, the NLO EW corrections and the NLO corrections to the gluon-gluon channel are available in `VH@NNLO` [85]. NNLO QCD corrections to $pp \to WH$+jet are important for signal modelling. NLO corrections to cross section inclusive in the number of jets show excellent convergence while NNLO QCD corrections to exclusive single jet cross section are much more significant [86].

As neither the Higgs boson nor the weak gauge bosons are stable particles, their decays also have to be taken into account. Providing full kinematical information for the decay products can furthermore help in the suppression of large QCD backgrounds. Differential distributions for the processes $pp \to WH \to \bar{\nu}_\ell \ell H$ and $pp \to ZH \to \ell^+\ell^- H/\nu_\ell \bar{\nu}_\ell H$, including NLO QCD and EW corrections, have been presented in Ref. [87]. The NNLO QCD corrections to differential observables for WH production at the LHC, including the leptonic decays of the W boson and the decay of the Higgs boson into a $b\bar{b}$ pair, are presented in Ref. [88]. Calculations at the same level, including also the ZH process have been performed [89]. The WH production mode has also been matched to a parton shower at NNLO QCD accuracy [90]. Full NNLO QCD results for both the production and decay are available [91] and show a large impact of radiation from the final-state bottoms. The WH and ZH production modes, especially in the boosted regime, provide a relatively clean environment for studying the decay of the Higgs boson into bottom quarks [92]. Bottom mass effects have been computed at NNLO [93, 94] and tend to increase the rates by 6-7%.

The inclusive cross section for associated Higgs boson production with a massive gauge boson is recently known up to N3LO QCD too [95].

iv. *Higgs boson production in association with $t\bar{t}$*

Higgs boson radiation off top quarks, $pp \to t\bar{t}H$, provides a direct probe of the top-Higgs Yukawa coupling. The LO cross section for this production process was computed in Ref. [96]. Later, the NLO QCD [97] and NLO EW corrections [98] were evaluated yielding a moderate increase in the total cross section of at most 20%, but significantly reducing the scale dependence of the inclusive cross section. The EW corrections can be enhanced by large electroweak Sudakov logarithms in particular in the boosted regime often used in the phenomenological analyses [99]. The resummation of soft gluon contributions close to the partonic kinematical threshold are considered in Refs. [100] to reach a result at NLO+NNLL QCD order. Full off-shell calculations with decaying top quarks are computed at NLO QCD [101] and NLO QCD + EW [102] order, respectively. The fixed-order NLO QCD calculation has been interfaced with the standard parton shower Monte-Carlo generators in Refs. [103], allowing an accurate description of the $t\bar{t}H$ signal, from the energy scale of the hard scattering to the hadronisation energy scale. These programs provide the most flexible tools to date for the computation of differential distributions, including experimental selection cuts and vetoes on the final-state particles and their decay products. The exploitation of this $t\bar{t}H$ channel requires, however, a proper description of the background, in particular $t\bar{t}b\bar{b}$, which exhibits a huge k-factor[1] enhancement from shower effects, see Ref. [40] for a detailed discussion. While the $H \to b\bar{b}$ decay mode was first considered, the focus has been broadened and other modes have been studied too, in particular the multilepton channel and other backgrounds such as $t\bar{t}W$ and $t\bar{t}Z$ have become relevant and intensively analyzed.

The total theoretical uncertainties, estimated by combining the ones from factorisation and renormalisation scales, strong gauge coupling, and parton distributions, amount to 10–15% of the corresponding inclusive cross section. To match the experimental precision envisioned at the end of HL-LHC, NNLO QCD predictions are required. Using the q_T subtraction formalism for $t\bar{t}H$ production, Ref. [104] presented the first quantitative results at NNLO. The calculation is accurate at NLO in QCD and agrees with the results obtained using the conventional subtraction methods. The NNLO corrections are computed for the flavour off-diagonal partonic channels but their contribution turn out to be at the permill level. The results for the diagonal channels have been obtained in Ref. [41]. The two-loop amplitudes are not yet known, but they have been reliably evaluated by using a soft Higgs boson approximation. At the 13 TeV centre-of-mass energy, the NNLO corrections increase the NLO result for the total cross section by about 4% and lead to a significant reduction of perturbative uncertainties. Also recently, the fragmentation and splitting functions for the production of a Higgs boson have been computed at order $y_t^2\alpha_s$ and they can be used to compute dif-

[1] the k-factor is defined as the ratio of a physical quantity with and without radiative corrections included.

ferential cross sections with arbitrary top-quark and Higgs-boson masses directly from the results in the massless limit [105].

v. *Other single Higgs boson production mechanisms at the LHC*

The Higgs boson production in association with a single top quark, though subdominant, can bring valuable information, in particular regarding the sign of the top Yukawa coupling. This is due to an almost totally destructive interference between two large contributions, one where the Higgs boson couples to a space-like W boson and the other where it couples to the top quark. This process has been computed at NLO QCD in a five-flavour scheme [106] and amounts to about 90 fb at $\sqrt{s} = 14$ TeV (with the opposite sign of the top Yukawa coupling, the cross section increases by one order of magnitude while the cross section for associated production with a pair of top quarks is unaffected). Recently, the tHj (and tZj) process has been computed at NLO QCD+EW accuracy [107]. The NLO EW correction is found to be within the NLO QCD theory uncertainties if the 4 vs 5 flavour scheme uncertainty is taken into account. The EW corrections reduce the total cross section by 3-4%.

The Higgs boson production in association with a pair of bottom quarks ($b\bar{b}H$) has been computed at the N3LO QCD order in the 5-flavour scheme [108], while the production with one/two b-jets, defined by specific kinematic cuts, is known respectively at NLO QCD in the 4-flavour scheme and at NNLO QCD in the 5-flavour scheme [109–111]. The coupling of the Higgs boson to a b-quark is suppressed in the SM by the bottom-quark mass over the Higgs VEV, m_b/v, implying that associated production of a SM Higgs boson with b-quarks is small at the LHC. Yet, at high energy, large logarithms are present and need to be resummed, leading to an enhancement of the inclusive cross section. At $\sqrt{s} = 14$ TeV, the $b\bar{b}H$ cross section can be as large as 550 fb, still two orders of magnitude below the ggF production cross section. Furthermore, the overwhelming ZH and VBF backgrounds (at the inclusive but also differential levels) make it challenging to extract genuine bottom Yukawa signal in a traditional cut-based analysis [112] but innovative machine-learning techniques are a promising avenue to obtain information complementary to the ones extracted from $gg \to h \to b\bar{b}$, in particular for what concerns the phase of the bottom Yukawa coupling [113]. In a two Higgs doublet model or a SUSY model, which will be discussed in Section 11.6, this coupling is proportional to the ratio of neutral Higgs boson vacuum expectation values, $\tan\beta$, and can be significantly enhanced for large values of this ratio. Consequently, the $b\bar{b}H$ mode can even become the dominant production process for the Higgs boson, unlike in the SM.

The Higgs boson production in association with charm quarks is also known at NNLO QCD and its cross section is approximately 85 fb at $\sqrt{s} = 13$ TeV [40].

vi. *Double Higgs boson production at the LHC*

The main interest in the double Higgs boson production is that it can provide invaluable information on the Higgs potential. In particular, it gives access to the Higgs trilinear self coupling. The dominant production is via gluon fusion $gg \to HH$ (slightly more than 31 fb at 13 TeV) and it accounts for more than 90% of the total inclusive cross-section, the sub-leading production mechanisms are VBF $HHjj$ (around 1.7 fb at 13 TeV), HHW (0.50 fb), HHZ (0.36 fb) and $t\bar{t}HH$ (0.8 fb). The fixed order QCD corrections, computed in the infinite top mass limit, are large, typically doubling the cross section from LO to NLO QCD [114], further enhancing it by 20% and reducing the scale uncertainty by a factor 2-3 from NLO to NNLO QCD [115], with a milder increase of order 3% at N3LO [116] to finally reach at 13 TeV

$$\sigma(gg \to HH)^{\rm N3LO}_{\rm ggF,m_t\to\infty} = 31.31\,^{+0.66\%}_{-2.8\%}\ \text{fb}. \qquad (11.11)$$

Recently, the complete NLO corrections with all top quark mass effects also became available numerically [117], intriguingly revealing a k-factor much less flat than predicted in the large top mass approximations. The non-trivial dependence of the results on the renormalisation scheme and scale for the top quark mass questions the assessment of the scale uncertainty and would warrant a proper NNLO computation that will however remain out of reach for quite some time. At the differential level, the destructive interference between the box and the triangle contributions complicates the predictions made in the infinite top mass limit for both the HH invariant mass and the leading Higgs boson p_T distributions. With an inclusive cross section of about 35 fb at $\sqrt{s} = 13$ TeV and a difficult signal vs background discrimination, the double Higgs boson production remains a challenging channel to probe and will greatly benefit from the high-luminosity run of the LHC and the combination of various decay modes [118]. The double Higgs channel is definitively a prime target on the Higgs physics agenda and the forthcoming analyses will greatly benefit from the solidification of the fixed order predictions and the detailed uncertainty budget estimate that is underway [119].

11.2.4.2 *Production mechanisms at e^+e^- colliders*

The dominant Higgs boson production cross sections at an e^+e^- collider are from the Higgs-strahlung process [21, 120], $e^+e^- \to ZH$, and the WW fusion process [121], $e^+e^- \to \bar{\nu}_e\nu_e W^*W^* \to \bar{\nu}_e\nu_e H$. The cross-section for the Higgs-strahlung process scales as the inverse of the collision centre-of-mass squared energy, s, and is predominant at low energies, while the cross-section for the WW fusion process scales as $\ln(s/m_H^2)$ and dominates at high energies [122]. The ZZ fusion mechanism, $e^+e^- \to e^+e^-Z^*Z^* \to e^+e^-H$, also contributes to the Higgs boson production, with a cross-section suppressed by an order of magnitude with respect to that of WW fusion. The process $e^+e^- \to t\bar{t}H$ [123] becomes important for $\sqrt{s} \geq 500$ GeV. For a more detailed discussion of Higgs boson production properties at lepton colliders, see for example Refs. [124]. Interesting progress has been made recently [125] to accurately account for beamstrahlung and initial state radiation using the factorisation approach primarily developed for hadron colliders and this method is being implemented in Monte Carlo event generators. Further information about Higgs physics at an e^+e^- collider can be found in Ref. [126].

11.2.4.3 *SM Higgs boson branching ratios and total width*

For the understanding and interpretation of the experimental results, the computation of all relevant Higgs boson decay widths is essential, including an estimate of their uncertainties and, when appropriate, the effects of Higgs boson decays into off-shell particles with successive decays into lighter SM ones. A Higgs boson mass of about 125 GeV allows to explore the Higgs boson couplings to many SM particles. In particular the dominant decay modes are $H \to b\bar{b}$ and $H \to WW^*$, followed by $H \to gg$, $H \to \tau^+\tau^-$, $H \to c\bar{c}$ and $H \to ZZ^*$. With much smaller rates follow the Higgs boson decays into $H \to \gamma\gamma$, $H \to \gamma Z$ and $H \to \mu^+\mu^-$. Since the decays into gluons, diphotons and $Z\gamma$ are loop induced, they provide indirect information on the Higgs boson couplings to WW, ZZ and $t\bar{t}$ in different combinations. The uncertainties in the branching ratios include the missing higher-order corrections in the theoretical calculations as well as the errors in the SM input parameters, in particular fermion masses and the QCD gauge coupling, involved in the decay. In the following the state-of-the-art of the theoretical calculations compiled by the LHC Higgs Working Group [43] will be discussed and the reader is referred to Refs. [37–40, 127] for detail.

The evaluation of the radiative corrections to the fermionic decays of the SM Higgs boson are implemented in HDECAY [128] at different levels of accuracy. The computations of the $H \to b\bar{b}$ and $H \to c\bar{c}$ decays include the complete massless QCD corrections up to N4LO, with a corresponding scale dependence of about 0.1% [129]. Both the electroweak corrections to $H \to b\bar{b}$, $c\bar{c}$ as well as $H \to \tau^+\tau^-$ are known at NLO [130] providing predictions with an overall accuracy of about 1–2% for $m_H \simeq 125$ GeV.

The loop induced decays of the SM Higgs boson are known fully at NLO and partially beyond that approximation. For $H \to gg$, the QCD corrections are known up to N3LO in the limit of heavy top quarks [47,131] and the uncertainty from the scale dependence is about 3%. For the $H \to \gamma\gamma$, the full NLO QCD corrections are available [47, 132] and the three-loop QCD corrections have also been evaluated [133]. The NLO electroweak corrections to

$H \to gg$ and $H \to \gamma\gamma$ have been computed in Ref. [134]. All these corrections are implemented in HDECAY [128]. For $m_H \simeq 125\,\text{GeV}$, the overall impact of known QCD and EW radiative effects turns out to be well below 1%. In addition, the contribution of the $H \to \gamma e^+ e^-$ decay via virtual photon conversion has been computed in Ref. [135]. The partial decay width $H \to Z\gamma$ is only implemented at LO in HDECAY, including the virtual W, top-, bottom-, and τ-loop contributions. The QCD corrections have been calculated and are at the percent level [136]. The theoretical uncertainty due to unknown electroweak corrections is estimated to be less than 5%, an accuracy that will be hard to achieve in the measurement of this process at the LHC.

Table 11.3: The branching ratios and the relative uncertainty for a SM Higgs boson with $m_H = 125\,\text{GeV}$ [39, 40].

Decay channel	Branching ratio	Rel. uncertainty
$H \to \gamma\gamma$	2.27×10^{-3}	2.1%
$H \to ZZ$	2.62×10^{-2}	$\pm$1.5%
$H \to W^+W^-$	2.14×10^{-1}	$\pm$1.5%
$H \to \tau^+\tau^-$	6.27×10^{-2}	$\pm$1.6%
$H \to b\bar{b}$	5.82×10^{-1}	$^{+1.2\%}_{-1.3\%}$
$H \to c\bar{c}$	2.89×10^{-2}	$^{+5.5\%}_{-2.0\%}$
$H \to Z\gamma$	1.53×10^{-3}	$\pm$5.8%
$H \to \mu^+\mu^-$	2.18×10^{-4}	$\pm$1.7%

The decays $H \to WW/ZZ \to 4f$ can be simulated with the `Prophecy4f` Monte-Carlo generator [137] that includes complete NLO QCD and EW corrections for Higgs decays into any possible four-fermion final state. All calculations are consistently performed with off-shell gauge bosons, without any on-shell approximation. For the SM Higgs boson, the missing higher-order corrections are estimated to be roughly 0.5%. Such uncertainties will have to be combined with the parametric uncertainties, in particular those associated to the bottom-quark mass and the strong gauge coupling, to arrive at the full theory uncertainty. A detailed treatment of the differential distributions for a Higgs boson decay into four charged leptons in the final state is discussed in Refs. [39, 138].

The total width of a 125 GeV SM Higgs boson is $\Gamma_H = 4.07 \times 10^{-3}\,\text{GeV}$, with a relative uncertainty of $^{+4.0\%}_{-3.9\%}$. The branching ratios for the most relevant decay modes of the SM Higgs boson as a function of m_H, including the most recent theoretical uncertainties, are shown in Fig. 11.2 (right) and listed for $m_H = 125\,\text{GeV}$ in Table 11.3. Further details of these calculations can be found in the reviews [37–40] and references therein.

11.3 The experimental profile of the Higgs boson

The observation [1, 2] at the LHC of a narrow resonance with a mass of about 125 GeV was an important landmark in the decades-long direct search [44, 139] for the SM Higgs boson. This observation is being followed by a detailed exploration of properties of the Higgs boson at the different runs of the LHC at $\sqrt{s} = 7$, 8,13 and 13.6 TeV.

The dataset at $\sqrt{s}$ =13 TeV collected during the Run-2 phase of the LHC operation is the largest analysed dataset so far and corresponds to an integrated luminosity of about $160\,\text{fb}^{-1}$ delivered to the ATLAS and CMS experiments, see Table 11.4 [140]. The datasets effectively useful for analysis need to take into account the data-taking efficiency with fully operational detectors and the data quality efficiency. The typical total inefficiency for both ATLAS and CMS is approximately 10%, where approximately half is due to the data aquisition inefficiency and the other half from data quality requirements.

In this section, most of the references for the Run-1 measurements that have been updated with the data delivered in Run 2 are given in the previous version of this review [141] and are not repeated herein.

Table 11.4: The LHC pp collision centre-of-mass energies and approximate collision samples delivered to ATLAS & CMS experiments.

Year	$\sqrt{s}$ (TeV)	$\int$ L.dt (fb^{-1})	Period
2010	7.0	0.04	Run 1
2011	7.0	6	Run 1
2012	8.0	23	Run 1
2015	13.0	4	Run 2
2016	13.0	39	Run 2
2017	13.0	51	Run 2
2018	13.0	61	Run 2
2022	13.6	39	Run 3
2023	13.6	32	Run 3

11.3.1 *The principal decay channels of the Higgs boson*

For a given m_H, the sensitivity of a channel depends on the production cross section of the Higgs boson, its decay branching fraction, the reconstructed mass resolution, the selection efficiency and the level of background in the final state. It is defined typically as the expected significance for the observation of a given process or in terms of expected upper limit at 95% Confidence Level (CL). At the LHC, for a Higgs boson with a mass close to 125 GeV, five decay channels play an important role. In the $H \to \gamma\gamma$ and $H \to ZZ^* \to 4\ell$ channels, all final state particles can be very precisely measured and the reconstructed m_H resolution is excellent (typically 1-2%). The $H \to W^\pm W^{\mp(*)} \to \ell^+\nu_\ell\ell'^-\bar{\nu}_{\ell'}$ channel has a relatively large branching fraction. However, the presence of neutrinos, which are not reconstructed in the final state, means that the m_H resolution, obtained through observables sensitive to the Higgs boson mass such as the transverse mass, is poor (approximately 20%). The $H \to b\bar{b}$ and the $H \to \tau^+\tau^-$ (with the tau subsequently decaying to electrons or muons and two neutrinos $\tau \to \ell\nu\bar{\nu}$ or to hadrons and one neutrino $\tau \to \text{hadrons}\,\nu$) channels suffer from large backgrounds and lead to an intermediate mass resolution of about 10% and 15% respectively.

With the increase in the size of datasets, measurements in the most sensitive channels are now carried out differentially or in exclusive modes depending on specific production characteristics. These measurements are discussed in Section 11.5.1.5.

The candidate events in each Higgs boson decay channel are split into several mutually exclusive categories (or event tags) based on the specific topological, kinematic or other features present in the event. The categorization of events increases the sensitivity of the overall analysis and allows a separation of different Higgs boson production processes. Most categories are dominated by signal from one Higgs boson decay mode but contain an admixture of various Higgs boson production processes. For example, a typical VBF selection requires Higgs boson candidates to be accompanied by two energetic jets ($\geq 30\,\text{GeV}$) with a large dijet mass ($\geq 400\,\text{GeV}$) and separated by a large pseudo-rapidity ($\Delta\eta_{jj} \geq 3.5$) [142]. While such a category is enriched in Higgs bosons produced via VBF, the contamination from the ggF or VH production mechanisms can be significant. Hence, a measurement of the signal rate in the VBF category is not equivalent to a measurement of VBF production cross section since one cannot resolve the contamination from ggF. Simulations are used to determine the relative contributions of the various Higgs boson production modes in each of the specific categories.

11.3.2 *The Higgs boson decay to vector bosons*

11.3.2.1 $H \to \gamma\gamma$

In the diphoton channel, the measurement of a narrow peak over a smoothly falling background in the invariant mass distribution of two high p_T photons is performed. The background in

this channel is conspicuous and stems from prompt $\gamma\gamma$ processes for the irreducible backgrounds, and the γ+jet and dijet processes for the reducible backgrounds where one jet fragments typically into a leading π^0. In order to optimise search sensitivity and also to separate the various Higgs boson production modes, ATLAS and CMS split events into several mutually exclusive categories. Diphoton events containing high p_T muons or electrons, or missing energy ($E_T^{\rm miss}$) consistent with the decay of a W or Z boson, are tagged in the VH production category. Diphoton events containing energetic dijets with a large mass and pseudo-rapidity difference are assigned to the VBF production category, and events with two jets compatible with the hadronic decay of a W or a Z are considered in the VH category. . While the leptonic VH category is relatively pure, the VBF category has significant contamination from the gluon fusion process. Finally more complex topologies aiming at selecting events from the $t\bar{t}H$ productiuon mode in the semi-leptonic and fully hadronic top decays are also considered and discussed in more detail in Section 11.3.5.1 Events are also further categorised according to their expected $m_{\gamma\gamma}$ resolution and signal-to-background ratio. Categories with good m_H resolution and larger signal-to-background ratio contribute most to the sensitivity of the search.

Both ATLAS and CMS have studied in detail the calibration of the energy response of photons, in particular using $Z \to e^+e^-$, $Z \to \mu^+\mu^-\gamma$ and the response of muons in the calorimeter (for ATLAS) from $Z \to \mu^+\mu^-$ events. This information is used to correct the simulated signal mass line-shapes. In each category, parametric signal models are adjusted to these line-shapes to provide a functional form for the signal. Simple functional forms of the backgrounds are determined by a fit to the $m_{\gamma\gamma}$ distribution in each category (typically exponential, Bernstein polynomials, Laurent series or power laws). All categories are fitted simultaneously to determine the signal yield at a given Higgs boson mass hypothesis.

The results are expressed in terms of signal strength, which can be defined as $\mu = (\sigma \cdot {\rm BR})_{\rm obs}/(\sigma \cdot {\rm BR})_{\rm SM}$, the observed product of the Higgs boson production cross section (σ) and its branching ratio (BR) normalised to the corresponding SM values. A more detailed definition is given in Section 11.3.6 and Eq. 11.14. The signal strength overall for this channel and for specific production processes are summarised in Fig. 11.3. All results are in agreement with the SM expectation within the overall measurement precisions of approximately 9% for both experiments.

11.3.2.2 $H \to ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$

In the $H \to ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ channel, a search is performed for a narrow mass peak over a small continuous background dominated by non-resonant ZZ^* production from $q\bar{q}$ annihilation and gg fusion processes. The contribution and the shape of this irreducible background is taken from simulation. The subdominant and reducible backgrounds stem from Z+$b\bar{b}$, $t\bar{t}$ and Z+jets events. Their contribution is suppressed by requirements on lepton isolation and lepton impact parameter and their yield is estimated from control samples in data.

To distinguish the Higgs boson signal from the dominant non-resonant ZZ^* background, both ATLAS and CMS use multivariate techniques as well as a matrix element likelihood approach to construct a kinematic discriminant built for each 4ℓ event based on the ratio of complete leading-order matrix elements $|\mathcal{M}_{\rm sig}{}^2/\mathcal{M}_{\rm bkg}{}^2|$ for the signal ($gg \to H \to 4\ell$,$qq \to VH(\to 4\ell)$ and $qq \to qqH(\to 4\ell)$) and background ($q\bar{q} \to ZZ \to 4\ell$) hypotheses.

To improve the sensitivity to more exclusive production processes such as VBF, VH, and $t\bar{t}H$, the experiments divide 4ℓ events into mutually exclusive categories. Events are categorised in terms of the number of reconstructed jets, the number of additional leptons (from the decay of a vector boson in the associated production mode), number of jet tagged as containing a b-hadron, the transverse momentum of the Higgs boson (or e.g. its associated vector boson) and missing transverse momentum. Dijets with a large mass and pseudo-rapidity difference populate the VBF category. ATLAS requires the presence of an additional lepton in the VH category. In events with less than two jets, CMS uses the $p_T^{4\ell}$ to distinguish between production via the gluon fusion and the VH/VBF processes.

Since the $m_{4\ell}$ resolutions and the reducible background levels are different in the 4μ, $4e$ and $2e2\mu$ sub-channels, they are analysed separately and statistically combined to produce the final results.

The results for this channel, overall and in specific production processes are summarised in Fig. 11.3. All results are in agreement with the SM expectation within the overall measurement precisions of approximately 9% and 12% for the ATLAS and CMS experiments respectively.

11.3.2.3 $H \to W^+W^- \to \ell^+\nu\ell^-\overline{\nu}$

In this challenging channel, experiments search for an excess of events with two leptons (electrons or muons) of opposite charge accompanied by missing energy and/or jets. A typical event selection is described below in order to give an idea of the main intricacies. Specific selections vary between experiments and between Run-1 and Run-2 analyses. Events are divided into several categories depending on the lepton flavour combination (e^+e^-, $\mu^+\mu^-$and $e^\pm\mu^\mp$) and the number of accompanying jets ($N_{\rm jet} = 0, 1, \geq 2$). The $N_{\rm jet} \geq 2$ category is optimised for the VBF production process by selecting two leading jets with a large pseudo-rapidity difference and with a large mass (typically $m_{jj} > 500\,{\rm GeV}$).

Backgrounds contributing to this channel are numerous and depend on the category of selected events. Reducing them and accurately estimating the remainder is a major challenge in this analysis. For events with opposite-flavour leptons and no accompanying high p_T jets, the dominant background stems from non-resonant WW production. Events with same-flavour leptons suffer from large Drell–Yan contamination (note that also the opposite-flavour leptons analysis has Drell–Yan $\tau\bar{\tau}$ background in 0-jet category). The $t\bar{t}$, tW and $W+$jets (with the jet misidentified as a lepton) events contaminate all categories. Non-resonant WZ, ZZ and $W\gamma$ processes also contribute to the background at a sub-leading level.

A requirement of large missing transverse energy ($E_T^{\rm miss}$) is used to reduce the Drell–Yan and multi-jet backgrounds. In the e^+e^- and $\mu^+\mu^-$ categories, events with $m_{\ell\ell}$ consistent with the Z mass are vetoed. The $t\bar{t}$ background is suppressed by a veto against identified b-jets and tight isolation requirements diminish the W+jets background. The scalar nature of the Higgs boson and the $V-A$ nature of the W boson decay implies that the two charged leptons in the final state are preferentially emitted at small angles with respect to each other. Therefore the dilepton invariant mass ($m_{\ell\ell}$) and the azimuthal angle difference between the leptons ($\Delta\phi_{\ell\ell}$) are used to discriminate between the signal and non-resonant WW events [143]. The transverse mass, constructed from the dilepton p_T ($p_T^{\ell\ell}$), $E_T^{\rm miss}$ and the azimuthal angle between $E_T^{\rm miss}$ and $p_T^{\ell\ell}$, is defined as $m_T = \sqrt{2p_T^{\ell\ell}E_T^{\rm miss}(1-\cos\Delta\phi_{E_T^{\rm miss}\ell\ell})}$ and serves as an effective discriminant against backgrounds. The transverse mass variable also tracks the Higgs boson mass but with a poor mass resolution. Background rates except for the small contributions typically from non-resonant WZ, ZZ and $W\gamma$ are evaluated from data control samples with floating normalization.

ATLAS and CMS have also searched for the associated Higgs boson production in this channel. The signal consists of up to three (WH) or four (ZH) high p_T isolated leptons with missing transverse energy and low hadronic activity. The major backgrounds stem from triboson and diboson production where each boson decays leptonically.

Measurements by ATLAS and CMS, in terms of signal strengths, for the five largest Higgs boson production modes are displayed in Fig. 11.3. All measurements are in agreement with the SM expectation within the overall measurement precisions of approximately 12% and 9% for ATLAS and CMS respectively.

11.3.3 *Measurement of the Higgs boson mass*

To measure the mass of the Higgs boson, ATLAS and CMS collaborations rely on the two high mass-resolution channels, $\gamma\gamma$ and $ZZ^*/4\ell$. The ATLAS and CMS approaches are very similar in these two analyses with small differences on the usage of cat-

egories, additional discriminating variables and per-event errors. In these two channels, the mass resolutions range from 1.4 GeV to 2 GeV for ATLAS and from 1.0 GeV to 2.8 GeV for CMS (see Ref. [144] and the reconstruction-performance references therein). An excellent mass resolution is obtained for both experiments in the diphoton channel for central diphoton pairs (typically for events where both photons are not converted). However, the best precision in this measurement at Run 2 is obtained using the four lepton channel and in particular in the sub-channel of four muons (followed, in precision, by the two-electrons and two muons channel where the mass resolution is driven by the reconstruction of the lower mass di-lepton pair with typically lower transverse momentum leptons).

Both ATLAS and CMS have produced several Higgs boson mass measurements, including the individual and combined Run-1 measurements [144] and several Run-2 measurements by ATLAS [145,146] and CMS [147,148] for both the 4ℓ and the diphoton channels. The measurements performed by ATLAS include the full Run-2 dataset whereas in the case of CMS, the mass measurements were done with a fraction of the Run-2 data corresponding to the data collected in 2016. An overall combination of all available measurements has not yet been performed. The Run-1 combination including both ATLAS and CMS measurements yielded [144]:

$$m_H = 125.09 \pm 0.21\,(\text{stat.}) \pm 0.11(\text{syst.})\ \text{GeV}.$$

The current most precise di-photon channel result is obtained by ATLAS using the full Run-2 dataset and a combination with the Run-1 measurements in the $H \to \gamma\gamma$ yielding a measurement of [149]:

$$m_H = 125.22 \pm 0.11\,(\text{stat.}) \pm 0.09(\text{syst.})\ \text{GeV}.$$

The systematic uncertainty of 90 MeV is worth noting, as it results from a very challenging calibration and estimates of the amount of material upstream of the calorimeter to extrapolate the calorimeter energy response calibration from electrons in Z boson decays to photons. This result is promising for prospects in precision measurements in this channel. In Ref. [149], ATLAS has also estimated the expected effect of the interference between the signal and the gluon fusion continuum di-photon background to be of 24 MeV. This ATLAS measurement is significantly more precise than the full Run-2 measurement in the 4ℓ channel, however the latter is dominated by the statistical uncertainty of 170 MeV with a systematic uncertainty of 30 MeV [150]. The ATLAS diphoton channel measurement reached the same senstivity as the early Run-2 and Run-1 combined measurement of CMS, which uses both channels but with a much smaller amount of Run-2 data, corresponding only to the 2016 LHC run, which yielded [148]:

$$m_H = 125.38 \pm 0.11\,(\text{stat.}) \pm 0.08(\text{syst.})\ \text{GeV}.$$

ATLAS has also combined its results in the diphoton and the four-lepton channels yielding the current most precise measurement with a precision of 0.09% [151]:

$$m_H = 125.11 \pm 0.09\,(\text{stat.}) \pm 0.06(\text{syst.})\ \text{GeV}.$$

The most precise single channel result has very recently been obtained by CMS in the 4ℓ channel with the full Run 2 dataset [152]:

$$m_H = 125.08 \pm 0.12\,\text{GeV}.$$

The analysis of the entire Run-2 dataset and the LHC combination of the two experiments will be of great interest and important for the combination of all Higgs boson measurements across experiments.

11.3.4 *Higgs decays to third generation fermions ($b\bar{b}$ and $\tau^+\tau^-$)*

In the SM, fermions acquire a mass through gauge invariant interactions with the Higgs field which is also responsible for the electroweak symmetry breaking and thus for generating the masses of gauge bosons (see Section 11.2 for more details). While this minimal solution is very elegant, there is no fundamental reason for it to be the case, and probing the couplings of the Higgs boson to fermions is therefore of fundamental importance, in particular since BSM physics can largely change the SM predictions.

The discovery of the Higgs boson was made essentially through the bosonic final states. These decays probed mostly the couplings of the Higgs boson to vector bosons (the decay of the Higgs boson to photons occurring only through loops is also dominated in the SM by the coupling of the Higgs boson to W bosons). However, the predominant Higgs boson production mode is the gluon fusion, occurring only through loops dominated by the coupling of the Higgs boson to fermions. The observation of the Higgs boson in the two photons or two gluons decay modes is also an indirect evidence for the coupling of the Higgs boson to fermions (and in particular to the top quark). Nevertheless, the observation of either decays to fermions or production modes which unambiguously proceed through fermion couplings provide direct probes of the coupling of the Higgs boson to fermions and is thus of fundamental importance.

At hadron colliders, the most promising channel for probing the coupling of the Higgs field to the quarks and leptons are $H \to b\bar{b}$ and $H \to \tau^+\tau^-$, respectively. For a Higgs boson with $m_H \approx 125$ GeV, the branching fraction to $b\bar{b}$ is about 58% and to $\tau^+\tau^-$ is about 6%. Nevertheless, the presence of very large backgrounds makes the measurement of a Higgs boson signal in these channels challenging.

One of the most prominent goals of the LHC Run-2 physics program was the direct observation of the Yukawa coupling of the Higgs boson to fermions of the third generation (bottom quarks, tau leptons and top quarks). This goal has been reached independently by both ATLAS and CMS and with only partial Run-2 datasets.

11.3.4.1 $H \to \tau^+\tau^-$

In the $H \to \tau^+\tau^-$ search, τ leptons decaying to electrons (τ_e), muons (τ_μ) and hadrons (τ_{had}) are considered. The $\tau^+\tau^-$ invariant mass ($m_{\tau\tau}$) is reconstructed from a kinematic fit of the visible products from the two τ leptons and the missing energy observed in the event. Due to the presence of missing neutrinos, the $m_{\tau\tau}$ resolution is poor ($\approx 10\% - 15\%$). As a result, a broad excess over the expected background in the $m_{\tau\tau}$ distribution is searched for. The major sources of background stem from Drell–Yan $Z \to \tau^+\tau^-$ and $Z \to e^+e^-$, W+jets, $t\bar{t}$ and multijet production. Events in all sub-channels are divided into categories based on the number and kinematic properties of additional energetic jets in the event and the transverse momentum of the reconstructed Higgs boson and the distance ΔR distance between the two τ's. The sensitivity of the search is generally higher for categories with one or more additional jets. The VBF category, consisting of a τ pair with two energetic jets separated by a large pseudo-rapidity, has the best signal-to-background ratio and search sensitivity, followed by the $\tau^+\tau^-$+1 jet category. The signal to background discrimination relies in part on the $m_{\tau\tau}$ resolution, which improves with the boost of the Higgs boson. The non-VBF categories are further subdivided according to the observed boost of the $\tau^+\tau^-$ system. ATLAS and CMS combine various kinematic properties of each event categories with multivariate techniques to build the final discriminant.

Searches for $H \to \tau^+\tau^-$ decays in the VH production mode are also performed in final states where the W or Z boson decays into leptons or jets. The irreducible background in this search arises from non-resonant WZ and ZZ diboson production. The reducible backgrounds originate from W, Z, and $t\bar{t}$ events that contain at least one fake lepton in the final state due to a misidentified jet. The shape and yield of the major backgrounds in each category are estimated from control samples in data. Contributions from non-resonant WZ and ZZ diboson production are estimated from simulations but corrected for reconstruction efficiency using control samples formed from observed data.

The first clear evidence of direct decays of the higgs boson to taus was achieved by ATLAS and CMS in combination [153], with the observation of an excess with a significance of 5.5σ and the combined signal strength is $\mu = 1.11^{+0.24}_{-0.22}$, consistent with the SM expectation. The early Run-2 data fully corroborated these

results to establish an unambiguous observation in each experiment independently. ATLAS [154] and CMS [155, 156] analysed an early Run-2 dataset to provide independent observations, with significances of 4.4σ and 4.9σ respectively.

Both ATLAS [157] and CMS [158,159] have then completed the analyses of the full Run-2 dataset in various production channels. These results are summarised in Fig. 11.3. These results perform simultaneously measurements of the VBF production, the gluon fusion mode where the Higgs boson has a sizeable boost, and the associated production with a vector boson as well as the associated production with a pair of top quarks. It is interesting to note that the with the current measurements the gluon fusion channels have a sensitivity which is very close to the VBF production.

11.3.4.2 $H \to b\bar{b}$

To measure the decays of the Higgs boson to a pair of b-quarks, the most sensitive production modes are the associated WH and ZH processes allowing use of the leptonic W and Z decays which are helpful for triggering the events and to reject QCD backgrounds. The W bosons are reconstructed via their leptonic decay $W \to \ell\bar{\nu}_\ell$ where $\ell = e, \mu$ or τ. The Z bosons are reconstructed via their decay into $e^+e^-, \mu^+\mu^-$or $\nu\bar{\nu}$. The Higgs boson candidate mass is reconstructed from two b-tagged jets in the event. Backgrounds arise from production of W and Z bosons in association with gluon, light and heavy-flavoured jets (V+jets), $t\bar{t}$, diboson (ZZ and WZ with $Z \to b\bar{b}$) and QCD multi-jet processes. Due to the limited $m_{b\bar{b}}$ mass resolution, a SM Higgs boson signal is expected to appear as a relatively broad enhancement in the reconstructed dijet mass distribution. The crucial elements in this search are b-jet tagging with high efficiency and low fake rate, accurate estimate of b-jet momentum and estimate of backgrounds from various signal depleted control samples constructed from data.

At the Tevatron, the $H \to b\bar{b}$ channel contributed the majority of the Higgs boson search sensitivity below $m_H = 130\,\text{GeV}$. To separate signal from background, CDF and D0 used multivariate analysis (MVA) techniques that combined several discriminating variables into a single final discriminant. Each channel was divided into exclusive sub-channels according to various lepton, jet multiplicity, and b-tagging characteristics in order to group events with similar signal-to-background ratio and thus optimise the overall search sensitivity. The combined CDF and D0 data showed [44, 160] an excess of events with respect to the predicted background in the 115–140 GeV mass range in the most sensitive bins of the discriminant distributions suggesting the potential presence of a signal. At $m_H = 125\,\text{GeV}$, the observed signal strength was $\mu = 1.59^{+0.69}_{-0.72}$.

At the LHC, in order to reduce the dominant V+jets background, following Ref. [92], experiments select a region in the VH production phase space where the vector boson is significantly boosted and recoils from the $H \to b\bar{b}$ candidate with a large azimuthal angle $\Delta\phi_{VH}$. For each channel, events are categorised into different $p_T(V)$ regions with varying signal/background ratios. Events with higher $p_T(V)$ have smaller backgrounds and better $m_{b\bar{b}}$ resolution. Experiments use MVA classifiers based on kinematic, topological and quality of b-jet tagging and trained on different values of m_H to separate Higgs boson signal in each category from backgrounds. The main discriminating variables in this analysis are the transverse momentum of the vector boson and the di-b-jet invariant mass.

The direct observation of the Higgs boson decaying to a pair of b-quarks, a major result of Run 2, was obtained by both ATLAS and CMS independently after the update of their search with similar analyses as those performed at Run 1 but with a larger dataset of approximately $80\,\text{fb}^{-1}$ of data collected in 2015, 2016 and 2017. The increase in signal cross sections of nearly a factor of 3 at the centre-of-mass energy of 13 TeV with respect to 7 TeV, has also been instrumental in bringing the two experiments to the required sensitivity to claim an evidence for this decay mode in the VH production mode (in the high transverse momentum of the vector boson fiducial region of interest for this channel). The expected significance for a SM Higgs boson was 4.3σ for ATLAS [161] and 4.9σ for CMS [162]. Both ATLAS and CMS observed significant excesses corresponding to 4.9σ and 4.8σ respectively with Run-2 data only. When combined with results obtained in Run 1, the observed (expected) significance of the excesses were 5.4σ (5.5σ) and 5.6σ (5.5σ) respectively. These results provided direct and unambiguous observation for the $H \to b\bar{b}$ decay through the VH production mode.

Since these important observations, both experiments have completed the analysis of the full Run-2 dataset using two reconstruction techniques. The first is based on the reconstruction of the Higgs boson with two jets is referred to as *resolved*. The second is based on the reconstruction of the Higgs boson as a large radius jet and is referred to as *boosted*. These measurements expand the range of measurements of the Higgs boson decays to b-quarks in association with a vector boson at higher transverse momentum, above 400 GeV. These results are summarised in Fig. 11.3. It should be noted that the sensitivity of these analyses are already limited by systematic uncertainties.

Also, the LHCb collaboration has performed a search for the VH production with subsequent decay of the Higgs boson to a pair of b-quarks [163] with $1.98\,\text{fb}^{-1}$ of data taken at a centre-of-mass energy of 8 TeV. The final state is required to have two reconstructed b quarks and one lepton in the LHCb acceptance of $2 < \eta < 5$. The sensitivity of this search is an expected 95% CL exclusion of 84 times the SM production rate. This analysis is also used to set a limit on the VH production with the subsequent decay of the Higgs boson in a pair of c quarks with a 95% CL limit at 6.4×10^3 times the SM production rate, while the expected sensitivity corresponds to an exclusion of 7.9×10^3 times the SM production rate.

ATLAS and CMS have also searched for $H \to b\bar{b}$ in the VBF production mode. The event topology consists of two VBF-tagging energetic light-quark jets in the forward and backward direction relative to the beam direction and two b-tagged jets in the central region of the detector. Due to the electroweak nature of the process, for the signal events, no additional energetic jet activity (excluding that from the Higgs boson) is expected in the rapidity gap between the two VBF-tagging jets. The dominant background in this search stems from QCD production of multi-jet events and the hadronic decays of vector bosons accompanied by additional jets. A contribution of Higgs boson events produced in the ggF process but with two or more associated jets is expected in the signal sample. The signal is expected as a relatively broad enhancement in the $m_{b\bar{b}}$ distribution over the smoothly falling contribution from the SM background processes. Both ATLAS [164] and CMS [165] have produced results in this channel with Run-1 data, but with limited sensitivity. Both experiments performed a similar analysis with Run-2 data [166,167].

Two of the main difficulties for the VBF production mode are the large QCD background and the difficulty in triggering fully hadronic events. Both difficulties are addressed, by the proposal made in Ref. [168], where the requirement of an additional photon in the final state reduces the background through an interference effect and enhances the possibilities for triggering. This analysis has been carried out by ATLAS at Run 2 [169] and its result combined with the standard VBF channel. The sensitivity in this channel is smaller than in the fully hadronic mode. Through the combination of these channels ATLAS has reached a first evidence at 3 standard deviations of the Higgs boson decaying to a pair of b quarks in the VBF production mode. The results are reported below

$$\begin{aligned} &\text{ATLAS}\ \ \mu^{b\bar{b}}_{VBF(\gamma)} = 0.99\,^{+0.30}_{-0.30}\,(\text{stat})\,^{+0.18}_{-0.16}\,(\text{syst}), \\ &\text{CMS}\ \ \mu^{b\bar{b}}_{VBF} = 1.01 \pm 0.36\,(\text{stat})\,^{+0.40}_{-0.27}\,(\text{syst}). \end{aligned} \tag{11.12}$$

The sensitivity in the inclusive search for the Higgs boson in the ggF production mode with $H \to b\bar{b}$ is limited by the overwhelming background from the inclusive production of $pp \to b\bar{b} + X$ via the strong interaction. With the increase in centre-of-mass energy to 13 TeV, and taking advantage of the harder transverse momentum spectrum of the $gg \to H$ production mode with respect to the QCD background, a search for high p_T Higgs boson decaying to a pair of b quarks in association with an energetic Initial State

Radiation (ISR) jet. Considerable efforts have been made using state-of-the-art deep learning techniques to improve the performance of the identification of a Higgs boson decaying to b quarks and reconstructed as a large radius jet at high transverse momentum. In order to gain sensitivity in this channel and reconstruct the Higgs boson within one jet of radius 0.8 or 1.0 a lower cut at 450 GeV of transverse momentum is required. This analysis was performed by both ATLAS [170] and CMS [171] with the entire Run-2 data dataset. As in the case of VH production mode, this analysis is sensitive also to the inclusive $Z \to b\bar{b}$ production, which is an important step in the validation of the analysis chain. The $Z \to b\bar{b}$ decay is observed with a significance in excess of five standard deviations, in agreement with the expected rate from the Standard Model. . This estimate has a non negligible uncertainty from the precise estimate of the fiducial signal cross section in the specific acceptance of this analysis. CMS observes an excesses at $m_H = 125\,\text{GeV}$ of 1.2σ [171] with a sensitivity of 0.9σ. It should be noted that the estimates of the signal expectation in this remote region of phase space at high transverse momentum for the production are highly non-trivial and subject to fairly large theoretical and statistical uncertainties:

$$\begin{aligned} &\text{ATLAS } \mu^{b\bar{b}}_{\text{inclusive}} = -0.1 \pm 3.5 \ (1.0 \pm 3.4\,\text{expected}), \\ &\text{CMS } \mu^{b\bar{b}}_{\text{inclusive}} = 2.1\,^{+1.9}_{-1.7}. \end{aligned} \tag{11.13}$$

In addition to the inclusive production, in [171] CMS has also performed a search sensitive to the VBF production in the boosted Higgs regime, yielding a sensitivity of 0.9σ. In this channel a broad excess has been observed which results in an observed excess with a significance of 3.0σ. These results are particularly interesting as these measurements will bring a strong complement to the main channels in the high transverse momentum regime.

Another important production mode sensitive to the decay of the Higgs boson to bottom quarks, is the associated production with a pair of top quarks. The results of the searches for this process have been combined with the channels described above, to provide an additional constraint on the Yukawa coupling of the Higgs boson to bottom quarks. The channels corresponding to this production mode are described in Section 11.3.5.

11.3.5 *Higgs boson production in association with top quarks*

11.3.5.1 *The associated production with top quark pairs*

As discussed in Section 11.2, the coupling of the Higgs boson to top quarks plays a special role in the electroweak symmetry breaking mechanism in the SM, as well as in its possible extensions. Substantial indirect evidence of this coupling is provided by the compatibility of observed rates of the Higgs boson in the principal discovery channels, given that the main production process – gluon fusion – is dominated by a top quark loop. Direct evidence of this coupling at the LHC and the future e^+e^- colliders will be mainly available through the $t\bar{t}H$ final state and will permit a clean measurement of the top quark-Higgs boson Yukawa coupling. The $t\bar{t}H$ production cross section at the LHC is small in comparison with the ggF or even VH production modes. The production cross section for a 125 GeV Higgs boson in pp collisions at $\sqrt{s} = 8\,\text{TeV}$ of about 130 fb made it challenging to measure the $t\bar{t}H$ process with the LHC Run-1 dataset. However, at Run 2, the increase in cross section at $\sqrt{s} = 13\,\text{TeV}$ is substantial, reaching approximately 500 fb.

The analysis channels for such complex final states can be separated in four classes according to the decays of the Higgs boson. In each of these classes, most of the decay final states of the top quarks are considered (fully hadronic, semi-leptonic and dilepton decay final states).

The first analysis is the search for $t\bar{t}H$ production in the $H \to \gamma\gamma$ channel. This analysis relies on the search for a narrow mass peak in the $m_{\gamma\gamma}$ distribution. The background is estimated from the $m_{\gamma\gamma}$ sidebands. The sensitivity in this channel is mostly limited by the available statistics.

The second analysis is the search for the Higgs boson decaying to ZZ^* and subsequently to four leptons (electrons and/or muons). This channel is currently limited by the low statistics due to the small branching fraction of the Z decays to leptons.

In the third analysis the W^+W^- , $\tau^+\tau^-$ and ZZ^* final states are searched for inclusively in multilepton event topologies (but not including the resonant $H \to 4\ell$ channel that is covered in the specific analysis described in Section 11.3.2). The corresponding $t\bar{t}H$ modes can be decomposed in terms of the decays of the Higgs boson and those of the top quarks as having two b-quarks and four W bosons (or two W and two taus, or two W and two Z) in the final state.

The fourth channel is the search in the $H \to b\bar{b}$ channel. This search is intricate due to the large backgrounds, both physical and combinatorial in resolving the $b\bar{b}$ system from the Higgs boson decay, in events with six jets and four b-tagged jets. Already with the Run-1 dataset, the sensitivity of this analysis was strongly impacted by the systematic uncertainties on the background predictions.

Prior to its start, it was unclear if this process would at all be observable at the LHC. A first milestone was reached with the completion of the Run-1 analyses by ATLAS and CMS with a complete set of results in these channels and their combination [172,173]. These results are reported in Table 11.5. However the sensitivity remained very limited. The breakthrough in the search for this process of fundamental importance came with the Run-2 data at a higher centre-of-mass energy of 13 TeV and the increase of a factor of nearly four of the production cross section of the $t\bar{t}H$ associated production process.

Using only a partial Run-2 dataset, ATLAS and CMS were able to independently make an unambiguous observation of this process. For these results ATLAS and CMS had different strategies. ATLAS relied mostly in the $t\bar{t}(H \to \gamma\gamma)$ channel where a narrow peak over a continuous background is searched for. It is interesting to note that the rapid evolution of the sensitivity in the diphoton channel owes not only to the large increase in cross section, but also to the fact that high mass diphoton events in an environment with additonal leptons, jets and b-tagged jets the search for a pair of photon at high mass has a low background. In contrast with the inclusive search for $H \to \gamma\gamma$, the analyses in this channel reached a signal-to-background ratio in excess of unity. This channel, which is characterised by a narrow peak over a continuous background, also has the advantage of being less prone to systematic uncertainties than channels where the assessment of backgrounds cannot be made through the use of sidebands. ATLAS used up to $79.8\,\text{fb}^{-1}$ of Run-2 data to reach an expected sensitivity of 4.9σ and an observed significance of 5.8σ with the Run-2 partial dataset alone, and 6.3σ (with 5.1σ expected) in combination with the Run-1 results [174]. CMS instead relied on a smaller dataset of $35.9\,\text{fb}^{-1}$ and relied on all channels. The most sensitive in this case was the $ttH(bb)$ whose sensitivity was limited by systematic uncertainties. CMS reached a sensitivity of 4.2σ and observed an excess with respect to the background-only hypothesis of 5.2σ, combining the Run-1 and Run-2 results [175].

This direct observation of the Yukawa coupling of the Higgs boson to top quarks was particularly important in comparison to the indirect evidence through the gluon fusion production process dominated by the top quark loop

Since the observation of this important process, with few exceptions, all channels have been updated with the full Run-2 dataset, by both experiments.

For the principal decays of the Higgs boson in the diphoton and four lepton channels, the measurements are done in the framework of 'Simplified Template Cross Section' discussed in Section 11.5.1.1.5). The diphoton channels were updated by both the ATLAS and CMS experiments in Refs. [176,177]. The four lepton decays of the Higgs boson in the associated production with a pair of top quarks is a search for a narrow peak in the busy $t\bar{t}H$ environment. It was also performed by ATLAS [176] and CMS [177] with the full Run-2 datasets. These results are reported in Table 11.5. This channel has currently very low statistic but also very high purity, reaching signal-to-background ratios in excess of 10.

To address the WW, ZZ and $\tau\tau$ decay modes, an approach based on multiple channels with electrons, muons and taus decaying hadronically, the so-called "multi-lepton", is adopted by both

experiments. This analysis excludes the $H \to 4\ell$ channel. CMS has analysed the Full Run-2 dataset [178] and ATLAS only part of it [179]. In a preliminary release of this analysis using a larger, but not full Run-2 dataset corresponding to an integrated luminosity of approximately $80\,\text{fb}^{-1}$, the ATLAS experiment found that the normalisation of the $t\bar{t}W$ background was larger than expected from SM calculations by factors ranging from 1.3 to 1.7 and modelling issues were observed in analysis regions where the $t\bar{t}W$ process is dominant [179]. The search for Higgs boson decays to tau leptons in association with a pair of top quarks was carried out by ATLAS with the full Run-2 dataset and discussed in 11.3.4.1 [180]. Using the full dataset in this channel CMS obtained an observation of the Higgs boson production in association with top quarks with an observed significance of 4.7 standard deviations (5.2σ expected). The results are reported in Table 11.5. The rate of the $t\bar{t}W$ background in this analysis is also high by a factor of approximately 1.4.

Both ATLAS and CMS have performed the analysis of Higgs bosons decaying to b-quarks in the $t\bar{t}H$ production mode with the full Run-2 dataset. In ATLAS, this analysis was performed in the semi-leptonic and di-leptonic channels [181], including a resolved mode where the Higgs boson is reconstructed as two standard jets and a boosted mode where the Higgs boson is reconstructed as a single large radius jet. CMS also performed this analysis with the full Run-2 dataset, including in addition the fully hadronic mode where both W bosons from top decays subsequently decay hadronically [182]. The results reported in Table 11.5. It should be noted that in this channel a deficit in observed Higgs boson decays is observed. This deficit is rather significant and in tension with the observation of the other $t\bar{t}H$ modes as well as the observation of the Higgs boson in the $b\bar{b}$ channels.

The discrepancies observed in both the multilepton and the $H \to b\bar{b}$ channels will require further studies.

A combination of all available channels has been performed by ATLAS [183] and CMS [184] and is reported in Fig. 11.3. It should be noted that the latest $t\bar{t}H(\to b\bar{b})$ channel from CMS with the full Run 2 data has not yet been included in the combination. A fit of individual decay modes in the ttH production is also given therein.

11.3.5.2 *The associated production with a single top quark*

An additional production mode of the Higgs boson in association with a top quark is the single top associated production mode. There is an interesting similarity between this production mode and the $H \to \gamma\gamma$ decay mode. Both processes proceed through either the top Yukawa coupling or the interaction of the Higgs boson with the W boson, with a negative interference between the two. Representative Feynman diagrams for this production process are shown in Fig. 11.1. Contrary to the diphoton decay channel, in this production mode the interference occurs at the tree level and is dominant. This process can therefore be used to further discriminate a negative relative sign between the couplings of the Higgs boson to fermions and its couplings to gauge bosons [185].

ATLAS and CMS have produced specific searches for the tH production mode with the Run-1 and Run-2 data exploiting a variety of Higgs boson decay modes resulting in final states with photons, bottom quarks, and multiple charged leptons, including tau leptons. In particular, with the Run-2 data, CMS has searched for multi-leptonic decay signatures from the $H \to WW^*$, $H \to \tau^+\tau^-$ and $H \to ZZ^*$ modes [186]. This analysis restricts values of κ_t, the top-Higgs coupling normalised to its SM value, to $[-1.25, 1.60]$ at 95% CL. CMS has also performed an analysis of the 2015 dataset to search for the $H \to b\bar{b}$ mode [187], yielding much less stringent constraints.

The diphoton channel has also been used to search specifically for this production mode by ATLAS using Run-1 data, yielding the restricted range of allowed values of κ_t at the 95% CL to $[-1.3, 8]$.

The strongest constraint on the negative (relative) sign of κ_t was obtained by CMS using the recent analysis of the full dataset [178] in the multilepton ($H \to WW$, $H \to ZZ$, $H \to \tau\tau$) discussed in 11.3.5.1, negative values of κ_t are disfavoured and the only non excluded negative values of κ_t at 95% CL. range between -0.9 and -0.7.

11.3.6 *Combining the main channels*

The analysis strategy used by the LHC experiments to perform the searches for the Higgs boson has been based on the Higgs boson decay modes. It is a natural choice given that it focusses on the decay products of the object searched for. However, for each channel, exclusive sub-channels have been defined to target different production modes and kinematic regimes, and these sub-channels have been combined. The natural extension of this approach in order to probe further the production and decay modes of the Higgs boson is to combine the analysis channels together. Such a combination is also used in Section 11.5 to further measure the coupling properties of the Higgs boson.

At the LHC, the total cross section cannot be measured independently of the decay branching fractions. As a consequence, the total width of the Higgs boson cannot be directly measured. However, a combined measurement of the large number of categories described above with different sensitivities to various production and decay modes, permits a wide variety of measurements of the production, decay and coupling properties. These measurements, however, rely on assumptions.

Combining Higgs observation channels requires that measurements in all channels are done under the same Higgs boson mass hypothesis. This is always the case within experiments but is not necessarily the case across experiments. At Run 1, prior to combining the measurements of rates in ATLAS and CMS, a common and thus combined Higgs boson mass measurement was made. Only thereafter were the ATLAS and CMS measurements combined [153]. The Run 1 full combination results were derived by the two collaborations, taking rigorously into account all correlations in the systematic uncertainties and in the large number of channels and their categories. For a review of the Run-1 combined results see former PDG reviews in [188] and references therein.

It is important to note that, between the Run-1 and the Run-2 results, the signal theoretical systematic uncertainties have improved significantly.

At Run 2, ATLAS [183] and CMS [184] have already produced combined measurements of the coupling properties and production cross section ratios of the Higgs boson.

In this section, only the results on the main Higgs boson production and decay modes will be discussed. Only a brief presentation of the combination framework is given here (a more detailed description is given in Ref. [189]). This framework will also be used in Section 11.5 to discuss the measurements of the coupling properties of the Higgs boson.

11.3.6.1 *Principles of the combination*

The combination of the Higgs boson analysis channels in each experiment and for the two experiments together was done using a fit of a signal and background model to the data. As described above, the data was made of a large number of categories, aiming at reconstructing exclusive production and decay modes. In the combination of ATLAS and CMS [153], there were approximately 600 categories. The combination was a simultaneous fit to the data across all these categories, using a reduced number of parameters of interest and the Higgs boson mass fixed to its measured value at Run 1 [144]. The much larger number of categories present in the ATLAS and CMS combination [153] is due to additional separation in terms of finer exclusive production regions, decay channels of the Z and the W bosons, and taus, control regions where little-to-no signal is present, and different center-of-mass energies.

In their Run-2 individual combinations, ATLAS and CMS have not considered the $Z\gamma$ channel. Both ATLAS and CMS experiment have included the $\mu\mu$ channel based on a partial Run-2 dataset corresponding to an integrated luminosity of $36\,\text{fb}^{-1}$ only.

The key to understanding how the combination of channels works relies on the combination master formula, which expresses for each category, indexed by c, of a given channel (typically a category covers mostly one decay mode, but possibly various production modes), the measured number of signal events n_s^c as a

Table 11.5: Summary of the results of searches for a Higgs boson in association with a top quark pair by ATLAS and CMS. The results are given in terms of a measured signal strength.

$t\bar{t}H$	ATLAS Run 1	CMS Run 1	ATLAS Run 2	CMS Run 2
$H \to \gamma\gamma$	$1.3\ ^{+2.6\ +2.5}_{-1.7\ -1.7}$	$1.2\ ^{+2.5\ +2.6}_{-1.7\ -1.8}$	$1.38\ ^{+0.33\ +0.26}_{-0.31\ -0.18}$	$2.27^{+0.86}_{-0.74}$
$H \to 4\ell$	—	—	$1.2\ ^{+1.4}_{-0.8}$	$0.00\ ^{+0.91}_{-0.00}$
$H \to WW/\tau\tau/ZZ$	$1.4\ \pm 0.6\ \pm 1.0$	3.3 ± 1.4	$1.56\ ^{+0.30\ +0.30}_{-0.29\ -0.27}$	$0.92\ ^{+0.26}_{-0.23}$
$H \to b\bar{b}$	$1.4\ \pm 1.0\ \pm 0.6$	$1.6\ ^{+1.6}_{-1.5}$	$0.35\ \pm 0.20\ \pm 0.30$	$0.33 \pm 0.16 \pm 0.21$
Combination	$1.7\ \pm 0.5\ \pm 0.8$	$2.6\ ^{+1.0}_{-0.9}$	$0.97\ \pm 0.14\ ^{+0.14}_{-0.13}$	$0.94\ \pm 0.20\ ^{+0.09}_{-0.14}$

function of a limited number of parameters as follows:

$$n_s^c = \left(\sum_{i,f} \mu_i \, \sigma_i^{\mathrm{SM}} \times A_{if}^c \times \varepsilon_{if}^c \times \mu_f \, \mathrm{BR}_f^{\mathrm{SM}} \right) \times \mathcal{L}^c. \quad (11.14)$$

The production index is defined as $i \in \{\mathrm{ggF}, \mathrm{VBF}, ZH, WH, t\bar{t}H, tH, \ldots\}$ (including specific modes and regions of phase space) and the decay index is defined as $f \in \{\gamma\gamma, WW, ZZ, b\bar{b}, \tau\tau, \mu\mu, Z\gamma\}$, while σ_i^{SM} and $\mathrm{BR}_f^{\mathrm{SM}}$ are the corresponding production cross sections and decay branching fractions, estimated as described in Section 11.2, assuming that the Higgs boson is that of the SM. A_{if}^c and ε_{if}^c are the signal acceptance and the reconstruction efficiency for the given production and decay modes in the category c. $\mathcal{L}^c$ is the integrated luminosity used for that specific category. For the purpose of this review, these parameters can be considered as fixed[2].

The parameters of interest in the master formula are the signal strength parameters μ_i and μ_f. It is important to note that the formula relies on the factorisation of the production cross section and decay branching fraction, which assumes the narrow width approximation. The width of the Higgs boson will be discussed in Section 11.4, however, for the precision needed here, the fact that the Higgs boson has been observed in decay channels with high mass resolution as a resonance is sufficient to validate this hypothesis. It is also manifest in the above equation that the ten parameters for the production modes (μ_i) and decay modes (μ_f) cannot be determined simultaneously. This illustrates that total cross sections or branching fractions cannot be measured without further assumptions in this fit.

The master formula also illustrates an important caveat to the measurement of signal strength parameters. In case these are interpreted as scale factors of the production cross sections or branching fractions, then all the other quantities such as the acceptances and efficiencies, A_{if}^c and ε_{if}^c, need to be assumed as independent and fixed to their estimated values for the SM Higgs boson. An additional important caveat to note concerning these combined results is that only the normalisation is varied, while the discriminating variables for the signal are not modified and are still used in the fit. These caveats are of particular importance in the use of the combination to measure the coupling properties of the Higgs boson, as discussed in Section 11.5. For relatively small perturbations of the couplings of the Higgs boson from the SM values, this hypothesis is valid.

However, the products $\mu_i \times \mu_f$ can be considered as free parameters and in principle measurable (if there is sufficient sensitivity from specific categories). Measuring the products of signal strengths can be viewed as measuring the cross sections times the branching fraction, $\sigma \cdot \mathrm{BR}$. Measurements by ATLAS and CMS of $\sigma \cdot \mathrm{BR}$, normalised to the SM predictions, for the five largest Higgs boson production modes and five major Higgs decay modes are displayed in Fig. 11.3.

[2] In the combination performed by ATLAS and CMS, the systematic uncertainties on these parameters are taken into account by allowing these parameters to vary within their constraints in the fit.

Other fits involving ratios of cross sections, which are less sensitive to theory uncertainties, are performed and reported in Ref. [189].

The most constrained fit in the combination allows for only one single parameter to vary, i.e., $\forall(i,f), \mu_i = \mu_f = \mu$. This global-signal-strength model provides the simplest probe of the compatibility of the signal with the SM Higgs boson. Indeed, it is sensitive to any deviation from the SM Higgs boson couplings provided that these deviations do not cancel overall. The full Run-1 combination determines the global signal strength to be

$$\begin{aligned} \mu = 1.09 \pm 0.11 = & 1.09 \pm 0.07\ (\mathrm{stat.})\ \pm 0.04\ (\mathrm{expt.}) \\ & \pm 0.03\ (\mathrm{th.\,bkg.})\ \pm 0.07\ (\mathrm{th.\,sig.}), \end{aligned} \quad (11.15)$$

where the statistical, experimental uncertainties as well as the theoretical uncertainties on the background and on the signal are reported separately. The ATLAS Run-2 combination of the global signal strength yields [183]:

$$\begin{aligned} \mu = 1.05 \pm 0.06 = 1.05\ & \pm 0.03\ (\mathrm{stat.}) \pm 0.03\ (\mathrm{exp.}) \\ & \pm 0.02\ (\mathrm{th.\,bkg.})\ \pm 0.04\ (\mathrm{th.\,sig.}), \end{aligned} \quad (11.16)$$

while the CMS Run-2 combination yields [184] $\mu = 1.002 \pm 0.057$.

These overall signal strengths are fully compatible with the SM expectation, $\mu = 1$, with a precision of 6%. It is interesting to note that the main uncertainty in these measurements arises from the limited precision in the theoretical predictions for the signal production processes. The precision reached with the individual experiments combinations using partial Run-2 data sets have already exceeded the full Run-1 ATLAS and CMS combination precision.

11.3.6.2 *Main decay modes*

Despite the large number of decay channels, since the cross sections cannot be independently measured, from the measurements described in this section it is impossible to measure the decay branching fractions without a loss of generality. The simplest assumption that can be made is that the production cross sections are those of the SM, which is equivalent to assume that, for all i indices, $\mu_i = 1$. All branching fractions μ_f can then be measured in a simple 7 parameter fit. Results of these measurements are reported in Fig. 11.3.

11.3.6.3 *Main production modes*

Most analysis channels are divided into exclusive categories allowing for an increased overall sensitivity and permitting to access the various Higgs boson production modes. The cross sections of the main production modes can be measured assuming that the branching fractions are those of the SM, i.e., for all f indices $\mu_f = 1$. These assumptions lead to a 6 parameter combination.

The gluon fusion production process is the dominant production mode. Although no numerical estimate of combined significance of observation for this process has been given by the experiments, it is considered as established due to the overwhelming evidence from the three main discovery channels. At the LHC, all production modes have been unambiguously observed. The intricate VH production mode has been unambiguously observed by ATLAS

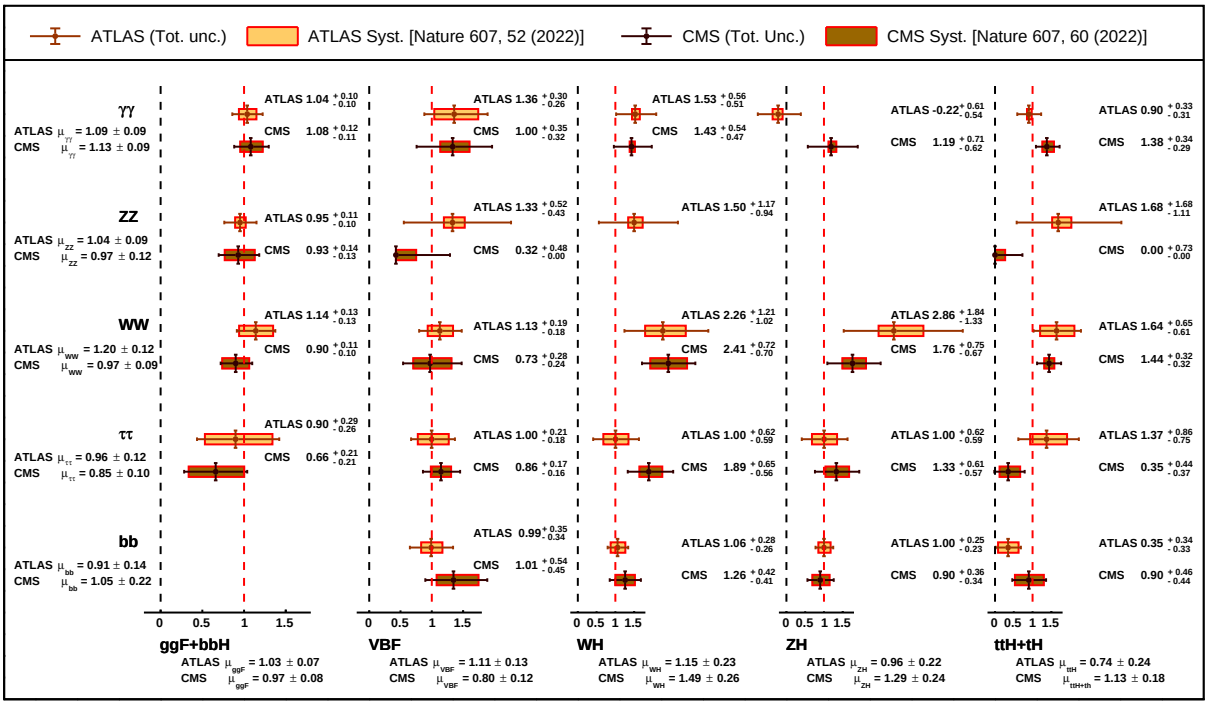

Figure 11.3: Combined measurements by ATLAS [183] and CMS [184] of the products $\sigma \cdot \mathrm{BR}$, normalised to the SM predictions, for the five main production and five main decay modes.

and CMS independently (as discussed in Section 11.3.4) through the $V(H \to b\bar{b})$ channel. The results of these measurements are reported in Fig. 11.3.

With the Run-2 data, all the main production processes have been established, and in particular the $pp \to t\bar{t}H$ process, which provides direct evidence of the coupling of the Higgs boson to top quarks. This is another milestone in the LHC physics program.

11.3.7 *Probing the Higgs boson coupling to the second generation*

11.3.7.1 *First evidence for $H \to \mu^+\mu^-$*

The branching fraction in the $H \to \mu^+\mu^-$ channel for a 125 GeV SM Higgs boson is 2.2×10^{-4}, about ten times smaller than that for $H \to \gamma\gamma$. The major challenge in this channel is the extremely small, permil level, signal-to-background ratio. The dominant and irreducible background arises from the $Z/\gamma^* \to \mu^+\mu^-$ process which has a rate several orders of magnitude larger than that from the SM Higgs boson signal. Due to the precise muon momentum measurement achieved by ATLAS and CMS, the $m_{\mu^+\mu^-}$ mass resolution is very good ($\approx$ 2–4% for ATLAS and $\approx$ 1–3% for CMS depending on the selected categories; a better resolution is expected for CMS due its higher magnetic field strength in the inner detector). A search is performed for a narrow peak over a large but smoothly falling background. For optimal search sensitivity, events are divided into several categories. Either taking advantage of the superior muon momentum measurement in the central region, events can be subdivided by the pseudo-rapidity of the muons, or designing selections aiming at specific production processes such in particular as the vector boson fusion.

ATLAS and CMS analyses target the main production modes such as gluon fusion, associated production with a vector boson (including in the vector boson leptonic decay modes), vector boson fusion and associated production with a top-quark pair. The analyses use multivariate and deep machine learning methods to discriminate signal from background in these Higgs production categories. The signal in both experiments is extracted from a fit to the di-muon invariant mass spectrum and the background is modeled using a suite of analytical functions, except in the case of the most sensitive channel (VBF) in the CMS analysis where the distribution of a discriminant Deep Neural Network output is used.

With the Run-2 dataset, ATLAS measured [190] a signal strengths of $\mu = 1.2 \pm 0.6$ with an observed (expected) significance of $2.0(1.7)\sigma$. The 95% CL limit on $pp \to H \to \mu^+\mu^-$ was set at 2.2 times the SM prediction while the expected limit on a $H \to \mu^+\mu^-$ signal assuming the absence (presence) of a SM signal was 1.1 (2.0). CMS reported [191] the first evidence for $H \to \mu^+\mu^-$ at 3σ level with a signal strength of $\mu = 1.19 \pm 0.40\,(\mathrm{stat.}) \pm 0.15\,(\mathrm{syst.})$ and an expected analysis sensitivity of 2.5σ. These measurements provide the first direct evidence for the decay $H \to \mu^+\mu^-$ and thus of the Yukawa coupling of the Higgs boson to second generation fermions.

11.3.7.2 *Constraints on Higgs boson coupling to charm quarks*

The possibility of probing the Yukawa coupling to the charm has been discussed early in Ref. [192] where indirect bounds are estimated from a combined fit to the Higgs data and the importance of using charm tagging is emphasised. A SM decay rate in standard production was long thought to be out of reach at the LHC. However recent results, in particular from CMS have shown that a different perspective might be emerging [193].

The channels which are currently foreseen to be most sensitive are similar to those aiming at the b-quark Yukawa coupling, and pertain to the VH production mode. As was discussed in [188], the typical sensitivity of these analysis using the LHC Run-2 data on the production times branching fraction was approximately a factor of 30 times the expected rate in the Standard Model.

The key aspect to bring sensitivity to the charm coupling is the ability of flavour tagging algorithms to discriminate charm quark initiated jets from both b quark and light quark jets. Significant progress was recently made in development of parton flavour taggers using state-of-the-art machine learning techniques [194] and additional information to these algorithms. Novel algorithms have also been used to identify pairs of charm quarks resulting from the decay of a Higgs boson, in particular in a regime where the Higgs boson is reconstructed as a large radius jets with a distinctive substructure. These new techniques have resulted in impressive improvements which have led to the first observation of Z boson decays to charm quarks at a hadron collider with a significance of 5.7 standard deviations [193] and an expected sensitivity to the exclusion of a Higgs boson signal decaying to a pair of charm quarks of 7.6 times the Standard Model rate. The observed limit

for CMS is at 14 times the SM rate. This led CMS to set limits on the absolute value of κ_c, the Yukawa coupling of the Higgs boson to charm quarks with respect to its value in the Standard Model. The expected 95% CL interval is $|\kappa_c| < 3.4$. The observed 95% CL interval is the following:

$$1.1 < |\kappa_c| < 5.5 \tag{11.17}$$

This is the most stringent constraint today. The ATLAS analysis [195], in contrast, is still relying on traditional techniques and sets an observed (expected) limit at 26 (31) times the SM rate, using the VH production mode where the vector boson decays to leptons.

CMS complemented this search in the VH production mode with an inclusive search for the Higgs boson produced at high transverse momentum (in excess of 450 GeV) and decaying to a pair of charm quarks [196]. The observed (expected) limit at 95% CL is 47 (39) times the SM rate, which is also an impressive result as it is almost comparable to the previous results obtained in the more sensitive VH channel.

With this striking improvement in sensitivity, CMS reappraised their prospect for the search of Higgs boson decays to charm quarks at the HL-LHC and showed that a CMS could reach a relative precision on the the production rate of approximately 80%. In combination with ATLAS and potential improvements in the analysis, this is bringing the Yukawa coupling of the Higgs boson closer to being at reach at the HL-LHC.

11.3.8 *Searches for rare decays of the Higgs boson*

11.3.8.1 *Combined evidence for $H \to Z\gamma$ and the first evidence for the Dalitz $H \to \ell^+\ell^-\gamma$ decay*

The search for $H \to Z\gamma$ is performed in the final states where the Z boson decays into opposite sign and same flavour leptons ($\ell^+\ell^-$), ℓ here refers to e or μ. While the branching fraction for $H \to Z\gamma$ is comparable to $H \to \gamma\gamma$ (about 10^{-3}) at $m_H = 125$ GeV, the observable signal yield is brought down by the small branching ratio of $Z \to (e^+e^- + \mu^+\mu^-) = 6.7 \times 10^{-2}$. In these channels, the $m_{\ell\ell\gamma}$ mass resolution is excellent (1–3%), therefore the analyses search for a narrow mass peak over a continuous background. The major backgrounds arise from the $Z+\gamma$ final state radiation in Drell–Yan decays and from the Z + jets processes where a jet is misidentified as a photon. The ratio of signal over background in this channel is typically of the order of 0.5%. In a narrow window of a few GeV around 125 GeV, several hundreds of events are expected in a Run-2 dataset corresponding to approximately 36 fb^{-1}. Events are divided into mutually exclusive categories on the basis either of the expected $m_{Z\gamma}$ resolution or exclusive production mode categories.

With the full Run-2 dataset, ATLAS observes an excess with a significance of 2.2σ while an excess with a significance of 1.2σ is expected. CMS observes an excess with a significance of 2.6σ while 1.2σ is expected. ATLAS and CMS have jointly published a combination of these results, yielding a first evidence for the Higgs boson decay to a Z boson and a photon at the LHC with an observed significance of 3.4σ and an expected sensitivity of 1.6σ [197]. This combined result is compatible with the SM hypothesis at 1.9σ.

Both ATLAS and CMS experiments have extended the search for the so-called Dalitz Higgs boson decays $H \to \gamma^*\gamma \to \ell^+\ell^-\gamma$ in the low mass γ^* range of approximately 20-30 GeV. This decay mode has a substantially larger branching fraction compared to the $Z\gamma$ decay, as $\Gamma(H \to \gamma^*\gamma \to e^+e^-\gamma) \sim 3.5\% \times \Gamma(H \to \gamma\gamma)$ and $\Gamma(H \to \gamma^*\gamma \to \mu^+\mu^-\gamma) \sim 1.7\% \times \Gamma(H \to \gamma\gamma)$, while $\Gamma(H \to Z\gamma) = 2.3\% \times \Gamma(H \to \gamma\gamma)$ (which does not account for the subsequent decay of the Z boson to electrons or muons). With the Run-1 dataset, CMS observes an upper limit of 6.7 times the SM branching ratio [198]. With a partial Run-2 dataset, in the $\gamma^*\gamma$ CMS obtained a much more stringent limits on the cross section times the corresponding branching fractions of 1.4 (6.1) times the SM cross section [199]. CMS also performed a combination of this mode with $H \to Z\gamma$, obtaining a combined observed (expected) limit of 3.9 (2.0) times the SM branching fractions.

Using the full Run-2 dataset corresponding to 139 fb^{-1}, ATLAS obtained the first evidence for Higgs boson decays to a low-mass dilepton pair and a photon with a significance of 3.2 (2.1) standard deviations (expected) [200]. The invariant mass requirement on the di-lepton is $m_{\ell\ell} < 30$ GeV. The corresponding signal strength is $\mu = 1.5 \pm 0.5$, compatible with the SM expectation.

11.3.8.2 *Higgs coupling to first generation, search for $H \to e^+e^-$*

Probing the Yukawa couplings to the first generation fermions is extremely challenging at the LHC given the overwhelming backgrounds and very small signal rates.

A search similar to the $H \to \mu^+\mu^-$ is performed in the non-VBF categories by CMS in the di-electron channel [201]. In this search, the contribution from the peaking background from Higgs boson decays to diphotons mis-identified as di-electrons (when converted photons are faking electrons) needs to be carefully assessed. The sensitivity to the SM Higgs decays is negligible given the extremely small branching fraction to e^+e^-, approximately 40,000 times smaller than the branching fraction to dimuons. It is nevertheless interesting to probe this decay channel to search for potential large anomalous couplings. Assuming a SM Higgs boson production cross section, the observed limit on the $H \to e^+e^-$ branching fraction at the 95% CL is 3.0×10^{-4}, more than five orders of magnitude larger than the expected SM prediction. ATLAS has also performed a search for the $H \to e^+e^-$ decay mode with the Run-2 dataset, placing a limit of 3.6×10^{-4} on the branching fraction [202].

It is important to note that processes not depending on the electron Yukawa coupling such as the $H \to e^+e^-\gamma$ (where the photon is soft), are sizeably larger than the direct Yukawa coupling process, but also much smaller than the current constraints, making any interpretation in terms of constraint on the electron Yukawa couplings far from straightforward.

11.3.8.3 *Invisible decays of the Higgs boson*

The discovery of the Higgs boson immediately raised the question of its couplings to DM and how it could be used to reveal at colliders the existence of a dark sector coupled to the SM via the Higgs boson portal, see Ref. [203] and references therein. If kinematically accessible and with a sufficiently large coupling to the Higgs boson, DM particles, such as, e.g., neutralinos in SUSY models, graviscalars in models with extra dimensions or heavy neutrinos in the context of four-generation fermion models, would manifest themselves as invisible decays of the Higgs boson, thus strongly motivating searches for the invisible decays of the Higgs boson.

It should be noted that in the Standard Model the branching fraction of a Higgs boson into invisible decays through the $H \to ZZ^* \to \nu\bar{\nu}\nu\bar{\nu}$ process has a branching fraction of 0.12%.

To identify an invisibly decaying Higgs boson at the LHC, it must be produced in association with other particles. Searches for invisible decays of the Higgs boson at the LHC have been carried out in the three associated production modes of the Higgs boson with the highest SM cross sections and target events with large missing energy.

The ggF production mode has the largest SM cross section but it usually results in the Higgs boson being created alone and hence leaving no characteristic signature in the detector of its invisible decay. One way to search for invisible decays in ggF production mode is to look for events with the monojet topology arising from initial state gluon radiation and containing missing energy. The major irreducible background in such searches stems from Z + jets events where the Z boson decays into a pair of neutrinos [204]. The analysis with the best sensitivity targets the VBF production topology but it suffers from large backgrounds arising from events with two jets and large missing energy. The VH mode has much smaller cross section but the presence of a W or Z boson allows a variety of final states that can be tagged with relatively low background.

ATLAS and CMS have searched for such final states at Run 1 and have observed no significant excess over the predicted backgrounds (for references, see the previous edition of this review [141]). Table 11.6 summarises the 95% CL limits on the invisible decays of the Higgs boson assuming a SM Higgs boson production cross section and the corresponding detector acceptances.

Table 11.6: Summary of the channels searched for and the corresponding 95% CL limits from ATLAS and CMS on the branching fraction for the Higgs boson decay to invisible particles assuming a SM Higgs boson production cross section. The results in parentheses are the expected exclusions.

	ATLAS (Run 1)	ATLAS (Run 2)	CMS (Run 1)	CMS (Run 2)

$t\bar{t}H$; $H \to$ inv.	–	38 (30)%	–	26 (30)%
Run 1 & 2 Combination	10.7 (7.7)%		15 (8)%	

ATLAS and CMS have performed the search for invisible decays of the Higgs boson at Run 2 with the full dataset in all the aforementionned channels [205–207]. The results are summarised in Table 11.6.

These constraints can then be further used to probe Higgs portal models to DM [203], where an additional weakly interacting particle χ with mass lower than $m_H/2$ is introduced as DM candidate and where the Higgs boson is considered as the only mediator between the SM particles and DM. In this model, it is interesting to express the limit on the invisible branching fraction in terms of strength of interaction of DM with standard matter, i.e., in terms of it interaction cross section with nucleons $\sigma_{\chi-N}$. In this model, the couplings of the Higgs boson to SM particles are assumed to be those of the SM and the interaction of the Higgs boson with the nucleon is parametrised in a Higgs-Nucleon form factor estimated using lattice QCD calculations [203]. The results for the ATLAS llimits are shown in Fig. 11.4.

11.3.8.4 *Exclusive Higgs boson decays*

A possibility to access the charm Yukawa coupling has been discussed in Ref. [208]. It relies on the decays of the Higgs boson to a final state with quarkonia. Searches have been performed in several channels including $H \to \Upsilon\gamma, J/\Psi\gamma, \phi\gamma, \rho\gamma$ these processes can provide indirect constraints on the Higgs boson Yukawa coupling to b, charm, strange and light quarks. The limits obtained so far in these channels [209, 210] are reported in the Higgs particle listings [188]. Limits on branching fractions range between 10^{-3}–10^{-4}.

CMS has also performed a search of the decays of the Higgs boson in the $J/\Psi J/\Psi$ and $\Upsilon\Upsilon$ final states to cover the cases where the photon in the $J/\Psi\gamma$ decay is virtual and transforms into a J/Ψ meson, These decays provide an additional channel potentially sensitive to BSM phenomena [211].

More recently a search for Higgs boson decays to mesons and a photon in the channels $H \to \omega\gamma$ and $H \to K^*\gamma$ have been carried out by the ATLAS experiment [212]. The limits on these processes are of 1.5×10^{-4} and 8.5×10^{-5} on the $\omega\gamma$ and the $K^*\gamma$ respectively.

Another class of searches for exclusive decays of the Higgs boson is $H \to ZQ$ where Q is a quarkomium state. This decay results from the interference of two contributions, one where the Higgs boson couples to a quark-anti-quark pair which forms a quarkonium and radiates a Z boson at leading order, and another one from the off-shell decay $H \to ZZ^*$ or $H \to Z\gamma^*$ and the conversion of the off-shell Z or photon into a quarkonium. A search was carried out by ATLAS in the ZJ/Ψ and Z/η_c channel in the $Z \to \ell^+\ell^-$ and a light hadronically decaying resonance signature [213] and by CMS in the ZJ/Ψ and ZJ/Υ channels in fully leptonic final states [214].

11.3.8.5 *Lepton flavour violating (LFV) Higgs boson decays*

Given the Yukawa suppression of the couplings of the Higgs boson to quarks and leptons of the first two generations and the small total width of the Higgs boson, new physics decay modes could easily have sizeable branching fractions. One very interesting possibility is the Lepton Flavour Violating (LFV) decays of the Higgs boson, in particular in the $\tau\mu$ and τe modes. These decays are suppressed in the SM but they could easily be enhanced in theories such as two-Higgs-doublet models (discussed in Section 11.6). Indirect constraints on the LFV Yukawa couplings $|Y_{\tau\mu}|$ can be obtained from channels such as the $\tau \to 3\mu$ or $\tau \to \mu\gamma$, or a re-interpretation of the search for Higgs boson decays to $\tau^+\tau^-$. A direct search at the LHC, however, complements these indirect limits.

The search for LFV decays in the $\tau\mu$, τe and μe channels were carried out with the Run-1 and early Run-2 datasets in several channels according to the subsequent decay of the τ [215–220]. The limits on LFV decays of the Higgs boson are reviewed in this volume of the particle listings [188] and reached 0.15% in the $\tau\mu$ channel and 0.22% in the τe channel.

ATLAS [221] has performed the analysis with the full Run-2 dataset, yielding limits of 0.20% and 0.18% on the $e\tau$ and $\mu\tau$ channels respectively. CMS [222] has performed analyses with the full Run-2 dataset of the $e\mu$ channel reaching a limit of 4.4×10^{-5} at 95% CL.

The CMS search in the $e\mu$ channel was done not only at the specific Higgs boson mass, but in a wider mass domain between 110 GeV and 160 GeV. A mild excess with a global significance of 2.8 standard deviations is observed for a mass hypothesis of approximately 146 GeV.

11.3.8.6 *Flavour changing neutral current decays of the top quark*

The discovery of the Higgs boson at a mass smaller than the top quark mass opened a new decay channel for the top quark. The decays of the top quark to a Higgs boson and a charm or an up quark proceed through a Flavour Changing Neutral Current (FCNC) which are forbidden in the Standard Model at tree level and suppressed at higher orders through the Glashow–Iliopoulos–Maiani (GIM) mechanism [3]. The SM prediction for these branching fractions is $\mathrm{BR}(t \to Hc) = 10^{-15}$ and two orders of magnitude less for the Hu final state. These decay channels of the top quark are, therefore, very interesting to probe possible FCNC interactions in the Yukawa couplings to the quark sector, see Section 11.6.

ATLAS has searched for FCNC top decays specifically in channels involving a Higgs boson that subsequently decays into a pair of b quarks, two photons, a tau pair or two W bosons [223]. It has also reinterpreted a search for the $t\bar{t}H$ production in the multilepton final state (discussed in Section 11.3.5.1) [173]. The latter channel covers Higgs boson decays to a pair of W bosons and a pair of taus. No significant excess was observed in any of the specific channels (as discussed in Section 11.3.5.1, a slight excess is observed in the $t\bar{t}H$ multilepton channel) and 95% CL upper limits are set on $\mathrm{BR}(t \to Hc) < 0.46\%$ with an expected sensitivity of 0.25% and $\mathrm{BR}(t \to Hu) < 0.45\%$ with an expected sensitivity of 0.29%. CMS has performed a search for these FCNC top decays in the diphoton and multi-lepton channels [224], placing a 95% CL upper limit on $\mathrm{BR}(t \to Hc) < 0.40\%$ with an expected sensitivity of 0.43%.

From these limits on branching fractions, constraints on non-flavour-diagonal Yukawa couplings of a FCNC Lagrangian of the form:

$$\mathcal{L}_{\mathrm{FCNC}} = \lambda_{tcH}\bar{t}Hc + \lambda_{tuH}\bar{t}Hu + h.c. \qquad (11.18)$$

can be derived. The 95% CL observed (expected) upper limits from ATLAS on the $|\lambda_{tcH}|$ and $|\lambda_{tuH}|$ couplings are 0.13 (0.10) and 0.13 (0.10), respectively.

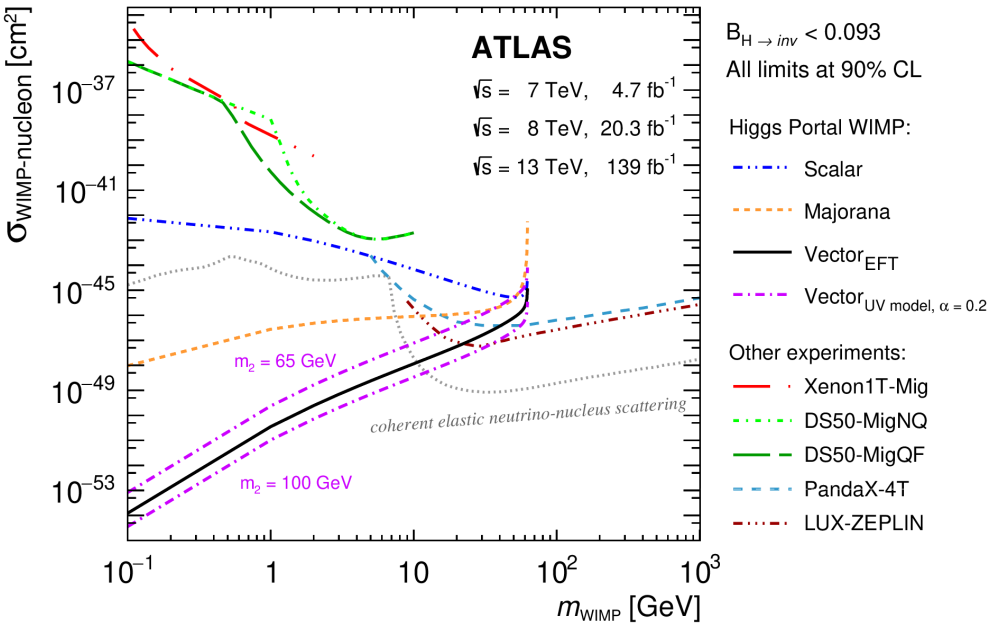

Figure 11.4: 90% CL upper limits on the spin-independent WIMP-nucleon scattering cross section as a function of the DM particle mass for direct detection experiments experiments and the interpretation of the H → invisible combination result in models where the Higgs boson is a portal between the SM matter and the Dark Sector. For the vector UV-model, m_2 are two representative values of the predicted Dark Higgs particle with mixing angle α. The regions above the limit contours are excluded in the range shown in the plot. From Ref. [205].

The results above are derived from the combination of several channels for searches performed with Run-1 data. Both ATLAS and CMS have produced updates of individual channels with Run-2 data. ATLAS has searched for FCNC top decays with subsequent decays of the Higgs boson to a pair of photons [225], yielding a 95% CL upper limit on BR($t \to Hc$) < 0.22% with an expected sensitivity of 0.16%. CMS has searched for FCNC top decays with subsequent decays of the Higgs boson to a pair of b-quarks [226], yiedling a 95% CL upper limit on BR($t \to Hu$) < 0.079% with an expected sensitivity of 0.011% and on BR($t \to Hc$) < 0.094% with an expected sensitivity of 0.086%.

11.3.8.7 *Exotic Higgs boson decays*

The 125 GeV Higgs boson serves not only as a probe for potential DM candidates, but also to search for other exotic particles arising from fields associated with a low-mass hidden sector (for a review, see for instance Ref. [227]). Such hidden sectors are composed of fields that are singlet under the SM gauge group SU(3) × SU(2) × U(1). These models are referred to as hidden valley models [228]. Since a light Higgs boson is a particle with a narrow width, even modest couplings to new states can give rise to a significant modification of the Higgs boson phenomenology through exotic decays. Simple hidden valley models exist in which the Higgs boson decays to an invisible fundamental particle, which has a long lifetime to decay back to SM particles through a small mixing with the SM Higgs boson, see Ref. [228] for a concrete example. The Higgs boson may also decay to a pair of hidden valley "v-quarks," which subsequently hadronise in the hidden sector, forming "v-mesons." These mesons often prefer to decay to the heaviest state kinematically available, so that a possible signature is $H \to 4b$. Some of the v-mesons may be stable, implying a mixed missing energy plus heavy flavour final state. In other cases, the v-mesons may decay to leptons, implying the presence of low mass lepton resonances in high-H_T events [229]. Other scenarios have been studied [230] in which the Higgs boson decays predominantly into light hidden sector particles, either directly, or through light SUSY states, and with subsequent cascades that increase the multiplicity of hidden sector particles. In such scenarios, the high-multiplicity hidden-sector particles, after decaying back into the SM, appear in the detector as clusters of collimated leptons known as "lepton jets".

A variety of models have been investigated searching for final states involving dark photons and hidden valley scalars. The resulting topologies typically have leptons or light hadrons which in some cases can be prompt (i.e., originating from the hard process interaction point) or not and are in some cases collimated and reconstructed as jets [231, 232], and long-lived weakly interacting particles. The latter occur not only in hidden valley scenarios, but also in gauge-mediated extensions of the minimal SUSY standard model (MSSM), the MSSM with R-parity violation, and inelastic DM scenarios [233]. Finally, CMS has performed a search for pair production of light bosons [234]. Such a scenario can occur in SUSY models with additional hidden (or dark) valleys.

11.3.9 *Higgs boson pair production and self-coupling*

Higgs boson pair production in the SM is a rare but very important mode to measure and search for. The measurement of Higgs boson pair production is essential to directly constrain the trilinear Higgs boson self coupling and the search for Higgs boson pair resonances is key in a variety of BSM models. The latter searches are discussed in Section 11.6.7.

In the SM, the main non-resonant production mode of two Higgs bosons proceeds through a loop, mainly of top quarks, see Fig. 11.1 (h). Another production mode is via the trilinear coupling of the Higgs boson, see Fig. 11.1 (i), whose amplitude is not negligible compared to the former. These diagrams interfere negatively, making the overall production rate smaller than what would be expected in the absence of a trilinear coupling.

11.3.9.1 *Searches for Higgs boson pair production*

The searches for Higgs boson pair production both resonant and non-resonant are important probes for a variety of BSM theories, and they can be done in a large number of Higgs boson decay channels. At Run 1, ATLAS and CMS have searched for both resonant and non resonant Higgs boson pair production in the following channels: (i) $HH \to b\bar{b}\gamma\gamma$; (ii) $HH \to b\bar{b}\tau^+\tau^-$; (iii) $HH \to b\bar{b}b\bar{b}$; (iv) $HH \to b\bar{b}4\ell$; (v) $HH \to WW^*\gamma\gamma$; (vi) in final states containing multiple leptons (electrons or muons) covering the WW^*WW^*, WW^*ZZ^*, ZZ^*ZZ^*, $ZZ^*\tau^+\tau^-$, $WW^*\tau^+\tau^-$, $ZZ^*b\bar{b}$, $\tau^+\tau^-\tau^+\tau^-$ channels; and (vi) $\gamma\gamma\tau^+\tau^-$ channels.

At Run 2, similarly to the $t\bar{t}H$ production process, the di-Higgs production profits from a significant increase in production cross section of a factor in excess of 3 from 8 TeV to 13 TeV, and most

of these channels have been updated both by ATLAS [235] and CMS [184, 236]. The detailed description of the various analyses used can be found in the references therein. All the results and their combinations are summarised in Table 11.7 and in Fig. 11.5 (left). The channels (i)-(iii) are the most sensitive to the HH production. These three channels have been updated with the full Run-2 dataset except the $HH \to b\bar{b}\tau^+\tau^-$ channel by CMS and the $HH \to b\bar{b}b\bar{b}$ channel by ATLAS which have both been analysed using a partial Run-2 dataset.

In several of these analysis channels the VBF production mode is searched for separately providing sensitivity to the coupling involving two vector bosons and two Higgs bosons HHVV which is an expected coupling in the Standard Model.

Table 11.7: Summary of the final states investigated in the search for Higgs boson pair production by ATLAS and CMS, the results reported in bold are based on the full Run-2 dataset. For ATLAS, the result indicated by (*) uses mostly the $b\bar{b}W^+W^-$ channel. Results are 95% CL upper limits on the observed (expected) signal strengths.

Channel	ATLAS	CMS
$b\bar{b}\gamma\gamma$	**4.2 (5.7)**	**8.4 (5.5)**
$b\bar{b}b\bar{b}$	**5.4 (8.1)**	**7.2 (4.2)**
$b\bar{b}\tau^+\tau^-$	**4.7 (3.9)**	**3.3 (5.2)**
$b\bar{b}4\ell$	-	**32 (40)**
$W^+W^-W^+W^-$	160 (120)	–
$W^+W^-\gamma\gamma$	230 (170)	**97 (52)**
$b\bar{b}VV$	305 (305)*	**14 (18)**
Multi-lepton	–	**19 (21)**
Combination	**2.4 (2.9)**	**3.4 (2.5)**

The current single channel most stringent limits obtained on the HHVV coupling modifier denoted κ_{2V} are obtained from the analysis performed by CMS [237] in the $b\bar{b}b\bar{b}$:

$$-0.1 < \kappa_{2V} < 2.2\,(\text{observed}), \quad -0.4 < \kappa_{2V} < 2.5\,(\text{expected})$$

and for the overall most stringent constraints are obtained through the combination of channels in ATLAS, yielding [235]:

$$-0.1 < \kappa_{2V} < 2.0\,(\text{observed}), \quad 0.0 < \kappa_{2V} < 2.1\,(\text{expected})$$

11.3.9.2 *The Higgs boson self coupling*

The Higgs boson self coupling is an extremely important direct probe of the Higgs potential with implications on our understanding of the electroweak phase transition. Constraints on the trilinear self coupling from HH processes is an outstanding long term goal of the LHC and the reach in sensitivity has been reappraised in the light of the recent HH analyses from ATLAS and CMS, shedding a different light on the achievable sensitivity [118]. Constraints from the HHH final state on the quartic Higgs boson self coupling are out of reach at the LHC due mostly to the very small production rates and intricate final states.

In the SM, the Higgs boson pair production through the trilinear Higgs boson self coupling has an on-shell component and a large off-shell component. The on-shell $H \to H^*H^*$ is strongly disfavoured, requiring two off-shell Higgs bosons in the final state. The sensitivity region to the trilinear coupling production as in Fig. 11.1 (*i*), is mainly in the kinematic region where the two Higgs boson in the final state are on-shell and the Higgs boson acts as a propagator (off-shell). As discussed in the introduction to this section, this process interferes negatively with the background Higgs boson pair production (Fig. 11.1 (*h*)). The extraction of the trilinear component of the di-Higgs production measurements is very similar to the extraction of the off-shell component of the Higgs coupling to vector bosons discussed in Section 11.4.2.

The measurement of the trilinear coupling requires separating the contributions of the diagram of Fig. 11.1 (*i*) from the box diagram of Fig. 11.1 (*h*), and therefore a precise knowledge of the top-Yukawa coupling is needed. Each diagram alone would produce a rather distinct m_{HH} distribution. And, for values of the trilinear coupling close to the SM value, an additional discriminating feature of the signal with respect to one obtained with the box contribution alone is a deficit in the number of events. With large variations of the trilinear coupling, an excess of events over the SM prediction would be observed (for a value of the trilinear coupling about 6 times larger than its SM value, the number of events is equal to the SM expectation). Additional sensitivity to the trilinear coupling is also obtained from the kinematical distributions of the signal taking in particular into account the effect of the HH mass distribution which discriminates the main contributions of Fig. 11.1. This further discrimination is instrumental in resolving the degeneracy in the total cross section mentioned above. Bounds on the trilinear coupling are obtained from limits on the HH production as a function of the trilinear coupling factor κ_λ as illustrated in Fig. 11.5. As the sensitivity in this channel grows it will be interesting to more closely look at the combined and individual likelihoods as a function of the trilinear coupling to quantify the exclusion of the secondary minimum induced by the degeneracy between the value of κ_λ yielding the same overall HH rate as the Standard Model (*i.e.* $\kappa_\lambda = 1$). The results obtained by ATLAS [235] and CMS [184] are the following:

$$\begin{aligned} (\text{ATLAS}) \; &-0.6 < \kappa_\lambda < 6.6\,(\text{observed}), \\ &-2.1 < \kappa_\lambda < 7.8\,(\text{expected}), \\ (\text{CMS}) \; &-1.2 < \kappa_\lambda < 6.5\,(\text{observed}), \end{aligned} \tag{11.19}$$

where κ_λ is the ratio between the trilinear coupling value left free in the fit and its expected value in the SM ($\kappa_\lambda = 1$ corresponds to the SM). For the CMS result the expected excluded range is not specified in [184], however its illustration in the exclusion figure therin shows that it is compatible with the observation. The so-called κ formalism is discussed in more detail in Section 11.5.1.1. These results are also illustrated in Fig. 11.5.

Single Higgs production can indirectly also be used to further constrain the trilinear coupling of the Higgs boson, both using inclusive total or differential cross sections. A combination of di-Higgs and single-Higgs boson production results has been performed by the ATLAS collaboration yielding the following limits [235]:

$$-0.4 < \kappa_\lambda < 6.3\,(\text{observed}),$$

It is interesting to note that currently the *direct* ($-0.6 < \kappa_\lambda < 6.6$) and *indirect* constraints ($-4.0 < \kappa_\lambda < 10.3$) on the Higgs boson trilinear self-coupling are of comparable strength. However, the double Higgs boson measurements are dominated by statistical uncertainties and are expected to improve more rapidly than the precision on single Higgs boson measurements. It should also be stressed that the constraints on the trilinear self-coupling obtained via the NLO fit of single Higgs boson data are model-dependent since the NLO effects induced by a shift of the trilinear self-coupling compete with possible LO effects sourced by the deviations of the Higgs boson couplings to the other SM particles. The different effects can be disentangled by the measurements of various kinematical differential distributions in addition to the study of the inclusive rates [238], but the expected sensitivity obtained in such global fits are not as strong as when only the Higgs boson self-coupling is allowed to deviate from its SM value [119]. It should also be noted that in this fit the parameters κ_t, κ_b, κ_τ and κ_V are fit simultaneously.

The analyses performed at Run 2 bring substantial improvements from those of Run 1, and they were first used to reappraise the sensitivity of the LHC in the High Luminosity regime in the framework of the update of the European Strategy for Particle Physics [118]. The result in terms of bounds on the trilinear coupling indicated that the significance of the observation of the HH

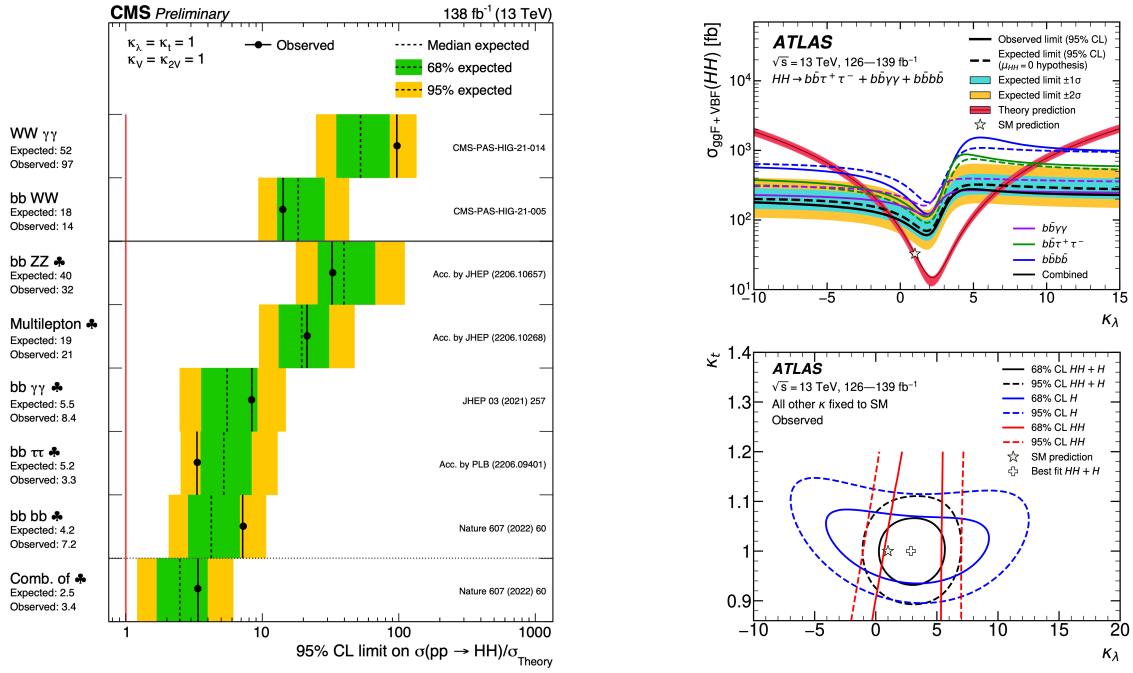

Figure 11.5: (Left) Upper limits obtained by CMS on the total $pp \to HH$ production cross section. (Top right) Upper limits obtained by ATLAS on the total $pp \to HH$ production cross section as a function of the trilinear coupling modifier κ_λ. The variation of the limit corresponds to variations in the signal acceptance. The expected total production cross section is also illustrated (red). (Bottom right) Likelihood contours for the ATLAS di-Higgs and single-Higgs combined results as a function of κ_λ and κ_t.

process reaches 4σ. It is also apparent that the degeneracy of secondary minimum at intermediate values of κ_λ is resolved by the use of the kinematic discriminants. This secondary minimum was expected to be excluded at 99.4% CL and at HL-LHC, the foreseen precision on κ_λ was estimated to reach approximately 50%. These studies were based on early LHC Run-2 analyses. Then in the framework of the Snowmass2021 studies [239] and more recently using the latest HH searches results, these projections have been updated. Both experiments have reappraised their studies at HL-LHC [240], to reach individually a sensitivity of approximately 3.5σ, a significant improvement compared to the sensitivities estimated between 2.5σ and 3σ in [118]. These studies indicate that a sensitivity of 5σ in combination of the two experiments should be reached at HL-LHC.

Higher precisions can be reached at pp colliders (and e^+e^- colliders) at higher centre-of-mass energies. The foreseen precision for a High-Energy (HE) LHC at a centre-of-mass energy of 27 TeV is expected to be within 10% to 20% [118]. At a very large hadron collider at a centre-of-mass energy of 100 TeV, a 5% sensitivity is expected to be reached, provided that the theoretical and parametric uncertainties are kept at the 1% level [241].

One of the main open questions in particle physics is related to the precise history of the EWSB mechanism. This in turn can be of relevance to provide a mechanism for generating the matter - antimatter asymmetry of the universe at the electroweak scale, the so called electroweak baryogenesis (EWBG) (see Refs. [242, 243] for some reviews). In the SM EWBG is ruled out, but new physics models, in particular those additional scalar particles coupled/mixed with the Higgs boson, can provide a successful alternative. Given that di-Higgs production will become an excellent probe of trilinear Higgs coupling modifications, it will provide a unique window into the history of EWSB and will become a powerful test of EWBG models.

11.3.10 *Beyond the main Higgs boson production modes*

Most of the production modes illustrated in Fig.11.1 have been investigated at the LHC so far. These processes are often referred to as the 'main production modes'. Beyond these production modes, two additional SM processes involving the Higgs boson have been investigated and are worth noting.

The first is the four top production mode which is closely related to the $t\bar{t}H$ mode. This process has recently been unambiguously observed at the LHC by both ATLAS [244] and CMS [245]. This production mode has a non trivial contribution from the exchange of a Higgs boson. A first limit on the Yukawa coupling of the Higgs boson has thus been derived using this four top process, $|\kappa_t| < 1.8(1.6)$, under the assumption that the Yukawa coupling of the Higgs boson to top quarks in CP even [244].

Another process beyond the main production modes is the associated WH production through Vector Boson Fusion (VBF) yielding a topology of events with two jets in the forward region with a large rapidity gap, a W boson and a Higgs boson. This process is particularly interesting as it is sensitive to the relative sign of the coupling of the Higgs boson to the W and Z boson through the interference of the processes where the Higgs boson couples either to the W or the Z bosons in the vector boson fusion process. ATLAS has carried out analyses targeting at the decay of the Higgs boson to $b\bar{b}$ and W^+W^- for this process, resulting in the exclusion of the opposite sign hypothesis by 8 standard deviations and an upper limit corresponding to 11.2 times the cross section expected in the Standard Model [246].

11.3.11 *First results on the main production and decay channels at 13.6 TeV*

After a long shutdown between 2019 and 2022, devoted to the upgrades of the experiments and the machine to prepare for the High Luminosity phase , in the Spring 2022 the LHC delivered pp collisions data at an enhanced centre-of-mass energy of 13.6 TeV. During this high-energy run, ATLAS and CMS have collected datasets corresponding to integrated luminosities of approximately 60 fb^{-1} each. The first preliminary measurements of Higgs boson production at this increased centre-of-mass energy using the two high-resolution channels $H \to \gamma\gamma$ and $H \to ZZ^* \to \ell^+\ell^-\ell'^+\ell'^-$ have been carried out by ATLAS [247], see Fig. 11.6. The measurements are in good agreement within the precision with the theoretical prediction which display the expected increase of approximately 7% in inclusive cross section from the increase in centre-of-mass energy.

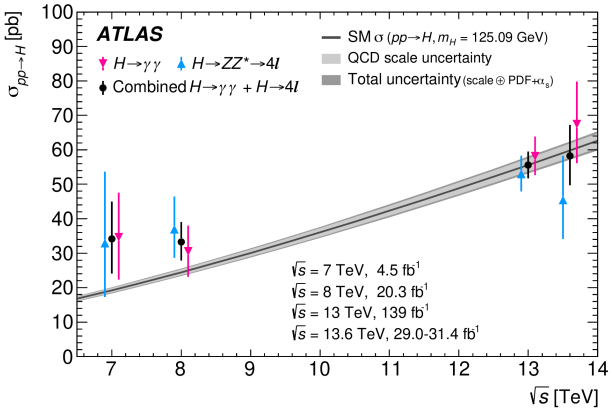

Figure 11.6: Higgs boson production cross sections as a function of the pp centre-of-mass energy. The SM predictions are shown by the shaded band.

11.4 Main quantum numbers and width of the Higgs boson

11.4.1 *Main quantum numbers* J^{PC}

Probing the Higgs boson quantum numbers is essential to further unveiling its coupling properties. The measurements of the signal event yields in all the channels discussed in Section 11.3 and their compatibility with the SM Higgs boson predictions, give a qualitative but, nonetheless, compelling indication of its nature. For the observed particle not to be of spin 0 and +1 parity would require an improbable conspiracy of effects. It is nevertheless important to test this hypothesis independently, in particular since the measurements of coupling properties of the Higgs boson assume that it is a CP-even state.

This qualitative picture is further complemented by the implications of the observation of the particle in the diphoton channel. According to the Landau–Yang theorem [248], the observation made in the diphoton channel excludes the spin-1 hypothesis and restricts possibilities for the spin to 0 or 2.

The Landau–Yang theorem does not apply if the observed state is not decaying to a pair of photons but to a pair of scalars subsequently decaying to two very collimated pairs of photons (as for example in the case of $H \to a_1 a_1 \to 4\gamma$). This possibility has not been rigorously excluded but is not experimentally favoured since tight selection criteria are applied on the electromagnetic shower shapes of the reconstructed photons. A more systematic analysis of shower shapes and the fraction of conversions could be performed to further discriminate between the single prompt photon and the two overlapping photons hypotheses. There are also potential theoretical loopholes concerning the applicability of the Landau–Yang theorem, such as off-shell vector boson decays.

The spin 1 hypothesis has therefore been investigated quantitatively with the LHC Run-1 dataset and has been excluded at more than 95% CL through the analysis of the Higgs boson decays to WW^* and ZZ^* channels. These results are reported in previous versions of this review and will not be covered herein. [188].

11.4.1.1 *Charge conjugation*

The charge conjugation quantum number is multiplicative, therefore given that the Higgs-like particle is observed in the $H \to \gamma\gamma$ channel, and given that photons are C-odd eigenstates, assuming C conservation, the observed neutral particle should be C-even.

11.4.1.2 *Spin and parity*

To probe the spin and parity quantum numbers of the discovered particle, a systematic analysis of its production and decay processes is performed in several analyses. These analyses are designed to be independent of the measured event yields and they rely instead on the production and the decay angles, and on the threshold distributions as long as a significant signal is observed, i.e., in situations when an excess over the expected background can be used to further discriminate between signal hypotheses. These analyses are based on probing various alternative models of spin and parity [249]. These models can be expressed in terms of an effective Lagrangian [250] or in terms of helicity amplitudes [251]. The two approaches are equivalent.

i. *Spin-0 models*

The interaction Lagrangian relevant for the analysis of spin-0 particle interaction with a pair of W or Z bosons with either fixed or mixed SM and BSM CP-even couplings or CP-odd couplings, is the following [252]:

$$\mathcal{L}_0^{W,Z} \supset \Big\{ \cos(\alpha)\kappa_{\rm SM} \left[\frac{1}{2} g_{HZZ} Z_\mu Z^\mu + g_{HWW} W_\mu^+ W^{-\mu}\right] - \frac{1}{4\Lambda}\left[\cos(\alpha)\kappa_{HZZ} Z_{\mu\nu} Z^{\mu\nu} + \sin(\alpha)\kappa_{AZZ} Z_{\mu\nu}\tilde{Z}^{\mu\nu}\right] - \frac{1}{2\Lambda}\left[\cos(\alpha)\kappa_{HWW} W_{\mu\nu}^+ W^{-\mu\nu} + \sin(\alpha)\kappa_{AWW} W_{\mu\nu}^+ \tilde{W}^{-\mu\nu}\right]\Big\} H, \tag{11.20}$$

where $V^\mu = Z^\mu, W^{+\mu}$ are the vector boson fields, $V^{\pm\mu\nu}$ are the reduced field tensors, $\tilde{V}^{\pm\mu\nu} = 1/2\,\varepsilon^{\mu\nu\rho\sigma} V_{\rho\sigma}$ are the dual tensor fields, and Λ defines an effective theory energy scale. The factors $\kappa_{\rm SM}, \kappa_{HZZ}, \kappa_{HWW}, \kappa_{AZZ}, \kappa_{AWW}$ denote the coupling constants corresponding to the coupling of the SM and BSM CP-even and CP-odd components of the Higgs boson to the W and Z fields. The mixing angle α allows for the production of a CP-mixed state and the CP-symmetry is broken when $\alpha \neq 0, \pi$.

This formalism can be used to probe both CP-mixing for a spin-0 state, as discussed in Section 11.4.1.5 or specific alternative hypotheses, as discussed below, such as a pure CP-odd state ($J^P = 0^-$) corresponding to $\alpha = \pi/2$, $\kappa_{\rm SM} = \kappa_{HVV} = 0$ and $\kappa_{AVV} = 1$. A BSM CP-even state $J^P = 0^+$ corresponds to $\alpha = 0$, $\kappa_{AVV} = 0$, $\kappa_{HVV} = 1$ and $\kappa_{\rm SM}$ arbitrary. These hypotheses are compared to the SM Higgs boson hypothesis corresponding to $\alpha = 0$ and $\kappa_{HVV} = \kappa_{AVV} = 0$ and $\kappa_{\rm SM} = 1$. This formalism has been adopted by the ATLAS experiment.

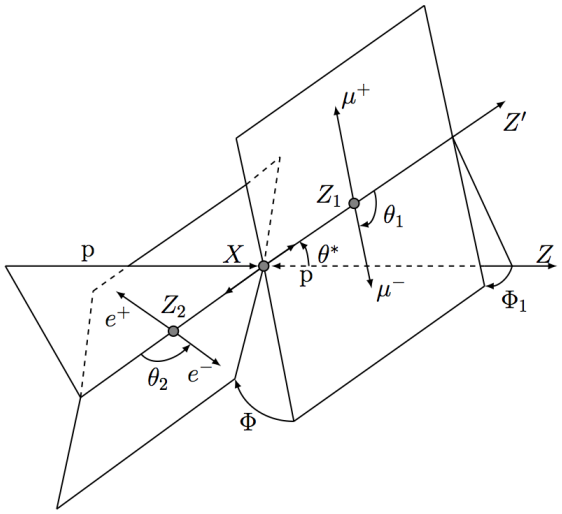

Figure 11.7: Definition of the production and decay angles defined for the $H \to ZZ^{(*)} \to 4\ell$ final state.

A different parametrisation of anomalous couplings of a spin-zero boson with two gauge bosons VV can also expressed in the

general form of the scattering amplitude A:

$$A \sim \left[a_1^{VV} - \frac{\kappa_1^{VV} q_1^2 + \kappa_2^{VV} q_2^2}{(\Lambda_1^{VV})^2} - \frac{\kappa_3^{VV}(q_1+q_2)^2}{(\Lambda_Q^{VV})^2} \right] m_{V_1}^2 \varepsilon_{V_1}^* \varepsilon_{V_2}^* + a_2^{VV} f_{\mu\nu}^{*(1)} f^{*(2)\mu\nu} + a_3^{VV} f_{\mu\nu}^{*(1)} \tilde{f}^{*(2)\mu\nu} \quad (11.21)$$

where ε_i is the polarization vector of the boson V_i, $f_{\mu\nu}^{*(i)} = \varepsilon_i^\mu q^\nu - \varepsilon_i^\nu q^\mu$ is a scalar tensor constructed from the vector boson V_i polarization and four momentum, $\tilde{f}_{\mu\nu}^{*(i)} = \frac{1}{2}\varepsilon_{\mu\nu\rho\sigma} f^{*(i)\rho\sigma}$ is the corresponding pseudo-scalar tensor. Λ_1 and Λ_Q are new physics scales, $a_{1,2,3}$ are coupling strength modifiers and $|\kappa_{(1,2,3)}^{VV}| = 0$ or 1. This parametrisation can be used both for gluons, photons and electroweak vector bosons, as well as the $Z\gamma$ coupling. In the case of the W and Z bosons, the custodial symmetry would require that $a^{WW} = a^{ZZ}$ and, at tree-level, the only non-zero contributions would come from the a_1 term. It is fully equivalent to the interaction Lagrangian approach described above. This formalism has been adopted by the CMS experiment.

Finally, CP-odd interactions can also be expressed in the framework of the Standard Model Effective Field Theory (SMEFT) in various possible bases (as discussed in Section 11.5.2). This formalism is more in line with analyses of a broader ensemble of observable probing the Standard Model. In this case the effective Lagrangian is defined as a function of the $\Phi^\dagger\Phi$ gauge invariant and the gauge field tensors before the electroweak symmetry breaking $W_{\mu\nu}^I$ and $B_{\mu\nu}$ with three operators, $\Phi^\dagger\Phi\tilde{W}_{\mu\nu}^I W^{I\mu\nu}$, $\Phi^\dagger\Phi\tilde{W}_{\mu\nu}^I B^{\mu\nu}$, and $\Phi^\dagger\Phi\tilde{B}_{\mu\nu}B^{\mu\nu}$, and their corresponding Wilson coefficients $c_{H\tilde{W}}$, $c_{H\tilde{W}B}$, and $c_{H\tilde{B}}$ respectively.

It is important to note that, as is apparant in Eq. (11.20), CP-odd couplings of the Higgs boson to vector boson are not allowed at tree level and are therefore suppressed at higher order by the scale Λ. Instead, CP-odd couplings of the Higgs boson to fermions are allowed at tree level, these can be parametrised in a somewhat simpler fashion with the following Lagrangian which accounts only for an additional pseudo-scalar term:

$$\mathcal{L}_0^{\psi_f} \supset \frac{\lambda_f}{\sqrt{2}} \left(\kappa_f H\overline{\psi}_f\psi_f + i\tilde{\kappa}_f H\overline{\psi}_f\gamma_5\psi_f \right). \quad (11.22)$$

This formulation is equivalent to a definition a CP-mixing angle $\varphi_f = \tan\frac{\tilde{\kappa}_f}{\kappa_f}$.

It is interesting to note that CP-odd Higgs couplings to fermions could have a significant impact on the very clean and precisely measured low energy observables as the electron EDM [253]. Owing to its large Yukawa couplings, the CP-odd top Yukawa is strongly constrained by the stringent electron EDM limits to better than $\tilde{\kappa}_t < 0.001$ [253]. This makes it very challenging at the LHC to surpass. However, one should keep in mind that EDM experiments provide an indirect constraint on the SM Yukawa couplings, in particular in this case they constrain the product $\kappa_e \times \tilde{\kappa}_t$, and one needs to make assumptions on the value of κ_e, a quantity that remains out of reach experimentally. The limits on the tau Yukawa coupling from the electron EDM constraints are much less stringent and at the level of $\tilde{\kappa}_\tau < 0.3$ [253]. This makes the possibility of measuring CP mixing of the fermion Higgs Yukawa couplings particularly interesting in the tau channels since these can be accessed from the Higgs decays directly using tau polarisation sensitive variable and will be discussed herein. For more details on the searches for CP-odd couplings of the Higgs boson to vector bosons please see previous versions of this review [188].

ii. *Spin-2 model*

The graviton-inspired interaction Lagrangian for a spin-2 boson $X^{\mu\nu}$ that does not carry any color, weak and electromagnetic charge and that uniquely interacts with the energy momentum tensor $\mathcal{T}^{V,f}$ of vector bosons V or fermions f, can be written as follows [252]:

$$\mathcal{L}_2 \supset \frac{1}{\Lambda}\left[\sum_V \xi_V \mathcal{T}_{\mu\nu}^V X^{\mu\nu} + \sum_f \xi_f \mathcal{T}_{\mu\nu}^f X^{\mu\nu} \right], \quad (11.23)$$

where the strength of the interaction is determined by the couplings ξ_V and ξ_f. The simplest scenarios, referred to as universal couplings (UC), correspond to $\xi_V = \xi_f$. They predict a large branching ratio to photons (of approximately 5%) and negligible couplings to massive gauge bosons (W and Z). They are therefore disfavoured, and other models are investigated where the couplings of the W, Z and γ are assumed to be independent. Universality of the couplings refers to $\xi_g = \xi_q$. Two other scenarios are considered: $\xi_q = 0$ and $\xi_q = 2\xi_g$. In these scenarios, a large enhancement of the tail of the transverse momentum of the spin-2 state is expected and requires a further selection requirement in order to probe the models within the range of validity of the effective field theory. Two requirements are considered, $p_T^X < 300\,\text{GeV}$ and $p_T^X < 125\,\text{GeV}$ [250].

11.4.1.3 *The VH production at D0*

The mass of the VH system is a powerful discriminant to distinguish a $J^P = 0^+$, with a threshold behaviour in $d\sigma/dM^2 \sim \beta, \beta^3, \beta^5$ from a 0^+, 0^- and 2^+ state, respectively [254]. The VH mass observable not only discriminates signal hypotheses, but also has an increased separation between the 0^- and 2^+ hypotheses with respect to the backgrounds, thus allowing, with a small and not yet significant signal yield, to exclude that the observed state is 0^- at 98% CL [255] and 2^+ at the 99.9% CL [256], assuming a signal produced with their best fit signal strength (which was $\mu = 1.23$).

11.4.1.4 *Probing the spin in the $\gamma\gamma$ channel at the LHC*

In the $H \to \gamma\gamma$ channel, the analysis is performed inclusively using the production angle $\cos\theta_{CS}^*$ and the transverse momentum of the diphoton pair [250]. The polar angle in the rest frame is defined with respect to the bisector axis of the momenta of the incoming protons and is referred to as the polar angle in the Collins–Soper frame [257]. The SM Higgs boson signal distribution is expected to be uniform with a cutoff due to the selection requirements on the photons transverse momentum. The $H \to \gamma\gamma$ channel is mostly sensitive to the gluon-initiated spin-2 production scenarios, which yield a $\cos\theta_{CS}^*$ distribution peaking at values close to 1. The ATLAS limits are derived from a fit of the signal in bins of $\cos\theta_{CS}^*$ and diphoton transverse momentum. The data is compatible with the SM 0^+ hypothesis and contributes strongly to the exclusion of several spin-2 scenarios. The conclusions are the same from CMS results [251].

11.4.1.5 *Probing CP-mixing and anomalous HVV couplings*

The careful study of the kinematic properties of angular distributions in events observed in the $H \to ZZ^{(*)} \to 4\ell$ and $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel, as well as the analysis of production observables sensitive to anomalous HVV interactions in the VBF or VH production have been used to set limits wither on CP-mixing parameters, amplitude terms ot Wilson coefficients in the framework of SMEFT. These analysis assume that the observed particle is a spin-0 state, several results were obtained by the ATLAS [258] and CMS [251] collaborations, all show a good agreement with the Standard Model CP-even hypothesis. Recent specific examples are given here.

In the $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel, the production and decay angles cannot be easily reconstructed due to the presence of neutrinos in the final state, however, sensitivity arises from the $V-A$ structure of the decay of the W bosons. A scalar state thus yields a clear spin correlation pattern that implies that the charged leptons e or μ from the decays of the W bosons are produced close to one another in the transverse plane. This feature impacts observables such as the azimuthal angle between the two leptons $\Delta\Phi_{\ell\ell}$ or their invariant mass $m_{\ell\ell}$ in addition to the threshold behaviour of the decay. It can be used to discriminate between various spin and parity hypotheses.

The $H \to ZZ^{(*)} \to 4\ell$ coupling analysis, as described in Section 11.3, also uses a discriminant based on the 0^+ nature of the Higgs boson to further separate signal and background. In this analysis, this feature is used to discriminate between signal hypotheses. The observables sensitive to the spin and parity have first been identified in Ref. [249, 259, 260] the masses of the two Z bosons (due to the threshold dependence of the mass of the

off-shell Z boson [249, 261]), two production angles θ^* and Φ_1, and three decay angles, Φ, θ_1 and θ_2. The production and decay angles are defined as:

– θ_1 and θ_2, the angles between the negative final state lepton and the direction of flight of Z_1 and Z_2 in the rest frame.

– Φ, the angle between the decay planes of the four final state leptons expressed in the four lepton rest frame.

– Φ_1, the angle defined between the decay plane of the leading lepton pair and a plane defined by the vector of the Z_1 in the four lepton rest frame and the positive direction of the proton axis.

– θ^*, the production angle of the Z_1 defined in the four lepton rest frame with respect to the proton axis.

These angles are illustrated in Fig. 11.7 [260].

These analyses are sensitive to various J^P hypotheses and in particular discriminate the 0^+ hypothesis from the 0^-. In all scenarios investigated, and for both ATLAS and CMS, the data is compatible with the 0^+ hypothesis. ATLAS and CMS exclude a pure pseudo-scalar nature of the observed boson at CL_S levels of 98% and 99.8% [251].

An individual ZZ^* channel measurement has also been carried out with a partial Run-2 dataset by ATLAS [258]. CMS has performed a CP-mixing analysis of a partial Run-2 dataset of $36\,\mathrm{pb}^{-1}$ combined with the full Run-1 data using the ZZ^* channel [262]. In this analysis the CMS experiment sets constraints on the parameters defined in the parametrisation (11.21) of the scattering amplitude.

With the full Run-2 dataset, analyses have started exploiting in combination both the production and decay modes of the Higgs boson as exemplified by the analysis carried out by ATLAS using the $H \to ZZ^* \to 4\ell$ analysis taking advantage of the production and decay angles of the process and VBF production sensitive observables [263]. Very similar analyses have been carried out in CMS as well. The analysis uses optimal observables constructed from matrix elements of the SMEFT. These optimal observables are defined from the ratio of the interference term between the Standard Model and the SMEFT matrix elements (normalised to the Standard Model) for given values of the Wilson coefficients $c_{H\tilde{W}}$, $c_{H\tilde{W}B}$, and $c_{H\tilde{B}}$ below Eq. (11.21). As illustrated in Fig. 11.8, all measurements are in agreement with the Standard Model. ATLAS has also performed a similar analysis with the Higgs boson decaying to two photons analysing the VBF production mode [264] which can then be used to constrain the $c_{H\tilde{W}}$ parameter as shown in Fig. 11.8.

An analysis of Higgs boson anomalous couplings HVV (as well as pseudo-scalar Yukawa coupling to the top) in the $H \to 4\ell$ channel was also carried out by CMS [265].

ATLAS has also performed an analysis using optimal observables [266], defined as the ratio of the interference between the CP-odd and the SM contributions normalised to the SM matrix element squared, using the Run-1 data. In this study, the CP-mixing contributions are described in the framework of an effective field theory governed by a single parameter $\tilde{d}$, found to be consistent with its SM value of $\tilde{d} = 0$ and constrained to the interval [-0.11,0.05] at the 68% CL.

CP invariance in the HVV coupling can also be probed with the VBF production process in the $H \to \tau^+\tau^-$ channel or similarly to the D0 analysis in the VH channels. CMS has performed an analysis in this channel and has combined its results with the aforementioned ZZ^* channel using the same dataset [267].

Finally two aditional specific measurements as for example in $H \to WW^*jj$ [268] by ATLAS and using the $H \to \tau^+\tau^-$ final state [269] by CMS in several production modes have also been used to set limits on both anomalous CP-even and CP-odd couplings.

These measurements show the complementarity of the study of production and decay modes, separately and in combination, and underscores the importance of a synthetic approach that combines all the available information.

11.4.1.6 *Probing $Hf\overline{f}$ coupling CP properties in $pp \to t\bar{t}H$ production*

Although EDM limits disfavour large CP-odd effects in the top Yukawa coupling of the Higgs boson, these indirect limits are model dependent. It is therefore important to further probe these effects directly. This can be achieved using the $pp \to t\bar{t}H$ process. The increased sensitivity to the this process at Run 2 in particular in the channels where the Higgs boson decays to a pair of photons provide a good sensitivity to the CP properties of the coupling through kinematics and angular distributions between the Higgs boson and the top quarks produced in the final state.

With the full Run-2 dataset, several Higgs boson decay channels have been investigated. ATLAS [270] excludes CP-mixing angles φ_t greater than 43° and smaller than −43° at 95% confidence level in the $H \to \gamma\gamma$ channel and has recently published constraints using the $H \to b\bar{b}$ channel with a measurement of $\varphi_t = 11^o\,{}^{+52^o}_{-73^o}$ [271].

Also using the full Run-2 dataset, CMS [272] measures the CP-odd fraction defined as follows:

$$f_{CP} = \frac{|\tilde{\kappa_t}|^2}{|\kappa_t|^2 + |\tilde{\kappa_t}|^2} \times \mathrm{sign}(\tilde{\kappa_t}/\kappa_t)$$

in the diphoton channel to be $f_{CP} = 0.00 \pm 0.33$. CMS also derived a constraint on the CP-odd fraction using the $H \to 4\ell$ channel [265]. More recently CMS has analysed the ttH multilepton channel, sensitive both to the $H \to WW$ and $H \to \tau^+\tau^-$ decays, to probe the top Yukawa CP properties [273], and combined its results with the two aforementioned channels to yield the following constraint on the CP-odd fraction:

$$|f_{CP}| = 0.28^{+0.27}_{-0.28}.$$

Both the ATLAS and CMS experiments used multivariate analyses in order to maximize the sensitivity to the measurement of the CP properties of the $Hf\overline{f}$ coupling. Both experiments used leptonic and hadronic decays of the top quarks.

11.4.1.7 *Probing $Hf\overline{f}$ coupling CP properties in $H \to \tau^+\tau^-$ decays*

As discussed in Section 11.4.1, it interesting to investigate the CP properties of the $Hf\overline{f}$ coupling is the Higgs decay to taus through tau polarisation sensitive variables.

CMS performed a first analysis with the full Run-2 dataset [274] of the transverse spin correlations between the tau leptons in the final state which are sensitive to the CP mixing angle or relative component of the scalar and pseudo scalar couplings of the Higgs boson to taus. These transverse spin correlations are in turn related to the direction of the decay products of the taus.

In the case of the two-body decay of a tau to a charged pion and a neutrino, the transverse momentum component of the charged pions are typically anti-aligned for the case of a scalar decay and aligned for the pseudo-scalar case. The angle between the decay planes as illustrated in Fig. 11.9-(left) is therefore sensitive to the CP-mixing. Given that the tau direction cannot be measured directly, the impact parameter direction is used instead as a proxy, where the impact parameter direction is defined as the direction between the interaction point and the point of closest approach of the pion track. This direction in the rest frame of the Higgs boson are denoted $\lambda^{\pm}$, as shown in Fig. 11.9-(centre). In the case of three-body or more decays of the taus as for example the decays to a intermediate rho or an $a_1(1260)$ vector mesons which subsequently decay to $\rho \to \pi^+\pi^0$ and $a_1 \to \pi^+\pi^0\pi^0$ respectively, the planes are defined as either as the (π^+, π^0) plane as as shown in Fig. 11.9-(centre) in the case of the ρ decay, or the plane formed by the cahrged pion and a combination of the two neutral pions in the case of the a_1 decay. The discrimination obtained, showing the two extreme fully scalar and pseudo-scalar cases are illustrated in Fig. 11.9-(right). ATLAS performed a similar analysis [275]. The results obtained are the following:

ATLAS	$\varphi_\tau = 9^o \pm 16^o$	$(0^o \pm 28^o)$	[274]
CMS	$\varphi_\tau = -1^o \pm 19^o$	$(0^o \pm 21^o)$	[275]

It is interesting to note that the precision reached by both experiments is already at the level that was foreseen for HL-LHC by initial studies [276], which yielded a precision ranging between $\pm 18^o$ and $\pm 30^o$.

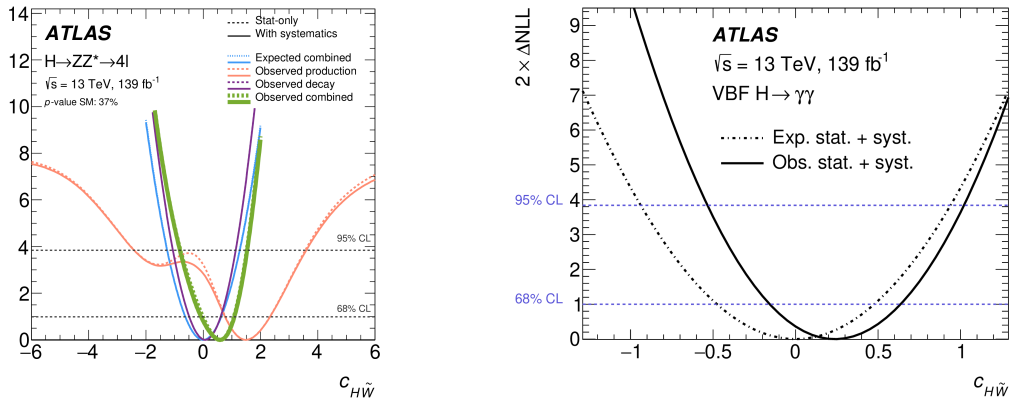

Figure 11.8: The measurement of the $c_{H\tilde{W}}$ Wilson coefficent based on the optimal observable sensitive to the Higgs boson production, its decay and their combination (left) for the ATLAS $H \to ZZ^* \to 4\ell$ analysis. The measurement of the $c_{H\tilde{W}}$ Wilson coefficent based on optimal observable sensitive to the Higgs boson production in the VBF channel (right) for the ATLAS $H \to \gamma\gamma$.

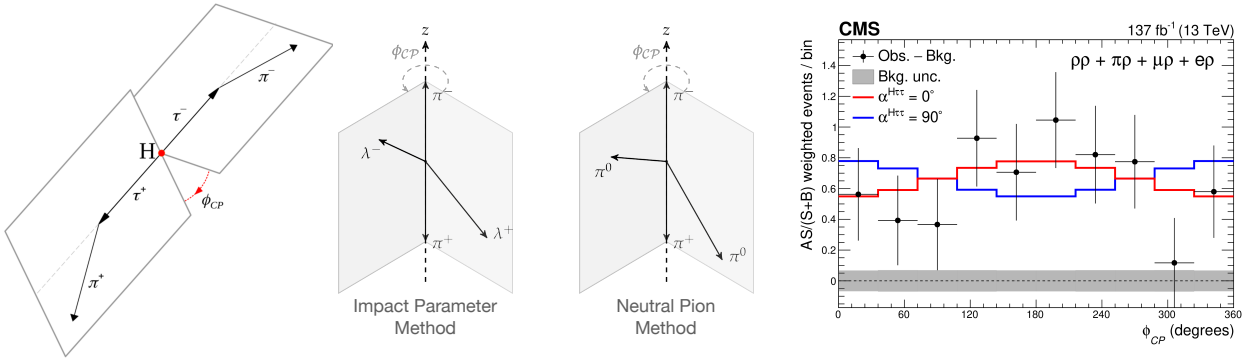

Figure 11.9: Sketch of the definition of the φ_{CP} angle for for the decays $\tau^{\pm} \to \pi^{\pm}\nu_{\tau}$ (left) and the definition at reconstruction level of φ_{CP} observables (center). The distribution weighted per tau decay categories of the φ_{CP} observables, including the expected distributions for the expected pure scalar or pure pseudo scalar cases.

11.4.2 *Off-shell couplings of the Higgs boson*

In the dominant ggF production mode with a subsequent decay of the Higgs boson into a pair of electroweak vector bosons, the production cross section of an off-shell Higgs boson is known to be sizeable. This follows as a consequence of the enhanced couplings of the Higgs boson to the longitudinal polarization of the massive vector bosons at high energy.

The off-shell to on-shell cross section ratio is approximately 8% in the SM [277]. This part of the 'off-shell' regime corresponding to the exchange of a Higgs boson as a propagator and not as a narrow mass state is very interesting as it is sensitive to physics beyond the SM. Still, the Higgs contribution to VV production at large invariant mass remains small compared to the background. In addition, the difficulty in the off-shell VV analysis, beyond the small signal-to-background ratio, is due to a large negative interference between the signal and the $gg \to VV$ background.

The resulting presence of a SM Higgs boson signal in the far off-shell domain results in a deficit of events with respect to the expectation from background only events. It is only when the off-shell couplings of the Higgs boson are larger than expected in the SM that the presence of a signal appears as an excess over the background expectation. One additional intricacy arises from the precision in the prediction of the rate for $gg \to VV$, a loop process at lowest order, and its interference with the signal.

Besides this 'continuum' $gg \to VV$ background with which the 'off-shell' Higgs process interferes, the largest background comes from the $qq \to VV$ production, making this analysis very challenging.

It is interesting to note that, in this regime, the Higgs boson is studied as a propagator and not as a particle. The measurement of its off-shell couplings is therefore absolute and does not rely on the knowledge of the total Higgs boson width. The off-shell coupling constraints can then be used to indirectly constrain the width of the Higgs boson, under specific assumptions detailed in Section 11.4.3.3.

This measurement has been carried out in the $H \to ZZ \to 4\ell$, $H \to ZZ \to \ell\ell\nu\nu$ and $H \to WW \to \ell\nu\ell\nu$ channels, via the ggF, VBF and VH production modes. To enhance the sensitivity of the analysis, the knowledge of the full kinematics of the events is important. In particular the signal and the background can be further distinguished by the invariant mass of the VV system, which is more accurately accessible in the $H \to ZZ \to 4\ell$ channel. Angular distributions also play an important role in this analysis. For these reasons, the $H \to ZZ^{(*)} \to 4\ell$ channel is significantly more sensitive than $H \to WW^{(*)} \to \ell\nu\ell\nu$.

Limits on the off-shell rates have been reported for the two channels by ATLAS [278] and CMS [279] with Run-1 data. The combined results, assuming that the off-shell rates in the ZZ and WW channels scale equally, are given for two different hypotheses on the VBF production rate: fixing it to its SM value or scaling it as the gluon fusion rate. The observed (expected) limits on the off-shell rate fraction with respect to its SM expectation is 6.7 (9.1) for ATLAS [278] with the VBF rate fixed to its SM value and 2.4 (6.2) for CMS [279] where no assumption is made on the relative production rates of gluon-fusion and VBF. In both cases, the custodial symmetry is assumed and the ratio of the rates in the ZZ and WW decays are fixed to those of the SM. Results without this assumption have also been reported in Ref. [279].

The situation using the Run-2 data has significantly changed. Both ATLAS [280] and CMS [281] have performed off-shell Higgs boson analyses to constrain the off-shell Higgs boson production rates with the full Run-2 datasets using the $H \to ZZ^*$ channel. The results obtained have already reached an impressive sensitivity. Both experiments have considered two independent off-shell contributions, the first corresponding to the ggF production denoted $\mu_{\mathrm{g,off-shell}}$ and the second corresponding the VBF and VH denoted $\mu_{\mathrm{V,off-shell}}$. For simplicity we will report only the results considering $\mu_{\mathrm{g,off-shell}} = \mu_{\mathrm{V,off-shell}} = \mu_{\mathrm{off-shell}}$ here.

The first striking result is that both experiments exclude the background-only hypothesis $\mu_{\mathrm{off-shell}} = 0$ with a significance of 3.2σ (2.2σ) observed (expected) for ATLAS [280] and 3.6σ for CMS [281]. This corresponds to a first evidence for the off-shell production of a Higgs boson, through the measurment of a significant deficit in the overall $gg \to VV$ production.

The measured off-shell signal strengths $\mu_{\mathrm{off-shell}}$ are the following:

$$\begin{aligned} &\text{(ATLAS)}\ \ \mu_{\mathrm{off-shell}} = 1.1^{+0.7}_{-0.6}\ \text{(obs)}\ \ [1.00^{+0.9}_{-0.9}\ \text{(exp)}], \\ &\text{(CMS)}\ \ \mu_{\mathrm{off-shell}} = 0.74^{+0.56}_{-0.38}\text{(obs)}\ \ [1.00^{+1.00}_{-0.84}\ \text{(exp)}]. \end{aligned} \tag{11.24}$$

11.4.3 *The Higgs boson width*

In the SM, the Higgs boson width is very precisely predicted once the Higgs boson mass is known. For a mass of 125 GeV, the Higgs boson has a very narrow width of 4.1 MeV [40]. It is dominated by the fermionic decays partial width at approximately 75%, while the vector boson modes are suppressed and contribute 25% only.

At the LHC or the Tevatron, in all production modes, only the cross sections times branching fractions can be measured. As a consequence, the total width of the Higgs boson cannot be directly derived form the measurements of Higgs boson rates without additional assumptions. Direct constraints on the Higgs boson width are much larger than the expected width of the SM Higgs boson.

11.4.3.1 *Direct constraints*

Analyses of the reconstructed mass line-shape in the two channels with a good mass resolution, the $H \to \gamma\gamma$ and $H \to ZZ^{(*)} \to 4\ell$ channels, allow for a direct measurement of the width of the SM Higgs boson. The intrinsic mass resolution in these channels is about 1–2 GeV, much larger than the expected width of the SM Higgs boson. As a result, only upper limits on the Higgs boson width have been set by ATLAS [282] and more recently CMS [152]. The two main challenges of direct constraints on the width through the measurement of the line-shape are: (i) the modelling of resolution uncertainties and (ii) the modelling of the interference between the signal and the continuum background which can be sizeable for large widths, in particular in the range where direct constraints are set. These challenges affect mostly the diphoton channel. Given that these interference effects are small with respect to the individual channels sensitivity, they are neglected in deriving constraints on the total width. The combined constraints, however, being more precise, could be affected by the interference. Direct lineshape measurements provide the most unambiguous access to the Higgs boson width, however constraints are still two orders of magnitude larger than the expected SM width. The current results are fully compatible with the SM hypothesis. The most stringent limit is obtained by CMS of 330 MeV at 95% CL [152].

Another direct constraint on the Higgs boson width can be obtained, in the $H \to ZZ^{(*)} \to 4\ell$ channel, from the measurement of the average lifetime of the Higgs boson calculated from the displacement of the four-lepton vertex from the beam spot. This analysis has been carried out by CMS (see references in Ref. [141]), using the measured decay length. The measured $c\tau_H$ is 2^{+25}_{-2} μm, yielding an observed (and expected) limit at the 95% CL of $c\tau_H < 57(56)\,\mu$m. From this upper limit on the lifetime of the Higgs boson, the 95% CL lower limit on its width is $\Gamma_H > 3.5 \times 10^{-12}$ GeV.

11.4.3.2 *Indirect constraints from mass shift in the diphoton channel*

In the diphoton channel, it was noticed in Ref. [283], that the effect of the interference between the main signal $gg \to H \to \gamma\gamma$ and the continuum irreducible background $gg \to \gamma\gamma$, taking into account detector resolution effects, is responsible for a non negligible mass shift. The size of the mass shift depends on the total width of the Higgs boson and it was suggested that measuring this mass shift could provide a constraint on the width [283]. It was further noticed that the mass shift has a dependence also on the diphoton transverse momentum. The total width of the Higgs boson could therefore be constrained using the diphoton channel alone.

Further studies were performed by ATLAS to estimate the size of the expected mass shift [284]. The expected shift in mass in the diphoton channel is 35±9 MeV for the SM Higgs boson. Very preliminary studies of the sensitivity of this method to estimate the width of the Higgs boson in the High-Luminosity regime have been made by ATLAS [285] and yield an expected 95% CL upper limit on the total width of approximately 200 MeV from 3 ab^{-1} of 14 TeV data.

11.4.3.3 *Indirect constraints from on-shell rate in the diphoton channel*

In the diphoton channel, it was noticed in Ref. [286], that the interference between the main signal $gg \to H \to \gamma\gamma$ amplitude and the continuum irreducible background $gg \to \gamma\gamma$ amplitude generates non-negligible change in the on-shell cross sections, as a result of the existence of a relative phase between these amplitudes. The size of this on-shell interference effect depends on the total width of the Higgs boson and it was suggested that measuring this on-shell cross section precisely could provide a constraint on the Higgs total width. This interference effect yields a reduction of around 2% for the $gg \to H \to \gamma\gamma$ cross section measurement in the SM. The current evaluation of this interference effect is performed at NLO and has a $^{+50\%}_{-30\%}$ uncertainty, due to the fact that the large relative phase is driven by the two-loop $gg \to \gamma\gamma$ background amplitude [283, 286]. This on-shell interference effect has a dependence on the p_T of the diphoton system and the photon polar angle in the diphoton rest frame, which can be further exploited to improve the measurement to constrain the Higgs total width.

Taking the ratios of the on-shell cross section of Higgs boson to diphoton channel and the cross section of Higgs boson to four-leptons channel where the interference effect is negligible could put a bound on the Higgs boson total width. This ratio is free from many dominant sources of systematic uncertainties for cross section measurements, i.e., PDF uncertainty and luminosity uncertainty, and can be further improved by the accumulation of the LHC data. From this cross section ratio measurement alone, a preliminary estimation of the current limit from this interference effect with current 30% precision puts an upper bound of 800 MeV on the Higgs boson total width and the limit improves to 60 MeV with 3 ab^{-1} of 14 TeV data [286, 287].

11.4.3.4 *Indirect constraints from off-shell couplings*

Using simultaneously on-shell and off-shell measurements in the VV channels, it was noticed [277, 288] that the total width of the Higgs boson could be constrained. This can be illustrated from the parametrisation of the signal strength measurements both on-shell ($\mu_{\mathrm{on-shell}}$) and off-shell ($\mu_{\mathrm{off-shell}}$) as a function of the couplings modifiers κ_g and κ_V parameterizing the main process $gg \to H \to VV$ (see Section 11.5.1 for the definition of these coupling modifiers). The on-shell and off-shell signal strengths can be written as:

$$\begin{aligned} \mu_{\mathrm{on-shell}} &= \frac{\kappa^2_{g,\,\mathrm{on-shell}}\,\kappa^2_{V,\,\mathrm{on-shell}}}{\Gamma_H/\Gamma_{\mathrm{SM}}}, \\ \mu_{\mathrm{off-shell}} &= \kappa^2_{g,\,\mathrm{off-shell}}\,\kappa^2_{V,\,\mathrm{off-shell}}. \end{aligned} \tag{11.25}$$

A bound on the Higgs boson width can then be obtained from the measurements of the on-shell and off-shell signal strengths. This assumes that no new physics alters the Higgs boson couplings in

the off-shell regime, i.e., that the running of its couplings in this energy range does not differ from the Standard Model [289, 290].

Both ATLAS [278] and CMS [281] have used their very strong off-shell production analyses described above, with kinematic event characteristics to further gain in sensitivity to discriminate between the signal and background.

In addition, in the CMS analysis, results are also derived allowing for anomalous couplings of the Higgs boson, therefore reducing the discriminating power of the kinematic variables used in the analysis but reducing the model dependence. The sensitivity already reached at Run 2 is remarkable:

$$\text{(ATLAS)}\quad \Gamma_H = 4.5^{+3.3}_{-2.5}\ [4.1^{+3.8}_{-3.8}\ \text{(exp)}]\ \text{MeV}, \qquad (11.26)$$

$$\text{(CMS)}\quad \Gamma_H = 3.2^{+2.4}_{-1.7}\ [4.1^{+4.0}_{-3.5}\ \text{(exp)}]\ \text{MeV}. \qquad (11.27)$$

ATLAS and CMS have also performed a study of the prospects for measuring the Higgs boson width mainly in the four lepton channel. Projecting to a luminosity of $3\,\text{ab}^{-1}$, it was concluded that, within assumptions similar to the ones mentioned above and assuming the SM central value, the width of the Higgs boson could be constrained with the following precision [118]:

$$\Gamma_H = 4.1^{+0.7}_{-0.8}\ \text{MeV}. \qquad (11.28)$$

11.5 Probing the coupling properties of the Higgs boson

As discussed in Section 11.2, within the SM, all the Higgs boson couplings are fixed unambiguously once all the particle masses are known. Any deviation in the measurement of the couplings of the Higgs boson could therefore signal BSM physics.

Measuring the Higgs boson couplings without relying on the SM assumption requires a general framework treating deviations from the SM coherently at the quantum level in order to provide theoretical predictions for relevant observables to be confronted with experimental data. An attempt in that direction has been formalised in the so-called κ-formalism [291], following earlier attempts [292] and initial phenomenological studies of the first hints of the existence of the Higgs boson [293]. In this LO-inspired approach, the SM Higgs boson couplings are rescaled by arbitrary factors, κ's, keeping the same Lorentz structure of the interactions. This formalism allows for simple interpretation of the signal strengths measured in the various Higgs channels. It has been utilised to test various physics scenarios, like the existence of additional new particles contributing to the radiative Higgs boson production and decays, or to probe various symmetries of the SM itself, as for example the custodial symmetry. It only compares the experimental measurements to their best SM predictions and does not require any new BSM computations per se. And, from a more theoretical perspective, its relevance arises from the fact that it actually fully captures the leading effects in single Higgs processes of well motivated scenarios. Still, the κ-formalism has obvious limitations and certainly does not capture the most general deformations of the SM, even under the assumptions of heavy and decoupling new physics. A particularly acute shortcoming at the time Higgs physics is entering a precision era is the lack of proficiency to assert the richness of kinematical distributions beyond simple signal strength measurements. Several extensions and alternative approaches are being developed as part of the activities of the LHC Higgs Cross Section Working Group [43].

The Higgs Pseudo-Observable (HPO) approach [294] allows one to report the data in terms of a finite set of on-shell form factors parametrising amplitudes of physical processes subject to constraints from Lorentz invariance and other general requirements like analyticity, unitarity, and crossing symmetry. These form factors are expanded in powers of kinematical invariants of the process around the known poles of SM particles, assuming that poles from BSM particles are absent in the relevant energy regime. A set of HPOs have been proposed to characterise both the Higgs boson decays and the EW Higgs boson production channels, thus exploring different kinematical regimes. Prospective studies concluded that these HPOs can be measured/bounded at the percent level at the HL-LHC and could therefore be used to constrain some explicit models of new physics.

Another systematic and popular approach to characterise the possible Higgs boson coupling deviations induced by BSM physics is the use of Effective Field Theories (EFT) [295, 296]. This approach assumes again that the new physics degrees of freedom are sufficiently heavy to be integrated out, and they give rise to effective interactions among the light SM particles. By construction, an EFT approach cannot systematically account for deviations in Higgs physics induced by light degrees of freedom unless they are added themselves as extra fields in the effective Lagrangians, requiring to know about these light fields beforehand. In Section 11.6, several examples of models with light degrees of freedom affecting Higgs boson production and decay rates will be presented. Like in explicit UV models and unlike the κ-approach, the main advantage of EFTs is their prowess to relate different observables in different sectors and at different energies to constrain a finite set of effective interactions among the SM degrees of freedom. In an EFT, the SM Lagrangian is extended by a set of higher-dimensional operators, and it reproduces the low-energy limit of a more fundamental UV description. It will be assumed that the Higgs boson is part of a CP-even EW doublet, Φ, and that the Lagrangian is an analytic function of the gauge invariant $\Phi^\dagger\Phi$. This scenario is commonly referred as SMEFT. Even though it is not fully established experimentally, this set-up is motivated by the measurements of the Higgs couplings to the different SM particles that show an alignement with their masses, such an alignment naturally follows under this assumption of a linear realisation of the $\text{SU(2)}_L \times \text{U(1)}_Y$ symmetry of the SM. General Lagrangians bypassing this linear assumption have been explicitly written down, see for instance Ref. [297], and connections with explicit UV models made [298, 299]. They rely on a chiral expansion with a specific power-counting, effectively resumming the expansion in powers of the Higgs field, usually referred as HEFT as opposed to SMEFT.

11.5.1 *Probing coupling properties*

11.5.1.1 *From effective Lagrangians to Higgs observables*

The κ framework, described in detail in Ref. [39,291], facilitates the characterisation of Higgs coupling properties in terms of a series of Higgs coupling strength modifier parameters κ_i, which are defined as the ratios of the couplings of the Higgs bosons to particles i to their corresponding SM values. The κ framework assumes a single narrow resonance so that the zero-width approximation can be used to decompose the cross section as a product of two factors characterising the production and the decay of the Higgs boson. The κ parameters are introduced by expressing each of the these factors as their SM expectation multiplied by the square of a coupling strength modifier for the corresponding process at leading order:

$$\begin{aligned}(\sigma\cdot\text{BR})(i\to\text{H}\ \to f) &= \frac{\sigma_i^{SM}\kappa_i^2\cdot\Gamma_f^{SM}\kappa_f^2}{\Gamma_H^{SM}\kappa_H^2} \quad\to\\ \to\quad \mu_i^f &\equiv \frac{\sigma\cdot\text{BR}}{\sigma_{\text{SM}}\cdot\text{BR}_{\text{SM}}} = \frac{\kappa_i^2\cdot\kappa_f^2}{\kappa_H^2},\end{aligned} \qquad (11.29)$$

where μ_i^f is the rate relative to the SM expectation and κ_H^2 is an expression that adjusts the SM Higgs width to take into account the modifications induced by the deformed Higgs boson couplings. When all κ_i are set to 1, the SM is reproduced. For loop-induced processes, e.g. $H\to\gamma\gamma$, there is a choice of either resolving the coupling strength modification in its SM expectation, i.e., $\kappa_\gamma(\kappa_t,\kappa_W)$ or keeping κ_γ as an effective coupling strength parameter.

The κ-framework is the simplest parametrisation directly related to experimental measurements of the Higgs boson production and decay modes. For this reason, it has been widely used by the community. It can also be connected to the SMEFT formalism as follows. Restricting to the EFT directions not probed outside Higgs physics [300], the Higgs boson couplings are written

in the unitary gauge as:

$$\begin{aligned}\mathcal{L} = &\kappa_Z \frac{m_Z^2}{v} Z_\mu Z^\mu H + \kappa_W \frac{2m_W^2}{v} W_\mu^+ W^{-\mu} H \\ &+ \kappa_{VV} \frac{\alpha}{2\pi v} \left(\cos^2\theta_W Z_{\mu\nu} Z^{\mu\nu} + 2\, W_{\mu\nu}^+ W^{-\mu\nu}\right) H \\ &+ \kappa_g \frac{\alpha_s}{12\pi v} G_{\mu\nu}^a G^{a\mu\nu} H + \kappa_\gamma \frac{2\alpha}{9\pi v} A_{\mu\nu} A^{\mu\nu} H + \kappa_{Z\gamma} \frac{\alpha}{\pi v} A_{\mu\nu} Z^{\mu\nu} H \\ &- \sum_F \kappa_F \frac{m_F}{v} \overline{F} F H + \kappa_3 \frac{m_H^2}{2v} H^3 + \ldots .\end{aligned} \tag{11.30}$$

The exact correspondence between the effective coefficients of the dimension-6 operators and the κ's can be found for instance in Ref. [40]. In the SM, the Higgs boson does not couple to massless gauge bosons at tree level, hence $\kappa_g = \kappa_\gamma = \kappa_{Z\gamma} = 0$. Nonetheless, the contact operators are generated radiatively by SM particle loops. In particular, the top quark gives a contribution to the 3 coefficients $\kappa_g, \kappa_\gamma, \kappa_{Z\gamma}$ that does not decouple in the infinite top mass limit (for instance, in that heavy limit, the top quark contribution amounts to $\Delta\kappa_\gamma = \Delta\kappa_g = 1$ [21, 22, 301], while the $W^\pm$ also contributes to κ_γ). Depending on the nature of new physics, these effective couplings can be generated at tree level or only at the radiative/loop level, see Refs. [295,302–304] for further discussions.

The coefficient for the contact interactions of the Higgs boson to the W and Z field strengths is not independent but obeys the relation

$$(1 - \cos^4\theta_W)\kappa_{VV} = \sin 2\theta_W \kappa_{Z\gamma} + \sin^2\theta_W \kappa_{\gamma\gamma}. \tag{11.31}$$

This relation is a general consequence of the custodial symmetry [305], which also imposes $\kappa_Z = \kappa_W$ at leading order ($\kappa_Z/\kappa_W - 1$ is a measure of custodial symmetry breaking and, as such, is already constrained by electroweak precision data and the bounds on anomalous gauge couplings). When the Higgs boson is part of an $\mathrm{SU}(2)_L$ doublet, the custodial symmetry in the bosonic sector could only be broken by the $\mathcal{O}_T = \frac{1}{2}\left(\Phi^\dagger \overleftrightarrow{D}^\mu \Phi\right)^2$ operator at the level of dimension-6 operators and it is accidentally realised among the interactions with four derivatives, like the contact interactions considered.

The coefficient κ_3 is the trilinear Higgs boson self-coupling parameter which corresponds to the more generic κ_λ self-coupling parameter discussed in Section 11.3.9.1. Before the associated production of a Higgs boson with a pair of top quarks was observed, the Higgs boson coupling to the top quark was only probed indirectly via the one-loop gluon fusion production or the radiative decay into two photons. However, these two processes are only sensitive to the combinations of couplings $(\kappa_t + \kappa_g)$ and $(\kappa_t + \kappa_\gamma)$ and not to the individual couplings. Therefore a deviation in the Higgs boson coupling to the top quark can in principle always be masked by new contact interactions to photons and gluons (and this is precisely what is happening in minimal incarnations of composite Higgs models [306]). The current and still limited sensitivity, of the order of 20%, in the $t\bar{t}H$ channel leaves elongated ellipses in the direction $\kappa_g = \kappa_\gamma = 1 - \kappa_t$.

The operators already bounded by EW precision data and the limits on anomalous gauge couplings modify in general the Lorentz structure of the Higgs couplings and hence induce some modifications of the kinematical differential distributions [307]. A promising way to have a direct access to the effective coefficients of these operators in Higgs physics is to study the VH associated production with a W or a Z at large invariant mass of the VH system [308]. These differential distributions could also be a way to test the hypothesis that the Higgs boson belongs to a $\mathrm{SU}(2)_L$ doublet together with the longitudinal components of the massive electroweak gauge bosons.

11.5.1.2 *Measurements of the Higgs boson coupling properties*

As described in Section 11.3, a framework was developed by ATLAS and CMS [153], individually and together, to combine the very large number of exclusive categories aimed at reconstructing the five main decay modes and the five main production modes of the Higgs boson. The general conclusion of this combination, illustrating the compatibility of the observation with the SM expectations, is given in Section 11.3. The same framework with its master formula, Eq. (11.14), can be used to further measure coupling properties of the Higgs boson under specific additional assumptions.

i. *Interpretations of the experimental data*

The measurements of the coupling properties of the Higgs boson are entirely based on the formalism of the effective Lagrangian described above. Measurements of coupling properties in this framework implies assessing the parameters of the model Eq. (11.30) or combinations of these parameters with different sets of assumptions.

These measurements are carried out with the combination framework described in Section 11.3.6, where the μ_i and μ_f signal strength parameters are further interpreted in terms of modifiers of the SM couplings κ_k where $k \in \{Z, W, f, g, \gamma, Z\gamma\}$ as in Eq. (11.30). The number of signal events per category for the various production modes are typically estimated at higher orders in the analyses but are scaled by these single LO-inspired factors, thus not taking into account possible intricacies and correlations of these parameters through the higher-order corrections. This approximation is valid within the level of precision of current results and their compatibility with the SM expectation.

In this formalism, further assumptions are explicitly made: (i) the signals observed in the different search channels originate from a single narrow resonance with a mass of 125 GeV; (ii) similarly to the combination described in Section 11.3.6, the narrow width approximation is assumed (to allow the decomposition of signal yields into products of production and decay signal strengths); (iii) the tensor structure of the couplings is assumed to be the same as that of a SM Higgs boson. This means in particular that the observed state is assumed to be a CP-even scalar as in the SM.

Loop-level couplings such as the $gg \to H$, $H \to \gamma\gamma$ and $H \to Z\gamma$ can either be treated effectively, with κ_g, κ_γ and $\kappa_{Z\gamma}$ as free parameters in the fit or these parameters can be expressed in terms of the know SM field content and as a function of the SM coupling modifiers, in the following way [309] by either scaling cross sections (for κ_g given for a centre-of-mass energy of 13 TeV and a Higgs boson mass of 125 GeV) or partial widths (for κ_γ and $\kappa_{Z\gamma}$ for a Higgs boson mass of 125 GeV):

$$\begin{aligned}\kappa_g^2(\kappa_t, \kappa_b, \kappa_c) = &\, 1.042\,\kappa_t^2 - 0.040\,\kappa_t\kappa_b + 0.002\,\kappa_b^2 \\ &- 0.005\kappa_t\kappa_c + 0.0005\kappa_b\kappa_c + 0.00002\kappa_c^2, \\ \kappa_\gamma^2(\kappa_t, \kappa_W) = &\, 1.59\,\kappa_W^2 - 0.66\,\kappa_W\kappa_t + 0.07\,\kappa_t^2, \\ \kappa_{Z\gamma}^2(\kappa_t, \kappa_W) = &\, 1.12\,\kappa_V^2 - 0.15\,\kappa_V\kappa_F + 0.03\,\kappa_F^2.\end{aligned} \tag{11.32}$$

It should be noted that the parametrisation of the gluon coupling modifier could also be used to scale the $H \to gg$ partial width and would be different from the cross section parametrisation. However when considered effectively, i.e., without resolving the content of the loop in terms of SM fields, it can be assumed that the scaling behaviour of the production cross section and partial width will be very similar.

The parametrisations are given for a Higgs boson mass hypothesis of 125 GeV (and in the last two expressions, all the Higgs-fermion couplings are assumed to be rescaled by an universal multiplicative factor κ_F). It can be noted from the expression of κ_γ that the coupling of the Higgs boson to photons is dominated by the loop of W bosons, and it is affected by the top quark loop mostly through its interference with the W loop. The sensitivity of the current measurements to the relative sign of the fermion and vector boson couplings to the Higgs boson is due to this large negative interference term. The κ_g parameter is expressed in terms of the scaling of production cross sections and therefore also depends on the pp collisions centre-of-mass energy. The parametrisations of κ_γ and $\kappa_{Z\gamma}$ are obtained from the scaling of partial widths and are only dependent on the Higgs boson mass hypothesis. Experiments use a more complete parametri-

sation with the contributions from the b-quarks, τ-leptons in the loops [39, 291].

The global fit is then performed expressing the μ_i and μ_f parameters in terms of a limited number of κ_k parameters or their ratios, under various assumptions. The parametrisation for the main production modes are: (i) $\mu_{\rm ggF} = \kappa_g^2$ for the gluon fusion and an effective coupling of the Higgs boson to the gluons; (ii) $\mu_{{\rm VBF},VH} = \kappa_V^2$ for the VBF and VH processes when the W and Z couplings are assumed to scale equally, and $\mu^2_{\rm VBF}(\kappa_W, \kappa_Z) = (\kappa_W^2\sigma_{WWH} + \kappa_Z^2\sigma_{ZZH})/(\sigma_{WWH} + \sigma_{ZZH})$, when the couplings to the W and Z bosons are varied independently (σ_{WWH} and σ_{ZZH} denote the VBF cross sections via the fusion of a W and a Z boson respectively, the small interference term is neglected); (iii) $\mu_{t\bar{t}H} = \kappa_t^2$ for the $t\bar{t}H$ production mode. Numerically the production modes signal strengths as a function of the coupling modifiers to the SM fields for a centre-of-mass energy of 13 TeV and and Higgs boson mass of 125 GeV are:

$$\begin{aligned} &\mu_{\rm ggF} = 1.040\kappa_t^2 + 0.002\kappa_b^2 - 0.038\kappa_t\kappa_b, \quad \text{and} \\ &\mu_{\rm VBF} = 0.73\kappa_W^2 + 0.27\kappa_Z^2. \end{aligned} \tag{11.33}$$

The decay mode signal strengths are parametrised as $\mu_k = \kappa_k^2/\kappa_H^2$ where $k \in \{Z, W, f, g, \gamma, Z\gamma\}$ denotes the decay mode and κ_H, the overall modifier of the total width that affects all the signal yields. κ_H is a priori an independent parameter. However, when it is assumed that the Higgs boson cannot decay to new particles beyond those of the SM, κ_H can also be treated as an effective parameter and expressed in terms of the coupling modifiers to the SM field content. Its general expression is:

$$\begin{aligned} \kappa_H^2 =& 0.57\kappa_b^2 + 0.06\kappa_\tau^2 + 0.03\kappa_c^2 + 0.22\kappa_W^2 + 0.03\kappa_Z^2 + 0.09\kappa_g^2 \\ &+ 0.0023\kappa_\gamma^2. \end{aligned} \tag{11.34}$$

The general expression of the total width of the Higgs boson can be written as follows:

$$\Gamma_H = \frac{\kappa_H^2 \Gamma_H^{\rm SM}}{1 - {\rm BR}_{\rm BSM}} \tag{11.35}$$

where $\Gamma_H^{\rm SM}$ is the total width of the SM Higgs boson and ${\rm BR}_{\rm BSM}$ is the branching fraction of the Higgs boson to new particles beyond the SM.

It is worth reminding that, in the absence of a measurement of the Higgs width wich can be accessed through Off-Shell couplings measurements as discussed inSection 11.4.2, LHC requires some hypotheses in order to extract the Higgs couplings from the measured Higgs signal strengths. In particular, one can assume either (i) no BSM particles in the decay, or (ii) any BSM particles in the decay would give rise to invisble signatures and thus be detectable through invisible Higgs boson channels (or in other terms that there is no BSM undetected contribution), or (iii) $|\kappa_V| \leq 1$. These scenarios will be examined below.

Specific parametrisations will be made in order to address the following aspects of the coupling properties of the Higgs boson under different assumptions, depending essentially on two assumptions concerning either the natural width of the Higgs boson, whether it consists of partial width from Standard Model particles only or not, or the effective couplings of the Higgs boson to photons, gluons, $Z\gamma$ and $\gamma^*\gamma$, whether these contributions are parametrised as function of the Standard Model field content in the loops or whether these couplings are considered as effective.

Negative values of couplings are not excluded a priori, but would imply the existence of new physics at a light scale and would also raise questions about the validity of the perturbative treatment of the SM deformations and also about the stability of the vacuum [310]. Since the results are only sensitive to the relative sign of vector bosons with respect to fermions, by convention negative coupling values will only be considered for vector boson couplings. Among the five main Higgs boson decay channels, only the $\gamma\gamma$ is sensitive to the sign of κ_F (or κ_V) through the interference of the W and t loops as shown in Eq. (11.32). The current global fit disfavours a negative value of κ_F at more than five standard deviations. A specific analysis for the Higgs boson production in association with a single top quark has been proposed in order to more directly probe the sign of κ_F (see references in Ref. [141]). All available experimental data show a fair agreement of the SM prediction of the couplings of the Higgs boson to fermions and gauge bosons.

ii. *Coupling measurements and probing BSM physics in loops and in the decay*

Measuring Higgs boson couplings to other Standard Model fields requires either assumptions on the total Higgs boson width, or an assumption on the coupling of the Higgs boson to vector bosons, or a direct constraint on the Higgs boson width as the one obtained from the ratio of off-shell to on-shell Higgs boson couplings. These three cases will be discussed briefly. With the precision reached by analyses discussed in Section 11.3.1, strong assumptions on the BSM content of the loop-induced couplings of the Higgs boson to vector bosons as Hgg, $H\gamma\gamma$ or $HZ\gamma$ are not needed and these couplings can be considered as effective and provide a stringent probe of new fields potentially entering the loop.

Using the full Run-2 dataset and the formalism described in Section i., ATLAS [183] and CMS [184], have performed interpretations of the results presented in Section 11.3.6 to derive measurements of the Higgs boson couplings. These results are summarised in Table 11.8.

The results above are obtained under the assumption that the Higgs boson decays only to SM particles. The degeneracy that originates from the fact that at LHC only production cross sections times branching fractions are measured is embodied in the degeneracy between all κ factors and κ_H. It is interesting to note that in order to measure all couplings to be in agreement with the Standard Model model value requires that any deviation in the Higgs boson total width or κ_H be precisely compensated by all couplings to Standard Model fields in the same fashion. This is often referred to a flat direction, meaning that all the couplings are scaled by a factor α and the Higgs boson width by a factor α^2. A model realising such flat direction is given in [311]. It requires the introduction of a scalar field which decays for instance light hadrons which would not be detectable in the current experimental setups and are referred to as 'undetected'. It cannot be 'invisible' as it would otherwise be constrained by direct invisible Higgs boson constraints. The model parameters would also have to lead to couplings of the Higgs to Standard Model fields to be larger than in the Standard Model and a coupling of the Higgs boson to the scalar which will have to match the scaling of the Standard Model couplings. The former condition is exotic and the later requires a 'conspiracy'.

As we have previously discussed, the flat direction can however be removed in two ways. The first is to impose $\kappa_V \leq 1$. This will induce a constraint on κ_H which can be seen for instance from processes such as VBF Higgs production with subsequent decays to two vector bosons which are proportional to κ_V^4/κ_H^2. As was discussed, BSM scenarios yielding $\kappa_V > 1$ can be considered exotic. The measurements using this constraints from the ATLAS experiment are shown in Fig. 11.10 (left). The second is to use the Higgs boson width derived from the off-shell Higgs boson production measurements. In this specific interpretation, the flat off-shell Higgs measurement constrain the visible, invisible and undetected branching fractions. The 'visible' branching fraction corresponds to the Higgs branchings to Standard Model fields. The invisible branching fraction is constrained from 'invisible' Higgs searches. The flat direction is therefore represented by the 'undetected' branching fraction which is then constrained by the off-shell Higgs boson measurements. This constraint was used in previous Higgs boson couplings measurements (see references for example the partial Run-2 combination performed in [312]).

Interpretations which are less sensitive to modelling systematic uncertainties and require no constraints on the natural width of the Higgs bosons have been considered, either through the ratio of cross section and branching ratios (see results in Ref. [141]) or through a more generic approach to avoid the degeneracy in the measurement of the coupling modifiers, probing the coupling properties of the Higgs boson through ratio of couplings. In the

Table 11.8: Coupling modifier combined measurements assuming the absence of perceptible new physics in the decay of the Higgs boson. No assumption is made for the loop level couplings of the Higgs boson to gluons and photons which are considered as effective. The last column gives the expected precision at the HL-LHC [118].

	LHC Run 1	ATLAS Run 2	CMS Run 2	HL-LHC (expected)
κ_γ	$0.87^{+0.14}_{-0.09}$	1.01 ± 0.06	1.10 ± 0.08	1.8%
κ_W	$0.87^{+0.13}_{-0.09}$	1.05 ± 0.06	1.02 ± 0.08	1.7%
κ_Z	-0.98 ± 0.10	0.99 ± 0.06	1.04 ± 0.07	1.5%
κ_g	$0.78^{+0.13}_{-0.10}$	0.95 ± 0.07	0.92 ± 0.08	2.5%
κ_t	$1.40^{+0.24}_{-0.21}$	0.94 ± 0.11	1.01 ± 0.11	3.4%
κ_b	$0.49^{+0.27}_{-0.15}$	0.89 ± 0.11	0.99 ± 0.16	3.7%
κ_τ	$0.84^{+0.15}_{-0.11}$	0.93 ± 0.07	0.92 ± 0.08	1.9%
κ_μ	–	$1.06^{+0.25}_{-0.30}$	1.12 ± 0.21	4.3%
$\kappa_{Z\gamma}$	–	$1.38^{+0.31}_{-0.36}$	1.65 ± 0.34	9.8%

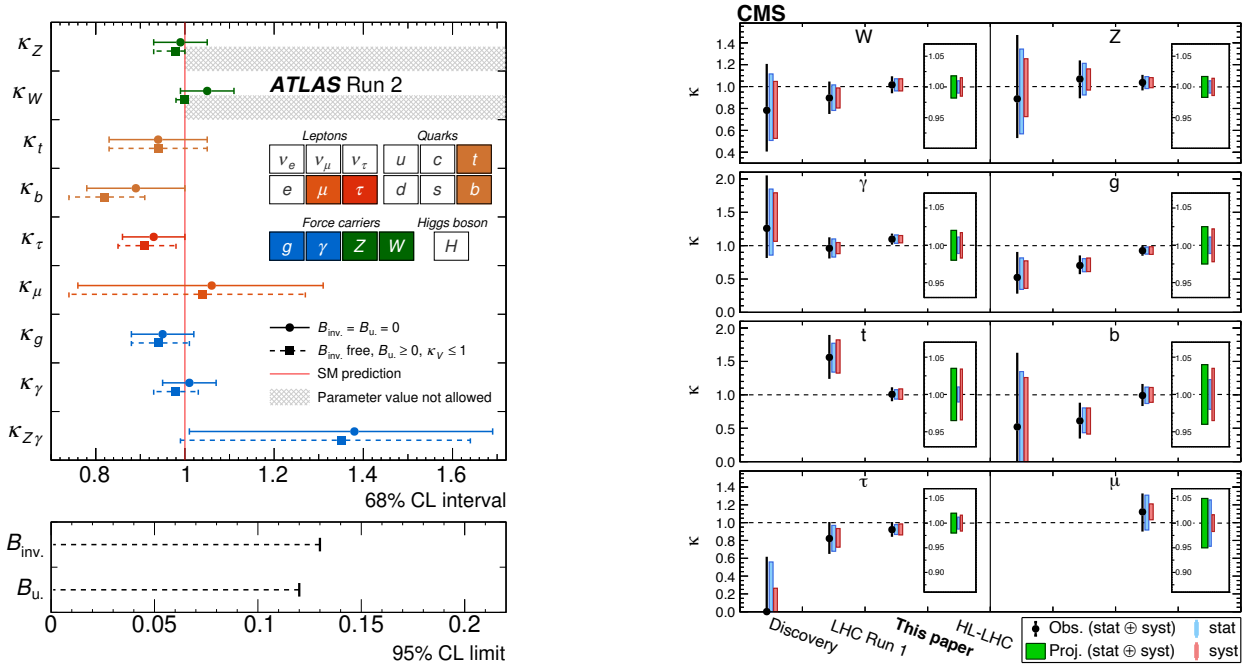

Figure 11.10: ATLAS [183] (left) and CMS [184] (right) combined measurements of coupling modifiers with various assumptions. The ATLAS measurments also use the off-shell Higgs measurements.

latter model, the cross section times branching fraction of the $gg \to H \to ZZ$ process is parametrised as a function of a single coupling modifier:

$$\kappa_{gZ} = \kappa_g \times \frac{\kappa_Z}{\kappa_H}. \tag{11.36}$$

Then all combination signals can be parametrised with the following ratios of coupling modifiers: (i) the $\lambda_{Zg} = \kappa_Z/\kappa_g$ ratio which is mainly probed by the measurements of the VBF and ZH production; (ii) the $\lambda_{tg} = \kappa_t/\kappa_g$ ratio constrained by the $t\bar{t}H$ production process; (iii) the $\lambda_{WZ} = \kappa_W/\kappa_Z$ ratio mainly probed by the WW and ZZ decay modes; (iv) the $\lambda_{\tau Z} = \kappa_\tau/\kappa_Z$ ratio constrained by the $\tau^+\tau^-$ channel; (v) the $\lambda_{bZ} = \kappa_b/\kappa_Z$ ratio probed mainly by the $VH(b\bar{b})$ channels; and (vi) the $\lambda_{\gamma Z} = \kappa_\gamma/\kappa_Z$ ratio constrained by the diphoton channel. In this parametrisation, the ZZ channel plays an important normalisation role (the results are discussed in detail in the previous edition of this review [141]).

11.5.1.3 *Differential cross sections*

To further characterise the production and decay properties of the Higgs boson, with the increase in size of the LHC datasets, measurements of fiducial and differential cross sections are being carried out by ATLAS and CMS both at Run 1 (the references can be found in the previous edition of this review [141]) and Run 2 and in several channels [313–316]: the diphoton, the four leptons, the WW, $b\bar{b}$ and $\tau^+\tau^-$ channels.

The definition of a fiducial volume as close as possible to the reconstruction level selection criteria is very important, as it will minimise the model dependence from possible variations in the signal reconstruction efficiencies. Minimising model dependence of unfolded fiducial differential cross section measurements is also key to ensure their usefulness to further probe and tune more accurate models in the future.

While strict fiducial requirements are key to minimise model dependence, if the decay products are part of the fiducial volume definition, these make combinations of decay channels impossible. To gain precision in the measurement of the production properties

of the Higgs boson, the fiducial volume can be defined in terms of the Higgs boson distributions, while its decay channels and properties are fully integrated. This has been used to combine differential cross section for instance in the transverse momentum of the Higgs boson. Such hybrid approaches are also discussed in Section 11.5.1.5.

A large number of observables have been studied aiming at probing the accuracy of the modelling of the Higgs boson production simulations as well as measuring the properties of the Higgs boson.

The measured differential cross section in the Higgs boson transverse momentum by ATLAS and CMS using the full Run-2 datasets are illustrated in Fig. 11.11 [314, 315, 317].

The Higgs boson transverse momentum distribution is of particular importance to probe new physics in the Higgs production. An example of interpretations that can be made using these measurements is the constraints on the b and charm quark Yukawa couplings through their impact on the production, both via the loop-level gluon fusion contribution or the $gg \to b\bar{b}H, c\bar{c}H$ processes. These results are also combined with the direct search for the $VH(b\bar{b})$ process and shown in Fig. 11.12. It is interesting to compare the constraint, $|\kappa_c| < 8.5$, from the $VH(c\bar{c})$ production analysis alone and the limit obtained using only the differential distribution which is approximately the double of the direct search limit as well as the limit that also uses the normalisation which yields $|\kappa_c| < 2.3$. The latter indirect limits assume that $\kappa_b = 1$. This shows the already good strength of the shape analysis as well as the limit coming from the parametrisation of the normalisation in the $H \to \gamma\gamma, 4\ell$ decay channels. The constraint coming from the normalisation is due to the modification of the total width from from the charm and b quark couplings [314].

11.5.1.4 *Constraints on non-SM Higgs boson interactions in an effective Lagrangian*

An example of the possible use of differential cross sections in constraining non-SM Higgs boson couplings in an EFT is given by ATLAS [318]. In this analysis, differential cross section measured in the diphoton channel are used to constrain an effective Lagrangian where the SM is supplemented by dimension six CP-even operators of the Strongly Interacting Light Higgs (SILH) formulation [295] and corresponding CP-odd operators. The diphoton differential cross sections are mainly sensitive to the operators that affect the Higgs boson interactions with gauge bosons. CMS has also recently analysed [313] the Higgs boson transverse momentum distribution to constrain the Higgs boson couplings to top, bottom, and charm quarks as well as the effective coupling to gluons. This analysis is, however, not performed in an EFT framework.

The differential distributions used in this combination are: (i) the transverse momentum of the Higgs boson, (ii) the number of reconstructed jets produced in association with the diphoton pair, (iii) the invariant mass of the diphoton system and (iv) the difference in azimuthal angle of the leading and sub-leading jets in events with two or more jets. This analysis shows how differential information significantly improves the sensitivity to dimension-6 operators.

11.5.1.5 *Simplified Template Cross Sections (STXS)*

An overarching subject of discussion between the theory and experimental communities in the field of Higgs physics has been how experimentalists could best communicate their results to be most efficiently used by others for further interpretation. The commonly used practice is that results are given at particle level within a well-defined fiducial volume of phase space. The fiducial volume is usually defined close enough to the experimental reconstruction to minimise the possible variations of the reconstruction efficiency within the particle level fiducial volume. In this way, results minimise their dependence on theoretical uncertainties.

ATLAS and CMS have produced fiducial and unfolded cross sections based on all objects reconstructed in the events. These measurements could be used for further interpretation. However, performing a proper combination of channels taking into account all experimental systematic uncertainties is non trivial and given the number of channels, combinations are very involved. A proposal [40, 319] was made by the LHC Higgs Working Group to produce results in each decay channel with a well defined fiducial phase space of the Higgs boson (and not its decay products) and for other associated objects pertaining to all channels, such as jets and missing transverse momentum (MET). The definition of the fiducial regions is motivated by maximising the experimental sensitivity, isolating possible BSM effects, and minimising the dependence on theoretical uncertainties. The number of regions is also minimised to avoid the loss of experimental sensitivity. The observables that are measured in this approach are still the standard production cross sections (the gluon fusion, the vector boson fusion, the VH and $t\bar{t}H$ associated production modes) within the defined fiducial volumes.

This approach is hybrid. It is fiducial on specific objects to reduce the theory dependence and inclusive in the Higgs kinematics in order to allow for a more straightforward combination. This approach also allows the use of multivariate techniques to enhance the sensitivity within given fiducial regions, at the expense of a greater extrapolation and therefore increased model dependence.

The currently used Simplified Template Cross Sections (STXS) scheme covers, with a limited number of bins, the ggF process in four categories in number of jets (0, 1, 2 and 2 VBF-like jets, where VBF-like means a selection of two high invariant mass jets with large pseudo rapidity difference) further subdivided in four transverse momentum categories covering the full spectrum with the last bin being inclusive for $p_T > 200\,\text{GeV}$. The VH process is subdivided in two categories depending on the number of reconstructed charged leptons corresponding to the decays of either a W boson or a Z boson, and two bins in transverse momentum. VBF and hadronic VH categories are defined using jet cuts and two bins in transverse momentum.

Measurements in this framework have been made in various decay channels. The first measurements have been performed in the main Higgs boson discovery channels. ATLAS and CMS have produced measurements of the diphoton and the 4ℓ channels with Run-2 data [258, 314, 320–325].

The ATLAS and CMS collaborations have also performed measurements of the STXS in the $H \to W^+W^-$ decay channel [326, 327].

CMS has also carried out a measurement of the STXS in the $H \to \tau^+\tau^-$ decay channel targeting the high transverse momentum of the Higgs boson [156], in particular in the channel where the Higgs boson is produced with one jet of transverse energy in excess of 200 GeV.

ATLAS [328] has made a measurement of the STXS aiming at the VH production mode in the $H \to b\bar{b}$ decay mode at high transverse momentum of the vector boson above 250 GeV, where the discrimination of the background further increases.

A combination of STXS across decay channels has also been carried out by ATLAS with the full Run-2 dataset [183, 329, 330].

11.5.2 *Effective Lagrangian framework*

The SMEFT has the same field content and it respects the same linearly-realised $\mathrm{SU}(3)_C \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ local symmetry as the SM. The difference is the presence of operators with canonical mass-dimension d larger than 4. These are organised in a systematic expansion in d, where each consecutive term is suppressed by a larger power of a high mass scale. Assuming baryon and lepton number conservation, the most general Lagrangian takes the form

$$\mathcal{L}_{\text{eff}} = \mathcal{L}_{\text{SM}} + \sum_i c_i^{(6)} \mathcal{O}_i^{(6)} + \sum_j c_j^{(8)} \mathcal{O}_j^{(8)} + \cdots . \qquad (11.37)$$

The contribution of the higher order operators of dimension d to physical amplitudes is suppressed by $(E/\Lambda)^{d-4}$, where E is the relevant energy scale of the process and Λ is the energy scale suppressing the higher-dimensional operators. The Wilson coefficients $c_i^{(d)}$ encode the virtual effects of the heavy new physics in low-energy observables. Their precise forms in terms of masses and couplings of the new particles can be obtained via matching with the ultraviolet (UV) completion of the SM [331–334], or inferred using specific power-counting rules [295, 335].

The list of dimension-6 operators was first classified in a systematic way in Ref. [336] after the works of Ref. [337]. Subsequent

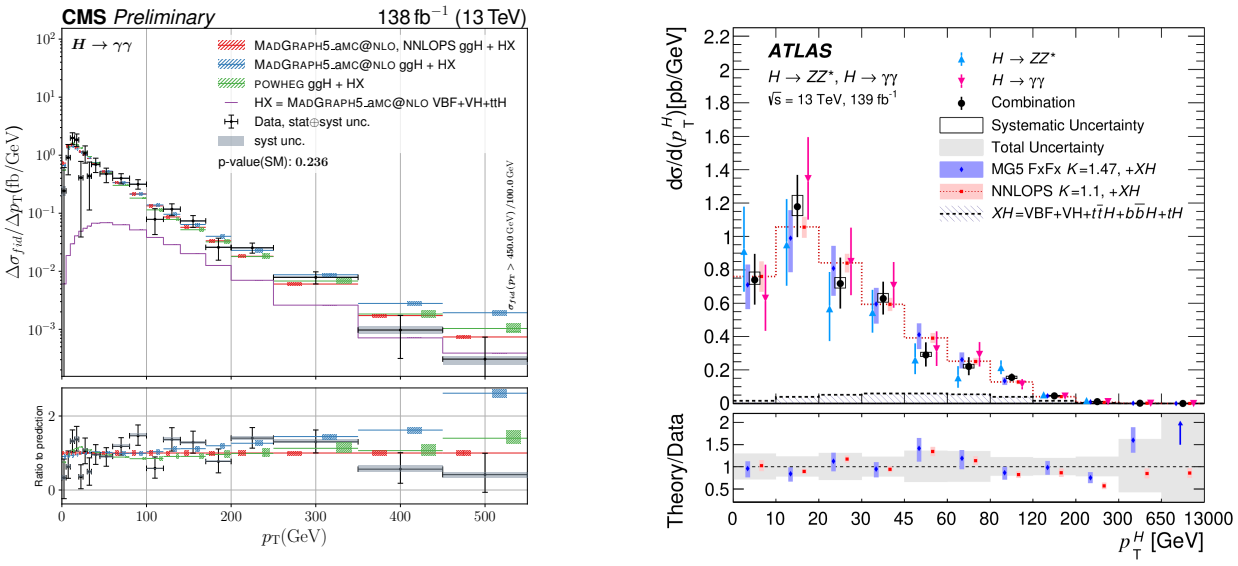

Figure 11.11: (Left) Fiducial differential cross sections in Higgs boson transverse momentum in the $H \to \gamma\gamma$ channel from the CMS experiment [315]. (Right) Partially fiducial combined cross sections using the $H \to \gamma\gamma$ and $H \to 4\ell$ channels from the ATLAS experiment [314].

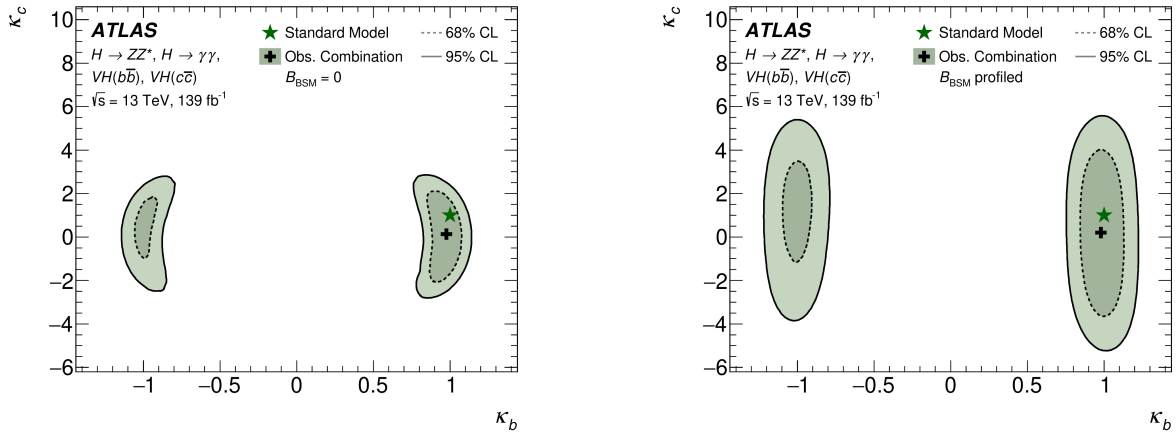

Figure 11.12: Measured likelihood contours for the κ_b and κ_c parameters from a simultaneous fit of the direct search for $VH(b\bar{b}, c\bar{c})$ analyses and the measurement of the differential cross section in transverse momentum in the $H \to \gamma\gamma, 4\ell$ channels, using the overall normalisation of the cross sections parametrised as a function of the κ_b and κ_c couplings and assuming no non-Standard Model contributions to the total width of the Higgs boson (left) and using only the differential shape in transverse momentum [314].

analyses pointed out the presence of redundant operators, and a minimal and complete list of operators was finally provided in Ref. [338][3]. For a single family of fermions, there are 76 real ways to deform the SM generated by 59 independent operators. With the 3 families of fermions of the SM, flavour indices can be added to these 59 operators, and furthermore, new operator structures, that have been dismissed by means of Fierz transformations in the single family case, have to be considered, for a total of 2499 real deformations [341].

The numbers of operators to constrain can be reduced by imposing suitable flavour assumptions. Inspired by flavour physics, a $U(2)_q \times U(2)_u \times U(2)_d \times U(3)_l \times U(3)_e$ symmetry can be enforced to impose a flavour symmetry in the first two quark generations and all three lepton generations. ATLAS performed a detailed analysis of Higgs and EW data from LEP/SLD and LHC. Under the previous flavour assumption, 22 operators are affecting Higgs observables alone, 22 operators are affecting EW precision observables alone and 11 operators are affecting both sets of observables simultaneously. Dedicated samples representing SM, linear, and quadratic effects of dimension-six operators are generated at leading order using `MadGraph5_aMC@NLO` and `SMEFTsim`. Events are interfaced to `Pythia 8` to simulate parton shower and hadronization. The decays of bottom and charm hadrons are performed by `EvtGen`. For the loop-induced processes, calculations are performed with `SMEFTatNLO`, which allows for the calculation of NLO QCD corrections, instead of `SMEFTsim`. Effects of dimension-six operators on background processes are usually not taken into account except in the analysis of VBF Z measurement and of WW production. The results are displayed in Fig. 11.14 [342]. The current measurements cannot currently constrain simultaneously

[3] Complete enumerations of d=8 operators have been obtained [339] and some preliminary constraints on peculiar subsets of these operators have been derived from experimental measurements [340]. Still, in this review, the EFT Lagrangians will be truncated at the level of dimension-6 operators.

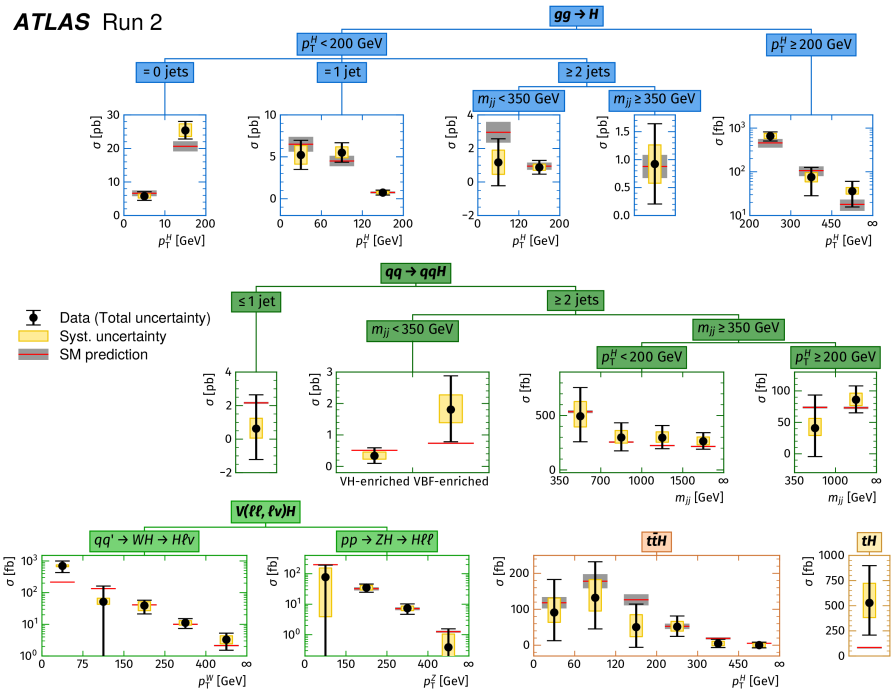

Figure 11.13: Simultaneous combined measurement of simplified template cross sections assuming SM branching fractions of the Higgs boson [183].

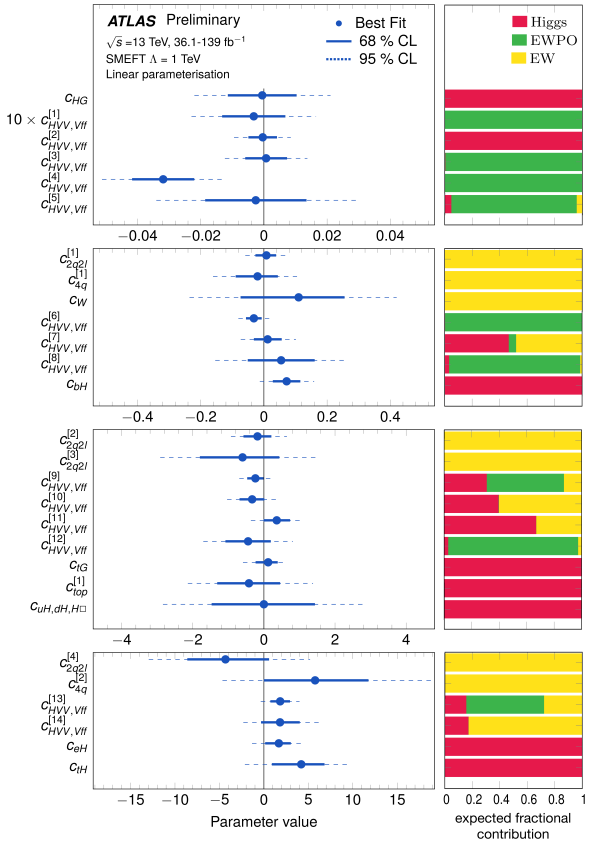

Figure 11.14: Constraints on Wilson coefficients from the combined LHC+EWPO analysis, presented in four blocks with different x-axis ranges. Right-hand side panel shows the contribution of each input measurement group to the eigenvector constraint in the Gaussian approximation.

all SMEFT Wilson coefficients as numerous degrees of freedom are not contrained by the data. One option is to fit a limited (typically one) coefficient while fixing the others. Another approach as shown in Fig. 11.14 is to perform a Principal Component Analysis (PCA) which will identify the sensitive and the flat directions of the likelihood and compute a modified basis corresponding to a linear combination of the SMEFT coefficients [342]. For this reason the results displayed in Fig. 11.14 illustrate coefficients with several indices, which correspond to the main Wilson coefficients represented in a given direction of the PCA analysis. The superscript represent a numbering of different linear combinations with similar coefficients. These results show the excellent agreement between measurements and the Standard Model expectations projected onto SMEFT sensitive directions. The largest discrepancy is observed for the $c^{[4]}_{HVV,Vff}$ coefficient which is driven by the longstanding discrepancy in the $A^{0,b}_{FB}$ measurements at LEP. In this paper [342], ATLAS has performed both fits in the linear and quadratic parametrisations of SMEFT effects corresponding to taking into account the interference between SM and SMEFT only or the entire SMEFT effect (including the quadratic SMEFT contributions) respectively.

Phenomenological studies [343, 344] have also combined Higgs, diboson, and top quark production and decay measurements from the LHC and LEP to produce global fit of SMEFT at the dimension-6 order. Automated codes like or `Matchete` [334] or `Matchmakereft` [333] allows one to match explicit UV models onto SMEFT and hence to interpret the global EFT fit to directly constrain these UV models.

11.6 New physics models of EWSB in the light of the Higgs boson discovery

The discovery of a light scalar with couplings to gauge bosons and fermions that are consistent with SM predictions, together with the slow running of the Higgs boson self-coupling at high energies allow one to consider the SM as a valid perturbative description of nature all the way to the Planck scale. This picture is admittedly very attractive, but it posits that the Higgs boson is an elementary scalar field, whose mass has quantum sensitivity to possible new physics scales. This EW/Higgs naturalness problem [6] has become much more definite after the Higgs boson discovery.

There are two broad classes of models addressing the naturalness problem[4]. One is based on SUSY [7] (for recent reviews, see Refs. [8, 9]). This is a weakly coupled approach to EWSB, maintaining the perturbativity of the SM, and, the Higgs boson remains elementary and the corrections to its mass are screened at the scale at which SUSY is broken so the value of the weak scale remains insensitive to the details of the physics at higher scales. These theories predict at least three neutral Higgs particles and a pair of charged Higgs particles [23]. One of the neutral Higgs bosons, most often the lightest CP-even one, has properties that can resemble those of the SM Higgs boson (at least in some regions of the parameter space referred to as the alignment limit [346, 347], which in the case of sufficiently heavy additional Higgs bosons is dubbed the decoupling limit [348, 349]). Such scalar is referred to as a SM-like Higgs boson, meaning that its couplings are close to the ones predicted in the SM. The other approach invokes the existence of strong interactions at a scale of the order of one TeV or above and these new interactions induce the breaking of the electroweak symmetry [350]. In the original incarnation, dubbed technicolor, the strong interactions themselves trigger EWSB without the need of a Higgs boson. Another possibility, more compatible with the ATLAS and CMS discovery, is that the strong interactions produce four light resonances identified with the Higgs doublet and EWSB proceeds through vacuum misalignment [10] (see Refs. [11, 12] for recent reviews). In that case, the Higgs boson itself has a finite size and thus never feels the UV degrees of freedom that would otherwise have dragged its mass to much higher scales. The Higgs boson could also correspond to the Goldstone boson associated with the spontaneous breaking of scale invariance, see Ref. [351] and references therein. However, this dilaton/radion scenario now requires a jumbled model-building to be consistent with the constraints from the coupling measurements. All these BSM scenarios can have important effects on the phenomenology of the Higgs boson. Also, in each case, the role of the Higgs boson in the unitarisation of scattering amplitudes is shared by other particles which remain targets of experimental searches.

The realisation of SUSY at low energies has many good qualities that render it attractive as a model of new physics. First of all since, for every SM degree of freedom, there is a superpartner of different spin but of equal mass and effective coupling to the SM-like Higgs boson, in the case of exact SUSY, an automatic cancellation of quantum corrections to the Higgs mass parameter holds. In practice, it is known that SUSY must be broken since no superpartners of the SM particles have been observed so far. The mass difference between the precise value of the mass of any particle and that of its corresponding superpartner is proportional to the correlated soft SUSY breaking parameter, generically called $M_{\rm SUSY}$. The quantum corrections to the Higgs boson mass parameter are proportional to $M^2_{\rm SUSY}$, and provided $M_{\rm SUSY}$ is of order of a few TeV, the low energy mass parameters of the Higgs sector become insensitive to physics at the GUT or Planck scale. Another interesting feature of SUSY theories is related to the dynamical generation of EWSB [352]. In the SM, a negative Higgs mass parameter, m^2, needs to be inserted by hand to induce EWSB, see Eq. (11.1). In SUSY, instead, even if the relevant Higgs mass parameter is positive in the ultraviolet, it may become negative and induce EWSB radiatively through the strong effect of the top quark-Higgs boson coupling in its renormalisation group evolution [352].

In the following, the Higgs sector will be explored in specific SUSY models. In all of them, it is often possible to find regions of the parameter space that accommodate one neutral Higgs boson with properties that resemble those of the SM Higgs boson, whereas additional neutral and charged Higgs bosons are also predicted and are intensively being sought for at the LHC (see Section 11.6.7). In the simplest SUSY model, accommodating a SM-like Higgs boson mass of about 125 GeV results in constraints on the stop sector, with at least one stop mass in the few TeV mass range. In non-minimal SUSY extensions of the SM (details and related references can be found in the 2018 edition of this review [141]), a SM-like Higgs boson with mass of 125 GeV can be accommodated with less restrictions on the stop sector. While naturalness dictates relatively light stops and - at the two loop level - also gluinos, the first and second generation of squarks and sleptons couple weakly to the Higgs sector and may be heavy. Moreover, small values of the μ parameter and therefore light Higgsinos, the fermionic superpartners of the Higgs bosons, would be a signature of a natural realization of electroweak symmetry breaking [353]. Such SUSY spectra, consisting of TeV range stop masses and light Higgsinos, continue to be under intense scrutiny by the experimental collaborations [354], in order to understand if such natural SUSY scenarios endure and can explain why the Higgs boson remains light.

In the context of weakly coupled models of EWSB, one can also consider multiple Higgs $\mathrm{SU}(2)_L$ doublets as well as additional Higgs singlets, triplets or even more complicated multiplet structures, with or without low energy SUSY. In general, for such models, one needs to take into account experimental constraints from precision measurements and flavour changing neutral currents. The LHC signatures of such extended Higgs sectors are largely shaped by the role of the exotic scalar fields in EWSB.

The idea that the Higgs boson itself could be a composite bound state emerging from a new strongly-coupled sector has been reconsidered thanks to the insights gained from the AdS/CFT duality. The composite Higgs boson idea is an incarnation of EWSB via strong dynamics that smoothly interpolates between the standard technicolor approach and the true SM limit. To avoid the usual conflict with EW data, it is sufficient, if not necessary, that a mass gap separates the Higgs resonance from the other resonances of the strong sector. Such a mass gap can naturally follow from dynamics if the strongly-interacting sector exhibits a global symmetry, G, broken dynamically to a subgroup H at the scale f, such that, in addition to the three Nambu–Goldstone bosons of SO(4)/SO(3) that describe the longitudinal components of the massive W and Z, the coset G/H contains a fourth Nambu–Goldstone boson that can be identified with the physical Higgs boson. Simple examples of such a coset are SU(3)/SU(2) or SO(5)/SO(4), the latter being favoured since it is invariant under the custodial symmetry. It is also possible to have non-minimal custodial cosets with extra Goldstone bosons leading to additional Higgs bosons in the spectrum, see for instance Ref. [355]. Modern incarnations of composite Higgs models have been recently investigated in the framework of 5D warped models where, according to the principles of the AdS/CFT correspondence, the holographic composite Higgs boson then originates from a component of a gauge field along the 5th dimension with appropriate boundary conditions.

A last crucial ingredient in the construction of viable composite Higgs boson models is the concept of partial compositeness [356], i.e., the idea that there are only linear mass mixings between elementary fields and composite states. After diagonalisation of the mass matrices, the SM particles, fermions and gauge bosons, are admixtures of elementary and composite states and thus they interact with the strong sector, and in particular with the Higgs boson, through their composite component. This setup has important consequences on the flavour properties, chiefly the suppression of large flavour changing neutral currents involving light fermions. It also plays an important role in dynamically generating a potential for the would-be Goldstone bosons. Partial compositeness also links the properties of the Higgs boson to the spectrum of the fermionic resonances, i.e., the partners of the top quark. As in the MSSM, these top partners are really the agents that trigger the EWSB and also generate the mass of the Higgs boson that otherwise would remain an exact Goldstone boson and hence massless. The bounds from the direct searches for the top partners, in addition to the usual constraints from EW precision data, force the minimal composite Higgs models into some unnatural corners of their parameter spaces [357].

11.6.1 *Higgs bosons in the minimal supersymmetric standard model (MSSM)*

The particle masses and interactions in a SUSY theory are uniquely defined as a function of the superpotential and the Kähler potential [9]. A fundamental theory of SUSY breaking, how-

[4] Another solution to the naturalness problem is to lower the fundamental scale of quantum gravity, like for instance in models with large extra-dimensions, see Ref. [345].

ever, is unknown at this time. Nevertheless, one can parametrise the low-energy theory in terms of the most general set of soft SUSY-breaking operators [9]. The simplest realistic model of low-energy SUSY is the minimal SUSY extension of the SM (MSSM) [9, 358], that associates a SUSY partner to each gauge boson and chiral fermion of the SM, and provides a realistic model of physics at the weak scale. However, in this minimal model, with the most general set of soft SUSY-breaking terms, more than 100 new parameters are introduced. Nevertheless, only a subset of these parameters impact the Higgs boson phenomenology either directly at tree-level or through quantum effects.

The MSSM contains the particle spectrum of a two-Higgs-doublet model (2HDM) extension of the SM and the corresponding SUSY partners. Two Higgs doublets, Φ_1 and Φ_2, with hypercharge $Y = -1$ and $Y = 1$, respectively, are required to ensure an anomaly-free SUSY extension of the SM and to generate mass for down-type quarks/charged leptons (Φ_1) and up-type quarks (Φ_2) [23]. The Higgs potential reads

$$\begin{aligned} V =& m_1^2 \Phi_1^\dagger \Phi_1 + m_2^2 \Phi_2^\dagger \Phi_2 - m_3^2 (\Phi_1^T i\sigma_2 \Phi_2 + \text{h.c.}) \\ &+ \frac{1}{2}\lambda_1 (\Phi_1^\dagger \Phi_1)^2 + \frac{1}{2}\lambda_2 (\Phi_2^\dagger \Phi_2)^2 + \lambda_3 (\Phi_1^\dagger \Phi_1)(\Phi_2^\dagger \Phi_2) \\ &+ \lambda_4 |\Phi_1^T i\sigma_2 \Phi_2|^2 + \frac{1}{2}\lambda_5 \left[(\Phi_1^T i\sigma_2 \Phi_2)^2 + \text{h.c.} \right] \\ &+ \left[[\lambda_6 (\Phi_1^\dagger \Phi_1) + \lambda_7 (\Phi_2^\dagger \Phi_2)] \Phi_1^T i\sigma_2 \Phi_2 + \text{h.c.} \right], \end{aligned} \tag{11.38}$$

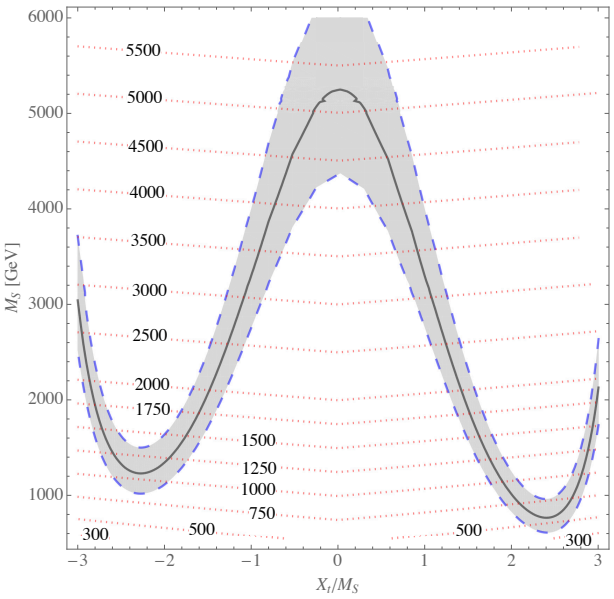
where $m_i^2 = \mu^2 + m_{H_i}^2$ $(i = 1, 2)$, with μ being the supersymmetric Higgsino mass parameter and m_{H_i} the soft supersymmetric breaking mass parameters of the two Higgs doublets; $m_3^2 \equiv B\mu$ is associated to the B-term soft SUSY breaking parameter; and λ_i, for $i = 1$ to 7, are all the Higgs quartic couplings.

After the spontaneous breaking of the electroweak symmetry, five physical Higgs particles are left in the MSSM spectrum: one charged Higgs pair, $H^\pm$, one CP-odd neutral scalar, A, and two CP-even neutral states, H and h, with h being the lightest.[5] The Higgs sector at tree level depends on the electroweak gauge coupling constants and the vacuum expectation value v – or equivalently the Z gauge boson mass – and is determined by only two free parameters: $\tan\beta$ - the ratio of the two Higgs doublets' vacuum expectation values v_2/v_1 - and one Higgs boson mass, conventionally chosen to be the CP-odd Higgs boson mass, m_A. The other tree-level Higgs boson masses are then given in terms of these parameters. The tree level value of m_h is maximised not only for $m_A \gg m_Z$ but also for $\tan\beta \gg 1$. For $m_A \gg m_Z$ it acquires a maximum value $m_h = m_Z \cos 2\beta$.

Radiative corrections have a significant impact on the values of Higgs boson masses and couplings in the MSSM. The dominant radiative effects to the SM-like Higgs boson mass arise from the incomplete cancellation between top and scalar-top (stop) loops and at large $\tan\beta$ also from sbottom and stau loops. The stop, sbottom and stau masses and mixing angles depend on the SUSY Higgsino mass parameter μ and on the soft-SUSY-breaking parameters [9, 358]: M_Q, M_U, M_D, M_L, M_E, and A_t, A_b A_τ. The first three of these are the left-chiral and the right-chiral top and bottom scalar quark mass parameters. The next two are the left-chiral stau/sneutrino and the right-chiral stau mass parameters, and the last three are the trilinear parameters that enter in the off-diagonal squark/slepton mixing elements: $X_t \equiv A_t - \mu \cot\beta$ and $X_{b,\tau} \equiv A_{b,\tau} - \mu \tan\beta$. At one-loop, the electroweak gauginos yield a small contribution to the Higgs boson mass, and at the two-loop level, the masses of the gluinos also enter in the calculations. Radiative corrections to the Higgs boson masses have been computed using a number of techniques, with a variety of approximations, see Ref. [359] for a recent review.

[5] Observe that in the SM sections of this review, H denotes the SM Higgs boson, whereas in the sections about SUSY, or extensions of the SM with two Higgs doublets, H is used for the heaviest CP-even Higgs boson, since this is the standard notation in the literature, and the 125 GeV SM-like light Higgs boson will be denoted by h. Generically, in the MSSM, the lightest CP-even Higgs boson is indeed SM-like and thus it is naturally identified with the 125 GeV Higgs boson discovered by ATLAS and CMS, while in general 2HDM extensions, with or without SUSY, there could still be lighter scalar states below 125 GeV.

Figure 11.15: Values of the SUSY mass scale $M_{\rm SUSY} = M_S$ versus the stop mixing parameter normalised by the SUSY mass scale $X_t/M_{\rm SUSY}$, for fixed $\tan\beta = 20$, $\mu = 200\,\text{GeV}$ and $A_t = A_b = A_\tau$. The solid black line corresponds to $m_h = 125\,\text{GeV}$ while in the grey band m_h varies by $\pm 1\,\text{GeV}$. The red dotted lines are iso-values of the stop mass in GeV. This figure is based on Ref. [360].



The discovered SM-like Higgs boson, if interpreted as the lightest MSSM Higgs boson with a mass of about 125 GeV, provides information on the possible MSSM parameter space, see Fig. 11.15.

The phenomenology of the Higgs sector depends on the couplings of the Higgs bosons to gauge bosons and fermions. At tree-level, the couplings of the two CP-even Higgs bosons to W and Z bosons are given in terms of the angles α, that diagonalises the CP-even Higgs boson squared-mass matrix, and β

$$g_{hVV} = g_V m_V \sin(\beta - \alpha), \quad g_{HVV} = g_V m_V \cos(\beta - \alpha), \tag{11.39}$$

where $g_V \equiv 2m_V/v$, for $V = W$ or Z ($g_V m_V$ is the SM hVV coupling). Observe that in the limit $\cos(\beta - \alpha) \to 0$, the lightest CP-even Higgs boson h behaves as the SM Higgs boson. This situation is called alignment and is achieved in specific regions of parameter space for $m_A \geq m_Z$ [348] or in the large $m_A \gg m_Z$ limit, in which alignment is achieved through decoupling [348, 349]. There are no tree-level couplings of A or $H^\pm$ to VV. The couplings of the Z boson to two neutral Higgs bosons are given by $g_{\phi AZ}(p_\phi - p_A)$, where $\phi = H$ or h, the momenta p_ϕ and p_A point into the vertex, and

$$g_{hAZ} = g_Z \cos(\beta - \alpha)/2, \quad g_{HAZ} = -g_Z \sin(\beta - \alpha)/2\,. \tag{11.40}$$

The expressions of the couplings between a charged Higgs boson, a neutral Higgs boson and the W boson as well as the expressions of the four-point couplings of vector bosons and Higgs bosons can be found in Ref. [23].

The tree-level Higgs boson couplings to fermions obey the following property: the neutral components of one Higgs doublet, Φ_1, couple exclusively to down-type fermion pairs while the neutral components of the other doublet, Φ_2, couple exclusively to up-type fermion pairs [23]. This Higgs-fermion coupling structure defines the Type-II 2HDM. In the MSSM, fermion masses are generated when both neutral Higgs components acquire a vacuum expectation value, and the relations between Yukawa couplings and fermion masses are (in third-generation notation)

$$h_{b,\tau} = \sqrt{2}\, m_{b,\tau}/(v \cos\beta), \quad h_t = \sqrt{2}\, m_t/(v \sin\beta)\,. \tag{11.41}$$

The couplings of the neutral Higgs bosons to $f\bar{f}$, relative to their SM values, $g\, m_f/(2m_W)$, are therefore given by

$$\begin{array}{ll} h b\bar{b}: & -\sin\alpha/\cos\beta, \qquad h t\bar{t}: \cos\alpha/\sin\beta\,, \\ H b\bar{b}: & \cos\alpha/\cos\beta, \qquad H t\bar{t}: \sin\alpha/\sin\beta\,, \\ A b\bar{b}: & \gamma_5\tan\beta, \qquad A t\bar{t}: \gamma_5\cot\beta\,. \end{array} \tag{11.42}$$

In each relation above, the factor listed for $b\bar{b}$ also pertains to $\tau^+\tau^-$. The charged Higgs boson couplings to fermion pairs, normalised to $g/(\sqrt{2}m_W)$, are given by

$$\begin{aligned} & g_{H^- t\bar{b}} : m_t\cot\beta\frac{1+\gamma_5}{2} + m_b\tan\beta\frac{1-\gamma_5}{2}, \\ & g_{H^-\tau^+\nu} : m_\tau\tan\beta\frac{1-\gamma_5}{2}\,. \end{aligned} \tag{11.43}$$

The non-standard neutral Higgs bosons have significantly enhanced couplings to down-type fermions at sizeable $\tan\beta$. Radiative corrections can modify significantly the values of the Higgs boson couplings to fermion pairs and to vector boson pairs, through a radiatively-corrected value for $\cos(\beta-\alpha)$ as well as from the one-loop vertex corrections to tree-level Higgs-fermion Yukawa couplings, see Ref. [9] and references therein, for a detailed discussion.

11.6.1.1 *MSSM Higgs boson phenomenology*

The MSSM parameters have to be arranged such that the mass, the CP properties, the decay and production properties of one of the neutral Higgs bosons agree with the LHC Higgs data. Given that present data allows only for moderate departures from the SM predictions, it implies that some degree of alignment is necessary.

The SM-like branching ratios of h can be modified if decays into SUSY particles are kinematically allowed, and, in particular, decays into a pair of the lightest SUSY particles – i.e., the lightest neutralinos, $\tilde{\chi}_1^0$ – can become dominant and would be invisible if R-parity is conserved [361]. Moreover, if light superpartners exist and couple to photons and/or gluons, the h loop-induced coupling to gg and $\gamma\gamma$ could deviate sizeably from the corresponding SM predictions (see for instance the review [362]), and would be in conflict with present data (see Section 11.3). For the heavier Higgs states, there are two possibilities to be considered[6]:

i) Alignment triggered by decoupling, hence $m_A \geq$ several hundred GeV: The HWW and HZZ couplings are very small. The dominant H, A decay branching ratios strongly depend on $\tan\beta$. The decay modes $H, A \to b\bar{b}, \tau^+\tau^-$ dominate when $\tan\beta$ is large (this holds even away from decoupling). For small $\tan\beta$, the $t\bar{t}$ decay mode dominates above its kinematic threshold. For the charged Higgs boson, $H^+ \to t\bar{b}$ dominates.

ii) Some degree of alignment without decoupling, hence $m_A \leq$ a few hundred GeV: The main difference with the previous case is that, in the low $\tan\beta$ regime ($\tan\beta \leq 5$), additional decay channels may be allowed which involve decays into the lightest SM-like Higgs boson; $A \to Zh$, $H \to hh$ as well as $H \to WW/ZZ$ decay modes are available (they are suppressed in the strict alignment limit). When kinematically open, the decays $A/H \to t\bar{t}$ become relevant or even dominant for sufficiently small $\tan\beta$. For the charged Higgs boson, $H^+ \to \tau^+\nu_\tau$ dominates below the $t\bar{b}$ threshold, and also $H^\pm \to W^\pm h$ may be searched for.

In both cases i) and ii), the heavier Higgs states, H, A and $H^\pm$, are roughly mass degenerate (with masses $\pm$ 20 GeV or less apart). If kinematically allowed, the heavy Higgs boson decays into charginos, neutralinos and third-generation squarks and sleptons can be important [365].

At hadron colliders, the dominant neutral Higgs boson production mechanism at moderate values of $\tan\beta$ is gluon fusion, mediated by loops containing heavy top and bottom quarks and the corresponding SUSY partners. The effect of light stops that may contribute to the gluon fusion production can be partially cancelled by mixing effects. Higgs boson radiation off bottom quarks becomes important for large $\tan\beta$, where at least two of the three neutral Higgs bosons have enhanced couplings to bottom-type fermions [366, 367]. Detailed discussions of the impact of radiative corrections in these search modes are presented for instance in Ref. [368]. The vector boson fusion and Higgs-strahlung production of the CP-even Higgs bosons as well as the associated production of neutral Higgs bosons with top quark pairs have lower production cross sections by at least an order of magnitude with respect to the dominant ones, depending on the precise region of MSSM parameter space [37–40]. Higgs boson pair production of non-standard MSSM Higgs bosons has been studied in Ref. [369]. For a discussion of charged Higgs boson production at LHC, see Refs. [38, 39, 370].

Strong production of a heavy neutral Higgs boson followed by its decay into top-quark pairs is a challenging channel, only most recently being searched for by ATLAS and CMS. Interference effects between the signal and the SM $t\bar{t}$ background need to be carefully taken into account [371, 372].

Summarising, the additional Higgs bosons are sought for mainly via the channels:

$$\begin{aligned} & pp \to A/H \to \tau^+\tau^- \text{ (inclusive)}, \\ & b\bar{b}A/H, A/H \to \tau^+\tau^- \text{ (with } b\text{-tag)}, \\ & b\bar{b}A/H, A/H \to b\bar{b} \text{ (with } b\text{-tag)}, \\ & pp \to t\bar{t} \to H^\pm W^\mp b\bar{b},\ H^\pm \to \tau^+\nu_\tau(\tau^-\bar{\nu}_\tau) \text{ or } t\bar{b}\,(b\bar{t})\,, \\ & gb \to H^- t \text{ or } g\bar{b} \to H^+\bar{t},\ H^\pm \to \tau^+\nu_\tau(\tau^-\bar{\nu}_\tau) \text{ or } t\bar{b}\,(b\bar{t}). \end{aligned} \tag{11.44}$$

After the Higgs boson discovery, updated MSSM benchmarks scenarios have been defined to highlight interesting conditions for the MSSM Higgs boson searches [39, 364] and are scrutinised by the LHC Higgs Working Group [373]. The latest benchmark scenarios update [364], partly based in MSSM parameter space discussions in Ref. [374], considers six benchmarks to illustrate different aspects of Higgs phenomenology in the MSSM. They include one case with complex parameters, but they all assume R-parity conservation and no flavour mixing. Each scenario contains one CP-even scalar with mass around 125 GeV and SM-like couplings. These scenarios include a M_h^{125} scenario with relatively heavy superparticles, so the Higgs phenomenology at the LHC resembles that of a 2HDM with MSSM-inspired Higgs boson couplings. Other two scenarios are characterised by some of the superparticles – staus or electroweakinos – being relatively light, that in turn is of relevance for heavy neutral Higgs boson searches. In particular, the traditional $A/H \to \tau^+\tau^-$ search channel varies depending on the values of μ and M_2, that may enable the A/H decays into electroweakinos. Another two scenarios are characterised by the phenomenon of alignment without decoupling, in which one of the two neutral CP-even scalars has SM-like couplings independently of the mass spectrum of the remaining Higgs bosons, hence allowing for all the Higgs bosons to have relatively low mass values (about few hundred GeV). Finally, there is one scenario which incorporates CP violation in the Higgs sector and gives rise to a strong admixture of the two heavier neutral states. All the above scenarios assume all parameters in the mass range from 1 to a few TeV, hence they are not applicable for values of $\tan\beta$ of order a few, for which a Higgs boson mass value of 125 GeV is out of reach. An additional study [375], relying on an EFT approach in the MSSM, focusses on two scenarios specifically designed for the low $\tan\beta$ region and ensures a 125 GeV Higgs boson mass in almost the entire parameter space by employing a flexible supersymmetric mass scale, reaching values of up to 10^{16} GeV.

An alternative approach to reduce the large number of parameters relevant to the Higgs sector is to consider that, in the Higgs basis, the only important radiative corrections are those affecting the Higgs boson mass [376]. This approximation is called hMSSM and works well in large regions of parameter space but it breaks down for sizeable values of μ and A_t, and moderate values of $\tan\beta$, for which the radiative corrections to the mixing between the two CP even eigenstates become relevant. The effect of such radiative corrections is to allow for alignment for small to intermediate

[6] In very special regions of the parameter space, there is still the possibility that the heavier CP-even Higgs state is identified with the 125 GeV Higgs boson discovered by ATLAS and CMS, see for instance the discussion in Ref. [363] and the benchmark M_H^{125} defined in Ref. [364].

values of $\tan\beta$, independent of the specific value of m_A [346]. In addition, the hMSSM assumption that the right value of the Higgs boson mass may be obtained for all values of m_A and $\tan\beta$ is in conflict with the MSSM predictions for the Higgs boson mass for small values of m_A and $\tan\beta \simeq \mathcal{O}(1)$. The recent M_h^{125} [364] and EFTMSSM benchmarks [375], are designed to address the limitations of the hMSSM, in particular the low $\tan\beta$ region for the EFTMSSM.

The compatibility between the predicted and measured Higgs boson mass sets stringent constraints on the parameter space of BSM models. The predictions are illustrated in Fig. 11.16 for two concrete scenarios. Note that to use the predicted Higgs boson mass as a constraint (exclusion at nearly constant $\tan\beta$ at high M_A in the (M_A,$\tan\beta$) plane), it is important to account for the theoretical uncertainty on the prediction which is in excess of an order of magnitude larger than the experimental uncertainty on the measured mass of the Higgs boson. The theoretical uncertainty depends itself on the specific SUSY spectrum for a given MSSM parameter set and should be estimated accordingly, however, a more generic estimate of ± 3 GeV is made and found to be a conservative choice [359].

Reviews of the properties and phenomenology of the Higgs bosons of the MSSM can be found for example in Refs. [9,362,378]. Future precision measurements of the Higgs boson couplings to fermions and gauge bosons together with information on heavy Higgs boson searches will provide powerful information on the SUSY parameter space [379].

Improvements in our understanding of B-physics observables put indirect constraints on additional Higgs bosons in mass ranges that would be accessible in direct LHC searches. In particular, $\mathrm{BR}(B_s \to \mu^+\mu^-)$, $\mathrm{BR}(b \to s\gamma)$, and $\mathrm{BR}(B_u \to \tau\nu)$ play an important role within minimal flavour-violating (MFV) models [380], in which flavour effects proportional to the CKM matrix elements are induced as in the SM [381].

11.6.2 *Supersymmetry with singlet extensions*

The Higgs mass parameter μ is a SUSY parameter, and as such, it should naturally be of order M_{GUT} or M_{Planck}. The fact that phenomenologically it is required that μ be at the electroweak/TeV scale is known as the μ problem [382]. SUSY models with additional singlets can provide a solution to the μ problem, by promoting the μ parameter to a dynamical singlet superfield S that only interacts with the MSSM Higgs doublets through a coupling λ_S at the level of the superpotential. An effective μ is generated when the real scalar component of S acquires a vacuum expectation value v_S, yielding $\mu_{\mathit{eff}} = \lambda_S\, v_S$. After the minimization of the Higgs potential, the vacuum state relates the vacuum expectation values of the three CP-even neutral scalars, v_1, v_2 and v_S, to the scalar doublet and singlet soft SUSY breaking masses, hence, one expects that these VEVs should all be of order M_{SUSY} and therefore the μ problem is solved.

The addition of a singlet superfield to the MSSM may come along with additional symmetries imposed to the theory. Depending on such symmetries, different models with singlet extensions of the MSSM (xMSSM) have been proposed, see Ref. [383] for a general review. Among the most studied examples are the NMSSM with an additional discrete Z_3 symmetry (first introduced in Ref. [384]), the Nearly-Minimal SUSY SM (nMSSM), with additional discrete Z_5^R, and Z_7^R symmetries [385], and the U(1)′-extended MSSM (UMSSM) [386]. A Secluded U(1)′-extended MSSM (sMSSM) [387] contains three singlets in addition to the standard UMSSM Higgs boson singlet; this model is equivalent to the nMSSM in the limit that the additional singlet VEV's are large, and the trilinear singlet coupling, λ_S, is small [388]. The non-zero neutrino masses provide also a motivation for a particular extension of the MSSM, $\mu\nu$SSM [389], which also happens to address the *mu* problem. The computation of the Higgs boson spectrum in these various models has been reviewed in Ref. [359].

A singlet extended SUSY Higgs sector opens new avenues for discovery. Since the singlet pseudoscalar particle may be identified as the pseudo-Goldstone boson of a spontaneously broken Peccei–Quinn symmetry, it may become naturally light [390]. Generally, there is mixing of the singlet sector with the MSSM Higgs sector, and for a sufficiently light, singlet-dominated scalar or pseudoscalar, h_S or A_S, respectively, the SM-like Higgs boson h may decay to pairs of h_S or A_S. The light scalar and/or pseudoscalar may subsequently decay to $\tau\tau$ or $b\bar{b}$ pairs. Such cascade decays are more difficult to detect than in standard searches due to the potentially soft decay products. There is also a rich phenomenology for the decays of the heavy CP-even and CP-odd doublets, H and A into two lighter Higgs bosons such as $H \to hh_S$, hh, h_Sh_S or $A \to A_Sh_S$, A_Sh as well as into a light Higgs boson and a gauge boson: $H \to A_SZ$; $A \to h_SZ$, hZ. If kinematically allowed, the heavy Higgs bosons decay into $t\bar{t}$. If the singlet-dominated scalar or pseudoscalar are somewhat heavier, the decays $h_S \to WW$ or $A_S \to h_SZ$ will be allowed.

In addition, the light singlet scenario in the NMSSM or nMSSM is typically associated with a light singlino-dominated neutralino. The 125 GeV SM-like Higgs boson can then decay to pairs of this neutralino [391], opening an invisible decay mode that is not excluded by present data. All of the Higgs bosons can decay into electroweakinos depending on kinematics and on the singlino or Higgsino composition of the electroweakinos.

In models with extended singlets, at low $\tan\beta$, it is possible to trade the requirement of a large stop mixing by a sizeable trilinear Higgs-singlet Higgs coupling λ_S, rendering more freedom on the requirements for gluon fusion production. As in the MSSM, mixing in the Higgs sector – additionally triggered by the extra new parameter λ_S – can produce variations in the Higgs–$b\bar{b}$ and Higgs–$\tau^-\tau^+$ couplings that can alter the Higgs to ZZ/WW and to diphoton rates. Light charginos at low $\tan\beta$ can independently contribute to enhance the di-photon rate, without altering any other of the Higgs boson decay rates, see for instance Ref. [392].

There is much activity in exploring the NMSSM phenomenology in the light of the 125 GeV Higgs boson as well as in defining benchmark scenarios with new topologies including Higgs decay chains, see Refs. [40, 393] and references therein. An analytic understanding of the alignment condition in the NMSSM is presented in Ref. [347]. The NMSSM with a Higgs boson of mass 125 GeV can be compatible with stop masses of order of the electroweak/TeV scale, thereby reducing the degree of fine-tuning necessary to achieve electroweak symmetry breaking. Interestingly, the alignment conditions point toward a more natural region of parameter space for electroweak symmetry breaking, while allowing for perturbativity of the theory up to the Planck scale and yielding a rich and interesting Higgs boson phenomenology at the LHC.

11.6.3 *Supersymmetry with extended gauge sectors*

In the MSSM, the tree-level value of the lightest CP-even Higgs boson mass originates from the D-term dependence of the scalar potential that comes from the SUSY kinetic terms in the Kähler potential. The D-terms lead to tree-level quartic couplings which are governed by the squares of the gauge couplings of the weak interactions, under which the Higgs boson has non-trivial charges. Hence, the lightest Higgs mass is bounded to be smaller than M_Z. In the presence of new gauge interactions at the TeV scale, and if the Higgs fields had non-trivial charges under them, new D-term contributions would lead to an enhancement of the tree-level Higgs boson mass value. Since the low energy gauge interactions reduce to the known $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ ones, in order for this mechanism to work, the extended gauge and Higgs sectors should be integrated out in a non-SUSY way. This means that there must be SUSY breaking terms that are of the order of, or larger than, the new gauge boson masses. The tree-level quartic couplings would then be enhanced through their dependence on the square of the gauge couplings of the extended Higgs sector. This effect will be suppressed when the heavy gauge boson masses are larger than the SUSY breaking scale and will acquire its full potential only for large values of this scale.

One of the simplest possibilities is to extend the weak interactions to a $\mathrm{SU}(2)_1 \times \mathrm{SU}(2)_2$ sector, such that the known weak interactions are obtained after the spontaneous breaking of these groups to $\mathrm{SU}(2)_L$ [394]. This example is briefly summarised in the previous editions of this review [141]. Assuming SUSY breaking terms of the order of the new gauge boson masses, enhancements of order 50% of the MSSM D-term contribution to the Higgs boson mass may be obtained. Such enhancements are sufficient to obtain

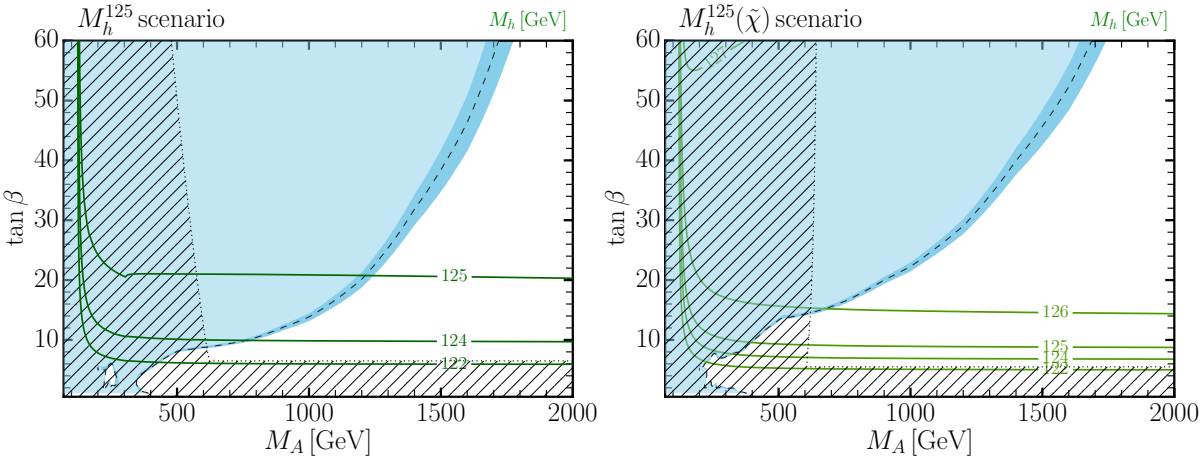


Figure 11.16: The 95% CL exclusion contours in the $(M_A, \tan\beta)$ parameter space for the M_h^{125} (right) and $M_h^{125}(\tilde{\chi})$(left) benchmark scenarios [377]. The M_h^{125} benchmark assumes that super partners are heavy, so that the phenomenology of the observed Higgs boson is not altered except in its couplings due to the existence of another doublet. The $M_h^{125}(\tilde{\chi})$ scenario on the other hand considers light electroweakinos and therefore the heavy Higgs bosons H and A can have sizeable decay rates to charginos and neutralinos, consequently suppressing the $\tau^+\tau^-$ decay rate. The nearly vertical dotted line illustrates the lower limit on the mass of the A boson from precision measurements of the Higgs boson couplings and the close-to horizontal dotted line represents the limit on $\tan\beta$ from the compatibility of the measured mass of the observed Higgs boson and the prediction using radiative corrections (mostly from the stop sector).

the measured Higgs mass value without the need for very heavy stops or large stop mixing parameters. This gauge extension leads to new, heavy gauge and Higgs bosons, as well as new neutralinos and charginos, that depending on the region of parameter space can induce novel phenomenology at the LHC. Gauge extensions including new Abelian gauge groups have also been considered.

Gauge extensions of the MSSM can also lead to an enhancement of the Higgs boson mass value by modifying the renormalisation group evolution of the Higgs quartic coupling to low energies. In the MSSM, the evolution of the quartic coupling is governed by the top-quark Yukawa interactions and depends on the fourth power of the top-quark Yukawa coupling. The neutralino and chargino contributions, which depend on the fourth power of the weak gauge couplings, are small due to the smallness of these couplings. Depending on the values of the soft SUSY breaking parameters in the gaugino and Higgsino sectors, the $\mathrm{SU}(2)_1$ gauginos may become light, with masses of the order of the weak scale. Since the $\mathrm{SU}(2)_1$ coupling may be significantly larger than the $\mathrm{SU}(2)_L$ one, for small values of the Higgsino mass parameter μ, the associated charginos and neutralinos may modify the evolution of the quartic coupling in a significant way [395]. This may lead to a significant increase of the lightest CP-even Higgs boson mass, even for small values of $\tan\beta \simeq 1$ for which the D-term contributions become small. Radiative corrections should be properly taken into account in this scenario as they might modify the tree-level result.

11.6.4 *Effects of CP violation*

SUSY scenarios with CP-violation (CPV) phases are theoretically appealing, since additional CPV beyond that observed in the K, D, and B meson systems is required to explain the observed cosmic matter-antimatter asymmetry. In the MSSM, CP-violation effects in the Higgs sector appear at the quantum level, while in singlet extensions of the MSSM CP-violation effects can already be effective at tree level. In general, CP-violation effects in the Higgs sector have significant constraints from electric dipole moments data [396].

In the MSSM, the gaugino mass parameters ($M_{1,2,3}$), the Higgsino mass parameter, μ, the bilinear Higgs squared-mass parameter, m_{12}^2, and the trilinear couplings of the squark and slepton fields to the Higgs fields, A_f, may carry non-trivial phases. The two parameter combinations $\arg[\mu A_f (m_{12}^2)^*]$ and $\arg[\mu M_i (m_{12}^2)^*]$ are invariant under phase redefinitions of the MSSM fields [397, 398]. Therefore, if one of these quantities is non-zero, there would be new sources of CP-violation affecting the Higgs sector through radiative corrections, see Ref. [399] and references therein. The mixing of the neutral CP-odd and CP-even Higgs boson states is no longer forbidden. Hence, m_A is no longer a physical parameter. However, the charged Higgs boson mass $m_{H^\pm}$ is still physical and can be used as an input for the computation of the neutral Higgs boson spectrum of the theory. For large values of $m_{H^\pm}$, corresponding to the decoupling limit, the properties of the lightest neutral Higgs boson state approach those of the SM Higgs boson. In particular, the upper bound on the lightest neutral Higgs boson mass takes the same value as in the CP-conserving case [398]. Nevertheless, there still can be significant mixing between the two heavier neutral mass eigenstates. For a detailed study of the Higgs boson mass spectrum and parametric dependence of the associated radiative corrections, see Ref. [399] and references therein.

Major variations to the Higgs boson phenomenology occur in the presence of explicit CPV phases. In the CPV case, vector boson pairs couple to all three neutral Higgs boson mass eigenstates, H_i $(i = 1, 2, 3)$, with couplings

$$\begin{aligned} g_{H_i VV} &= \cos\beta\, \mathcal{O}_{1i} + \sin\beta\, \mathcal{O}_{2i}\,, \\ g_{H_i H_j Z} &= \mathcal{O}_{3i}\,(\cos\beta\, \mathcal{O}_{2j} - \sin\beta\, \mathcal{O}_{1j}) \\ &\quad - \mathcal{O}_{3j}\,(\cos\beta\, \mathcal{O}_{2i} - \sin\beta\, \mathcal{O}_{1i})\,, \end{aligned} \tag{11.45}$$

where the $g_{H_i VV}$ couplings are normalised to the analogous SM coupling and the $g_{H_i H_j Z}$ have been normalised to $g_Z^{\mathrm{SM}}/2$. The orthogonal matrix $\mathcal{O}_{ij}$, only defined in the $p^2 \to 0$ limit, is relating the weak eigenstates to the mass eigenstates. It has non-zero off-diagonal entries mixing the CP-even and CP-odd components of the weak eigenstates. Moreover, CPV phases imply that all neutral Higgs bosons can couple to both scalar and pseudoscalar fermion bilinear densities. The couplings of the mass eigenstates H_i to fermions depend on the loop-corrected fermion Yukawa couplings (similarly to the CP conserving (CPC) case), on $\tan\beta$ and on $\mathcal{O}_{ji}$ [400].

The production processes of neutral MSSM Higgs bosons in the CPV scenario are similar to those in the CPC scenario. Regarding the decay properties, the lightest mass eigenstate, H_1, predominantly decays to $b\bar{b}$ if kinematically allowed, with a smaller fraction decaying to $\tau^+\tau^-$. If kinematically allowed, a SM-like neutral Higgs boson, H_2 or H_3 can decay predominantly to $H_1 H_1$ leading to many new interesting signals both at lepton and hadron colliders; otherwise it will decay preferentially to $b\bar{b}$.

The discovery of a 125 GeV Higgs boson has put strong constraints on the realisation of the CPV scenario within the MSSM. This is partly due to the fact that the observed Higgs boson rates

are close to the SM values, and a large CP-violating component would necessarily induce a large variation in the rate of the SM-like Higgs boson decays into the weak gauge bosons $W^{\pm}$ and Z. The measured Higgs mass imposes additional constraints on the realisation of this scenario. Once all effects are considered, the CP-odd Higgs boson A component of the lightest Higgs boson tends to be smaller than about 10% [401]. This restriction can be alleviated in the NMSSM or more general two Higgs doublet models. CP-violating effects can still be significant in the heavy Higgs sector. For instance, the Higgs bosons H_2 and H_3 may be admixtures of CP-even and CP-odd scalars, and therefore both may be able to decay into pairs of weak gauge bosons. The observation of such decays would be a clear signal of CP-violation. In the MSSM, the proximity of the masses of H_2 and H_3 makes the measurement of such effect quite challenging, but in generic two Higgs doublet models, the mass splitting between the two heavy mass eigenstates may become larger, facilitating the detection of CP-violating effects at collider experiments [402].

11.6.5 *Non-supersymmetric extensions of the Higgs sector*

There are many ways to extend the minimal Higgs sector of the SM. In the preceding sections the phenomenology of SUSY Higgs sectors is considered, which at tree level implies a constrained type-II 2HDM (with restrictions on the Higgs boson masses and couplings). In the following discussion, more generic 2HDM's are presented (for some comprehensive reviews, see the reviews [403]). These models are theoretically less compelling since they do not provide an explanation for the SM Higgs naturalness problem, but can lead to different patterns of Higgs-fermion couplings, hence, to different phenomenology. It is also possible to consider models with a SM Higgs boson and one or more additional scalar SU(2) doublets that acquire no VEV and hence play no role in the EWSB mechanism. Such models are dubbed Inert Higgs Doublet Models (IHD) [404]. Without a VEV associated to it, a Higgs boson from an inert doublet has no tree-level coupling to gauge bosons and hence cannot decay into a pair of them. Moreover, imposing a Z_2 symmetry that prevents them from coupling to the fermions, it follows that, if the lightest inert Higgs boson is neutral, it becomes a good DM candidate with interesting associated collider signals. Various studies of IHD models in the light of a 125 GeV Higgs boson have been performed, see for instance Ref. [405], showing an interesting interplay between collider and direct DM detection signals.

An interesting type of 2HDMs are those in which an Abelian flavour symmetry broken at the electroweak scales creates the fermion mass hierarchies and mixing angles [406]. This idea is based on the Froggatt–Nielsen model [407], where a flavon field couples differently to the SM fermions of different flavour charges. Such flavon acquires a vacuum expectation value, breaking the flavour symmetry but leaving both the flavour breaking and the new physics scales undetermined. In Refs. [408], it was proposed to relate the flavour breaking scale to the electroweak scale by identifying the flavon with the modulus square of the Higgs field. A 2HDM, however, provides a more compelling realisation of the electroweak scale flavour breaking idea. In the most ambitious constructions of two Higgs doublet flavour models (2HDFM), the textures of the Yukawa couplings are a result of an Abelian flavour symmetry that only allows renormalisable Yukawa couplings of the top quark to the Higgs bosons. All other Yukawa couplings are generated by higher dimensional operators that produce hierarchical entries of the Yukawa matrices, explaining the observed quark masses and mixing angles. Flavour observables, LHC Higgs signal strength measurements, electroweak precision measurements, unitarity and perturbativity bounds, as well as collider searches for new scalar resonances result in precise predictions for the parameters of these 2HDFMs. In particular, correlated departures from SM Higgs boson couplings, as well as additional Higgs bosons with masses < 700 GeV must be observed at the LHC. Other incarnations of 2HDFMs can aim at only partially explaining the fermion mass hierarchies but are therefore less restrictive.

Other extensions of the Higgs sector can include multiple copies of $\mathrm{SU}(2)_L$ doublets [409], additional Higgs singlets [410], triplets or more complicated combinations of Higgs multiplets. It is also possible to enlarge the gauge symmetry beyond $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ along with the necessary Higgs field structure to generate gauge boson and fermion masses. There are two main experimental constraints on these extensions: (i) precision measurements which constrain $\rho = m_W^2/(m_Z^2 \cos^2\theta_W)$ to be very close to 1 and (ii) flavour changing neutral current (FCNC) effects. In electroweak models based on the SM gauge group, the tree-level value of ρ is determined by the Higgs multiplet structure. By suitable choices for the hypercharges, and in some cases the mass splitting between the charged and neutral Higgs sector or the vacuum expectation values of the Higgs fields, it is possible to obtain a richer combination of singlets, doublets, triplets and higher multiplets compatible with precision measurements. Concerning the constraints coming from FCNC effects, the Glashow–Weinberg (GW) criterion [411] states that, in the presence of multiple Higgs doublets, the tree-level FCNC's mediated by neutral Higgs bosons will be absent if all fermions of a given electric charge couple to no more than one Higgs doublet. An alternative way of suppressing FCNC in a two Higgs doublet model has been considered in Ref. [412], where it is shown that it is possible to have tree level FCNC completely fixed by the CKM matrix, as a result of an Abelian symmetry.

There is a lot of activity on the study of non-supersymmetric models with an extended Higgs sector with an intense collaboration between theorists and experimentalists, in particular inside the LHC Higgs Working Group [373].

11.6.5.1 *Two-Higgs-doublet models*

General two Higgs doublet models [403] can have a more diverse Higgs-fermion coupling structure than in SUSY, and can be viewed as a simple extension of the SM to realise the spontaneous breakdown of $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ to $\mathrm{U}(1)_{\mathrm{em}}$. Quite generally, if the two Higgs doublets contain opposite hypercharges, the scalar potential will contain mixing mass parameters of the kind $m_{12}^2 \Phi_1^T i\sigma_2 \Phi_2 + h.c.$. In the presence of such terms, both Higgs doublets will acquire vacuum expectation values, $v_1/\sqrt{2}$ and $v_2/\sqrt{2}$, respectively, and the gauge boson masses will keep their SM expressions with the Higgs VEV v replaced by $\sqrt{v_1^2 + v_2^2}$. Apart from the mass terms, the most generic renormalisable and gauge invariant scalar potential for two Higgs doublets with opposite hypercharges contains seven quartic couplings, as presented in Eq. (11.38).

Just as in the MSSM case, after electroweak symmetry breaking and in the absence of CP-violation, the physical spectrum contains a pair of charged Higgs bosons $H^{\pm}$, a CP-odd Higgs boson A and two neutral CP-even Higgs bosons, h and H. The angles α and β diagonalise the CP-even, and the CP-odd and charged Higgs sectors, respectively. The complete 2HDM is defined only after considering the interactions of the Higgs fields to fermions. Yukawa couplings of the generic form

$$- h_{ij}^a \bar{\Psi}_L^i H_a \Psi_R^j + h.c. \qquad (11.46)$$

may be added to the renormalisable Lagrangian of the theory. Contrary to the SM, the two Higgs doublet structure does not ensure the alignment of the fermion mass terms $m_{ij} = h_{ij}^a v_a/\sqrt{2}$ with the Yukawa couplings h_{ij}^a. This implies that quite generally the neutral Higgs boson will mediate flavour changing interactions between the different mass eigenstates of the fermion fields. Such flavour changing interactions should be suppressed in order to describe properly the Kaon, D and B meson phenomenology. Based on the Glashow–Weinberg criterion, it is clear that the simplest way of avoiding such transitions is to assume the existence of a symmetry that ensures the couplings of the fermions of each given quantum number (up-type and down-type quarks, charged and neutral leptons) to only one of the two Higgs doublets. Different models may be defined depending on which of these fermion fields couple to a given Higgs boson, see Table 11.9. Models of type-I are those in which all SM fermions couple to a single Higgs field. In type-II models, down-type quarks and charged leptons couple to a common Higgs field, while the up-type quarks and neutral leptons couple to the other. In models of type-III (lepton-specific), quarks couple to one of the Higgs bosons, while leptons couple to the other. Finally, in models of type-IV (flipped), up-type quarks and charged leptons couple to one of the Higgs fields

while down-quarks and neutral leptons couple to the other.

Table 11.9: Higgs boson couplings to up, down and charged lepton-type $SU(2)_L$ singlet fermions in the four discrete types of 2HDM models that satisfy the Glashow–Weinberg criterion.

Model	2HDM I	2HDM II	2HDM III	2HDM IV
u	Φ_2	Φ_2	Φ_2	Φ_2
d	Φ_2	Φ_1	Φ_2	Φ_1
e	Φ_2	Φ_1	Φ_1	Φ_2

The two Higgs doublet model phenomenology depends strongly on the size of the mixing angle α and therefore on the quartic couplings. For large values of m_A, $\sin\alpha \to -\cos\beta$, $\cos\alpha \to \sin\beta$, $\cos(\beta-\alpha) \to 0$, and the lightest CP-even Higgs boson h behaves as the SM Higgs boson. The same behaviour is obtained if the quartic couplings are such that $\mathcal{M}_{12}^2 \sin\beta = -(\mathcal{M}_{11}^2 - m_h^2)\cos\beta$. The latter condition represents a situation in which the couplings of h to fermions and weak gauge bosons become the same as in the SM, without decoupling the rest of the non-standard scalars and it is of particular interest due to the fact that the discovered Higgs boson has SM-like properties. This situation will be referred to as alignment, as in the MSSM case.

In analogy to the effects of CP violation in the SUSY 2HDM, some parameters of the Higgs potential can be complex and one has a model that is explicitly CP violating. The three neutral mass eigenstates mixed with each other and the Higgs phenomenology is analogous to the one described for the SUSY case above, with the caveat that when considering the neutral Higgs boson couplings to the scalar and pseudoscalar fermion bilinear densities, the proper weight should be considered for the respective 2HDM's.

In type-II Higgs doublet models, at large values of $\tan\beta$ and moderate values of m_A, the non-standard Higgs bosons H, A and $H^\pm$ couple strongly to bottom quarks and τ leptons. Hence, the decay modes of the non-standard Higgs bosons tend to be dominated by the b-quark and τ-lepton modes, including top quarks or neutrinos in the case of the charged Higgs boson. However, for large and negative values of λ_4, the charged Higgs boson mass may be sufficiently heavy to allow on-shell decays $H^\pm \to W^\pm + (H, A)$, via a trilinear coupling

$$g_{H^\pm W^\mp H,A} \simeq \frac{M_W}{v}\sin(\beta-\alpha)(p_{H^+} - p_{H,A})\,, \quad (11.47)$$

where p_{H^+} and $p_{H,A}$ are the charged and neutral scalar Higgs boson momenta pointing into the vertex. On the other hand, for large and positive values of λ_5, the above charged Higgs boson decay into a $W^\pm$ and the CP-odd Higgs boson may be allowed, but the heavy Higgs boson H may be sufficiently heavy to decay into a CP-odd Higgs boson and an on-shell Z, $H \to Z + A$, via

$$g_{HZA} \simeq \frac{M_Z}{v}\sin(\beta-\alpha)(p_H - p_A). \quad (11.48)$$

The decay $H^\pm \to W^\pm + H$, on the other hand may be allowed only if $\lambda_4 < -\lambda_5$. The couplings controlling all the above decay modes are proportional to $\sin(\beta-\alpha)$ and therefore they are unsuppressed in the alignment limit. Moreover, these could still be the dominant decay modes at moderate values of $\tan\beta$, offering a way to evade the current bounds obtained assuming a dominant decay into b-quarks or τ-leptons.

The quartic couplings are restricted by the condition of stability of the effective potential as well as by the restriction of obtaining the proper value of the lightest CP-even Higgs boson mass. Close to the alignment limit, the lightest CP-even Higgs boson mass becomes

$$\begin{aligned} m_h^2 \simeq\ & v^2(\lambda_1\cos^4\beta + \lambda_2\sin^4\beta + 2\tilde{\lambda}_3 v^2\cos^2\beta\sin^2\beta \\ & + 4\lambda_6\cos^3\beta\sin\beta + 4\lambda_7\sin^3\beta\cos\beta)\,, \end{aligned} \quad (11.49)$$

where $\tilde{\lambda}_3 = \lambda_3 + \lambda_4 + \lambda_5$.

The stability conditions imply the positiveness of all masses, as well as the avoidance of run-away solutions to large negative values of the fields in the scalar potential. These conditions imply

$$\begin{aligned} &\lambda_1 \geq 0,\ \ \lambda_2 \geq 0,\ \ \lambda_3 + \lambda_4 - |\lambda_5| \geq -\sqrt{\lambda_1\lambda_2},\ \ \lambda_3 \geq -\sqrt{\lambda_1\lambda_2}, \\ &2|\lambda_6 + \lambda_7| < \frac{\lambda_1+\lambda_2}{2} + \tilde{\lambda}_3, \end{aligned} \quad (11.50)$$

where the first four conditions are necessary and sufficient conditions in the case of $\lambda_6 = \lambda_7 = 0$, while the last one is a necessary condition in the case all couplings are non-zero. Therefore, to obtain the conditions that allow the decays $H^\pm \to W^\pm H, A$ and $H \to ZA$, λ_3 should take large positive values in order to compensate for the effects of λ_4 and λ_5. For more detailed discussions about 2HDM phenomenology, see for example Refs. [40, 403].

11.6.5.2 *Higgs triplets*

Electroweak triplet scalars are the simplest non-doublet extension of the SM that can participate in the spontaneous breakdown of $\mathrm{SU(2)}_L \times \mathrm{U(1)}_Y$ to $\mathrm{U(1)}_{\mathrm{em}}$. Two types of model have been developed in enough detail to make a meaningful comparison to LHC data: the Higgs triplet model (HTM) [413] and the Georgi–Machacek model (GM) [414].

The Higgs triplet model extends the SM by the addition of a complex $\mathrm{SU(2)}_L$ triplet scalar field Δ with hypercharge $Y = 2$, and a general gauge-invariant renormalisable potential $V(\Phi, \Delta)$ for Δ and the SM Higgs doublet Φ. The components of the triplet field can be parameterised as

$$\Delta = \frac{1}{\sqrt{2}}\begin{pmatrix} \Delta^+ & \sqrt{2}\Delta^{++} \\ v_\Delta + \delta + i\xi & -\Delta^+ \end{pmatrix}. \quad (11.51)$$

where Δ^+ is a singly-charged field, Δ^{++} is a doubly-charged field, δ is a neutral CP-even scalar, ξ is a neutral CP-odd scalar, and v_Δ is the triplet VEV. The general scalar potential mixes the doublet and triplet components. After electroweak symmetry breaking there are seven physical mass eigenstates, denoted $H^{\pm\pm}$, $H^\pm$, A, H, and h.

A distinguishing feature of the HTM is that it violates the custodial symmetry of the SM; thus the ρ parameter deviates from 1 even at tree level. Letting x denote the ratio of triplet and doublet VEVs, the tree level expression is

$$\rho = \frac{1+2x^2}{1+4x^2}\,. \quad (11.52)$$

The measured value of the ρ parameter then limits the triplet VEV to be quite small, $x \lesssim 0.03$, or $v_\Delta < 8\,\mathrm{GeV}$. This constraint severely limits the role of the triplet scalar in the EWSB mechanism.

The small VEV of the Higgs triplet in the HTM is a virtue from the point of view of generating neutrino masses without the necessity for introducing right-handed neutrino fields. The gauge invariant dimension four interaction

$$h_{\nu_{ij}}\,\ell_i^T C^{-1} i\sigma_2\,\Delta\,\ell_j\,, \quad (11.53)$$

where ℓ_i are the lepton doublets, C is the charge conjugation matrix, and $h_{\nu_{ij}}$ is a complex symmetric coupling matrix, generates a Majorana mass matrix for the neutrinos:

$$m_{\nu_{ij}} = \sqrt{2}h_{\nu_{ij}}v_\Delta\,. \quad (11.54)$$

This can be combined with the usual neutrino seesaw to produce what is known as the type-II seesaw [415].

The HTM suggests the exciting possibility of measuring parameters of the neutrino mass matrix at the LHC. If the doubly-charged Higgs boson is light enough and/or its couplings to W^+W^+ are sufficiently suppressed, then its primary decay is into same-sign lepton pairs: $H^{++} \to \ell_i^+\ell_j^+$; from Eq. (11.53) and Eq. (11.54), it is apparent that these decays are in general lepton-flavour violating with branchings proportional to elements of the neutrino mass matrix [416].

Precision electroweak data constrain the mass spectrum as well as the triplet VEV of the HTM [417]. These constraints favour a spectrum where H^{++} is the lightest of the exotic bosons, and where the mass difference between H^+ and H^{++} is a few hundred GeV. The favoured triplet VEV is a few GeV, which also favours H^{++} decays into W^+W^+ over same-sign dileptons.

The GM model addresses the ρ parameter constraint directly by building in a custodial symmetry (it was however argued that large corrections to $\rho = 1$ are generated at one-loop [418], requiring some fine-tuning to preserves agreement with EW precision data). Writing the complex scalar doublet of the SM as a $(2, 2)$ under $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$, it is obvious that the next simplest construction respecting custodial symmetry is a scalar transforming like a $(3, 3)$ [419]. These nine real degrees of freedom correspond to a complex electroweak triplet combined with a real triplet, with the scalar potential required to be invariant under $\mathrm{SU}(2)_R$. Under the custodial $\mathrm{SU}(2)_{L+R}$, they transform as $1 \oplus 3 \oplus 5$, with a CP-even neutral scalar as the custodial singlet (thus matching the SM Higgs boson), a CP-odd neutral scalar in the custodial triplet, and another CP-even neutral scalar in the custodial 5-plet.

The scalar components can be decomposed as

$$\Xi = \begin{pmatrix} \chi_3^* & \xi_1 & \chi_1 \\ -\chi_2^* & \xi_2 & \chi_2 \\ \chi_1^* & -\xi_1^* & \chi_3 \end{pmatrix}, \tag{11.55}$$

where ξ_2 is a real scalar and the others are complex scalars. Linear combinations of these scalars account for the neutral custodial singlet, a neutral and singly-charged field making up the custodial triplet, and neutral, singly-charged, and doubly-charged fields making up the custodial 5-plet.

When combined with the usual SM doublet field Φ, the electroweak scale v is now related to the doublet and triplet VEVs by

$$v^2 = v_\Phi^2 + 8v_\Xi^2 \, . \tag{11.56}$$

Note that the GM triplets by themselves are sufficient to explain electroweak symmetry breaking and the existence of a 125 GeV neutral boson along with a custodial triplet of Goldstone bosons; the complex doublet field in the GM model is required to generate fermion masses via the usual dimension four Yukawa couplings. This raises the question of whether one can rule out the possibility that the 125 GeV boson is the neutral member of a custodial 5-plet rather than a custodial singlet, without invoking decays to fermions. A conclusive answer is given by observing that the ratio of the branching fractions to W versus Z bosons is completely determined by the custodial symmetry properties of the boson. For a custodial 5-plet, the ratio of the signal strength to WW over that to ZZ is predicted to be 1/4 that of a SM Higgs boson [419], and thus already ruled out by the experimental results presented in Section 11.5.

Another interesting general feature of Higgs triplet models is that, after mixing, the SM-like neutral boson can have stronger couplings to WW and ZZ than predicted by the SM [420]; this is in contrast to mixing with additional doublets and singlet, which can only reduce the WW and ZZ couplings versus the SM. This emphasises that LHC Higgs data cannot extract model independent coupling strengths for the Higgs boson [291].

Because of the built-in custodial symmetry, the triplet VEV in the GM model can be large compared to the doublet VEV. The custodial singlet neutral boson from the triplets mixes with the neutral boson from the doublet. Two interesting special cases are (i) the triplet VEV is small and the 125 GeV boson is SM-like except for small deviations, and (ii) the 125 GeV boson is mostly the custodial singlet neutral boson from the electroweak triplets. The phenomenology of the doubly-charged and singly-charged bosons is similar to that of the HTM. The constraints on the GM model from precision electroweak data, LEP data, and current LHC data are summarised in Ref. [40].

11.6.6 *Composite Higgs models*

Within the SM, EWSB is posited but has no dynamical origin. Furthermore, the Higgs boson appears to be unnaturally light. A scenario that remedies these two catches is to consider the Higgs boson as a bound state of new dynamics becoming strong around the weak scale. The Higgs boson can be made significantly lighter than the other resonances of the strong sector if it appears as a pseudo-Nambu–Goldstone boson, see Refs. [11] for reviews.

11.6.6.1 *Little Higgs models*

The idea behind the Little Higgs boson models [421] is to identify the Higgs doublet as a (pseudo) Nambu–Goldstone boson while keeping some sizeable non-derivative interactions, in particular a largish Higgs quartic interaction. By analogy with QCD where the pions $\pi^{\pm,0}$ appear as Nambu–Goldstone bosons associated to the breaking of the chiral symmetry $\mathrm{SU(2)_L} \times \mathrm{SU(2)_R}/\mathrm{SU(2)}$, switching on some interactions that break explicitly the global symmetry will generate masses for the would-be massless Nambu–Goldstone bosons of the order of $g\Lambda_{G/H}/(4\pi)$, where g is the coupling of the symmetry breaking interaction and $\Lambda_{G/H} = 4\pi f_{G/H}$ is the dynamical scale of the global symmetry breaking G/H. In the case of the Higgs boson, the top Yukawa interaction or the gauge interactions themselves will certainly break explicitly (part of) the global symmetry since they act non-linearly on the Higgs boson. Therefore, obtaining a Higgs boson mass around 125 GeV would demand a dynamical scale $\Lambda_{G/H}$ of the order of 1 TeV, which is known to lead to too large oblique corrections. Raising the strong dynamical scale by at least one order of magnitude requires an additional selection rule to ensure that a Higgs boson mass is generated at the 2-loop level only

$$m_H^2 = \frac{g^2}{16\pi^2}\Lambda_{G/H}^2 \to m_H^2 = \frac{g_1^2 g_2^2}{(16\pi^2)^2}\Lambda_{G/H}^2. \tag{11.57}$$

The way to enforce this selection rule is through a "collective breaking" of the global symmetry:

$$\mathcal{L} = \mathcal{L}_{G/H} + g_1\mathcal{L}_1 + g_2\mathcal{L}_2. \tag{11.58}$$

Each interaction $\mathcal{L}_1$ or $\mathcal{L}_2$ individually preserves a subset of the global symmetry such that the Higgs boson remains an exact Nambu–Goldstone boson whenever either g_1 or g_2 is vanishing. A mass term for the Higgs boson can be generated only by diagrams involving simultaneously both interactions. At one-loop, such diagrams are not quadratically divergent, so the Higgs boson mass is not UV sensitive. Explicitly, the cancellation of the SM quadratic divergences is achieved by a set of new particles around the Fermi scale: gauge bosons, vector-like quarks, and extra massive scalars, which are related, by the original global symmetry, to the SM particles with the same spin. Contrary to SUSY, the cancellation of the quadratic divergences is achieved by same-spin particles. These new particles, with definite couplings to SM particles as dictated by the global symmetries of the theory, are perfect goals for the LHC.

The simplest incarnation of the collective breaking idea, the so-called littlest Higgs boson model, is based on a non-linear σ-model describing the spontaneous breaking SU(5) down to SO(5). A subgroup $\mathrm{SU(2)_1} \times \mathrm{U(1)_1} \times \mathrm{SU(2)_2} \times \mathrm{U(1)_2}$ is weakly gauged. This model contains a weak doublet, that is identified with the Higgs doublet, and a complex weak triplet whose mass is not protected by collective breaking. Other popular little Higgs models are based on different coset spaces: minimal moose $(\mathrm{SU}(3)^2/\mathrm{SU}(3))$, the simplest little Higgs $(\mathrm{SU}(3)^2/\mathrm{SU}(2)^2)$, the bestest little Higgs $(\mathrm{SO}(6)^2/\mathrm{SO}(6))$. For comprehensive reviews, see Ref. [422].

Generically, oblique corrections in Little Higgs models are reduced either by increasing the coupling of one of the gauge groups (in the case of product group models) or by increasing the masses of the W and Z partners, leading ultimately to a fine-tuning of the order of a few percents (see for instance Ref. [423] and references therein). The compatibility of Little Higgs models with experimental data is significantly improved when the global symmetry involves a custodial symmetry as well as a T-parity [424] under which, in analogy with R-parity in SUSY models, the SM particles are even and their partners are odd. Such Little Higgs models would therefore appear in colliders as jet(s) with missing transverse energy [425] and the ATLAS and CMS searches for squarks and gluinos can be recast to obtain limits on the masses of the heavy vector-like quarks. The T-even top partner, with an expected mass below 1 TeV to cancel the top loop quadratic divergence without too much fine-tuning, would decay dominantly into

a $t+Z$ pair or into a $b+W$ pair or even into $t+H$. The latest CMS and ATLAS direct searches [426] for vector-like top partners put a lower bound around 1.1–1.3 TeV (for various branching fraction combinations), excluding the most natural region of the parameter space of these models, i.e., imposing a fine-tuning below the percent level.

The motivation for Little Higgs models is to solve the little hierarchy problem, i.e., to push the need for new physics (responsible for the stability of the weak scale) up to around 10 TeV. Per se, Little Higgs models are effective theories valid up to their cut-off scale $\Lambda_{G/H}$. Their UV completions could either be weakly or strongly coupled.

11.6.6.2 *Models of partial compositeness*

Even in composite models, the Higgs boson cannot appear as a regular resonance of the strong sector without endangering the viability of the setup when confronted to data. The way out is that the Higgs boson appears as a pseudo Nambu–Goldstone boson: the new strongly coupled sector is supposed to be invariant under a global symmetry G spontaneously broken to a subgroup H at the scale f (the typical mass scale of the resonances of the strong sector is $m_\rho \sim g_\rho f$ with g_ρ the characteristic coupling of the strong sector). To avoid conflict with EW precision measurements, the strong interactions themselves should better not break the EW symmetry. Hence the SM gauge symmetry itself should be contained in H. See Table 11.10 for a few examples of coset spaces.

Table 11.10: Global symmetry breaking patterns and the corresponding Goldstone boson contents of the SM, the minimal composite Higgs model, the next to minimal composite Higgs model, and the minimal composite two Higgs doublet model. Note that the SU(3) model does not have a custodial invariance. a denotes a CP-odd scalar while h and H are CP-even scalars.

Model	Symmetry Pattern	Goldstones
SM	SO(4)/SO(3)	W_L, Z_L
–	SU(3)/SU(2)×U(1)	W_L, Z_L, H
MCHM	SO(5)/SO(4)	W_L, Z_L, H
NMCHM	SO(6)/SO(5)	W_L, Z_L, H, a
MC2HM	SO(6)/SO(4)×SO(2)	$W_L, Z_L, h, H, H^\pm, a$

The SM (light) fermions and gauge bosons cannot be part of the strong sector itself since LEP data have already put stringent bounds on the compositeness scale of these particles far above the TeV scale. The gauge bosons couple to the strong sector by a weak gauging of a SU(2)×U(1) subgroup of the global symmetry G. Inspiration for the construction of such models comes from the AdS/CFT correspondence: the components of a gauge field along an extra warped space dimension can be interpreted as the Goldstone bosons resulting from the breaking of global symmetry of the strong sector. The couplings of the SM fermions to the strong sector could a priori take two different forms:

(i) a bilinear coupling of two SM fermions to a composite scalar operator, $\mathcal{O}$, of the form $\mathcal{L} = y\,\bar{q}_L u_R \mathcal{O} + h.c.$, in simple analogy with the SM Yukawa interactions. This is the way fermion masses were introduced in technicolor theories and it generically comes with severe flavour problems and calls for extended model-building gymnastics [12] to circumvent them;

(ii) a linear mass mixing with fermionic vector-like operators: $\mathcal{L} = \lambda_L\,\bar{q}_L \mathcal{Q}_R + \lambda_R \bar{\mathcal{U}}_L u_R$. $\mathcal{Q}$ and $\mathcal{U}$ are two fermionic composite operators of mass M_Q and M_U.

Being part of the composite sector, the composite fermionic operators can have a direct coupling of generic order Y_* to the Higgs boson. In analogy with the photon-ρ mixing in QCD, once the linear mixings are diagonalised, the physical states are a linear combination of elementary and composite fields. Effective Yukawa couplings are generated and read for instance for the up-type quark

$$y = Y_* \sin\theta_L \sin\theta_R \tag{11.59}$$

where $\sin\theta_i = \lambda_i/\sqrt{M_{Q,U}^2 + \lambda_i^2}$, $i = L, R$, measure the amount of compositeness of the SM left- and right-handed up-type quark. If the strong sector is flavour-anarchic, i.e., if the couplings of the Higgs boson to the composite fermions does not exhibit any particular flavour structure, the relation Eq. (11.59) implies that the light fermions are mostly elementary states ($\sin\theta_i \ll 1$), while the third generation quarks need to have a sizable degree of compositeness. The partial compositeness paradigm offers an appealing dynamical explanation of the hierarchies in the fermion masses. In fact, assuming the strong sector to be almost conformal above the confinement scale, the low-energy values of the mass-mixing parameters $\lambda_{L,R}$ are determined by the (constant) anomalous dimension of the composite operator they mix with. If the UV scale at which the linear mixings are generated is large, then $\mathcal{O}(1)$ differences in the anomalous dimensions can generate naturally large hierarchies in the fermion masses via renormalisation group running [427]. While the introduction of partial compositeness greatly ameliorated the flavour problem of the original composite Higgs models, nevertheless, it did not solve the issue completely, at least in the case where the strong sector is assumed to be flavour-anarchic [428]. While the partial compositeness set-up naturally emerges in models built in space-times with extra dimensions, no fully realistic microscopic realisation of partial compositeness has been proposed in the literature.

Another nice aspect of the partial compositeness structure is the dynamical generation of the Higgs potential that is not arbitrary like in the SM. The Higgs boson being a pseudo-Nambu–Goldstone boson, its mass does not receive any contribution from the strong sector itself but it is generated at the one-loop level via the couplings of the SM particles to the strong sector since these interactions are breaking the global symmetries under which the Higgs doublet transforms non-linearly. Obtaining $v \ll f$, as required phenomenologically, requires some degree of tuning, which scales like $\xi \equiv v^2/f^2$. A mild tuning of the order of 10% ($\xi \approx 0.1$) is typically enough to comply with electroweak precision constraints. This is an important point: in partial compositeness models, the entire Higgs potential is generated at one loop, therefore the separation between v and f can only be obtained at a price of a tuning. This marks a difference with respect to the Little Higgs models which realise a parametric hierarchy between the quartic and mass terms through the collective symmetry breaking mechanism. In fact in Little Higgs models, the quartic coupling is a tree-level effect, leading to a potential

$$V(H) \approx \frac{g_{\rm SM}^2}{16\pi^2} m_\rho^2 H^2 + g_{\rm SM}^2 H^4, \tag{11.60}$$

where $g_{\rm SM}$ generically denotes the SM couplings. The minimisation condition reads $v^2/f^2 \sim g_\rho^2/(16\pi^2)$, therefore v is formally loop suppressed with respect to f. This is the major achievement of the Little Higgs constructions, which however comes at the price of the presence of sub-TeV vectors carrying EW quantum numbers and therefore giving rise generically to large oblique corrections to the propagators of the W and the Z gauge bosons.

After minimisation, the dynamically generated potential leads to an estimate of the Higgs boson mass as

$$m_H^2 \approx g_\rho^3\, y_t 2\pi^2 v^2. \tag{11.61}$$

It follows that the limit $f \to \infty$, i.e., $\xi \to 0$, is a true decoupling limit: all the resonances of the strong sector become heavy but the Higgs boson whose mass is protected by the symmetries of the coset G/H. When compared to the experimentally measured Higgs boson mass, this estimate puts an upper bound on the strength of the strong interactions: $g_\rho \lesssim 2$. In this limit of not so large coupling, the Higgs potential receives additional contributions. In particular, the fermionic resonances in the top sector which follow from the global symmetry structure of the new physics sector can help raising the Higgs boson mass. Using some dispersion relation techniques, the mass of the Higgs is connected to the resonance masses. In the minimal SO(5)/SO(4) model, it was shown [429] that a 125 GeV mass can be obtained if at least one of the fermionic resonances is lighter than $\sim 1.4\,f$. As in SUSY scenarios, the top sector is playing a crucial role in the

dynamics of EWSB and can provide the first direct signs of new physics. The direct searches for these top partners, in particular the ones with exotic electric charges 5/3, are already exploring the natural parameter spaces of these models [430].

The main physics properties of a pseudo Nambu–Goldstone Higgs boson can be captured in a model-independent way by a small number of higher-dimensional operators. Indeed, the strong dynamics at the origin of the composite Higgs boson singles out a few operators among the complete list discussed earlier in Section 11.5: these are the operators that involve extra powers of the Higgs doublets, and they are therefore generically suppressed by a factor $1/f^2$ as opposed to the operators that involve extra derivatives or gauge bosons that are suppressed by a factor $1/(g_\rho^2 f^2)$. The relevant effective Lagrangian describing a strongly interacting light Higgs boson is:

$$\mathcal{L}_{\rm SILH} = \frac{c_H}{2f^2}\left(\partial_\mu\left(\Phi^\dagger\Phi\right)\right)^2 + \frac{c_T}{2f^2}\left(\Phi^\dagger \overleftrightarrow{D}^\mu \Phi\right)^2 - \frac{c_6\lambda}{f^2}\left(\Phi^\dagger\Phi\right)^3 + \left(\sum_f \frac{c_f\, y_f}{f^2}\Phi^\dagger\Phi\bar{f}_L\Phi f_R + \text{h.c.}\right). \tag{11.62}$$

Typically, these new interactions induce deviations in the Higgs boson couplings that scale like $\mathcal{O}(v^2/f^2)$. Hence, the measurements of the Higgs boson couplings can be translated into some constraints on the compositeness scale, $4\pi f$, of the Higgs boson. The peculiarity of these composite models is that, due to the Goldstone nature of the Higgs boson, the direct couplings to photons and gluons are further suppressed and generically the coupling modifiers scale like

$$\kappa_{W,Z,f} \sim 1 + \mathcal{O}\left(\frac{v^2}{f^2}\right), \quad \kappa_{Z\gamma} \sim \mathcal{O}\left(\frac{v^2}{f^2}\right), \quad \kappa_{\gamma,g} \sim \mathcal{O}\left(\frac{v^2}{f^2}\times\frac{y_t^2}{g_\rho^2}\right), \tag{11.63}$$

where g_ρ denotes the typical coupling strength among the states of the strongly coupled sector and y_t is the top Yukawa coupling, the largest interaction that breaks the Goldstone symmetry. The $\kappa_{Z\gamma,\gamma,g}$ coupling modifiers are not generated by the strong coupling operators of Eq. (11.62) but by some subleading form-factor operator generated by loops of heavy resonances of the strong sector. The coupling modifiers also receive additional contributions from the other resonances of the strong sector, in particular the fermionic resonances of the top sector that are required to be light to generate a 125 GeV Higgs boson mass. Some indirect information on the resonance spectrum could thus be inferred by a precise measurement of the Higgs boson coupling deviations. However, it was realised, see in particular Ref. [306], that the task is actually complicated by the fact that, in the minimal models, these top partners give a contribution to both κ_t (resulting from a modification of the top Yukawa coupling) and κ_γ and κ_g (resulting from new heavy particles running into the loops) and the structure of interactions is such that the net effect vanishes for inclusive quantities like $\sigma(gg \to H)$ or $\Gamma(H \to \gamma\gamma)$ as a consequence of the Higgs low energy theorem [21, 22, 301]. So, one would need to rely on differential distribution, like the Higgs boson p_T distribution discussed in Section 11.2.4.1, to *see* the top partner effects in Higgs data [431]. The off-shell channel $gg \to H^* \to 4\ell$ [290] and the double Higgs boson production $gg \to HH$ [432] can also help to resolve the gluon loop and separate the top and top-partner contributions.

11.6.6.3 *Minimal composite Higgs models*

The minimal composite Higgs models (MCHM) are concrete examples of the partial compositeness paradigm. The Higgs doublet is described by the coset space SO(5)/SO(4) where a subgroup $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ is weakly gauged and under which the four Goldstone bosons transform as a doublet of hypercharge 1. There is some freedom on how the global symmetry is acting on the SM fermions: in MCHM4 the quarks and leptons are embedded into spinorial representations of SO(5), while in MHCM5 they are part of fundamental representations (it might also be interesting phenomenologically to consider larger representations like MCHM14 [433] with the SM fermions inside a representation of dimension 14). It is also possible to consider that fermions of different chirality and flavour are in different representations of SO(5), leading to a more varied phenomenology [434]. The non-linearly realised symmetry acting on the Goldstone bosons leads to general predictions of the coupling of the Higgs boson to the EW gauge bosons. For instance, it can be shown that the quadratic terms in the W and Z bosons read

$$m_W^2(H)\left(W_\mu W^\mu + \frac{1}{2\cos^2\theta_W} Z_\mu Z^\mu\right), \tag{11.64}$$

with $m_W(H) = \frac{gf}{2}\sin\frac{H}{f}$. Expanding around the EW vacuum, the expression of the weak scale is $v = f\sin(\langle H\rangle/f)$. And the values of the modified Higgs boson couplings to the W and Z become:

$$g_{HVV} = \frac{2m_V^2}{v}\sqrt{1-v^2/f^2}\,, \quad g_{HHVV} = \frac{2m_V^2}{v^2}(1-2v^2/f^2)\,. \tag{11.65}$$

Note that the Higgs boson couplings to gauge bosons is always suppressed compared to the SM prediction. This is a general result [435] that holds as long as the coset space is compact.

The Higgs boson couplings to the fermions depend on the representation which the SM fermions are embedded into. The most commonly used embeddings consider all fermion doublets and singlets in the same representations. While, in MCHM4 and MCHM5, the modifications of the couplings depend only on the Higgs boson compositeness scale, in MCHM14 the leading corrections depend also on the mass spectrum of the resonances [433]. This is due to the fact that more than one SO(5) invariant gives rise to SM fermion masses. The (κ_V, κ_f) experimental fit of the Higgs boson couplings can be used to derive a lower bound on the Higgs boson compositeness scale $4\pi f \gtrsim 9\,\text{TeV}$, which is less stringent than the indirect bound obtained from EW precision data, $4\pi f \gtrsim 15\,\text{TeV}$ [436] but more robust and less subject on assumptions [437].

11.6.6.4 *Twin Higgs models*

In all composite models presented above, the particles responsible for canceling the quadratic divergences in the Higgs boson mass are charged under the SM gauge symmetries. In particular, the top partner carries color charge, implying a reasonably large minimal production cross section at the LHC. An alternative scenario, which is experimentally quite challenging and might explain the null result in various new physics searches, is the case nowadays referred to as "neutral naturalness" [13, 14], where the particles canceling the 1-loop quadratic divergences are neutral under the SM. The canonical example for such theories is the Twin Higgs model of Ref. [13]. This is an example of a pseudo-Goldstone boson model with an approximate global SU(4) symmetry broken to SU(3). The Twin Higgs model is obtained by gauging the $\mathrm{SU}(2)_A \times \mathrm{SU}(2)_B$ subgroup of SU(4), where $\mathrm{SU}(2)_A$ is identified with the SM $\mathrm{SU}(2)_L$, while $\mathrm{SU}(2)_B$ is the twin SU(2) group. Gauging this subgroup breaks the SU(4) symmetry explicitly, but quadratically divergent corrections do not involve the Higgs boson when the gauge couplings of the two SU(2) subgroups are equal, $g_A = g_B$. The SU(4)$\to$ SU(3) breaking will also result in the breaking of the twin $\mathrm{SU}(2)_B$ group and, as a result, three of the seven Goldstone bosons will be eaten, leaving 4 Goldstone bosons corresponding to the SM Higgs doublet. In fact, imposing the Z_2 symmetry on the full model will ensure the cancellation of all 1-loop quadratic divergences to the Higgs boson mass. Logarithmically divergent terms can, however, arise for example from gauge loops, leading to a Higgs boson mass of order $g^2 f/4\pi$, which is of the order of the physical Higgs boson mass for $f \sim 1\,\text{TeV}$. The quadratic divergences from the top sector can be eliminated if the Z_2 protecting the Higgs boson mass remains unbroken by the couplings that result in the top Yukawa coupling. This can be achieved by introducing top partners charged under a twin $\mathrm{SU}(3)_C$. In this case, the quadratic divergences are cancelled by top partners that are neutral under the SM gauge symmetries.

Twin Higgs models are low-energy effective theories valid up to a cutoff scale of order $\Lambda \sim 4\pi f \sim$ 5–10 TeV, beyond which a UV completion has to be specified. The simplest such possibility is to also make the Higgs boson composite, and to UV complete the twin Higgs model via gauge and top partners at masses of the order of a few TeV. A concrete implementation is the holographic twin Higgs model [438], which also incorporates a custodial symmetry to protect the T-parameter from large corrections. It is based on a warped extra dimensional theory with a bulk SO(8) gauge group, which incorporates the SU(4) global symmetry discussed above enlarged to contain the $\mathrm{SU}(2)_L \times \mathrm{SU}(2)_R$ custodial symmetry. In addition, the bulk contains either a full SU(7) group or an $\mathrm{SU}(3) \times \mathrm{SU}(3) \times \mathrm{U}(1) \times \mathrm{U}(1) \times Z_2$ subgroup of it to incorporate the QCD, its twin, and the hypercharge local symmetries. The breaking on the UV brane is to the SM symmetries and their twin symmetries, while on the IR brane $\mathrm{SO}(8) \to \mathrm{SO}(7)$, giving rise to the 7 Goldstone bosons, three of which will be again eaten by the twin W, Z. The main difference compared to ordinary composite Higgs models is that, in composite twin Higgs models, the cancellation of the one-loop quadratic divergences is achieved by the twin partners. They have a mass of order 700 GeV–1 TeV and they are uncharged under the SM gauge group. This allows the IR scale of the warped extra dimension to be raised to the multi-TeV range without reintroducing the hierarchy problem. The role of the composite partners is to UV complete the theory, rather than to cancel the one-loop quadratic divergences. For more details about the composite twin Higgs models, see Refs. [439].

11.6.7 *Searches for signatures of extended Higgs sectors*

The measurements described in Sections 11.3 to 11.5 have established the existence of one state of the electroweak symmetry breaking sector, compatible with a SM Higgs boson, but not that it is the only one. As was discussed above, several classes of models beyond the SM require extended Higgs sectors. The searches are typically designed to be as model-independent as possible[7] and can be categorised in the classes summarised as follows:

- **(i)** the search for an additional CP-even state mostly in the high mass domain decaying to vector bosons, which would correspond either to the heavy CP-even state in a generic 2HDM where the light state would be the discovered Higgs boson at 125 GeV or to a generic additional singlet;
- **(ii)** the search for a state in the high mass domain decaying to pairs of fermions, which would correspond to the CP-odd A or the heavy CP-even state H in a generic 2HDM;
- **(iii)** the search for charged Higgs bosons, which also appear in generic 2HDMs;
- **(iv)** the search for a CP-odd state a in the low mass region which appears in the NMSSM in a variety of final states, e.g., with one or two a bosons decaying to pairs of photons, muons, taus, and b-quarks;
- **(v)** the search for doubly charged Higgs bosons which are expected in extensions of the Higgs sector with triplets.

Below is a concise description of the most recent searches performed at the LHC and elsewhere. A summary of these searches in terms of final states is given in Table 11.11 where the corresponding references are given for more details.

11.6.7.1 *Searches for an additional CP-even state*

(a) Exclusion limits from LEP

The searches for the SM Higgs boson at LEP provided an absolute lower limit of 114 GeV on its mass. These searches are also relevant for non-SM Higgs bosons. These searches were interpreted as 95% CL upper bounds on the ratio of the coupling g_{HZZ} to its SM prediction as a function of the Higgs boson mass [139, 523]. These results have an impact on MSSM benchmarks such as the low-m_H scenario where the heavy CP-even Higgs boson is the discovered 125 GeV boson [374], which is also nearly ruled out by current direct constraints and charged Higgs boson limits from LHC. These results also impact scenarios of light CP-even Higgs boson of the NMSSM which are constrained to project predominantly onto the EW singlet component. Additional interest for these scenarios is due to the slight excess observed at LEP [139] at a Higgs boson mass hypothesis of approximately 98 GeV, bolstered by a possible excess in the diphoton channel at 96 GeV in Run-2 data of CMS [445].

(b) Searches at the LHC

At the LHC, the searches for the SM Higgs boson before the 2012 discovery covered a wide range of mass hypotheses up to approximately 1 TeV. After the discovery, the SM Higgs boson searches have been reappraised to search for a heavy CP-even state, extending progressively the search mass range beyond 1 TeV. This state could be the heavy CP-even Higgs boson of a 2HDM, or a generic additional singlet. In both cases, the natural width of the additional H state can be very different from that of the SM Higgs boson. To preserve unitarity of the longitudinal vector boson scattering and the longitudinal vector boson scattering into fermion pairs, the couplings of the additional CP-even Higgs boson to gauge bosons and fermions should not be too large and should constrain the natural width to be smaller than that of a unique Higgs boson at high mass with couplings to fermions and gauge bosons as predicted by the SM (and provided that trilinear and quartic couplings are not too large and that no new state affects the heavy state total width). It is therefore reasonable to consider total widths for the high mass CP-even state smaller than the equivalent SM width. Two specific cases have been considered: (i) the SM width using the complex pole scheme (CPS), and (ii) the narrow width approximation. For the sake of generality, these searches are now done as a function of the Higgs boson mass and total width.

Searches for the Higgs boson in the channels $H \to \gamma\gamma$, $H \to Z\gamma$, $H \to WW^{(*)}$ leptonic and semi-leptonic, and in the $H \to ZZ^{(*)}$ searches in the 4ℓ, $\ell\ell q\bar{q}$ and $\ell\ell\nu\nu$ channels have also been done, but some of them are simple reinterpretations of the SM Higgs boson search in the CPS scheme. References for these searches are summarised in Table 11.11.

(c) Searches for an additional resonance decaying to a pair of Higgs bosons

In addition to the rare and expected Higgs boson pair production mode, high mass CP-even Higgs bosons can be searched for in the resonant double Higgs boson mode. Searches for such processes, where the Higgs boson is used as a tool for searches for BSM phenomena, have been carried out in a variety of distinct modes depending on the subsequent decays of each Higgs bosons. ATLAS and CMS have searched for the $H \to hh \to b\bar{b}\tau\tau$, $b\bar{b}\gamma\gamma$, $H \to hh \to 4b$, $H \to hh \to \gamma\gamma WW^*$, $H \to hh \to bbWW^*$, $H \to hh \to WW^*WW^*$ and $H \to hh \to bbZZ^*$ final states. For mass hypotheses of an additional Higgs boson below 500 GeV, the two dominant search channels are the $b\bar{b}\gamma\gamma$ and the $b\bar{b}\tau\tau$ channels. For masses above 500 GeV, the most powerful search is with the $4b$ final state. As illustrated in Fig. 11.17, these searches provide useful limits in the low $\tan\beta$ and high mass domain. The list of references for these searches is given in Table 11.11.

(d) Searches for an additional state with the presence of the Higgs boson

In the post-discovery era, analyses searching for additional Higgs bosons need to take into account the presence of the 125 GeV Higgs boson. For searches with sufficiently high mass resolution to disentangle the additional states which are not degenerate in mass, the strength of the observed state and limits on the signal strength of a potential additional state can be set independently, as discussed in the next section. However, in some cases where channels do not have a sufficiently fine mass resolution to resolve states nearly degenerate in mass, specific analyses need to be designed. There are two examples of such analyses: (i) the search for an additional state in the $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel in ATLAS, and (ii) the search for nearly degenerate states in the $H \to \gamma\gamma$ channel with the CMS detector.

[7] Still, most non-SUSY models are likely to include further states and dynamics above the weak scale to stabilise the scalar sector and this new and unknown physics may influence the searches described in this section in a way difficult to estimate.

Table 11.11: Summary of references to the searches for additional states from extended Higgs sectors. (BBr) denotes the BaBar experiment and (TeV), the Tevatron experiments. V denotes either the W or the Z boson. Only Run-2 searches references are indicated except when searches have been carried out using Run-1 data only. References for Run-1 searches are available in Ref. [141].

In the $H \to WW^{(*)} \to \ell\nu\ell\nu$ channel, the search for an additional state is done using a boosted decision tree combining several discriminating kinematic characteristics to separate both the signal from the background and a high mass signal H from the lower mass state h [524]. A simultaneous fit of the two states h and H is then made to test the presence of an additional state. In this case, the usual null hypothesis of background includes the SM signal.

The CMS search for nearly degenerate mass states decaying to a pair of photons [525] is more generic and could for instance apply to CP-odd Higgs bosons as well. It consists of a fit to the diphoton mass spectrum using two nearly degenerate mass templates.

(e) Type I 2HDM and fermiophobia

The measurements of coupling properties of the 125 GeV Higgs boson directly establish its couplings to fermions. However, the presence of an additional fermiophobic state, as predicted by Type I 2HDMs, is not excluded. Prior to the discovery, ATLAS and CMS have performed searches for a fermiophobic Higgs boson, i.e., produced through couplings with vector bosons only (VBF and VH) and decaying in two photons. CMS has further combined these results with searches in the W^+W^- and ZZ channels, assuming fermiophobic production and decay. This way, CMS excluded a fermiophobic Higgs boson in the range 110 GeV $< m_H <$ 188 GeV at the 95% CL. References for these Run-1 measurements can be found in Ref. [141]

11.6.7.2 *Searches for additional neutral states ($\phi \equiv h$, H, A) decaying to fermions*

(a) Exclusion limits from LEP

In e^+e^- collisions, around the centre-of-mass energies reached by LEP, the main production mechanisms of the neutral MSSM Higgs bosons were the Higgs-strahlung processes $e^+e^- \to hZ$, HZ and the pair production processes $e^+e^- \to hA$, HA, while the vector boson fusion processes played a marginal role. Higgs boson decays to $b\bar{b}$ and $\tau^+\tau^-$ were used in these searches.

The searches and limits from the four LEP experiments are described in Refs. [526]. The combined LEP data did not contain any excess of events which would imply the production of a Higgs boson. Combined limits were derived [523]. For $m_A \gg M_Z$, the limit on m_h is nearly that of the SM searches, as $\sin^2(\beta-\alpha) \approx 1$. For high values of $\tan\beta$ and low m_A ($m_A \leq m_h^{max}$), the $e^+e^- \to hA$ searches become the most important, and the lightest Higgs boson h is non SM-like. In this region, the 95% CL mass bounds are $m_h > 92.8$ GeV and $m_A > 93.4$ GeV. In the m_h^{max}

scenario [527], values of $\tan\beta$ from 0.7 to 2.0 are excluded taking $m_t = 174.3\,\text{GeV}$, while a much larger $\tan\beta$ region is excluded for other benchmark scenarios such as the no-mixing one.

A flavour-independent limit for Higgs bosons in the Higgs-strahlung process at LEP has also been set at 112 GeV [528].

Neutral Higgs bosons may also be produced by Yukawa processes $e^+e^- \to f\bar{f}\phi$, where the Higgs particle $\phi \equiv h$, H, A, is radiated off a massive fermion ($f \equiv b$ or $\tau^\pm$). These processes can be dominant at low masses, and whenever the $e^+e^- \to hZ$ and hA processes are suppressed. The corresponding ratios of the $f\bar{f}h$ and $f\bar{f}A$ couplings to the SM coupling are $-\sin\alpha/\cos\beta$ and $\tan\beta$, respectively. The LEP data have been used to search for $b\bar{b}\,b\bar{b}$, $b\bar{b}\tau^+\tau^-$, and $\tau^+\tau^-\,\tau^+\tau^-$ final states [529]. Regions of low mass and high enhancement factors are excluded by these searches.

The searches for the Higgs boson at LEP also included the case where it does not predominantly decay to a pair of b quarks. All four collaborations conducted dedicated searches for the Higgs boson with reduced model dependence, assuming it is produced via the Higgs-strahlung process, and not addressing its flavour of decay, a lower limit on the Higgs boson mass of 112.9 GeV is set by combining the data of all four experiments [528].

Using an effective Lagrangian approach and combining results sensitive to the $h\gamma\gamma$, $hZ\gamma$ and hZZ couplings, an interpretation of several searches for the Higgs boson was made and set a lower limit of 106.7 GeV on the mass of a Higgs boson that can couple anomalously to photons [528].

(b) Searches at the Tevatron and the LHC

The best sensitivity is in the regime with low to moderate m_A and with large $\tan\beta$ which enhances the couplings of the Higgs bosons to down-type fermions. The corresponding limits on the Higgs boson production cross section times the branching ratio of the Higgs boson into down-type fermions can be interpreted in MSSM benchmark scenarios [530]. The most promising channels at the Tevatron are the inclusive $p\bar{p} \to \phi \to \tau^+\tau^-$ process ($\phi = A, H, h$), with contributions from both $gg \to \phi$ and $b\bar{b}\phi$ production, and $b\bar{b}\phi, \phi \to \tau^+\tau^-$ or $\phi \to b\bar{b}$, with $b\tau\tau$ or three tagged b-jets in the final state, respectively. Although the Higgs boson production via gluon fusion has a higher cross section in general than via associated production, it cannot be used to study the $\phi \to b\bar{b}$ decay mode since the signal is overwhelmed by the QCD background.

CDF and D0 have searched for neutral Higgs bosons produced in association with bottom quarks and which decay into $b\bar{b}$ [484, 485], or into $\tau^+\tau^-$ [471,472]. The most recent searches in the $b\bar{b}\phi$ channel with $\phi \to b\bar{b}$ analyse approximately $2.6\,\text{fb}^{-1}$ (CDF) and $5.2\,\text{fb}^{-1}$ (D0) of data, seeking events with at least three b-tagged jets. The cross section is defined such that at least one b quark not from ϕ decay is required to have $p_T > 20\,\text{GeV}$ and $|\eta| < 5$. The invariant mass of the two leading jets as well as b-tagging variables are used to discriminate the signal from the backgrounds. The QCD background rates and shapes are inferred from data control samples, in particular, the sample with two b-tagged jets and a third, untagged jet. Separate-signal hypotheses are tested and limits are placed on $\sigma(p\bar{p} \to b\bar{b}\phi) \times \text{BR}(\phi \to b\bar{b})$. A local excess of approximately 2.5σ significance has been observed in the mass range of 130–160 GeV, but D0's search is more sensitive and sets stronger limits. The D0 result had a $\mathcal{O}(2\sigma)$ local upward fluctuation in the 110 to 125 GeV mass range. These results have been superseded by the LHC searches and the excess seen by D0 has not been confirmed elsewhere.

A substantially larger sensitivity in the search for the $\phi \to \tau^+\tau^-$ is obtained with the ATLAS and CMS analyses. The higher centre-of-mass energy reached at the Run 2 brings a substantial, though not excessively large, increase in sensitivity due to the intermediate masses probed. Both ATLAS and CMS have reported the result of their searches in this important channel with the full 2016 dataset. The searches are performed in categories of the decays of the two tau leptons: $e\tau_{\text{had}}$, $\mu\tau_{\text{had}}$, $e\mu$, and $\mu\mu$, where τ_{had} denotes a tau lepton which decays to one or more hadrons plus a tau neutrino, e denotes $\tau \to e\nu\nu$, and μ denotes $\tau \to \mu\nu\nu$. The dominant background comes from $Z \to \tau^+\tau^-$ decays, although $t\bar{t}$, W+jets and Z+jets events contribute as well. Separating events into categories based on the number of b-tagged jets improves the sensitivity in the MSSM. The $b\bar{b}$ annihilation process and radiation of a Higgs boson from a b quark gives rise to events in which the Higgs boson is accompanied by a $b\bar{b}$ pair in the final state. Requiring the presence of one or more b-jets reduces the background from Z+jets. Data control samples are used to constrain background rates. The rates for jets to be identified as a hadronically decaying tau lepton are measured in dijet samples, and W+jets samples provide a measurement of the rate of events that, with a fake hadronic tau, can pass the signal selection requirements. Lepton fake rates are measured using samples of isolated lepton candidates and same-sign lepton candidates. Constraints from the ATLAS searches are shown in Fig. 11.17 (left) in the hMSSM approximation defined in Ref. [376]. The neutral Higgs boson searches consider the contributions of both the CP-odd and CP-even neutral Higgs bosons with enhanced couplings to bottom quarks, similarly to was done for the Tevatron results. In Fig. 11.17, decays of the charged Higgs boson into $\tau\nu$ and decays of the heavy Higgs boson into a pair of SM-like Higgs bosons or gauge bosons, or decays of A into hZ are also being constrained. In addition, decays of the neutral Higgs bosons into muon pairs are also being explored. In the $m_h^{\text{mod+}}$ scenario, the region of $\tan\beta$ lower than 5 does not allow for a Higgs boson mass m_h close to 125 GeV. For the hMSSM scenario, instead, the SM-like Higgs boson mass is fixed as an input and hence the requirement that it is close to 125 GeV is always fulfilled, although this may imply other limitations as discussed in Section 11.6.1.1.

A search for $\phi \to \mu^+\mu^-$ has also been performed by ATLAS [475] and CMS [476] and no significant deviations from the SM expectation were observed, allowing to set model-independent limit on the product of the branching fraction for the decay into a muon pair and the cross section for the production of a scalar neutral boson, either via gluon fusion, or in association with b quarks, in the mass range from 130 to 1000 GeV.

Finally, searches for a resonance decaying to a top quark pair were done by ATLAS [480, 531] and CMS [481, 532]. These searches were interpreted as searches for scalar resonances by ATLAS [480], however, an important component of these searches is an accurate treatment of the interference effects between the signal and the continuum background. These effects can yield a dip and peak structure instead of a simple peak [372]. ATLAS has performed a search for a high mass state decaying to a pair of top quarks taking into account the deformation in mass shape of the signal in the presence of the continuum background [533].

The LHC has the potential to explore a broad range of SUSY parameter space through the search for non-SM-like Higgs bosons. As illustrated in Fig. 11.17, the parameter space corresponding to large $\tan\beta$ values and large masses of the A boson are covered mostly by the searches in the $A, H \to \tau^+\tau^-$ channel. A projection of the combined sensitivity of ATLAS and CMS at the HL-LHC has been performed in Ref. [118], showing that, compared to the current sensitivity, the full HL-LHC luminosity can expand the exclusion domain by nearly 1 TeV. In the low $\tan\beta$ limit, the parameter space spanning large A boson masses is best excluded indirectly from the observed Higgs boson measurements. This is illustrated in the M_h^{125} scenario by the nearly horizontal exclusion which is due to the compatibility of the Higgs boson mass measurement with its prediction from radiative corrections (mostly from the stop sector). Nevertheless, Fig. 11.17 (right) shows a broad region with intermediate $\tan\beta$ and large values of m_A that is not accessed by current searches, and in which the most promising channel is the very difficult search for $t\bar{t}$ decays with its aforementioned intricacies [379]. In this region of parameter space, it is possible that only the SM-like Higgs boson can be within the LHC's reach. If no other state of the EWSB sector than the 125 GeV state is discovered, it may be challenging to determine only from the Higgs sector whether there is a SUSY extension of the SM in nature.

11.6.7.3 *Searches for a CP-odd state decaying to hZ*

Similarly, to the search for a CP-even high mass Higgs boson decaying to a pair of Higgs bosons, the search for a CP-odd states decaying to hZ was carried out at the LHC by ATLAS and CMS

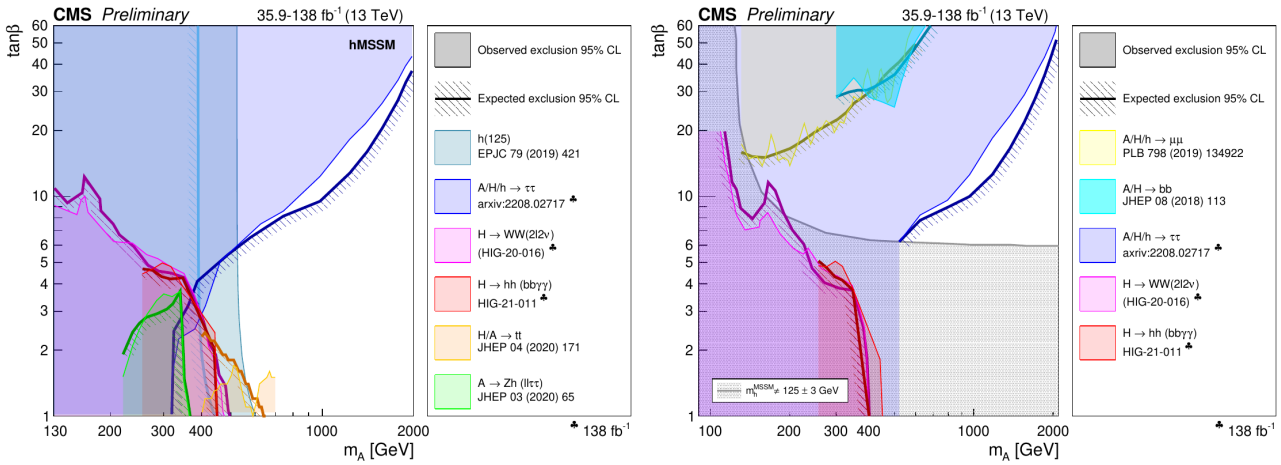

Figure 11.17: The 95% CL exclusion contours in the $(M_A, \tan\beta)$ parameter space for: (left) a summary of CMS Run-2 searches in the hMSSM and (right) in the M_h^{125} scenario.

in various channels: (i) $(Z \to \ell\ell)(h \to b\bar{b})$, (ii) $(Z \to \nu\nu)(h \to b\bar{b})$, (iii) $(Z \to \ell\ell)(h \to \tau\tau)$, and (iv) $(Z \to \ell\ell)(h \to \tau\tau)$. The searches where the A boson decays to a pair of b quarks have been performed both in the regime where both b-jets are resolved and in the boosted regime where the two b-jets are merged in a single larger radius jet. These searches have been used to constrain the parameter space of 2HDMs. In the MSSM, these searches place limits on small values of $\tan\beta$ for masses of A between 220 GeV and 360 GeV.

11.6.7.4 *Searches for low mass states*

Searches for pseudo-scalar Higgs boson at intermediate to low masses, below the Z mass (in the 25 GeV to 80 GeV mass range) have been performed by CMS both in the $\tau^+\tau^-$ [534] and the $\mu^+\mu^-$ [535] decay channels. A light pseudo-scalar in this mass range is excluded by current direct constraints in the MSSM but not in general 2HDMs [536]. These searches are done in the decay channels where the pseudo-scalar Higgs boson is produced in association with a pair of b-quarks and decays into a pair of taus or muons.

CMS has also reported an anomaly observed in the search for $\mu^+\mu^-$ resonances produced with one jet tagged as containing a b-hadron and a forward jet in the Run-1 data. A mild excess appeared in the di-muon mass distribution at approximately 28 GeV. Another very mild excess was then also found in the 2016 Run-2 data [479]. ATLAS then performed a similar analysis with the full Run-2 dataset corresponding to an integrated luminosity of approximately 139 fb^{-1}, and no significant excess was found [478].

Searches for low mass Higgs bosons were also performed in the diphoton channel by both ATLAS and CMS [537, 538] at Run 1. ATLAS and CMS have updated the results of this search with Run-2 data [440, 442]. A modest excess has been observed by CMS at a mass of 95.4 GeV with a local significance of 2.9σ (the corresponding global significance is 1.3σ). A slight excess was also seen by ATLAS at the same mass of 95.4 GeV with a local significance of 1.7σ. No significant excess has been observed in this region by ATLAS at Run 1. This mildly significant excess also coincides in mass with the excess observed at LEP and discussed in Section 11.6.7.1. It is interesting to note that the sensitivity of searches at masses very near that of the Z boson, require a very strong rejection of events where electrons are misidentified as photons. Dedicated experimental methods have been developped to reduce the vulnerability of the analysis in this specific mass region to this background. It has therefore raised interest and speculations on its possible nature, see for instance Ref. [539] and references therein.

11.6.7.5 *Searches for charged Higgs bosons* $H^\pm$

At e^+e^- colliders, charged Higgs bosons can be pair produced in the s-channel via γ or Z boson exchange. This process is dominant in the LEP centre-of-mass energies range, i.e., up to 209 GeV. At higher centre-of-mass energies, other processes can play an important role such as the production in top quark decays via $t \to b + H^+$ if $m_{H^\pm} < m_t - m_b$ or via the one-loop process $e^+e^- \to W^\pm H^\mp$ [540, 541], which allows the production of a charged Higgs boson with $m_{H^\pm} > \sqrt{s}/2$, even when H^+H^- production is kinematically forbidden. Other single charged Higgs boson production mechanisms include $t\bar{b}H^-/\bar{t}bH^+$ production [123], $\tau^+\nu H^-/\tau^-\bar{\nu}H^+$ production [542], and a variety of processes in which $H^\pm$ is produced in association with a one or two other gauge and/or Higgs bosons [543].

At hadron colliders, charged Higgs bosons can be produced in several different modes depending on the value of its mass with respect to the top-quark mass. For light values of the charged Higgs boson mass, defined by Higgs boson masses smaller than the mass of the top quark (with experimental analyses typically considering masses up to $m_{H^\pm} \leq 160$ GeV), the top-quark decay $t \to Hb$ is allowed and the charged Higgs boson is light enough so that top-quark off-shell effects can be neglected. The cross section for the production of a light charged Higgs boson is simply given by the product of the top-pair production cross section and the branching ratio of a top quark into a charged Higgs boson. The top-pair production cross section is known up to NNLO in perturbative QCD [544], and relevant QCD and SUSY-QCD including NLO corrections to the branching ratio for $t \to H^+b$ have been computed in the literature, see Refs. [545–547] and references therein. At present, the theoretical accuracy for the production of a light charged Higgs boson is at the few percent level. For the intermediate mass range, values of $m_{H^\pm}$ near m_t, the finite top-width effects as well as the interplay between top-quark resonant and non-resonant diagrams cannot be neglected. Hence, the full process $pp \to H^\pm W^\mp b\bar{b}$ (with massive b-quarks) must be considered to perform a reliable perturbative calculation of the charged Higgs boson production cross section [547]. For heavy charged Higgs boson scenarios, with charged Higgs boson masses larger than the top-quark mass (typically above 180 GeV), the dominant charged Higgs boson production channel is the associated production with a top quark/antiquark and a (possibly low transverse momentum) bottom antiquark/quark. Theoretical calculation at NLO have been computed both at the inclusive and fully-differential level in the five-flavour scheme and in the four-flavour scheme, see Ref. [40] and references therein. Charged Higgs bosons can also be produced via associated production with $W^\pm$ bosons through $b\bar{b}$ annihilation and gg-fusion annihilation [548].

For charged Higgs boson production cross section predictions

for the Tevatron and the LHC, see Refs. [38, 39, 370].

(a) Exclusion limits from LEP

Charged Higgs bosons have been searched for at LEP, where the combined data of the four experiments, ALEPH, DELPHI, L3, and OPAL, were sensitive to masses of up to about 90 GeV [523] in two decay channels, $\tau\nu$ and $c\bar{s}$. The combined LEP data exclude, at 95% CL, charged Higgs bosons with mass below 80 GeV (Type II scenario) or 72.5 GeV (Type I scenario) [549].

(b) Exclusion limits from Tevatron

Compared to the mass domain covered by LEP searches, the Tevatron covered a complementary range of charged Higgs boson masses. CDF and D0 have also searched for charged Higgs bosons in top quark decays with subsequent decays to $\tau\nu$ or to $c\bar{s}$ [550]. For the $H^+ \to c\bar{s}$ channel, the limits on $\mathrm{BR}(t \to H^+ b)$ from CDF and D0 are $\approx 20\%$ in the mass range $90\,\mathrm{GeV} < m_{H^+} < 160\,\mathrm{GeV}$ and assuming a branching fraction of 100% in this specific final state. $H^+ \to \tau^+\nu_\tau$ channel, D0's limits on $\mathrm{BR}(t \to H^+ b)$ are also $\approx 20\%$ in the same mass range and assuming a branching fraction of 100% in this final state. These limits are valid in general 2HDMs, and they have also been interpreted in terms of the MSSM [550].

(c) Exclusion limits from LHC

Similarly, to the Tevatron, at the LHC, light charged Higgs bosons can be searched for in the decays of top quarks. The main initial production mode for light charged Higgs bosons ($m_{H^\pm} < m_t - m_b$) is top pair production. The subsequent decay modes of the charged Higgs boson for these searches are $\tau\nu$ and $c\bar{s}$. More recently, ATLAS and CMS have also searched for higher mass charged Higgs bosons ($m_{H^\pm} > m_t + m_b$) in $H^+ \to t\bar{b}$. The main production modes are the associated production of a charged Higgs boson in association with a top and a bottom quark or in association with a top quark only.

The decay $H^+ \to \tau^+\nu_\tau$ is searched typically in three final state topologies:

(i) lepton+jets: with $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(q\bar{q}')(\tau_{\mathrm{lep}}\nu)$, i.e., the W boson decays hadronically and the tau decays into an electron or a muon, with two neutrinos;

(ii) τ +lepton: with $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(l\nu)(\tau_{\mathrm{had}}\nu)$, i.e., the W boson decays leptonically (with $\ell = e, \mu$) and the tau decays hadronically;

(iii) τ+jets: $t\bar{t} \to \bar{b}WH^+ \to b\bar{b}(q\bar{q}')(\tau_{\mathrm{had}}\nu)$, i.e., both the W boson and the τ decay hadronically.

CMS has also searched for the charged Higgs boson in the decay products of top quark pairs: $t\bar{t} \to H^\pm W^\mp b\bar{b}$ and $t\bar{t} \to H^+H^- b\bar{b}$ as well. Three types of final states with large missing transverse energy and jets originating from b-quark hadronisation have been analysed: the fully-hadronic channel with a hadronically decaying tau in association with jets, the dilepton channel with a hadronically decaying tau in association with an electron or muon and the dilepton channel with an electron-muon pair. The results of the searches at the LHC are illustrated in Figure 11.17.

Both ATLAS and CMS have also searched for high mass charged Higgs bosons decaying to a top and bottom quarks. The main production mode for this search is the associated production with one top quark (5-flavour scheme) or a top quark and and bottom quark (4-flavour scheme) in the final state. The s-channel production mode where the charged Higgs boson is produced alone in the final state at tree level is also considered. This search is particularly intricate and it is sensitive to the modelling of the top pair production background produced in association with additional partons and in particular b-quarks. No excess was found and the results are expressed in terms of exclusion limits of cross section times branching fractions.

ATLAS and CMS have also searched for charged Higgs bosons in top quark decays assuming $\mathrm{BR}(H^+ \to c\bar{s}) = 100\%$ [496, 551], and sets limits of $\approx 20\%$ on $\mathrm{BR}(t \to H^+ b)$ in the $90\,\mathrm{GeV} < m_{H^+} < 160\,\mathrm{GeV}$ mass range.

In 2HDMs, the decay of the charged Higgs boson to a W and a Z boson is allowed only at loop level and is therefore suppressed. However the $H^\pm \to W^\pm Z$ decay channel is allowed in Higgs triplet models. ATLAS [500] has searched for such decays, requiring that the charged Higgs boson is produced through the fusion of vector bosons. No excess with respect to the SM backgrounds has been observed in this channel, and the results are interpreted in the Georgi–Machacek model [414] discussed in Section 11.6.5.2.

At the LHC, various other channels still remain to be explored, in particular searches involving additional neutral scalars in particular in the WH, WA channels (A is the pseudo-scalar MSSM Higgs boson), and in the Wa channel (a is the light CP-odd scalars of the NMSSM).

11.6.7.6 *Interpretation of the measurements of the coupling properties of the Higgs boson*

The 125 GeV Higgs boson being part of any hypothetically extended EWSB sector, it can be used through the compatibility of its measured couplings and mass with those predicted in specific models to provide constraints on these specific models parameters.

As discussed in Section 11.6.1.1, the mass of the Higgs boson limits drastically the MSSM parameter space and can be used to set limits on specific MSSM benchmarks. This is the case for the Mh125 scenario as illustrated in Fig. 11.16 and in Fig. 11.17, corresponding approximately to a lower limit on $\tan\beta$ in this model [118].

The measurements of the Higgs boson couplings, discussed in Section 11.5, can be interpreted in the framework of a constrained model where the couplings of the Higgs boson to vector bosons, up-type quarks, down-type quarks and leptons, are varied. In 2HDMs, these couplings are functions of the mixing angle α between the observed Higgs boson and the heavy CP-even neutral scalar, and of the ratio of the vacuum expectation values of the two doublets, $\tan\beta$. In the case of the MSSM, the two parameters are the A boson mass and $\tan\beta$ (the sole two parameters needed to describe the MSSM Higgs sector at tree level). The coupling measurements have been interpreted both by ATLAS [312] and CMS [552] in specific MSSM benchmarks and in 2HDMs. The exclusion contour in the hMSSM for the ATLAS combination [312] is illustrated in Fig. 11.17.

11.6.7.7 *Searches for a light CP-odd Higgs boson*

A light pseudo-scalar boson a is present in any two Higgs doublet model enhanced with an additional singlet field. A prominent example is the NMSSM. The theoretical motivations for singlet extensions of the MSSM are discussed in Section 11.6.2. There is also a variety of other models with light additional spin-0 bosons such as two Higgs doublet models with a scalar, Little Higgs models or light scalar mediator to a dark sector.

In the framework of the NMSSM, the searches now focus on the low a mass region for several reasons:

(i) in the NMSSM, the light pseudo-scalar a boson can, as a pseudo-Goldstone boson, be a natural candidate for an axion;

(ii) scenarios where $m_a > 2m_b$ and a CP-even state h decaying to a pair of a ($m_h > 2m_a$) are excluded by direct searches at LEP in the four b's channel [514, 523, 553];

(iii) in the pre-discovery era, LEP limits on a CP-even Higgs boson resulted in fine-tuning MSSM constraints [554] which could be evaded through non standard decays of the Higgs boson to aa;

(iv) in the NMSSM, a CP-odd a boson with a mass in the range 9.2–12 GeV can also account for the difference observed between the measured anomalous muon magnetic moment and its prediction [555].

The benchmark scenarios have also changed in the light of the Higgs boson discovery. The 125 GeV state could be the lightest or the next-to-lightest of the three CP-even states of the NMSSM. Light pseudo-scalar scenarios are still very interesting in particular for the potential axion candidate. There are three main types of direct searches for the light a boson:

(i) for masses below the Υ resonance, the search is for radiative decays $\Upsilon \to a\gamma$ at B-factories;

(ii) the inclusive search in high energy pp collisions at the LHC;

(iii) the search for decays of the observed CP-even Higgs h boson into a pair of a bosons;

Radiative decays $\Upsilon \to a\gamma$ have been searched for in various colliders, the most recent results are searches for radiative decays of the $\Upsilon(1s)$ to $a\gamma$ with a subsequent decay of the a boson to a pair of taus at CLEO [556], and the radiative decays of the $\Upsilon(1s, 2s, 3s)$ to $a\gamma$ with subsequent decays to a pair of muons or taus by BaBar [519, 520].

Direct inclusive searches for the light pseudo scalar a boson were performed in the $a \to \mu\mu$ channel at the Tevatron by D0 [514] and by ATLAS [506], CMS [507], and LHCb [164] at the LHC.

Finally, searches for the decays of the Higgs boson to a pair of a bosons were performed with subsequent decays to four photons, in the four muons final state, in the two muons and two taus final state, and in the four taus final state.

No significant excess in the searches for a light CP-odd a boson was found and limits on the production times branching fractions of the a boson have been set.

References for all these searches are summarised in Table 11.11.

11.6.7.8 *Searches in Higgs decays*

Dark-photons or axion-like particles searches can also be carried out within the decays of the Higgs boson to four leptons through dilepton pair resonances. Such search has been carried out by ATLAS and CMS [557]. Alternatively signatures of dark photons escaping detection with mising transverse momentum signatures have also been searched for by ATLAS [558].

11.6.7.9 *Searches for doubly charged Higgs bosons $H^{\pm\pm}$*

As discussed in Section 11.6.5, the generation of small neutrino masses via the standard EWSB mechanism described in Section 11.2 requires unnaturally small Yukawa couplings, provided that neutrinos are Dirac-type fermions. A Majorana mass term with a see-saw mechanism for neutrinos, would allow for naturally small masses and would also yield a framework for the appealing scenario of leptogenesis. However, within the SM, Majorana mass terms correspond to (non-renomalizable) dimension-5 operators. Such effective interactions can be generated via renormalisable interactions with an electroweak triplet of complex scalar fields (corresponding to a type-II see-saw mechanism). Other models such as the Zee–Babu model, with the introduction of two $\mathrm{SU}(2)_L$ singlets, also generate Majorana mass terms. The signature of such models would be the presence of doubly charged Higgs bosons $H^{\pm\pm}$.

The main production mechanisms of $H^{\pm\pm}$ bosons at hadron colliders are the pair production in the s-channel through the exchange of a Z boson or a photon and the associated production with a charged Higgs boson through the exchange of a W boson. Various searches for doubly charged Higgs bosons have been performed by ATLAS and CMS at Run 1 [559] and Run 2 [521, 522]. Typically, these searches aim at low values of the Higgs triplet vacuum expectation for which the doubly charged Higgs boson will decay mostly to leptons (for high values, the decay to W bosons will become predominant). These searches assume that the coupling to W bosons is negligible and that the main production mode is through the Drell–Yan process.

11.6.7.10 *Searches for non-standard production processes of the Higgs boson*

The discovery of the Higgs boson has also allowed for searches of BSM processes involving standard decays of the Higgs boson. One example directly pertaining to the search for additional states of the EWSB sector is the search for Higgs bosons in the cascade decay of a heavy CP-even Higgs boson decaying to charged Higgs boson and a W boson, and the charged Higgs boson subsequently decaying to H and another W boson. This search has been performed by ATLAS in $b\bar{b}$ decays of the 125 GeV Higgs boson [560].

11.6.7.11 *Outlook on searches for additional states*

The LHC program of searches for additional states covers a large variety of decay and production channels. Since the Higgs boson discovery, many new channels have been explored at the LHC, e.g., the searches for additional states decaying into hh or Vh or ZA. The search for charged Higgs bosons has been extended to include the WZ, WA and the very difficult $t\bar{b}$ decay channel.

11.7 Summary and outlook

Summary– The discovery of the Higgs boson is a major milestone in the history of particle physics as well as an extraordinary achievement of the LHC machine and the ATLAS and CMS experiments. Eleven years after the discovery, substantial progress in the field of Higgs boson physics has been accomplished and a significant number of measurements probing the nature of this unique particle have been made. They are revealing an increasingly precise profile of the Higgs boson.

The LHC has concluded its Run 2 in 2018, delivering a dataset of 13 TeV pp collisions corresponding to an integrated luminosity of more than $150\,\mathrm{fb}^{-1}$ of data collected by ATLAS and CMS. The Run 3 started in 2022 at 13.6 TeV and more than $70\,\mathrm{fb}^{-1}$ of additional data were delivered. First cross section measurements at this new centre-of-mass energy have been presented and are reported herein. With the substantial increase in production rates at the higher center-of-mass energy (mostly from Run 1 to Run 2) and the larger datasets, new landmark results in Higgs physics have been achieved. They are highlighted in the 10th anniversary papers of the Higgs boson discovery [183, 184].

Three new results of fundamental importance have been achieved with Run-2 datasets by ATLAS and CMS independently: (i) the clear and unambiguous observation of the Higgs boson decay to taus; (ii) the clear and unambiguous observation of the Higgs boson decay to a pair of b quarks; (iii) the clear and unambiguous observation of the production of the Higgs boson through the $t\bar{t}H$ process. These results provide direct evidence for the Yukawa coupling of the Higgs boson to fermions of the third generation: taus, bottom quarks and top quarks, at rates compatible with those expected in the SM. In addition, the evidence for the decay of the Higgs boson to muons is being consolidated. These, and all other experimental measurements, are consistent with the EWSB mechanism of the SM.

New theoretical calculations and developments in Monte-Carlo simulations pertaining to Higgs physics are still occurring at a rapid pace. For example, the theoretical prediction for the dominant gluon fusion production mode now includes the latest N3LO result at the inclusive and differential levels, which is twice as precise as previous N2LO calculations. With these improvements in the state-of-the-art theory predictions and the increase in luminosity and center-of-mass energy, Higgs physics has definitively entered a precision era. Its impact can already be seen on the latest Run-2 combined measurements of the Higgs boson couplings (see Section 11.5).

Since the discovery of the Higgs boson, new ideas have emerged to probe its rare decays and production modes, as well as to indirectly measure the Higgs boson width through the study of its off-shell couplings, or via on-shell interference effects. The Higgs boson has now become part of the standard toolkit in searches for new physics, with Higgs measurements being used in SMEFT global fits.

Many extensions of the SM at higher energies call for an enlargement of the EWSB sector. Hence, direct searches for additional scalar states can provide valuable insights on the dynamics of the EWSB mechanism. The ATLAS and CMS experiments have searched for additional Higgs bosons in the Run-2 data, and have imposed constraints in broad ranges of mass and couplings for various scenarios with an extended Higgs sector.

The landscape of Higgs physics has been scrutinized extensively since its discovery. The current precisions on the measurements of the couplings of the Higgs boson to gauge bosons and third generation fermions are typically of the order of 10–20%. The uncertainty on the Higgs boson coupling to the muon shrank below 50%, and the upper limits on the branching fraction to new invisible particles are approximately 10%. Sensitivity to the Higgs boson self-coupling has not reached the SM value yet, and there is no information on how the Higgs field acquired its VEV in the early times of the Universe. However, significant progress in being made through exploration of di-Higgs production, including new analyses based on machine learning algorithms. This situation allows for new challenges to ultimately increase further the reach in

precision and it also widens the possibilities of unveiling the true nature and the dynamics of the electroweak symmetry breaking mechanism.

Outlook– The unitarisation of the vector boson scattering (VBS) amplitudes, dominated at high energies by their longitudinal polarisation, has been the basis of the *no lose* theorem at the LHC, and was a determining consideration in the building of the accelerator and detectors. It motivated the existence of a Higgs boson or the observability of manifestations of strong dynamics at the TeV scale. Now that a Higgs boson has been found and its couplings to gauge bosons are - within current accuracy - consistent with the SM predictions, perturbative unitarity is preserved to a large extent with the sole exchange of the Higgs boson, and without the need for any additional states. VBS remains still an important channel to further investigate in order to better understand the nature of the Higgs sector and the possible completion of the SM at the TeV scale. In association with the double Higgs boson production channel by vector boson fusion, VBS could, for instance, confirm that the Higgs boson is part of a weak doublet and also establish whether it is an elementary object or a composite state that could emerge as a pseudo-Nambu–Goldstone boson from a new underlying broken symmetry.

The fermion-Higgs boson couplings are not governed by local gauge symmetry. Thus, in addition to a new particle, the LHC has also discovered a new force, different in nature from the other fundamental interactions since it is non-universal and distinguishes between the three families of quarks and leptons. The existence of the Higgs boson embodies the problem of an unnatural cancellation among the quantum corrections to its mass if new physics is present at scales significantly higher than the EW scale. The non-observation of additional states which could stabilise the Higgs boson mass is a challenge for natural scenarios like Supersymmetry or models with a new strong interaction in which the Higgs boson is not a fundamental particle. This increasingly pressing paradox starts questioning the principle of naturalness and it also inspires new solutions tied to the cosmological evolution of the Universe.

The search for the Higgs boson has occupied the particle physics community for the last 50 years. Its discovery has shaped and sharpened the physics programs of the LHC and of prospective future accelerators [126, 561]. With respect to current data, at the HL-LHC the precision will improve by a factor of approximately 5–10 depending on the observables considered. Table 11.8 displays the expected sensitivities in the characterization of the Higgs boson at HL-LHC: in this table, the parameters κ_i specify by how much the coupling of the Higgs boson to a given particle i deviates from the SM expectation. The only channels which are expected to be limited by data statistics are the rare decays to muons and $Z\gamma$. In all other cases, the experimental systematic uncertainties are similar to the statistical uncertainties, but the dominant source of uncertainty arises from theory, and this remains the case even after assuming that, by the end of the HL-LHC run, the theory uncertainties can be reduced by a factor two compared to the current uncertainties, a hypothesis that appears realistic but still requires dedicated and concerted work [118]. For both hadron and lepton colliders, some theoretical progress is crucial to fully exploit and capitalise on the experimental data. In particular, the expected HL-LHC data together with rapid ongoing progress in theoretical calculations are defining a new era of precision Higgs boson measurements.

12. CKM Quark-Mixing Matrix

Revised April 2024 by A. Ceccucci (CERN), Z. Ligeti (LBNL) and Y. Sakai (KEK).

12.1 Introduction

The masses and mixings of quarks have a common origin in the Standard Model (SM). They arise from the Yukawa interactions with the Higgs condensate,

$$\mathcal{L}_Y = -Y^d_{ij}\,\overline{Q^I_{Li}}\,\phi\,d^I_{Rj} - Y^u_{ij}\,\overline{Q^I_{Li}}\,\epsilon\,\phi^*\,u^I_{Rj} + \text{h.c.}, \tag{12.1}$$

where $Y^{u,d}$ are 3×3 complex matrices, ϕ is the Higgs field, i,j are generation labels, and ϵ is the 2×2 antisymmetric tensor. Q^I_L are left-handed quark doublets, and d^I_R and u^I_R are right-handed down- and up-type quark singlets, respectively, in the weak-eigenstate basis. When ϕ acquires a vacuum expectation value, $\langle\phi\rangle = (0, v/\sqrt{2})$, Eq. (12.1) yields mass terms for the quarks. The physical states are obtained by diagonalizing $Y^{u,d}$ by four unitary matrices, $V^{u,d}_{L,R}$, as $M^f_{\rm diag} = V^f_L\,Y^f\,V^{f\dagger}_R(v/\sqrt{2})$, $f = u, d$. As a result, the charged-current $W^\pm$ interactions couple to the physical u_{Lj} and d_{Lk} quarks with couplings given by

$$\frac{-g}{\sqrt{2}}(\overline{u_L},\,\overline{c_L},\,\overline{t_L})\gamma^\mu\,W^+_\mu\,V_{\rm CKM}\begin{pmatrix} d_L \\ s_L \\ b_L\end{pmatrix} + \text{h.c.},$$
$$V_{\rm CKM} \equiv V^u_L V^{d\dagger}_L = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb}\end{pmatrix}. \tag{12.2}$$

This Cabibbo-Kobayashi-Maskawa (CKM) matrix [1,2] is a 3×3 unitary matrix. It can be parameterized by three mixing angles and the CP-violating KM phase [2]. Of the many possible conventions, a standard choice has become [3]

$$V_{\rm CKM} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & c_{23} & s_{23} \\ 0 & -s_{23} & c_{23}\end{pmatrix}\begin{pmatrix} c_{13} & 0 & s_{13}e^{-i\delta} \\ 0 & 1 & 0 \\ -s_{13}e^{i\delta} & 0 & c_{13}\end{pmatrix}\begin{pmatrix} c_{12} & s_{12} & 0 \\ -s_{12} & c_{12} & 0 \\ 0 & 0 & 1\end{pmatrix}$$
$$= \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13}\end{pmatrix}, \tag{12.3}$$

where $s_{ij} = \sin\theta_{ij}$, $c_{ij} = \cos\theta_{ij}$, and δ is the phase responsible for all CP-violating phenomena in flavor-changing processes in the SM. The angles θ_{ij} can be chosen to lie in the first quadrant, so $s_{ij}, c_{ij} \geq 0$.

It is known experimentally that $s_{13} \ll s_{23} \ll s_{12} \ll 1$, and it is convenient to exhibit this hierarchy using the Wolfenstein parameterization. We define [4–6]

$$s_{12} = \lambda = \frac{|V_{us}|}{\sqrt{|V_{ud}|^2 + |V_{us}|^2}}\,, \qquad s_{23} = A\lambda^2 = \lambda\left|\frac{V_{cb}}{V_{us}}\right|,$$
$$s_{13}e^{i\delta} = V^*_{ub} = A\lambda^3(\rho + i\eta) = \frac{A\lambda^3(\bar\rho + i\bar\eta)\sqrt{1 - A^2\lambda^4}}{\sqrt{1-\lambda^2}\,[1 - A^2\lambda^4(\bar\rho + i\bar\eta)]}\,. \tag{12.4}$$

These relations ensure that $\bar\rho + i\bar\eta = -(V_{ud}V^*_{ub})/(V_{cd}V^*_{cb})$ is phase convention independent, and the CKM matrix written in terms of λ, A, $\bar\rho$, and $\bar\eta$ is unitary to all orders in λ. The definitions of $\bar\rho$, $\bar\eta$ reproduce all approximate results in the literature; *i.e.*, $\bar\rho = \rho(1-\lambda^2/2+\ldots)$ and $\bar\eta = \eta(1-\lambda^2/2+\ldots)$, and one can write $V_{\rm CKM}$ to $\mathcal{O}(\lambda^4)$ either in terms of $\bar\rho, \bar\eta$ or, traditionally,

$$V_{\rm CKM} = \begin{pmatrix} 1-\lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1-\lambda^2/2 & A\lambda^2 \\ A\lambda^3(1-\rho-i\eta) & -A\lambda^2 & 1\end{pmatrix} + \mathcal{O}(\lambda^4)\,. \tag{12.5}$$

The CKM matrix elements are fundamental parameters of the SM, so their precise determination is important. The unitarity of the CKM matrix imposes $\sum_i V_{ij}V^*_{ik} = \delta_{jk}$ and $\sum_j V_{ij}V^*_{kj} = \delta_{ik}$. The six vanishing combinations can be represented as triangles in a complex plane, of which those obtained by taking scalar products of neighboring rows or columns are nearly degenerate. The areas of all triangles are the same, half of the Jarlskog invariant, J [7], which is a phase-convention-independent measure of CP violation, defined by $\text{Im}\left[V_{ij}V_{kl}V^*_{il}V^*_{kj}\right] = J\sum_{m,n}\varepsilon_{ikm}\varepsilon_{jln}$.

The most commonly used unitarity triangle arises from

$$V_{ud}\,V^*_{ub} + V_{cd}\,V^*_{cb} + V_{td}\,V^*_{tb} = 0\,, \tag{12.6}$$

by dividing each side by $V_{cd}V^*_{cb}$ (see Fig. 12.1). Its vertices are exactly $(0,0)$, $(1,0)$, and, due to the definition in Eq. (12.4), $(\bar\rho, \bar\eta)$. An important goal of flavor physics is to overconstrain the CKM elements, and many measurements can be conveniently displayed and compared in the $\bar\rho, \bar\eta$ plane. While the Lagrangian in Eq. (12.1) is renormalized, and the CKM matrix has a well-known scale dependence above the weak scale [8], below $\mu = m_W$ the CKM elements can be treated as constants, with all μ-dependence contained in the running of quark masses and higher-dimension operators.

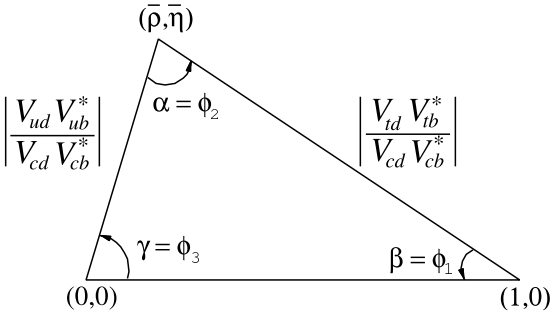

Figure 12.1: Sketch of the unitarity triangle.

Unless explicitly stated otherwise, we describe all measurements assuming the SM, to extract magnitudes and phases of CKM elements in Sec. 12.2 and 12.3. Processes dominated by loop-level contributions in the SM are particularly sensitive to new physics beyond the SM (BSM). We give the global fit results for the CKM elements in Sec. 12.4, and discuss some implications for beyond standard model physics in Sec. 12.5.

12.2 Magnitudes of CKM elements

12.2.1 $|V_{ud}|$

The most precise determination of $|V_{ud}|$ comes from the study of superallowed $0^+ \to 0^+$ nuclear beta decays, which are pure vector transitions. Taking the average of the fifteen most precise determinations [9] yields [10]

$$|V_{ud}| = 0.97367 \pm 0.00032\,. \tag{12.7}$$

This uncertainty is slightly more than twice as large as that in the 2020 edition, due to a more conservative estimate of the nuclear structure uncertainties. A less precise determination of $|V_{ud}|$ can be obtained from the measurement of the neutron lifetime. The theoretical uncertainties are very small, but the determination is limited by the knowledge of the ratio of the axial-vector and vector couplings, $g_A = G_A/G_V$ [10]. The PIBETA experiment [11] has improved the measurement of the $\pi^+ \to \pi^0 e^+\nu$ branching ratio to 0.6%, and Ref. [12] quotes $|V_{ud}| = 0.9739 \pm 0.0027$, in

agreement with the more precise result listed above. The interest in this measurement is that the determination of $|V_{ud}|$ is very clean theoretically, because it is a pure vector transition and is free from nuclear-structure uncertainties.

12.2.2 $|V_{us}|$

The product of $|V_{us}|$ and the form factor at $q^2 = 0$, $|V_{us}|\, f_+(0)$, has been extracted traditionally from $K^0_L \to \pi e\nu$ decays in order to avoid isospin-breaking corrections ($\pi^0 - \eta$ mixing) that affect $K^\pm$ semileptonic decay, and the complications induced by a second (scalar) form factor present in the muonic decays. The last round of measurements has led to enough experimental constraints to justify the comparison between different decay modes. Systematic errors related to the experimental quantities, *e.g.*, the lifetime of neutral or charged kaons, and the form factor determinations for electron and muonic decays, differ among decay modes, and the consistency between different determinations enhances the confidence in the final result. For this reason, we follow the prescription [13] to average $K^0_L \to \pi e\nu$, $K^0_L \to \pi\mu\nu$, $K^\pm \to \pi^0 e^\pm\nu$, $K^\pm \to \pi^0\mu^\pm\nu$ and $K^0_S \to \pi e\nu$. The average of these five decay modes yields $|V_{us}|\, f_+(0) = 0.21656 \pm 0.00035$. Results obtained from each decay mode, and exhaustive references to the experimental data, are listed for instance in Ref. [10]. The form factor average $f_+(0) = 0.9698 \pm 0.0017$ [14] from $N_f = 2+1+1$ lattice QCD calculations gives $|V_{us}| = 0.2233 \pm 0.0005$ [10].[1] The broadly used classic calculation of $f_+(0)$ [16] is in good agreement with this value, while other calculations [18] differ by as much as 2%.

The calculation of the ratio of the kaon and pion decay constants enables one to extract $|V_{us}/V_{ud}|$ from $K \to \mu\nu(\gamma)$ and $\pi \to \mu\nu(\gamma)$, where (γ) indicates that radiative decays are included [19]. The value of $\Gamma(K \to \mu\nu(\gamma))$ [10] derived from the KLOE measurement of the corresponding branching ratio [20], combined with the lattice QCD result, $f_K/f_\pi = 1.1932 \pm 0.0021$ [14], leads to $|V_{us}| = 0.2250 \pm 0.0004$, where the accuracy is limited by the knowledge of the ratio of the decay constants. The average of these two determinations, with the error scaled according to the PDG prescription [21] by $\sqrt{\chi^2} = 2.5$, is quoted as [10]

$$|V_{us}| = 0.22431 \pm 0.00085\,. \tag{12.8}$$

It is important to include both QED and QCD sources of isospin violations in the lattice QCD calculations.

The latest determination from hyperon decays can be found in Ref. [22]. The authors focus on the analysis of the vector form factor, protected from first order flavor $SU(3)$ breaking effects by the Ademollo-Gatto theorem [23], and treat the ratio between the axial and vector form factors g_1/f_1 as experimental input, thus avoiding first order $SU(3)$ breaking effects in the axial-vector contribution. They find $|V_{us}| = 0.2250 \pm 0.0027$, although this does not include an estimate of the theoretical uncertainty due to second-order $SU(3)$ breaking, contrary to Eq. (12.8). Concerning hadronic τ decays to strange particles, averaging the inclusive decay and the exclusive $\tau \to h\nu$ ($h = \pi$, K) measurements yields $|V_{us}| = 0.2207 \pm 0.0014$ [24].

12.2.3 $|V_{cd}|$

The magnitude of V_{cd} can be extracted from semileptonic charm decays, using theoretical knowledge of the form factors. In semileptonic D decays, lattice QCD calculations have predicted the normalization of the $D \to \pi\ell\nu$ and $D \to K\ell\nu$ form factors [14]. The dependence on the invariant mass of the lepton pair, q^2, is determined from lattice QCD and theoretical constraints from analyticity [15]. Using $N_f = 2+1+1$ lattice QCD calculations for $D \to \pi\ell\nu$, $f_+^{D\pi}(0) = 0.612 \pm 0.035$ [14], and the average [24] of the measurements of $D \to \pi\ell\nu$ decays by *BABAR* [25], BESIII [26], CLEO-c [27], and Belle [28], one obtains $|V_{cd}| = 0.2330 \pm 0.0029 \pm 0.0133$, where the first uncertainty is experimental, and the second is from the theoretical uncertainty of the form factor.

The determination of $|V_{cd}|$ is also possible from the leptonic decay $D^+ \to \mu^+\nu$ and $\tau^+\nu$. The experimental uncertainties have not decreased significantly recently. Averaging the BESIII [29] and earlier CLEO [30] for $\mu^+\nu$ and BESIII [31] for $\tau^+\nu$ measurements, and using the $N_f = 2+1+1$ lattice QCD result, $f_D = 212.0 \pm 0.7$ MeV [14], yields $|V_{cd}| = 0.2181 \pm 0.0049 \pm 0.0007$ [24] [2]

Earlier determinations of $|V_{cd}|$ came from neutrino scattering data. The difference of the ratio of double-muon to single-muon production by neutrino and antineutrino beams is proportional to the charm cross section off valence d quarks, and therefore to $|V_{cd}|^2$ times the average semileptonic branching ratio of charm mesons, $\mathcal{B}_\mu$. The method was used first by CDHS [32] and then by CCFR [33] and CHARM II [34]. Averaging these results is complicated, because it requires assumptions about the scale of the QCD corrections, and because $\mathcal{B}_\mu$ is an effective quantity, which depends on the specific neutrino beam characteristics. With no recent experimental input available, we quote the average from a past review, $\mathcal{B}_\mu |V_{cd}|^2 = (0.463 \pm 0.034) \times 10^{-2}$ [35]. Analysis cuts make these experiments insensitive to neutrino energies smaller than 30 GeV. Thus, $\mathcal{B}_\mu$ should be computed using only neutrino interactions with visible energy larger than 30 GeV. An appraisal [36] based on charm-production fractions measured in neutrino interactions [37] gives $\mathcal{B}_\mu = 0.088 \pm 0.006$. Data from the CHORUS experiment [38] are sufficiently precise to extract $\mathcal{B}_\mu$ directly, by comparing the number of charm decays with a muon to the total number of charmed hadrons found in the nuclear emulsions. Requiring the visible energy to be larger than 30 GeV, CHORUS found $\mathcal{B}_\mu = 0.085 \pm 0.009 \pm 0.006$. We use the average of these two determinations, $\mathcal{B}_\mu = 0.087 \pm 0.005$, and obtain $|V_{cd}| = 0.230 \pm 0.011$. Averaging the three determinations above, we find

$$|V_{cd}| = 0.221 \pm 0.004\,. \tag{12.9}$$

12.2.4 $|V_{cs}|$

The direct determination of $|V_{cs}|$ is possible from semileptonic D or leptonic D_s decays, using lattice QCD calculations of the semileptonic D form factor or the D_s decay constant. For muonic decays, the average of Belle [39], CLEO-c [40], *BABAR* [41], and BESIII [42,43] is $\mathcal{B}(D_s^+ \to \mu^+\nu) = (5.43 \pm 0.16) \times 10^{-3}$ [24]. For decays to τ leptons, the average of CLEO-c [40,44], *BABAR* [41], Belle [39], and BESIII [42] gives $\mathcal{B}(D_s^+ \to \tau^+\nu) = (5.40 \pm 0.23) \times 10^{-2}$ [24]. From each of these values, determinations of $|V_{cs}|$ can be obtained using the PDG values for the mass and lifetime of the D_s, the masses of the leptons, and $f_{D_s} = (249.9 \pm 0.5)$ MeV [14]. The average of these determinations gives $|V_{cs}| = 0.984 \pm 0.012$, where the error is dominated by the experimental uncertainty. In semileptonic D decays, lattice QCD calculations of the $D \to K\ell\nu$ form factor are available [14]. Using $f_+^{DK}(0) = 0.7385 \pm 0.0044$ and the average [24] of CLEO-c [27], Belle [28], *BABAR* [45], and recent BESIII [26,46] measurements of $D \to K\ell\nu$ decays, one obtains $|V_{cs}| = 0.972 \pm 0.007$, where the dominant uncertainty is from the theoretical calculation of the form factor. Averaging the determinations from leptonic and semileptonic decays, we find

$$|V_{cs}| = 0.975 \pm 0.006\,. \tag{12.10}$$

Measurements of on-shell $W^\pm$ decays sensitive to $|V_{cs}|$ were made by LEP-2. The W branching ratios depend on the six CKM elements involving only the quarks lighter than m_W. The W branching ratio to each lepton flavor is $1/\mathcal{B}(W \to \ell\bar{\nu}_\ell) = 3\big[1 + \sum_{u,c,d,s,b} |V_{ij}|^2\,(1 + \alpha_s(m_W)/\pi) + \ldots\big]$. Assuming lepton universality, the measurement $\mathcal{B}(W \to \ell\bar{\nu}_\ell) = (10.83 \pm 0.07 \pm 0.07)\,\%$ [47] implies $\sum_{u,c,d,s,b} |V_{ij}|^2 = 2.002 \pm 0.027$. This is a precise test of unitarity; however, only flavor-tagged W-decays determine $|V_{cs}|$ directly, such as DELPHI's tagged $W^+ \to c\bar{s}$ analysis, yielding $|V_{cs}| = 0.94^{+0.32}_{-0.26} \pm 0.13$ [48].

12.2.5 $|V_{cb}|$

This matrix element can be determined from exclusive and inclusive semileptonic decays of B mesons to charm. The in-

[1] For lattice QCD inputs, we use the averages from Ref. [14], unless the minireviews [10,15] choose different values. We only use unquenched results, and if both $N_f = 2+1+1$ and $2+1$ calculations are available, we use the former.

[2] Hereafter the first error is statistical and the second is systematic, unless mentioned otherwise.

clusive determinations use the semileptonic decay rate measurement, together with (certain moments of) the lepton energy and the hadronic invariant-mass spectra. The theoretical basis is the operator product expansion [49, 50], which allows calculation of the decay rate and various spectra as expansions in α_s and inverse powers of the heavy-quark mass. The dependence on m_b, m_c, and the parameters that occur at subleading order is different for different moments. The measurements of many moments overconstrain these parameters, and also test the consistency of their determination. The precise extraction of $|V_{cb}|$ requires using a "threshold" quark mass definition [51, 52]. Inclusive measurements have been performed using B mesons from Z^0 decays at LEP, and at e^+e^- colliders operated at the $\Upsilon(4S)$. At LEP, the large boost of B mesons from the Z^0 decay allows the determination of the moments throughout phase space, which is not possible otherwise, but the large statistics available at the B factories lead to more precise determinations. An average of the measurements and a compilation of the references are provided in Ref. [15]: $|V_{cb}| = (42.2 \pm 0.5) \times 10^{-3}$.

Complementary determinations are based on exclusive semileptonic B decays to D and D^*. In the $m_{b,c} \gg \Lambda_{\rm QCD}$ limit, all form factors are given by a single Isgur-Wise function [53], which depends on the product of the four-velocities of the B and $D^{(*)}$ mesons, $w = v \cdot v'$. Heavy-quark symmetry determines the rate (in the symmetry limit) at $w = 1$, the point in phase space at which the invariant mass of the $\ell\bar{\nu}$ pair is maximal; $|V_{cb}|$ is obtained from extrapolating a fit to the spectrum to $w = 1$. The current update of the V_{cb} and V_{ub} minireview quotes from exclusive decays $|V_{cb}| = (39.8 \pm 0.6) \times 10^{-3}$ [15], based on the only unfolded measurement of $B \to D^*$ semileptonic decay distributions [54], and using a more general fit [55] than in earlier B factory measurements. With the uncertainty scaled by $\sqrt{\chi^2} = 3.0$, this yields the combination [15],

$$|V_{cb}| = (41.1 \pm 1.2) \times 10^{-3} \,. \tag{12.11}$$

Determinations of $|V_{cb}|$ that are currently less precise and not included in this average, can be obtained from the measurement of $B_s \to D_s^{(*)} \mu\bar{\nu}$ decays [56]. In addition, semileptonic decays to τ leptons measured in $B \to D^{(*)}\tau\bar{\nu}$ and related modes are also sensitive to $|V_{cb}|$. The most precise data involving τ leptons are the $|V_{cb}|$-independent ratios, $\mathcal{B}(B \to D^{(*)}\tau\bar{\nu})/\mathcal{B}(B \to D^{(*)}\ell\bar{\nu})$ measured by BaBar, Belle, and LHCb. If the current, approximately $3.3\,\sigma$ [24] hint of lepton non-universality prevails, the determination of $|V_{cb}|$ becomes more complicated.

12.2.6 $|V_{ub}|$

The determination of $|V_{ub}|$ from inclusive $B \to X_u \ell\bar{\nu}$ decay is complicated due to large $B \to X_c \ell\bar{\nu}$ backgrounds. In most regions of phase space where the charm background is kinematically forbidden, the hadronic physics enters via unknown nonperturbative functions, so-called shape functions. (By contrast, the nonperturbative physics for $|V_{cb}|$ is encoded in a few parameters.) At leading order in $\Lambda_{\rm QCD}/m_b$, there is only one shape function, which can be extracted from the photon energy spectrum in $B \to X_s\gamma$ [57, 58], and applied to several spectra in $B \to X_u \ell\bar{\nu}$. The subleading shape functions are modeled in the current determinations. Phase space cuts for which the rate has only subleading dependence on the shape function are also possible [59]. The measurements of both the hadronic and the leptonic systems are important for an optimal choice of phase space. A different approach is to make the measurements more inclusive by extending them deeper into the $B \to X_c \ell\bar{\nu}$ region, and thus reduce the theoretical uncertainties. Analyses of the electron-energy endpoint from CLEO [60], *BABAR* [61], and Belle [62] quote $B \to X_u e\bar{\nu}$ partial rates for $|\vec{p}_e| \geq 2.0\,\text{GeV}$ and 1.9 GeV, which are well below the charm endpoint. The large and pure $B\overline{B}$ samples at the B factories permit the selection of $B \to X_u \ell\bar{\nu}$ decays in events where the other B is fully reconstructed [63]. With this full-reconstruction tag method, the four-momenta of both the leptonic and the hadronic final states can be measured. It also gives access to a wider kinematic region, because of improved signal purity. Ref. [15] quotes the inclusive average, $|V_{ub}| = (4.13 \pm 0.12\ ^{+0.13}_{-0.14} \pm 0.18) \times 10^{-3}$, where the first error is experimental, the second arises from the model dependence quoted by the individual measurements, and the third is an additional one estimated in Ref. [15].

To extract $|V_{ub}|$ from exclusive decays, the form factors have to be known. Experimentally, better signal-to-background ratios are offset by smaller yields. The $B \to \pi\ell\bar{\nu}$ branching ratio is now known to 5%. Lattice QCD calculations of the $B \to \pi\ell\bar{\nu}$ form factor are available [64] for the high q^2 region ($q^2 > 16$ or $18\,\text{GeV}^2$). A fit to the experimental partial rates and lattice QCD results versus q^2 yields $|V_{ub}| = (3.70 \pm 0.10 \pm 0.12) \times 10^{-3}$ [24]. Using additional input from light-cone QCD sum rules (which are thought to be reliable in the small q^2 region), yield a combination, $|V_{ub}| = (3.67 \pm 0.09 \pm 0.12) \times 10^{-3}$ [15, 24].

The uncertainties in extracting $|V_{ub}|$ from inclusive and exclusive decays are different to a large extent. An average of these determinations, with the uncertainty scaled by $\sqrt{\chi^2} = 1.4$, is [15]

$$|V_{ub}| = (3.82 \pm 0.20) \times 10^{-3} \,. \tag{12.12}$$

A determination of $|V_{ub}|$ not included in this average can be obtained from $\mathcal{B}(B \to \tau\bar{\nu}) = (1.09 \pm 0.21) \times 10^{-4}$ [24]. Using $f_B = (190.0 \pm 1.3)\,\text{MeV}$ [14] and $\tau_{B^\pm} = (1.638 \pm 0.004)\,\text{ps}$ [65], we find the remarkably consistent result, $|V_{ub}| = (4.11 \pm 0.39) \times 10^{-3}$. This decay is sensitive, for example, to tree-level charged Higgs contributions, and the measured rate is consistent with the SM expectation. The LHCb measurement $|V_{ub}/V_{cb}| = 0.083 \pm 0.004$ [15] from the ratios of $\Lambda_b \to p^+\mu^-\bar{\nu}$ and $\Lambda_b \to \Lambda_c^+\mu^-\bar{\nu}$ [66] and $B_s^0 \to K^-\mu^+\nu$ and $B_s^0 \to D_s^-\mu^+\nu$ [67] in different regions of q^2, provides another complementary determination.

12.2.7 $|V_{td}|$ *and* $|V_{ts}|$

The CKM elements $|V_{td}|$ and $|V_{ts}|$ are not likely to be precisely measurable in tree-level processes involving top quarks, so one has to rely on determinations from $B^0 - \overline{B}^0$ mixing, dominated by box diagrams with top quarks, or loop-mediated rare K and B decays. Theoretical uncertainties in hadronic effects limit the accuracy of the current determinations. These can be reduced by taking ratios of processes that are equal in the flavor $SU(3)$ limit to determine $|V_{td}/V_{ts}|$.

The phenomenon of $B^0 - \overline{B}^0$ mixing was discovered by ARGUS [68], and the mass difference is now precisely measured as $\Delta m_d = (0.5069 \pm 0.0019)\,\text{ps}^{-1}$ [69]. In the B_s^0 system, Δm_s was first measured significantly by CDF [70] and the world average, dominated by an LHCb measurement [71], is $\Delta m_s = (17.765 \pm 0.006)\,\text{ps}^{-1}$ [69]. Neglecting corrections suppressed by $|V_{tb}| - 1$, and using the lattice QCD results $f_{B_d}\sqrt{\widehat{B}_{B_d}} = (210.6 \pm 5.5)\,\text{MeV}$ and $f_{B_s}\sqrt{\widehat{B}_{B_s}} = (256.1 \pm 5.7)\,\text{MeV}$ [14],

$$|V_{td}| = (8.6 \pm 0.2) \times 10^{-3} \,, \qquad |V_{ts}| = (41.5 \pm 0.9) \times 10^{-3} \,. \tag{12.13}$$

The uncertainties are dominated by lattice QCD. Several uncertainties are reduced in the calculation of the ratio $\xi = \left(f_{B_s}\sqrt{\widehat{B}_{B_s}}\right)/\left(f_{B_d}\sqrt{\widehat{B}_{B_d}}\right) = 1.216 \pm 0.016$ [14] and therefore the constraint on $|V_{td}/V_{ts}|$ from $\Delta m_d/\Delta m_s$ is more reliable theoretically. These provide a theoretically clean and significantly improved determination,

$$\left|V_{td}/V_{ts}\right| = 0.207 \pm 0.001 \pm 0.003 \,. \tag{12.14}$$

The inclusive branching ratio $\mathcal{B}(B \to X_s\gamma) = (3.49 \pm 0.19) \times 10^{-4}$ extrapolated to $E_\gamma > E_0 = 1.6\,\text{GeV}$ [24] is also sensitive to $|V_{tb}V_{ts}|$. In addition to t-quark penguins, a substantial part of the rate comes from charm contributions proportional to $V_{cb}V_{cs}^*$ via the application of 3×3 CKM unitarity (which is used here). With the NNLO calculation of $\mathcal{B}(B \to X_s\gamma)_{E_\gamma > E_0}/\mathcal{B}(B \to X_c e\bar{\nu})$ [72], we obtain $|V_{ts}/V_{cb}| = 1.00 \pm 0.04$. The $B_s \to \mu^+\mu^-$ rate is also proportional to $|V_{tb}V_{ts}|^2$ in the SM, and the world average, $\mathcal{B}(B_s \to \mu^+\mu^-) = (3.01 \pm 0.35) \times 10^{-9}$ [65], is consistent with the SM, with sizable uncertainties.

A complementary determination of $|V_{td}/V_{ts}|$ is possible from the ratio of $B \to \rho\gamma$ and $K^*\gamma$ rates. The ratio of the neutral modes is theoretically cleaner than that of the charged ones, because the poorly known spectator-interaction contribution is expected to be

smaller (W-exchange vs. weak annihilation). For now, because of low statistics, we average the charged and neutral rates assuming the isospin symmetry and heavy-quark limit motivated relation, $|V_{td}/V_{ts}|^2/\xi_\gamma^2 = [\Gamma(B^+ \to \rho^+\gamma) + 2\Gamma(B^0 \to \rho^0\gamma)]/[\Gamma(B^+ \to K^{*+}\gamma) + \Gamma(B^0 \to K^{*0}\gamma)] = (3.35 \pm 0.48)\%$ [24, 73]. Here ξ_γ contains the poorly known hadronic physics. Using $\xi_\gamma = 1.2 \pm 0.2$ [74] gives $|V_{td}/V_{ts}| = 0.220 \pm 0.016 \pm 0.037$, where the first uncertainty is experimental and the second is theoretical.

A theoretically clean determination of $|V_{td}V_{ts}^*|$ is possible from $K^+ \to \pi^+\nu\bar{\nu}$ decay [75]. Experimentally, more than 20 candidates have been observed [76, 77] and the rate is consistent with the SM within errors. Much more data are needed for a precision measurement.

12.2.8 $|V_{tb}|$

The determination of $|V_{tb}|$ from top decays uses the ratio of branching fractions $R = \mathcal{B}(t \to Wb)/\mathcal{B}(t \to Wq) = |V_{tb}|^2/(\sum_q |V_{tq}|^2) = |V_{tb}|^2$, where $q = b, s, d$. The CDF and DØ measurements performed on data collected during Run II of the Tevatron give $|V_{tb}| > 0.85$ [78] and $0.99 > |V_{tb}| > 0.90$ [79], respectively, at 95% CL. CMS measured the same quantity at 8 TeV and obtained $|V_{tb}| > 0.975$ [80] at 95% CL.

The direct determination of $|V_{tb}|$, without assuming unitarity, is possible from the single top quark production cross section. The $(3.30^{+0.52}_{-0.40})$ pb combined cross section [81] of DØ and CDF measurements implies $|V_{tb}| = 1.02^{+0.06}_{-0.05}$. The LHC experiments, ATLAS and CMS, have measured single top quark production cross sections (and extracted $|V_{tb}|$) in t-channel, Wt-channel, and s-channel at 7 TeV, 8 TeV, and 13 TeV [82]. The average of these $|V_{tb}|$ values is calculated to be $|V_{tb}| = 1.007 \pm 0.030$, where all systematic errors and theoretical errors are treated to be fully correlated. The average of Tevatron and LHC values gives

$$|V_{tb}| = 1.010 \pm 0.027\,. \tag{12.15}$$

The experimental systematic uncertainties dominate, and a dedicated combination would be welcome.

A weak constraint on $|V_{tb}|$ can be obtained from precision electroweak data, where top quarks enter in loops. The sensitivity is best in $\Gamma(Z \to b\bar{b})$ and yields $|V_{tb}| = 0.77^{+0.18}_{-0.24}$ [83].

12.3 Phases of CKM elements

As can be seen from Fig. 12.1, the angles of the unitarity triangle are

$$\begin{aligned}
\beta &= \phi_1 = \arg\Big(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\Big),\\
\alpha &= \phi_2 = \arg\Big(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\Big),\\
\gamma &= \phi_3 = \arg\Big(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\Big).
\end{aligned} \tag{12.16}$$

Since CP violation involves phases of CKM elements, many measurements of CP-violating observables can be used to constrain these angles and the $\bar{\rho}, \bar{\eta}$ parameters.

12.3.1 ϵ and ϵ'

The measurement of CP violation in K^0–$\overline{K}^0$ mixing, $|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}$ [84], provides important information about the CKM matrix. The phase of ϵ is determined by long-distance physics, $\epsilon = \frac{1}{2}\, e^{i\phi_\epsilon} \sin\phi_\epsilon \arg(-M_{12}/\Gamma_{12})$, where $\phi_\epsilon = \arctan|2\Delta m_K/\Delta\Gamma_K| \simeq 43.5°$. The SM prediction can be written as

$$\begin{aligned}
\epsilon = \kappa_\epsilon\, e^{i\phi_\epsilon}\, \frac{G_F^2 m_W^2 m_K}{12\sqrt{2}\,\pi^2 \Delta m_K}\, f_K^2 \widehat{B}_K \Big\{ &\eta_{tt} S(x_t)\, \mathrm{Im}[(V_{ts}V_{td}^*)^2]\\
&+ 2\eta_{ct} S(x_c, x_t)\, \mathrm{Im}(V_{cs}V_{cd}^* V_{ts}V_{td}^*) + \eta_{cc}\, x_c\, \mathrm{Im}[(V_{cs}V_{cd}^*)^2]\Big\},
\end{aligned} \tag{12.17}$$

where $\kappa_\epsilon \simeq 0.94 \pm 0.02$ [85] includes the effects of strangeness changing $\Delta s = 1$ operators and additional dependence on $\phi_\epsilon \neq \pi/4$ (see also Ref. [86]). The displayed terms are the short-distance $\Delta s = 2$ contribution to $\mathrm{Im}M_{12}$ in the usual phase convention, S is an Inami-Lim function [87], $x_q = m_q^2/m_W^2$, and η_{ij} are perturbative QCD corrections. The constraint from ϵ in the $\bar{\rho}, \bar{\eta}$ plane is bounded by approximate hyperbolas. Lattice QCD determined the bag parameter $\widehat{B}_K = 0.717 \pm 0.024$ [14] and the main uncertainties are from $(V_{ts}V_{td}^*)^2$ (approximately given by that of $|V_{cb}|^4$ or A^4), the η_{ij} coefficients, and estimates of κ_ϵ.

The measurement of $6\,\mathrm{Re}(\epsilon'/\epsilon) = 1 - |\eta_{00}/\eta_{+-}|^2$, where each $\eta_{ij} = \langle\pi^i\pi^j|\mathcal{H}|K_L\rangle/\langle\pi^i\pi^j|\mathcal{H}|K_S\rangle$ violates CP, provides a qualitative test of the CKM mechanism, and strong constraints on many BSM scenarios. Its nonzero value, $\mathrm{Re}(\epsilon'/\epsilon) = (1.67 \pm 0.23) \times 10^{-3}$ [84], demonstrated the existence of direct CP violation, a prediction of the KM ansatz. While $\mathrm{Re}(\epsilon'/\epsilon) \propto \mathrm{Im}(V_{td}V_{ts}^*)$, this quantity cannot easily be used to extract CKM parameters, because cancellations between the electromagnetic and gluonic penguin contributions for large m_t [88] enhance the hadronic uncertainties. Most SM estimates [89] agree with the observed value, indicating that $\bar{\eta}$ is positive. Progress in lattice QCD [90] may yield a precise SM prediction in the future, and trigger new work on assessing the consistency of the SM with the measured value [91, 92].

12.3.2 β / ϕ_1

12.3.2.1 *Charmonium modes*

CP-violation measurements in B-meson decays provide direct information on the angles of the unitarity triangle, shown in Fig. 12.1. These overconstraining measurements serve to improve the determination of the CKM elements, and to reveal possible effects beyond the SM.

The time-dependent CP asymmetry of neutral B decays to a final state f common to B^0 and $\overline{B}^0$ is given by [93–95]

$$\begin{aligned}
\mathcal{A}_f &= \frac{\Gamma(\overline{B}^0(t) \to f) - \Gamma(B^0(t) \to f)}{\Gamma(\overline{B}^0(t) \to f) + \Gamma(B^0(t) \to f)}\,,\\
&= S_f \sin(\Delta m_d\, t) - C_f \cos(\Delta m_d\, t)\,,
\end{aligned} \tag{12.18}$$

where

$$S_f = \frac{2\,\mathrm{Im}\lambda_f}{1 + |\lambda_f|^2}\,, \qquad C_f = \frac{1 - |\lambda_f|^2}{1 + |\lambda_f|^2}\,, \qquad \lambda_f = \frac{q}{p}\frac{\bar{A}_f}{A_f}\,. \tag{12.19}$$

Here, q/p describes B^0–$\overline{B}^0$ mixing and, to a good approximation in the SM, $q/p = V_{tb}^* V_{td}/V_{tb}V_{td}^* = e^{-2i\beta + \mathcal{O}(\lambda^4)}$ in the usual phase convention. A_f ($\bar{A}_f$) is the amplitude of the $B^0 \to f$ ($\overline{B}^0 \to f$) decay. If f is a CP eigenstate, and amplitudes with one CKM phase dominate the decay, then $|A_f| = |\bar{A}_f|$, $C_f = 0$, and $S_f = \sin(\arg\lambda_f) = \eta_f \sin 2\phi$, where η_f is the CP eigenvalue of f and 2ϕ is the phase difference between the $B^0 \to f$ and $B^0 \to \overline{B}^0 \to f$ decay paths. A contribution of another amplitude to the decay with a different CKM phase makes the value of S_f sensitive to relative strong-interaction phases between the decay amplitudes (it also makes $C_f \neq 0$ possible).

The $b \to c\bar{c}s$ decays to CP eigenstates ($B^0 \to$ charmonium $K^0_{S,L}$) give currently the most precise measurements of $S_f = -\eta_f \sin 2\beta$. The $b \to s$ penguin amplitudes have dominantly the same weak phase as the $b \to c\bar{c}s$ tree amplitude. Since only λ^2-suppressed penguin amplitudes introduce a different CP-violating phase, amplitudes with a single weak phase dominate, and we expect $\left||\bar{A}_{\psi K}/A_{\psi K}| - 1\right| < 0.01$. The e^+e^- asymmetric-energy B-factory experiments, *BABAR* [96] and Belle [97], and LHCb [98] provided precise measurements. The world average, including some other measurements, is [24, 95, 99]

$$\sin 2\beta = 0.709 \pm 0.011\,. \tag{12.20}$$

This measurement has a four-fold ambiguity in β, which can be resolved by a global fit as mentioned in Sec. 12.4. Experimentally, the two-fold ambiguity $\beta \to \pi/2 - \beta$ (but not $\beta \to \pi + \beta$) can be resolved by a time-dependent angular analysis of $B^0 \to J/\psi K^{*0}$ [100, 101], or a time-dependent Dalitz plot analysis of $B^0 \to \overline{D}^0 h^0$. The time-dependent Dalitz plot analysis of $B^0 \to \overline{D}^0 h^0$ ($h^0 = \pi^0, \eta, \omega$) with $\overline{D}^0 \to K^0_S\pi^+\pi^-$, jointly performed by Belle and *BABAR*, excludes the $\pi/2 - \beta$ solution with

7.3σ confidence level [102]. These results exclude the negative $\cos 2\beta$ solutions, in agreement with the global CKM fit, which is no longer shown in Fig. 12.2.

The $b \to c\bar{c}d$ mediated transitions, such as $B^0 \to J/\psi\pi^0$ and $B^0 \to D^{(*)+}D^{(*)-}$, also measure approximately $\sin 2\beta$. However, the dominant component of the $b \to d$ penguin amplitude has a different CKM phase ($V_{tb}^* V_{td}$) than the tree amplitude ($V_{cb}^* V_{cd}$), and their magnitudes are of the same order in λ. Therefore, the effect of penguins could be large, resulting in $S_f \neq -\eta_f \sin 2\beta$ and $C_f \neq 0$. Such decay modes have been measured by *BABAR*, Belle, and LHCb. The world averages [24], $S_{J/\psi\pi^0} = -0.86 \pm 0.14$, $S_{J/\psi\rho^0} = -0.66^{+0.16}_{-0.12}$, $S_{D^+D^-} = -0.84 \pm 0.12$, and $S_{D^{*+}D^{*-}} = -0.71 \pm 0.09$ (where $\eta_f = +1$ for the $J/\psi\pi^0$ and D^+D^- modes, while $J/\psi\rho^0$ and $D^{*+}D^{*-}$ are mixtures of CP even and odd states), are consistent with $\sin 2\beta$ obtained from $B^0 \to$ charmonium K^0 decays, and the C_f's are consistent with zero, although the uncertainties are sizable.

The $b \to c\bar{u}d$ decays $B^0 \to \overline{D}^{0(*)}h^0$, with $\overline{D}^0 \to CP$ eigenstates and $\overline{D}^0 \to K^0_S\pi^+\pi^-$ with Dalitz plot analysis, have no penguin contributions, and provide theoretically clean $\sin 2\beta$ measurements. The average of joint analyses of *BABAR* and Belle data [102, 103] give $\sin 2\beta = 0.71 \pm 0.09$ [24].

12.3.2.2 *Penguin-dominated modes*

The $b \to s\bar{q}q$ penguin-dominated decays have the same CKM phase as the $b \to c\bar{c}s$ tree level decays, up to corrections suppressed by λ^2, since $V_{tb}^* V_{ts} = -V_{cb}^* V_{cs}[1 + \mathcal{O}(\lambda^2)]$. Therefore, decays such as $B^0 \to \phi K^0$ and $\eta' K^0$ provide $\sin 2\beta$ measurements in the SM. Any BSM contribution to the amplitude with a different weak phase would give rise to $S_f \neq -\eta_f \sin 2\beta$, and possibly $C_f \neq 0$. Therefore, the main interest in these modes is not simply to measure $\sin 2\beta$, but to search for new physics. Measurements of many other decay modes in this category, such as $B \to \pi^0 K^0_S$, $K^0_S K^0_S K^0_S$, *etc.*, have also been performed by *BABAR* and Belle. The results and their uncertainties are summarized in Fig. 13.3 and Table 13.1 of Ref. [94]. The comparison of CP violation measurements between tree-dominated and penguin-dominated modes in B^0_s decays provides similar sensitivity to new physics.

12.3.3 α / ϕ_2

Since α is the phase between $V_{tb}^* V_{td}$ and $V_{ub}^* V_{ud}$, only time-dependent CP asymmetries in decay modes dominated by $b \to u\bar{u}d$ transitions can directly measure $\sin 2\alpha$, in contrast to $\sin 2\beta$, where several different quark-level transitions can be used. Since $b \to d$ penguin amplitudes have a different CKM phase than $b \to u\bar{u}d$ tree amplitudes, and their magnitudes are of the same order in λ, the penguin contribution can be sizable, which makes the determination of α complicated. To date, α has been measured in $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ decay modes.

12.3.3.1 $B \to \pi\pi$

It is well-established from the data that there is a sizable contribution of $b \to d$ penguin amplitudes in $B \to \pi\pi$ decays. Thus, $S_{\pi^+\pi^-}$ in the time-dependent $B^0 \to \pi^+\pi^-$ analysis does not measure $\sin 2\alpha$, but

$$S_{\pi^+\pi^-} = \sqrt{1 - C^2_{\pi^+\pi^-}}\, \sin(2\alpha + 2\Delta\alpha)\,, \tag{12.21}$$

where $2\Delta\alpha$ is the phase difference between $e^{2i\gamma}\bar{A}_{\pi^+\pi^-}$ and $A_{\pi^+\pi^-}$. The value of $\Delta\alpha$, and hence α, can be extracted using the isospin relation among the amplitudes of $B^0 \to \pi^+\pi^-$, $B^0 \to \pi^0\pi^0$, and $B^+ \to \pi^+\pi^0$ decays [104],

$$\frac{1}{\sqrt{2}}\, A_{\pi^+\pi^-} + A_{\pi^0\pi^0} - A_{\pi^+\pi^0} = 0\,, \tag{12.22}$$

and a similar expression for the $\bar{A}_{\pi\pi}$'s. This method utilizes the fact that a pair of pions from $B \to \pi\pi$ decay must be in a zero angular momentum state, and, because of Bose statistics, they must have even isospin. Consequently, $\pi^\pm\pi^0$ is in a pure isospin-2 state, while the penguin amplitudes only contribute to the isospin-0 final state. The latter does not hold for the electroweak penguin amplitudes, but their effect is expected to be small. The isospin analysis uses the world averages of *BABAR*, Belle, and LHCb measurements, $S_{\pi^+\pi^-} = -0.666 \pm 0.029$, $C_{\pi^+\pi^-} = -0.311 \pm 0.030$, the decay widths of all three modes, and the direct CP asymmetry $C_{\pi^0\pi^0} = -0.33 \pm 0.22$ [24]. This analysis leads to 16 mirror solutions for $0 \leq \alpha < 2\pi$. Because of this, and due to the experimental uncertainties, some of these solutions are not well separated [95].

12.3.3.2 $B \to \rho\rho$

The decay $B^0 \to \rho^+\rho^-$ contains two vector mesons in the final state, and so in general is a mixture of CP-even and CP-odd components. At the current level of precision, it simplifies the analysis that the longitudinal polarization fractions in $B^+ \to \rho^+\rho^0$ and $B^0 \to \rho^+\rho^-$ decays were measured to be close to unity [105], which implies that the final states are almost purely CP-even. Furthermore, $\mathcal{B}(B^0 \to \rho^0\rho^0) = (0.96 \pm 0.15) \times 10^{-6}$ is much smaller than $\mathcal{B}(B^0 \to \rho^+\rho^-) = (27.5 \pm 1.7) \times 10^{-6}$ and $\mathcal{B}(B^+ \to \rho^+\rho^0) = (23.8 \pm 1.7) \times 10^{-6}$ [24], which implies that the effect of the penguin contributions is small. The isospin analysis using the world averages, $S_{\rho^+\rho^-} = -0.14 \pm 0.13$ and $C_{\rho^+\rho^-} = 0.00 \pm 0.09$ [24], together with the time-dependent CP asymmetry, $S_{\rho^0\rho^0} = -0.3 \pm 0.7$ and $C_{\rho^0\rho^0} = -0.2 \pm 0.9$ [106], and the above mentioned branching fractions and longitudinal polarization fractions, gives two solutions (with mirror solutions at $3\pi/2 - \alpha$) [95]. A possible small violation of Eq. (12.22) due to the finite width of the ρ [107] is so far neglected.

12.3.3.3 $B \to \rho\pi$

The final state in $B^0 \to \rho^+\pi^-$ decay is not a CP eigenstate, but this decay proceeds via the same quark-level diagrams as $B^0 \to \pi^+\pi^-$, and both B^0 and $\overline{B}^0$ can decay to $\rho^+\pi^-$, while the final state in $B^0 \to \rho^0\pi^0$ is a CP eigenstate. Consequently, mixing-induced CP violation can occur in B^0 and $\overline{B}^0$ decays to $\rho^\pm\pi^\mp$ and $\rho^0\pi^0$. The time-dependent Dalitz plot analysis of $B^0 \to \pi^+\pi^-\pi^0$ decays permits the extraction of α with a single discrete ambiguity, $\alpha \to \alpha + \pi$, since one knows the variation of the strong phases in the interference regions of the $\rho^+\pi^-$, $\rho^-\pi^+$, and $\rho^0\pi^0$ amplitudes in the Dalitz plot [108]. The combination of Belle [109] and *BABAR* [110] measurements gives only moderate constraints [95].

Combining the $B \to \pi\pi$, $\rho\pi$, and $\rho\rho$ decay modes [24, 95, 99], α is constrained as

$$\alpha = \left(84.1^{+4.5}_{-3.8}\right)^\circ\,. \tag{12.23}$$

Similar results can be found in Refs. [111, 112].

12.3.4 γ / ϕ_3

By virtue of Eq. (12.16), γ does not depend on CKM elements involving the top quark, so it can be measured in tree-level B decays. This is an important distinction from the measurements of α and β, and implies that measurements of γ are unlikely to be affected by physics beyond the SM.

12.3.4.1 $B_{(s)} \to D_{(s)}K^{(*)}$

The interference of $B^- \to D^0K^-$ ($b \to c\bar{u}s$) and $B^- \to \overline{D}^0K^-$ ($b \to u\bar{c}s$) transitions can be studied in final states accessible in both D^0 and $\overline{D}^0$ decays [93]. In principle, it is possible to extract the B and D decay amplitudes, the relative strong phases, and the weak phase γ from the data [95].

A practical complication is that the precision depends sensitively on the ratio of the interfering amplitudes

$$r_B = \left|A(B^- \to \overline{D}^0K^-)\big/A(B^- \to D^0K^-)\right|, \tag{12.24}$$

which is around 0.1. The original GLW method [113, 114] considers D decays to CP eigenstates, such as $B^\pm \to D^{(*)}_{CP}(\to \pi^+\pi^-)K^{(*)\pm}$. To alleviate the smallness of r_B and make the interfering amplitudes (which are products of the B and D decay amplitudes) comparable in magnitude, the ADS method [115] considers final states where Cabibbo-allowed $\overline{D}^0$ and doubly-Cabibbo-suppressed D^0 decays interfere. Measurements have been made by the B factories, CDF, and LHCb, using both methods [24]. The GLW method currently gives only a loose constraint on γ, while the ADS method provides a moderate constraint.

The BPGGSZ method [116, 117] utilizes the fact that both D^0 and $\overline{D}^0$ can have large branching fractions to CP self-conjugate

three- and four-body final states, such as $K^0_S\pi^+\pi^-$, and the analysis can be optimized by studying the Dalitz plot dependence of the interferences. The best present determination of γ comes from this method, dominated by 3-body D decay modes. Combining results in 3-body decay modes from Belle [118], *BABAR* [119], and the most precise LHCb [120] one, $\gamma = (70.0\pm4.0)^\circ$ is obtained [95]. The uncertainty is sensitive to the central value of the amplitude ratio r_B (and r^*_B for the D^*K mode), for which Belle found somewhat larger central values than *BABAR* and LHCb. The same values of $r_B^{(*)}$ enter the ADS analyses, and the data (including 4-body D decays [121]) can be combined to fit for $r_B^{(*)}$ and γ. The effect of $D^0-\overline{D}^0$ mixing on γ is either below the present experimental accuracy or can be taken into account in the analysis [122] (even if $D^0-\overline{D}^0$ mixing is due to CP-violating new physics [123]).

The amplitude ratio is much larger in the analogous $B^0_s \to D^\pm_s K^\mp$ decays, which allows a model-independent extraction of $\gamma - 2\beta_s$ [124] (here $\beta_s = \arg(-V_{ts}V^*_{tb}/V_{cs}V^*_{cb})$ is related to the phase of B_s mixing). Measurements by LHCb with $B^0_s \to D^\pm_s K^\mp$ [125] and $B^0_s \to D^\pm_s K^\mp\pi^+\pi^-$ [126] give $\gamma = (79^{+19}_{-21})^\circ$ using a constraint on $2\beta_s$ (see Sec. 12.5).

Combining all the above measurements [24, 95, 99], γ is constrained as

$$\gamma = \left(65.7 \pm 3.0\right)^\circ . \qquad (12.25)$$

Similar results can be found in Refs. [111, 112].

12.3.4.2 $B^0 \to D^{(*)\pm}\pi^\mp$

The interference of $b \to u$ and $b \to c$ transitions can be studied in $\overline{B}^0 \to D^{(*)+}\pi^-$ ($b \to c\bar{u}d$) and $\overline{B}^0 \to B^0 \to D^{(*)+}\pi^-$ ($\bar{b} \to \bar{u}cd$) decays and their CP conjugates, since both B^0 and $\overline{B}^0$ decay to $D^{(*)\pm}\pi^\mp$ (or $D^\pm\rho^\mp$, *etc.*). Since there are only tree and no penguin contributions to these decays, in principle, it is possible to extract from the four time-dependent rates the magnitudes of the two hadronic amplitudes, their relative strong phase, and the weak phase between the two decay paths, which is $2\beta+\gamma$.

A complication is that the ratio of the interfering amplitudes is very small, $r_{D\pi} = A(B^0 \to D^+\pi^-)/A(\overline{B}^0 \to D^+\pi^-) = \mathcal{O}(0.01)$ (and similarly for $r_{D^*\pi}$ and $r_{D\rho}$), and therefore it has not been possible to measure it. To obtain $2\beta+\gamma$, $SU(3)$ flavor symmetry and dynamical assumptions have been used to relate $A(\overline{B}^0 \to D^-\pi^+)$ to $A(\overline{B}^0 \to D^-_s\pi^+)$, so this measurement is not model independent at present. Combining the $D^\pm\pi^\mp$, $D^{*\pm}\pi^\mp$ and $D^\pm\rho^\mp$ measurements [127] gives $\sin(2\beta+\gamma) > 0.68$ at 68% CL [111], consistent with the previously discussed results for β and γ.

12.4 Global fit in the Standard Model

Using the independently measured CKM elements mentioned in the previous sections, the unitarity of the CKM matrix can be checked. We obtain $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9984 \pm 0.0007$ (1st row), $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.001 \pm 0.012$ (2nd row), $|V_{ud}|^2 + |V_{cd}|^2 + |V_{td}|^2 = 0.9971 \pm 0.0020$ (1st column), and $|V_{us}|^2 + |V_{cs}|^2 + |V_{ts}|^2 = 1.003 \pm 0.012$ (2nd column), respectively. Due to the recent reduction of the value of $|V_{ud}|$, there is a 2.3σ tension with unitarity in the 1st row, leading also to poor consistency of the SM fit below. The uncertainties in the second row and column are dominated by that of $|V_{cs}|$. For the second row, another check is obtained from the measurement of $\sum_{u,c,d,s,b}|V_{ij}|^2$ in Sec. 12.2.4, minus the sum in the first row above: $|V_{cd}|^2 + |V_{cs}|^2 + |V_{cb}|^2 = 1.002 \pm 0.027$. These provide strong tests of the unitarity of the CKM matrix. With the significantly improved direct determination of $|V_{tb}|$, the unitarity checks for the third row and column have also become fairly precise, leaving decreasing room for mixing with other states. The sum of the three angles of the unitarity triangle, $\alpha+\beta+\gamma = \left(172 \pm 5\right)^\circ$, is also consistent with the SM expectation.

The CKM matrix elements can be most precisely determined using a global fit to all available measurements and imposing the SM constraints (*i.e.*, three generation unitarity). The fit must also use theory predictions for hadronic matrix elements, which sometimes have significant uncertainties. There are several approaches to combining the experimental data. CKMfitter [6, 111] and Ref. [128] (which develops [129, 130] further) use frequentist statistics, while UTfit [112, 131] uses a Bayesian approach. These approaches provide similar results.

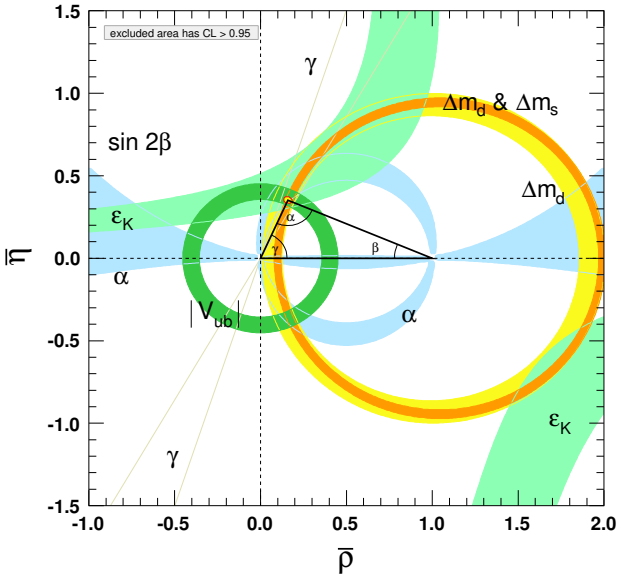

Figure 12.2: Constraints on the $\bar{\rho},\bar{\eta}$ plane. The shaded areas have 95% CL.

The constraints implied by the unitarity of the three generation CKM matrix significantly reduce the allowed range of some of the CKM elements. The fit for the Wolfenstein parameters defined in Eq. (12.4) gives

$$\lambda = 0.22501 \pm 0.00068\,, \qquad A = 0.826^{+0.016}_{-0.015}\,,$$
$$\bar{\rho} = 0.1591 \pm 0.0094\,, \qquad \bar{\eta} = 0.3523^{+0.0073}_{-0.0071}\,. \qquad (12.26)$$

These values are obtained using the method of Refs. [6, 111]. The prescription of Refs. [112, 131] gives $\lambda = 0.22497 \pm 0.00070$, $A = 0.839 \pm 0.011$, $\bar{\rho} = 0.1581 \pm 0.0092$, and $\bar{\eta} = 0.3548 \pm 0.0072$ [132]; these results are now very close to one another. The fit results for the magnitudes of all nine CKM elements are

$$\left|V_{\rm CKM}\right| = \begin{pmatrix} 0.97435 \pm 0.00016 & 0.22501 \pm 0.00068 & 0.003732^{+0.000090}_{-0.000085} \\ 0.22487 \pm 0.00068 & 0.97349 \pm 0.00016 & 0.04183^{+0.00079}_{-0.00069} \\ 0.00858^{+0.00019}_{-0.00017} & 0.04111^{+0.00077}_{-0.00068} & 0.999118^{+0.000029}_{-0.000034} \end{pmatrix}, \qquad (12.27)$$

and the Jarlskog invariant is $J = \left(3.12^{+0.13}_{-0.12}\right) \times 10^{-5}$. The parameters in Eq. (12.3) are

$$\sin\theta_{12} = 0.22501 \pm 0.00068\,, \qquad \sin\theta_{13} = 0.003732^{+0.000090}_{-0.000085}\,,$$
$$\sin\theta_{23} = 0.04183^{+0.00079}_{-0.00069}\,, \qquad \delta = 1.147 \pm 0.026\,. \qquad (12.28)$$

Fig. 12.2 illustrates the constraints on the $\bar{\rho},\bar{\eta}$ plane from various measurements, and the global fit result. The shaded 95% CL regions all overlap consistently around the global fit region.

If one uses only tree-level inputs (magnitudes of CKM elements not coupling to the top quark and the angle γ), the resulting fit is almost identical for λ in Eq. (12.26), while the other parameters' central values can change by about a sigma and their uncertainties double, yielding $\lambda = 0.22509 \pm 0.00068$, $A = 0.811 \pm 0.024$, $\bar{\rho} = 0.166^{+0.022}_{-0.021}$, and $\bar{\eta} = 0.367^{+0.024}_{-0.023}$. This illustrates how the constraints can be less tight in the presence of BSM physics.

12.5 Implications beyond the SM

The effects in B, B_s, K, and D decays and mixings due to high-scale physics (W, Z, t, H in the SM, and unknown heavier particles) can be parameterized by operators composed of SM

fields, obeying the $SU(3)\times SU(2)\times U(1)$ gauge symmetry. Flavor-changing neutral currents, suppressed in the SM, are especially sensitive to beyond SM contributions. Processes studied in great detail, both experimentally and theoretically, include neutral meson mixings, $B_{(s)} \to X\gamma$, $X\ell^+\ell^-$, $\ell^+\ell^-$, $K \to \pi\nu\bar{\nu}$, etc. The BSM contributions to these operators are suppressed by powers of the scale at which they are generated. Already at lowest order, there are many dimension-6 operators, and the observable effects of BSM interactions are encoded in their coefficients. In the SM, these coefficients are determined by just the four CKM parameters, and the W, Z, and quark masses. For example, Δm_d, $\Gamma(B \to \rho\gamma)$, $\Gamma(B \to \pi\ell^+\ell^-)$, and $\Gamma(B \to \ell^+\ell^-)$ are all proportional to $|V_{td}V_{tb}|^2$ in the SM, however, they may receive unrelated BSM contributions. These BSM contributions may or may not obey the SM relations. (For example, the flavor sector of the MSSM contains 69 CP-conserving parameters and 41 CP-violating phases, *i.e.*, 40 new ones [133]). Thus, similar to the measurements of $\sin 2\beta$ in tree- and loop-dominated decay modes, overconstraining measurements of the magnitudes and phases of flavor-changing neutral-current amplitudes gives good sensitivity to BSM.

To illustrate the level of suppression required for BSM contributions, consider a class of models in which the unitarity of the CKM matrix is maintained, and the dominant BSM effects modify the neutral meson mixing amplitudes [134] by $(z_{ij}/\Lambda^2)(\bar{q}_i\gamma^\mu P_L q_j)^2$, where z_{ij} is an unknown coefficient and Λ is the scale suppressing this BSM contribution (see, [135, 136]). It is only known since the first measurements of γ and α that the SM gives the leading contribution to $B^0 - \overline{B}^0$ mixing [6,137]. Nevertheless, new physics with a generic weak phase may still contribute to neutral meson mixings at a significant fraction of the SM [131,138,139]. The existing data imply that $\Lambda/|z_{ij}|^{1/2}$ has to exceed about 10^4 TeV for $K^0 - \overline{K}^0$ mixing, 10^3 TeV for $D^0 - \overline{D}^0$ mixing, 500 TeV for $B^0 - \overline{B}^0$ mixing, and 100 TeV for $B_s^0 - \overline{B}_s^0$ mixing [131, 136]. (Some other operators are even better constrained [131].) The constraints are the strongest in the kaon sector, because the CKM suppression is the most severe. Thus, if there is new physics at the TeV scale, $|z_{ij}| \ll 1$ is required. Even if $|z_{ij}|$ are suppressed by a loop factor and $|V_{ti}^* V_{tj}|^2$ (in the down quark sector), similar to the SM, one expects percent-level effects, which may be observable in forthcoming flavor physics experiments. To constrain such extensions of the SM, many measurements irrelevant for the SM-CKM fit, such as the CP asymmetry in semileptonic $B_{d,s}^0$ decays, $A_{\rm SL}^{d,s}$, are important [140]. The current world averages [24] are consistent with the SM, with experimental uncertainties far greater than those of the theory predictions.

There are many key measurements sensitive to BSM physics, which do not constrain the unitarity triangle in Fig. 12.1. For example, a key quantity in the B_s system is $\beta_s = \arg(-V_{ts}V_{tb}^*/V_{cs}V_{cb}^*)$, which is the small, λ^2-suppressed, angle of a "squashed" unitarity triangle, obtained by taking the scalar product of the second and third columns of the CKM matrix. This angle can be measured via time-dependent CP violation in $B_s^0 \to J/\psi\,\phi$, similar to β in $B^0 \to J/\psi K^0$. Since the $J/\psi\,\phi$ final state is not a CP eigenstate, an angular analysis of the decay products is needed to separate the CP-even and CP-odd components, which give opposite asymmetries. In the SM, the asymmetry for the CP-even part is $2\beta_s$, when one neglects subdominant amplitudes with a weak phase V_{ub}. (Sometimes the notation $\phi_s = -2\beta_s$ plus a possible BSM contribution to the B_s mixing phase is used.) Testing if the data agree with the SM prediction, $2\beta_s = 0.03726^{+0.00078}_{-0.00077}$ [111], is another sensitive probe of the SM. The current world average, dominated by LHC measurements including the $B_s \to J/\psi\,K^+K^-$ and $J/\psi\,\pi^+\pi^-$ decay modes, is $2\beta_s = 0.040 \pm 0.016$ [69]. Since the uncertainty is much larger than that in the SM, a lot will be learned from more precise future measurements. Searches for CP violation in the charm sector, in particular in $D^0 - \overline{D}^0$ mixing, provide complementary sensitivity to BSM.

In the kaon sector, the CP-violating observables, ϵ and ϵ', are tiny, so models in which all sources of CP violation are small were viable before the B-factory measurements. Since the measurement of $\sin 2\beta$, we know that CP violation can be an $\mathcal{O}(1)$ effect, and only flavor mixing is suppressed between the three quark generations. Thus, many models with spontaneous CP violation were excluded. In the kaon sector, clean tests of the SM can come from measurements of $K^+ \to \pi^+\nu\bar{\nu}$ [77] and $K_L^0 \to \pi^0\nu\bar{\nu}$ [141]. These loop-induced rare decays are sensitive to BSM, and will allow precise tests [142] of the CKM paradigm, independent of B decays.

The CKM elements are fundamental parameters, so they should be measured as precisely as possible. The overconstraining measurements of CP asymmetries, mixing, semileptonic, and rare decays severely constrain the magnitudes and phases of possible BSM contributions to flavor-changing interactions. If new particles are observed at the LHC, it will be important to explore their flavor parameters as precisely as possible to understand the underlying physics.

13. *CP* Violation in the Quark Sector

Revised August 2023 by T. Gershon (Warwick U.) and Y. Nir (Weizmann Inst.).

The *CP* transformation combines charge conjugation C with parity P. Under C, particles and antiparticles are interchanged, by conjugating all internal quantum numbers, *e.g.*, $Q \to -Q$ for electromagnetic charge. Under P, the handedness of space is reversed, $\vec{x} \to -\vec{x}$. Thus, for example, a left-handed electron e^-_L is transformed under *CP* into a right-handed positron, e^+_R.

If *CP* were an exact symmetry, the laws of nature would be the same for matter and for antimatter. We observe that most phenomena are C- and P-symmetric, and therefore, also *CP*-symmetric. In particular, these symmetries are respected by the electromagnetic and strong interactions. The weak interactions, on the other hand, violate C and P in the strongest possible way. For example, the W bosons couple to left-handed electrons, e^-_L, and to their *CP*-conjugate right-handed positrons, e^+_R, but to neither their C-conjugate left-handed positrons, e^+_L, nor their P-conjugate right-handed electrons, e^-_R. While weak interactions violate C and P separately, *CP* is still preserved in most weak interaction processes. The *CP* symmetry is, however, violated in certain processes involving interference effects, as discovered in neutral K decays in 1964 [1], and established later in B (2001) and D (2019) decays. For example, as discovered in 1967, a K_L meson decays more often to $\pi^- e^+ \nu_e$ than to $\pi^+ e^- \overline{\nu}_e$, thus allowing electrons and positrons to be unambiguously distinguished, but the decay-rate asymmetry is only at the 0.003 level. The *CP*-violating effects observed in the B system are larger: the parameter describing the *CP* asymmetry in the decay time distribution of $B^0/\overline{B}^0$ meson transitions to *CP* eigenstates like $J/\psi K_S$ is about 0.7 [2,3]. These effects are related to K^0–$\overline{K}^0$ and B^0–$\overline{B}^0$ mixing, but *CP* violation arising solely from decay amplitudes has also been observed, first in $K \to \pi\pi$ decays [4–6], subsequently in B^0 [7,8], B^+ [9–11], and B^0_s [12] decays, and most recently in charm decays [13]. All of these observed *CP* asymmetries are consistent with the Standard Model predictions. Similar effects could also occur in decays of baryons, but have not yet been observed. Given that neutrino masses and lepton mixing have been established, it is expected that *CP* is violated also in the lepton sector [14]. Discovering *CP* violation in the lepton sector is one of the main goals of current and near-future experiments. *CP* violation has not yet been observed in processes involving the top quark, nor in flavor-conserving processes such as electric dipole moments; for these, any significant observation would be a clear indication of physics beyond the Standard Model.

In addition to parity and to continuous Lorentz transformations, there is one other spacetime operation that could be a symmetry of the interactions: time reversal T, $t \to -t$. Violations of T symmetry have been observed in neutral K decays [15]. More recently, T violation has been observed between states that are not *CP*-conjugate [16], exploiting the fact that for neutral B mesons both flavor tagging and *CP* tagging can be used [17]. Moreover, T violation is expected as a corollary of *CP* violation if the combined *CPT* transformation is a fundamental symmetry of nature [18]. All observations indicate that *CPT* is indeed a symmetry of nature [15]. Furthermore, one cannot build a locally Lorentz-invariant quantum field theory with a Hermitian Hamiltonian that violates *CPT*. (At several points in our discussion, we avoid assumptions about *CPT*, in order to identify cases where evidence for *CP* violation relies on assumptions about *CPT*.)

Within the Standard Model, *CP* symmetry is broken by complex phases in the Yukawa couplings (that is, the couplings of the Higgs scalar to quarks). When all transformations to remove unphysical phases in this model are exhausted, a single *CP*-violating parameter remains [19]. In the basis of mass eigenstates, this single phase appears in the 3×3 unitary matrix that gives the W-boson couplings to an up-type antiquark and a down-type quark. (If the Standard Model is supplemented with Majorana mass terms for the neutrinos, the analogous mixing matrix for leptons has three *CP*-violating phases.) The beautifully consistent and economical Standard-Model description of *CP* violation in terms of Yukawa couplings, known as the Kobayashi-Maskawa (KM) mechanism [19], agrees with all measurements to date. Furthermore, one can fit the data allowing contributions from beyond the Standard Model (referred to subsequently as new physics) to loop processes to compete with, or even dominate over, the Standard Model amplitudes [20,21]. Such an analysis provides model-independent proof that the KM phase is different from zero, and that the matrix of three-generation quark mixing is the dominant source of *CP* violation in meson decays.

The current level of experimental accuracy and the theoretical uncertainties involved in the interpretation of the various observations leave room, however, for additional subdominant sources of *CP* violation from new physics. Indeed, almost all extensions of the Standard Model imply that there are such additional sources. Moreover, *CP* violation is a necessary condition for baryogenesis, the process of dynamically generating the matter-antimatter asymmetry of the Universe [22]. Despite the phenomenological success of the KM mechanism, it fails (by several orders of magnitude) to accommodate the observed asymmetry [23]. This discrepancy strongly suggests that nature provides additional sources of *CP* violation beyond the KM mechanism. The evidence for neutrino masses implies that *CP* can be violated also in the lepton sector. This situation makes leptogenesis [24,25], a scenario where *CP*-violating phases in the Yukawa couplings of the neutrinos play a crucial role in the generation of the baryon asymmetry, a very attractive possibility. The expectation of new sources motivates the large ongoing experimental effort to find deviations from the predictions of the KM mechanism.

CP violation can be experimentally searched for in a variety of processes, such as hadron decays, electric dipole moments of neutrons, electrons and nuclei, and neutrino oscillations. Hadron decays via the weak interaction probe flavor-changing *CP* violation. The search for electric dipole moments may find (or constrain) sources of *CP* violation that, unlike the KM phase, are not related to flavor-changing couplings. Following the discovery of the Higgs boson [26,27], searches for *CP* violation in the Higgs sector are becoming feasible. Future searches for *CP* violation in neutrino oscillations might provide further input on leptogenesis.

The present measurements of *CP* asymmetries provide some of the strongest constraints on the weak couplings of quarks. Future measurements of *CP* violation in K, D, B, and B^0_s meson decays will provide additional constraints on the flavor parameters of the Standard Model, and can probe new physics. In this review, we give the formalism and basic physics motivations that are relevant to present and near future measurements of *CP* violation in the quark sector.

13.1 Formalism

The phenomenology of *CP* violation for neutral flavored mesons is particularly interesting, since many of the observables can be cleanly interpreted. Although the phenomenology is superficially different for K^0, D^0, B^0, and B^0_s decays, this is primarily because each of these systems is governed by a different balance between decay rates, oscillations, and lifetime splitting. However, the general considerations presented in this section are identical for all flavored neutral pseudoscalar mesons. The phenomenology of *CP* violation for neutral mesons that do not carry flavor quantum numbers (such as the $\eta^{(\prime)}$ state) is quite different: such states are their own antiparticles and have definite *CP* eigenvalues, so the signature of *CP* violation is simply the decay to a final state with the opposite *CP*. Such decays are mediated by the electromagnetic or (OZI-suppressed [28–30]) strong interaction, where *CP* violation is not expected and has not yet been observed. In the remainder of this review, we restrict ourselves to considerations of weakly decaying hadrons.

In this section, we present a general formalism for, and classification of, *CP* violation in the decay of a weakly decaying hadron, denoted M. We pay particular attention to the case that M is a K^0, D^0, B^0, or B^0_s meson. Subsequent sections describe the *CP*-violating phenomenology, approximations, and alternative formalisms that are specific to each system.

13.1.1 *Charged- and neutral-hadron decays*

We define decay amplitudes of M (which could be charged or neutral) and its *CP* conjugate $\overline{M}$ to a multi-particle final state f

and its CP conjugate $\overline{f}$ as

$$A_f = \langle f\,|\mathcal{H}|\,M\rangle\ , \quad \overline{A}_f = \langle f\,|\mathcal{H}|\,\overline{M}\rangle\ , \tag{13.1a}$$

$$A_{\overline{f}} = \langle \overline{f}\,|\mathcal{H}|\,M\rangle\ , \quad \overline{A}_{\overline{f}} = \langle \overline{f}\,|\mathcal{H}|\,\overline{M}\rangle\ , \tag{13.1b}$$

where $\mathcal{H}$ is the Hamiltonian governing weak interactions. The action of CP on these states introduces phases ξ_M and ξ_f that depend on their flavor content, according to

$$CP|M\rangle = e^{+i\xi_M}\,|\overline{M}\rangle\ , \quad CP|f\rangle = e^{+i\xi_f}\,|\overline{f}\rangle\ , \tag{13.2a}$$

$$CP|\overline{M}\rangle = e^{-i\xi_M}\,|M\rangle\ , \quad CP|\overline{f}\rangle = e^{-i\xi_f}\,|f\rangle\ , \tag{13.2b}$$

so that $(CP)^2 = 1$. The phases ξ_M and ξ_f are arbitrary and unobservable because of the flavor symmetry of the strong interaction. If CP is conserved by the dynamics, $[CP, \mathcal{H}] = 0$, then A_f and $\overline{A}_{\overline{f}}$ have the same magnitude and an arbitrary unphysical relative phase

$$\overline{A}_{\overline{f}} = e^{i(\xi_f - \xi_M)}\,A_f\ . \tag{13.3}$$

13.1.2 *Neutral-meson mixing*

A state that is initially a superposition of M^0 and $\overline{M}^0$, say

$$|\psi(0)\rangle = a(0)|M^0\rangle + b(0)|\overline{M}^0\rangle\ , \tag{13.4}$$

will evolve in time acquiring components that describe all possible decay final states $\{f_1, f_2, \ldots\}$, that is,

$$|\psi(t)\rangle = a(t)|M^0\rangle + b(t)|\overline{M}^0\rangle + c_1(t)|f_1\rangle + c_2(t)|f_2\rangle + \cdots\ . \tag{13.5}$$

If we are interested in computing only the values of $a(t)$ and $b(t)$ (and not the values of all $c_i(t)$), and if the times t under study are much larger than the typical strong interaction scale, then we can use a much simplified formalism [31]. The simplified time evolution is determined by a 2×2 effective Hamiltonian $\mathbf{H}$ that is not Hermitian, since otherwise the mesons would only oscillate and not decay. Any complex matrix, such as $\mathbf{H}$, can be written in terms of Hermitian matrices $\mathbf{M}$ and $\mathbf{\Gamma}$ as

$$\mathbf{H} = \mathbf{M} - \frac{i}{2}\,\mathbf{\Gamma}\ . \tag{13.6}$$

$\mathbf{M}$ and $\mathbf{\Gamma}$ are associated with $(M^0, \overline{M}^0) \leftrightarrow (M^0, \overline{M}^0)$ transitions via off-shell (dispersive), and on-shell (absorptive) intermediate states, respectively. Diagonal elements of $\mathbf{M}$ and $\mathbf{\Gamma}$ are associated with the flavor-conserving transitions $M^0 \to M^0$ and $\overline{M}^0 \to \overline{M}^0$, while off-diagonal elements are associated with flavor-changing transitions $M^0 \leftrightarrow \overline{M}^0$.

The eigenvectors of $\mathbf{H}$ have well-defined masses and decay widths. To specify the components of the strong interaction eigenstates, M^0 and $\overline{M}^0$, in the light (M_L) and heavy (M_H) mass eigenstates, we introduce three complex parameters: p, q, and, for the case that both CP and CPT are violated in mixing, z. Then

$$|M_L\rangle \propto p\sqrt{1-z}\,|M^0\rangle + q\sqrt{1+z}\,|\overline{M}^0\rangle\ , \tag{13.7a}$$

$$|M_H\rangle \propto p\sqrt{1+z}\,|M^0\rangle - q\sqrt{1-z}\,|\overline{M}^0\rangle\ , \tag{13.7b}$$

with the normalization $|q|^2 + |p|^2 = 1$ when $z = 0$. (Another possible choice of labeling, which is in standard usage for K mesons, defines the mass eigenstates according to their lifetimes: K_S for the short-lived and K_L for the long-lived state. The K_L is experimentally found to be the heavier state. Yet another choice is often used for the D mesons [32]: the eigenstates are labeled according to their dominant CP content.)

The real and imaginary parts of the eigenvalues $\omega_{L,H}$ corresponding to $|M_{L,H}\rangle$ represent their masses and decay widths, respectively. The mass and width splittings are

$$\Delta m \equiv m_H - m_L = \mathcal{R}e(\omega_H - \omega_L)\ , \tag{13.8a}$$

$$\Delta\Gamma \equiv \Gamma_H - \Gamma_L = -2\,\mathcal{I}m(\omega_H - \omega_L)\ . \tag{13.8b}$$

Note that here Δm is positive by definition, while the sign of $\Delta\Gamma$ must be experimentally determined. The sign of $\Delta\Gamma$ has not yet been established for B^0 mesons, while $\Delta\Gamma < 0$ is established for K and B_s^0 mesons. The Standard Model predicts $\Gamma_L > \Gamma_H$ for $B^0_{(s)}$ mesons; for this reason, $\Delta\Gamma = \Gamma_L - \Gamma_H$, which is still a signed quantity, is often used in the $B^0_{(s)}$ literature and is the convention used in the PDG experimental summaries.

Solving the eigenvalue problem for $\mathbf{H}$ yields

$$\left(\frac{q}{p}\right)^2 = \frac{\mathbf{M}_{12}^* - (i/2)\mathbf{\Gamma}_{12}^*}{\mathbf{M}_{12} - (i/2)\mathbf{\Gamma}_{12}} \tag{13.9}$$

and

$$z \equiv \frac{\delta m - (i/2)\delta\Gamma}{\Delta m - (i/2)\Delta\Gamma}\ , \tag{13.10}$$

where

$$\delta m \equiv \mathbf{M}_{11} - \mathbf{M}_{22}\ , \quad \delta\Gamma \equiv \mathbf{\Gamma}_{11} - \mathbf{\Gamma}_{22} \tag{13.11}$$

are the differences in effective mass and decay-rate expectation values for the strong interaction states M^0 and $\overline{M}^0$.

If either CP or CPT is a symmetry of $\mathbf{H}$ (independently of whether T is conserved or violated), then the values of δm and $\delta\Gamma$ are both zero, and hence $z = 0$. We also find that

$$\omega_H - \omega_L = 2\sqrt{\left(\mathbf{M}_{12} - \frac{i}{2}\mathbf{\Gamma}_{12}\right)\left(\mathbf{M}_{12}^* - \frac{i}{2}\mathbf{\Gamma}_{12}^*\right)}\ . \tag{13.12}$$

If either CP or T is a symmetry of $\mathbf{H}$ (independently of whether CPT is conserved or violated), then $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is real, leading to

$$\left(\frac{q}{p}\right)^2 = e^{2i\xi_M} \quad \Rightarrow \quad \left|\frac{q}{p}\right| = 1\ , \tag{13.13}$$

where ξ_M is the arbitrary unphysical phase introduced in Eq. (13.2). If, and only if, CP is a symmetry of $\mathbf{H}$ (independently of CPT and T), then both of the above conditions hold, with the result that the mass eigenstates are orthogonal

$$\langle M_H|M_L\rangle = |p|^2 - |q|^2 = 0\ . \tag{13.14}$$

13.1.3 *CP-violating observables*

All CP-violating observables in M and $\overline{M}$ decays to final states f and $\overline{f}$ can be expressed in terms of phase-convention-independent combinations of A_f, $\overline{A}_f$, $A_{\overline{f}}$, and $\overline{A}_{\overline{f}}$, together with, for neutral meson decays only, q/p. CP violation in charged meson and all baryon decays depends only on the combination $|\overline{A}_{\overline{f}}/A_f|$, while CP violation in flavored neutral meson decays is enriched by $M^0 \leftrightarrow \overline{M}^0$ oscillations, and depends, additionally, on $|q/p|$ and on $\lambda_f \equiv (q/p)(\overline{A}_f/A_f)$.

The decay rates of the two neutral kaon mass eigenstates, K_S and K_L, are different enough ($\Gamma_S/\Gamma_L \sim 500$) that one can, in most cases, actually study their decays independently. For D^0, B^0, and B_s^0 mesons, however, values of $\Delta\Gamma/\Gamma$ (where $\Gamma \equiv (\Gamma_H + \Gamma_L)/2$) are relatively small, and so both mass eigenstates must be considered in their evolution. We denote the state of an initially pure $|M^0\rangle$ or $|\overline{M}^0\rangle$ after an elapsed proper time t as $|M^0_{\rm phys}(t)\rangle$ or $|\overline{M}^0_{\rm phys}(t)\rangle$, respectively. Using the effective Hamiltonian approximation, but not assuming CPT to be a good symmetry, we obtain

$$|M^0_{\rm phys}(t)\rangle = (g_+(t) + z\,g_-(t))\,|M^0\rangle - \sqrt{1-z^2}\,\frac{q}{p}\,g_-(t)|\overline{M}^0\rangle\ , \tag{13.15a}$$

$$|\overline{M}^0_{\rm phys}(t)\rangle = (g_+(t) - z\,g_-(t))\,|\overline{M}^0\rangle - \sqrt{1-z^2}\,\frac{p}{q}\,g_-(t)|M^0\rangle\ , \tag{13.15b}$$

where

$$g_\pm(t) \equiv \frac{1}{2}\left[\exp\left(-im_H t - \frac{1}{2}\Gamma_H t\right) \pm \exp\left(-im_L t - \frac{1}{2}\Gamma_L t\right)\right] \tag{13.16}$$

and $z = 0$ if either CPT or CP is conserved.

Defining $x \equiv \Delta m/\Gamma$ and $y \equiv \Delta\Gamma/(2\Gamma)$, and assuming $z = 0$, one obtains the following time-dependent decay rates:

$$\frac{d\Gamma\left[M^0_{\rm phys}(t) \to f\right]/dt}{e^{-\Gamma t}\mathcal{N}_f} = \left(|A_f|^2 + |(q/p)\overline{A}_f|^2\right)\cosh(y\Gamma t) + \left(|A_f|^2 - |(q/p)\overline{A}_f|^2\right)\cos(x\Gamma t) + 2\,\mathcal{R}e((q/p)A_f^*\overline{A}_f)\sinh(y\Gamma t) - 2\,\mathcal{I}m((q/p)A_f^*\overline{A}_f)\sin(x\Gamma t)\,, \tag{13.17a}$$

$$\frac{d\Gamma\left[\overline{M}^0_{\rm phys}(t) \to f\right]/dt}{e^{-\Gamma t}\mathcal{N}_f} = \left(|(p/q)A_f|^2 + |\overline{A}_f|^2\right)\cosh(y\Gamma t) - \left(|(p/q)A_f|^2 - |\overline{A}_f|^2\right)\cos(x\Gamma t) + 2\,\mathcal{R}e((p/q)A_f\overline{A}_f^*)\sinh(y\Gamma t) - 2\,\mathcal{I}m((p/q)A_f\overline{A}_f^*)\sin(x\Gamma t)\,, \tag{13.17b}$$

where $\mathcal{N}_f$ is a common, time-independent, normalization factor that can be determined bearing in mind that the range of t is $0 < t < \infty$. Decay rates to the CP-conjugate final state $\overline{f}$ are obtained analogously, with $\mathcal{N}_f = \mathcal{N}_{\overline{f}}$ and the substitutions $A_f \to A_{\overline{f}}$ and $\overline{A}_f \to \overline{A}_{\overline{f}}$ in Eqs. (13.17a) and (13.17b). Terms proportional to $|A_f|^2$ or $|\overline{A}_f|^2$ are associated with decays that occur without any net $M^0 \leftrightarrow \overline{M}^0$ oscillation, while terms proportional to $|(q/p)\overline{A}_f|^2$ or $|(p/q)A_f|^2$ are associated with decays following a net oscillation. The $\sinh(y\Gamma t)$ and $\sin(x\Gamma t)$ terms of Eqs. (13.17a) and (13.17b) are associated with the interference between these two cases. Note that, in multi-body decays such as $D^0 \to K_S\pi^+\pi^-$ or $B^0 \to \pi^+\pi^-\pi^+\pi^-$, amplitudes are functions of variables that describe the phase-space of the final state. Interference may be present in some regions but not others, and is strongly influenced by resonant substructure.

When neutral pseudoscalar mesons are produced coherently in pairs from the decay of a vector resonance, $V \to M^0\overline{M}^0$ (for example, $\Upsilon(4S) \to B^0\overline{B}^0$, $\psi(3770) \to D^0\overline{D}^0$ or $\phi \to K^0\overline{K}^0$), the time-dependence of their subsequent decays to final states f_1 and f_2 has a similar form to Eqs. (13.17a) and (13.17b):

$$\frac{d\Gamma\left[V_{\rm phys}(t_1,t_2) \to f_1 f_2\right]/d(\Delta t)}{e^{-\Gamma|\Delta t|}\mathcal{N}_{f_1f_2}} = \left(|a_+|^2 + |a_-|^2\right)\cosh(y\Gamma\Delta t) + \left(|a_+|^2 - |a_-|^2\right)\cos(x\Gamma\Delta t) - 2\,\mathcal{R}e(a_+^*a_-)\sinh(y\Gamma\Delta t) + 2\,\mathcal{I}m(a_+^*a_-)\sin(x\Gamma\Delta t)\,, \tag{13.18}$$

where $\Delta t \equiv t_2 - t_1$ is the difference in the production times, t_1 and t_2, of f_1 and f_2, respectively, and the dependence on the average decay time and on decay angles has been integrated out. The normalization factor $\mathcal{N}_{f_1f_2}$ can be evaluated, noting that the range of Δt is $-\infty < \Delta t < \infty$. The coefficients in Eq. (13.18) are determined by the amplitudes for no net oscillation from $t_1 \to t_2$, $\overline{A}_{f_1}A_{f_2}$, and $A_{f_1}\overline{A}_{f_2}$, and for a net oscillation, $(q/p)\overline{A}_{f_1}\overline{A}_{f_2}$ and $(p/q)A_{f_1}A_{f_2}$, via

$$a_+ \equiv \overline{A}_{f_1}A_{f_2} - A_{f_1}\overline{A}_{f_2}\,, \tag{13.19a}$$

$$a_- \equiv -\sqrt{1-z^2}\left(\frac{q}{p}\overline{A}_{f_1}\overline{A}_{f_2} - \frac{p}{q}A_{f_1}A_{f_2}\right) + z\left(\overline{A}_{f_1}A_{f_2} + A_{f_1}\overline{A}_{f_2}\right)\,. \tag{13.19b}$$

Assuming CPT conservation, $z = 0$, and identifying $\Delta t \to t$ and $f_2 \to f$, we find that Eqs. (13.18) and (13.19) reduce to Eq. (13.17a) with $A_{f_1} = 0$, $\overline{A}_{f_1} = 1$, or to Eq. (13.17b) with $\overline{A}_{f_1} = 0$, $A_{f_1} = 1$. Indeed, this plays an important role in experiments that exploit the coherence of $V \to M^0\overline{M}^0$ production. Final states f_1 with $A_{f_1} = 0$ or $\overline{A}_{f_1} = 0$ are called tagging states, because they identify the decaying pseudoscalar meson as, respectively, $\overline{M}^0$ or M^0. Before one of M^0 or $\overline{M}^0$ decays, they evolve in phase, so that there is always one M^0 and one $\overline{M}^0$ present. A tagging decay of one meson sets the clock for the time evolution of the other: it starts at t_1 as purely M^0 or $\overline{M}^0$, with time evolution that depends only on $t_2 - t_1$.

When f_1 is a state that both M^0 and $\overline{M}^0$ can decay into, then Eq. (13.18) contains interference terms proportional to $A_{f_1}\overline{A}_{f_1} \neq 0$ that are not present in Eqs. (13.17a) and (13.17b). Even when f_1 is dominantly produced by M^0 decays rather than $\overline{M}^0$ decays, or vice versa, $A_{f_1}\overline{A}_{f_1}$ can be non-zero owing to doubly-CKM-suppressed decays (with amplitudes suppressed by at least two powers of λ relative to the dominant amplitude, in the language of Section 13.3), and these terms should be considered for precision studies of CP violation in coherent $V \to M^0\overline{M}^0$ decays [33]. The correlations in $V \to M^0\overline{M}^0$ decays can also be exploited to determine phase differences between favored and suppressed decay amplitudes [34, 35].

13.1.4 *Classification of CP-violating effects*

We distinguish three types of CP-violating effects that can occur in the quark sector:

I. CP violation in decay is defined by

$$|\overline{A}_{\overline{f}}/A_f| \neq 1\,. \tag{13.20}$$

In charged meson (and all baryon) decays, where mixing effects are absent, this is the only possible source of CP asymmetries:

$$\mathcal{A}_{f^\pm} \equiv \frac{\Gamma(M^- \to f^-) - \Gamma(M^+ \to f^+)}{\Gamma(M^- \to f^-) + \Gamma(M^+ \to f^+)} = \frac{|\overline{A}_{f^-}/A_{f^+}|^2 - 1}{|\overline{A}_{f^-}/A_{f^+}|^2 + 1}\,. \tag{13.21}$$

Note that the usual sign convention for CP asymmetries of hadrons is for the difference between the rate involving the particle that contains a heavy quark and that which contains an antiquark. Hence, Eq. (13.21) corresponds to the definition for $B^\pm$ mesons, but the opposite sign is used for $D^\pm_{(s)}$ decays.

II. CP (and T) violation in mixing is defined by

$$|q/p| \neq 1\,. \tag{13.22}$$

In charged-current semileptonic neutral meson decays $M, \overline{M} \to \ell^\pm X^\mp$ (taking $|A_{\ell^+X^-}| = |\overline{A}_{\ell^-X^+}|$ and $A_{\ell^-X^+} = \overline{A}_{\ell^+X^-} = 0$, as is the case in the Standard Model, to lowest order in G_F, and in most of its extensions), this is the only source of CP violation, and can be measured via the asymmetry of "wrong-sign" decays induced by oscillations:

$$\mathcal{A}_{\rm SL}(t) \equiv \frac{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to \ell^+X^-\right] - d\Gamma/dt\left[M^0_{\rm phys}(t) \to \ell^-X^+\right]}{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to \ell^+X^-\right] + d\Gamma/dt\left[M^0_{\rm phys}(t) \to \ell^-X^+\right]}\,, \tag{13.23a}$$

$$= \frac{1 - |q/p|^4}{1 + |q/p|^4}\,. \tag{13.23b}$$

Note that this asymmetry of time-dependent decay rates is actually time-independent.

III. CP violation in interference between a decay without mixing, $M^0 \to f$, and a decay with mixing, $M^0 \to \overline{M}^0 \to f$ (such an effect occurs only in decays to final states that are common to M^0 and $\overline{M}^0$, including all CP eigenstates), is defined by

$$\arg(\lambda_f) + \arg(\lambda_{\bar{f}}) \neq 0\,, \qquad \text{with} \qquad \lambda_f \equiv \frac{q}{p}\frac{\overline{A}_f}{A_f}\,. \tag{13.24}$$

For final CP eigenstates, f_{CP}, the condition Eq. (13.24) simplifies to

$$\mathcal{I}m(\lambda_{f_{CP}}) \neq 0\,, \tag{13.25}$$

This form of *CP* violation can be observed, for example, using the asymmetry of neutral meson decay rates into *CP* eigenstates

$$\mathcal{A}_{f_{CP}}(t) \equiv \equiv \frac{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to f_{CP}\right] - d\Gamma/dt\left[M^0_{\rm phys}(t) \to f_{CP}\right]}{d\Gamma/dt\left[\overline{M}^0_{\rm phys}(t) \to f_{CP}\right] + d\Gamma/dt\left[M^0_{\rm phys}(t) \to f_{CP}\right]} . \tag{13.26}$$

If $\Delta\Gamma = 0$, as expected to a good approximation for B^0 mesons but not for K^0 and B^0_s mesons, and $|q/p| = 1$, then $\mathcal{A}_{f_{CP}}$ has a particularly simple form (see Eq. (13.75), below). If, in addition, the decay amplitudes fulfill $|\overline{A}_{f_{CP}}| = |A_{f_{CP}}|$, the interference between decays with and without mixing is the only source of asymmetry and $\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_{f_{CP}})\sin(x\Gamma t)$.

Examples of these three types of *CP* violation will be given in Sections 13.4, 13.5, and 13.6.

13.2 Theoretical Interpretation: General Considerations

Consider the $M \to f$ decay amplitude A_f, and the *CP* conjugate process, $\overline{M} \to \overline{f}$, with decay amplitude $\overline{A}_{\overline{f}}$. There are two types of phases that may appear in these decay amplitudes. Complex parameters in any Lagrangian term that contributes to the amplitude will appear in complex conjugate form in the *CP*-conjugate amplitude. Thus, their phases appear in A_f and $\overline{A}_{\overline{f}}$ with opposite signs. In the Standard Model, these phases occur only in the couplings of the $W^\pm$ bosons, and hence, are often called "weak phases." The weak phase of any single term is convention-dependent. However, the difference between the weak phases in two different terms in A_f is convention-independent. A second type of phase can appear in scattering or decay amplitudes, even when the Lagrangian is real. This phase originates from the possible contribution from intermediate on-shell states in the decay process. Since such phases are generated by *CP*-invariant interactions, they are the same in A_f and $\overline{A}_{\overline{f}}$. Usually the dominant rescattering is due to strong interactions; hence the designation "strong phases" for the phase shifts so induced. Again, only the relative strong phases between different terms in the amplitude are physically meaningful.

The "weak" and "strong" phases discussed here appear in addition to the spurious *CP*-transformation phases of Eq. (13.3). Those spurious phases are due to an arbitrary choice of phase convention, and do not originate from any dynamics or induce any *CP* violation. For simplicity, we set them to zero from here on.

It is useful to write each contribution a_i to A_f in three parts: its magnitude $|a_i|$, its weak phase ϕ_i, and its strong phase δ_i. If, for example, there are two such contributions, $A_f = a_1 + a_2$, we have

$$A_f = |a_1|e^{i(\delta_1+\phi_1)} + |a_2|e^{i(\delta_2+\phi_2)} , \tag{13.27a}$$

$$\overline{A}_{\overline{f}} = |a_1|e^{i(\delta_1-\phi_1)} + |a_2|e^{i(\delta_2-\phi_2)} . \tag{13.27b}$$

Similarly, for neutral mesons, it is useful to write

$$\mathbf{M}_{12} = |\mathbf{M}_{12}|e^{i\phi_M} , \quad \mathbf{\Gamma}_{12} = |\mathbf{\Gamma}_{12}|e^{i\phi_\Gamma} . \tag{13.28}$$

Each of the phases appearing in Eqs. (13.27) and (13.28) is convention-dependent, but combinations such as $\delta_1 - \delta_2$, $\phi_1 - \phi_2$, $\phi_M - \phi_\Gamma$, and $\phi_M + \phi_1 - \overline{\phi}_1$ (where $\overline{\phi}_1$ is a weak phase contributing to $\overline{A}_f$) are physical.

It is now straightforward to evaluate the various asymmetries in terms of the theoretical parameters introduced here. We will do so with approximations that are often relevant to the most interesting measured asymmetries.

1. The *CP* asymmetry in charged meson and all baryon decays [Eq. (13.21)] is given by

$$\mathcal{A}_f = -\frac{2|a_1a_2|\sin(\delta_2-\delta_1)\sin(\phi_2-\phi_1)}{|a_1|^2+|a_2|^2+2|a_1a_2|\cos(\delta_2-\delta_1)\cos(\phi_2-\phi_1)} . \tag{13.29}$$

The quantity of most interest to theory is the weak phase difference $\phi_2 - \phi_1$. Its extraction from the asymmetry requires, however, that the amplitude ratio $|a_2/a_1|$ and the strong phase difference $\delta_2 - \delta_1$ are known. Both quantities depend on nonperturbative hadronic parameters that are difficult to calculate, but in some cases can be obtained from experiment.

2. In the approximation that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| \ll 1$ (valid for B^0 and B^0_s mesons), the *CP* asymmetry in semileptonic neutral-meson decays [Eq. (13.23)] is given by

$$\mathcal{A}_{\rm SL} = -\left|\frac{\mathbf{\Gamma}_{12}}{\mathbf{M}_{12}}\right|\sin(\phi_M - \phi_\Gamma) . \tag{13.30}$$

The quantity of most interest to theory is the weak phase $\phi_M - \phi_\Gamma$. Its extraction from the asymmetry requires, however, that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}|$ is known. State of the art calculations of this quantity for the B^0 and B^0_s mesons have uncertainties of around 10% [36].

3. In the approximations that only a single weak phase contributes to decay, $A_f = |a_f|e^{i(\delta_f+\phi_f)}$, and that $|\mathbf{\Gamma}_{12}/\mathbf{M}_{12}| = 0$, we obtain $|\lambda_f| = 1$, and the *CP* asymmetries in decays to a final *CP* eigenstate f [Eq. (13.26)] with eigenvalue $\eta_f = \pm 1$ are given by

$$\mathcal{A}_{f_{CP}}(t) = \mathcal{I}m(\lambda_f)\ \sin(\Delta m t)\ \text{ with }\ \mathcal{I}m(\lambda_f) = \eta_f \sin(\phi_M + 2\phi_f) . \tag{13.31}$$

Note that the phase measured is purely a weak phase, and no hadronic parameters are involved in the extraction of its value from $\mathcal{I}m(\lambda_f)$.

The discussion above allows us to introduce another classification of *CP*-violating effects:

1. *Indirect CP violation* is consistent with taking $\phi_M \neq 0$ and setting all other *CP* violating phases to zero. *CP* violation in mixing (type II) belongs to this class.
2. *Direct CP violation* cannot be accounted for by just $\phi_M \neq 0$. *CP* violation in decay (type I) belongs to this class.

The historical significance of this classification is related to theory. In superweak models [37], *CP* violation appears only in diagrams that contribute to $\mathbf{M}_{12}$, hence predicting no direct *CP* violation. In most models and, in particular, in the Standard Model, *CP* violation is both direct and indirect. As concerns type III *CP* violation, a single observation of such an effect would be consistent with indirect *CP* violation, but observing $\eta_{f_1}\mathcal{I}m(\lambda_{f_1}) \neq \eta_{f_2}\mathcal{I}m(\lambda_{f_2})$ (for the same decaying meson and two different final *CP* eigenstates f_1 and f_2) would establish direct *CP* violation. The experimental observation of $\epsilon' \neq 0$, which was achieved by establishing that $\mathcal{I}m(\lambda_{\pi^+\pi^-}) \neq \mathcal{I}m(\lambda_{\pi^0\pi^0})$ (see Section 13.4), excluded the superweak scenario.

13.3 Theoretical Interpretation: The KM Mechanism

Of all the Standard Model quark parameters, only the Kobayashi-Maskawa (KM) phase is *CP*-violating. Having a single source of *CP* violation, the Standard Model is very predictive for *CP* asymmetries: some vanish, and those that do not are correlated.

To be precise, *CP* could be violated also by strong interactions. The experimental upper bound on the electric-dipole moment of the neutron [38] implies, however, that $\theta_{\rm QCD}$, the nonperturbative parameter that determines the strength of this type of *CP* violation, is tiny, if not zero [39]. The smallness of $\theta_{\rm QCD}$ constitutes a theoretical puzzle, known as "the strong *CP* problem." This, however, is irrelevant to our discussion of hadron decays.

The charged current interactions (that is, the $W^\pm$ interactions) for quarks are given by

$$-\mathcal{L}_{W^\pm} = \frac{g}{\sqrt{2}}\ \overline{u_{Li}}\ \gamma^\mu\ (V_{\rm CKM})_{ij}\ d_{Lj}\ W^+_\mu + \text{h.c.} \tag{13.32}$$

Here $i,j = 1,2,3$ are generation numbers. The Cabibbo-Kobayashi-Maskawa (CKM) mixing matrix for quarks is a 3×3 unitary matrix [40]. Ordering the quarks by their masses, *i.e.*, $(u_1,u_2,u_3)\to(u,c,t)$ and $(d_1,d_2,d_3)\to(d,s,b)$, the elements of $V_{\rm CKM}$ are written as follows:

$$V_{\rm CKM} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} . \qquad (13.33)$$

While a general 3×3 unitary matrix depends on three real angles and six phases, the freedom to redefine the phases of the quark mass eigenstates can be used to remove five of the phases, leaving a single physical phase, the Kobayashi-Maskawa phase, that is responsible for all *CP* violation in the Standard Model.

The fact that one can parameterize $V_{\rm CKM}$ by three real and only one imaginary physical parameters can be made manifest by choosing an explicit parametrization. The Wolfenstein parametrization [41,42] is particularly useful:

$$V_{\rm CKM} = \begin{pmatrix} 1-\frac{1}{2}\lambda^2-\frac{1}{8}\lambda^4 & \lambda & A\lambda^3(\rho-i\eta) \\ -\lambda+\frac{1}{2}A^2\lambda^5[1-2(\rho+i\eta)] & 1-\frac{1}{2}\lambda^2-\frac{1}{8}\lambda^4(1+4A^2) & A\lambda^2 \\ A\lambda^3[1-(1-\frac{1}{2}\lambda^2)(\rho+i\eta)] & -A\lambda^2+\frac{1}{2}A\lambda^4[1-2(\rho+i\eta)] & 1-\frac{1}{2}A^2\lambda^4 \end{pmatrix} . \qquad (13.34)$$

Here $\lambda\approx 0.23$ (not to be confused with λ_f), the sine of the Cabibbo angle, plays the role of an expansion parameter, and η represents the *CP*-violating phase. Terms of $\mathcal{O}(\lambda^6)$ have been neglected.

The unitarity of the CKM matrix, $(VV^\dagger)_{ij} = (V^\dagger V)_{ij} = \delta_{ij}$, leads to twelve distinct complex relations among the matrix elements. The six relations with $i\neq j$ can be represented geometrically as triangles in the complex plane. Two of these,

$$V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0 , \qquad (13.35a)$$
$$V_{td}V_{ud}^* + V_{ts}V_{us}^* + V_{tb}V_{ub}^* = 0 , \qquad (13.35b)$$

have terms of equal order, $\mathcal{O}(A\lambda^3)$, and so have corresponding triangles whose interior angles are all $\mathcal{O}(1)$ physical quantities that can be independently measured. The angles of the first triangle (see Fig. 13.1) are given by

$$\alpha\equiv\varphi_2\equiv \arg\left(-\frac{V_{td}V_{tb}^*}{V_{ud}V_{ub}^*}\right)\simeq\arg\left(-\frac{1-\rho-i\eta}{\rho+i\eta}\right) , \qquad (13.36a)$$
$$\beta\equiv\varphi_1\equiv \arg\left(-\frac{V_{cd}V_{cb}^*}{V_{td}V_{tb}^*}\right)\simeq\arg\left(\frac{1}{1-\rho-i\eta}\right) , \qquad (13.36b)$$
$$\gamma\equiv\varphi_3\equiv \arg\left(-\frac{V_{ud}V_{ub}^*}{V_{cd}V_{cb}^*}\right)\simeq\arg\left(\rho+i\eta\right) . \qquad (13.36c)$$

The angles of the second triangle are equal to (α,β,γ) up to corrections of $\mathcal{O}(\lambda^2)$. The notations (α,β,γ) and $(\varphi_1,\varphi_2,\varphi_3)$ are both in common usage but, for convenience, we only use the first convention in the following.

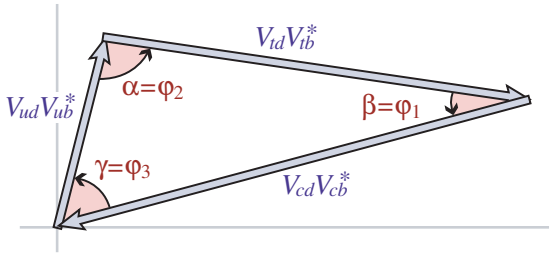

Figure 13.1: Graphical representation of the unitarity constraint $V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0$ as a triangle in the complex plane.

Another relation that can be represented as a triangle,

$$V_{us}V_{ub}^* + V_{cs}V_{cb}^* + V_{ts}V_{tb}^* = 0 , \qquad (13.37)$$

and, in particular, its small angle, of $\mathcal{O}(\lambda^2)$,

$$\beta_s\equiv\arg\left(-\frac{V_{ts}V_{tb}^*}{V_{cs}V_{cb}^*}\right) , \qquad (13.38)$$

is convenient for analyzing *CP* violation in the B_s^0 sector.

All unitarity triangles have the same area, commonly denoted by $J/2$ [43]. If *CP* is violated, J is different from zero and can be taken as the single *CP*-violating parameter. In the Wolfenstein parametrization of Eq. (13.34), $J\simeq\lambda^6A^2\eta$.

13.4 Kaons

CP violation was discovered in $K\to\pi\pi$ decays in 1964 [1]. The same mode provided the first observation of direct *CP* violation [4–6].

The decay amplitudes actually measured in neutral K decays refer to the mass eigenstates K_L and K_S, rather than to the K and $\overline{K}$ states referred to in Eq. (13.1). The final $\pi^+\pi^-$ and $\pi^0\pi^0$ states are *CP*-even. In the *CP* conservation limit, K_S (K_L) would be *CP*-even (odd), and therefore would (would not) decay to two pions. We define *CP*-violating amplitude ratios for two-pion final states,

$$\eta_{00}\equiv\frac{\langle\pi^0\pi^0|\mathcal{H}|K_L\rangle}{\langle\pi^0\pi^0|\mathcal{H}|K_S\rangle} , \quad \eta_{+-}\equiv\frac{\langle\pi^+\pi^-|\mathcal{H}|K_L\rangle}{\langle\pi^+\pi^-|\mathcal{H}|K_S\rangle} . \qquad (13.39)$$

Another important observable is the asymmetry of time-integrated semileptonic decay rates:

$$\delta_L\equiv\frac{\Gamma(K_L\to\ell^+\nu_\ell\pi^-)-\Gamma(K_L\to\ell^-\overline{\nu}_\ell\pi^+)}{\Gamma(K_L\to\ell^+\nu_\ell\pi^-)+\Gamma(K_L\to\ell^-\overline{\nu}_\ell\pi^+)} . \qquad (13.40)$$

CP violation has been observed as an appearance of K_L decays to two-pion final states [44],

$$|\eta_{00}| = (2.220\pm0.011)\times10^{-3} , \qquad (13.41a)$$
$$|\eta_{+-}| = (2.232\pm0.011)\times10^{-3} , \qquad (13.41b)$$
$$|\eta_{00}/\eta_{+-}| = 0.9950\pm0.0007 , \qquad (13.41c)$$

where the *CP*-conserving phases ϕ_{ij} of the amplitude ratios η_{ij} have been determined both assuming *CPT* invariance:

$$\phi_{00} = (43.52\pm0.05)^\circ , \qquad \phi_{+-} = (43.51\pm0.05)^\circ , \qquad (13.42)$$

and without assuming *CPT* invariance:

$$\phi_{00} = (43.7\pm0.6)^\circ , \qquad \phi_{+-} = (43.4\pm0.5)^\circ . \qquad (13.43)$$

CP violation has also been observed in semileptonic K_L decays [44]

$$\delta_L = (3.32\pm0.06)\times10^{-3} , \qquad (13.44)$$

where δ_L is a weighted average of muon and electron measurements, as well as in K_L decays to $\pi^+\pi^-\gamma$ and $\pi^+\pi^-e^+e^-$ [44]. *CP* violation in $K\to3\pi$ decays has not yet been observed [44,45].

Historically, *CP* violation in neutral K decays has been described in terms of the complex parameters ϵ and ϵ'. The observables η_{00}, η_{+-}, and δ_L are related to these parameters, and to

those of Section 13.1, by

$$\eta_{00} = \frac{1-\lambda_{\pi^0\pi^0}}{1+\lambda_{\pi^0\pi^0}} = \epsilon - 2\epsilon' \,, \tag{13.45a}$$

$$\eta_{+-} = \frac{1-\lambda_{\pi^+\pi^-}}{1+\lambda_{\pi^+\pi^-}} = \epsilon + \epsilon' \,, \tag{13.45b}$$

$$\delta_L = \frac{1-|q/p|^2}{1+|q/p|^2} = \frac{2\mathcal{R}e(\epsilon)}{1+|\epsilon|^2} \,, \tag{13.45c}$$

where, in the last line, we have assumed that $\left|A_{\ell^+\nu_\ell\pi^-}\right| = \left|\overline{A}_{\ell^-\overline{\nu}_\ell\pi^+}\right|$ and $\left|A_{\ell^-\overline{\nu}_\ell\pi^+}\right| = \left|\overline{A}_{\ell^+\nu_\ell\pi^-}\right| = 0$. (The convention-dependent parameter $\tilde{\epsilon} \equiv (1-q/p)/(1+q/p)$, sometimes used in the literature, is, in general, different from ϵ but yields a similar expression, $\delta_L = 2\mathcal{R}e(\tilde{\epsilon})/(1+|\tilde{\epsilon}|^2)$.) A fit to the $K \to \pi\pi$ data yields [44]

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3} \,, \tag{13.46a}$$

$$\mathcal{R}e(\epsilon'/\epsilon) = (1.66 \pm 0.23) \times 10^{-3} \,. \tag{13.46b}$$

In discussing two-pion final states, it is useful to express the amplitudes $A_{\pi^0\pi^0}$ and $A_{\pi^+\pi^-}$ in terms of their isospin components via

$$A_{\pi^0\pi^0} = \sqrt{\frac{1}{3}}\,|A_0|\,e^{i(\delta_0+\phi_0)} - \sqrt{\frac{2}{3}}\,|A_2|\,e^{i(\delta_2+\phi_2)} \,, \tag{13.47a}$$

$$A_{\pi^+\pi^-} = \sqrt{\frac{2}{3}}\,|A_0|\,e^{i(\delta_0+\phi_0)} + \sqrt{\frac{1}{3}}\,|A_2|\,e^{i(\delta_2+\phi_2)} \,, \tag{13.47b}$$

where we parameterize the amplitude $A_I(\overline{A}_I)$ for $K^0(\overline{K}^0)$ decay into two pions with total isospin $I = 0$ or 2 as

$$A_I \equiv \langle(\pi\pi)_I\,|\mathcal{H}|\,K^0\rangle = |A_I|\,e^{i(\delta_I+\phi_I)} \,, \tag{13.48a}$$

$$\overline{A}_I \equiv \langle(\pi\pi)_I\,|\mathcal{H}|\,\overline{K}^0\rangle = |A_I|\,e^{i(\delta_I-\phi_I)} \,. \tag{13.48b}$$

The smallness of $|\eta_{00}|$ and $|\eta_{+-}|$ allows us to approximate

$$\epsilon \simeq \frac{1}{2}(1-\lambda_{(\pi\pi)_{I=0}}) \,, \qquad \epsilon' \simeq \frac{1}{6}\left(\lambda_{\pi^0\pi^0} - \lambda_{\pi^+\pi^-}\right) \,. \tag{13.49}$$

The parameter ϵ represents indirect *CP* violation, while ϵ' parameterizes direct *CP* violation: $\mathcal{R}e(\epsilon')$ measures *CP* violation in decay (type I), $\mathcal{R}e(\epsilon)$ measures *CP* violation in mixing (type II), and $\mathcal{I}m(\epsilon)$ and $\mathcal{I}m(\epsilon')$ measure the interference between decays with and without mixing (type III).

The following expressions for ϵ and ϵ' are useful for theoretical evaluations:

$$\epsilon \simeq \frac{e^{i\pi/4}}{\sqrt{2}}\frac{\mathcal{I}m(\mathbf{M}_{12})}{\Delta m} \,, \qquad \epsilon' = \frac{i}{\sqrt{2}}\left|\frac{A_2}{A_0}\right| e^{i(\delta_2-\delta_0)}\sin(\phi_2-\phi_0) \,. \tag{13.50}$$

The expression for ϵ is only valid in a phase convention where $\phi_2 = 0$, corresponding to a real $V_{ud}V_{us}^*$, and in the approximation that also $\phi_0 = 0$. The phase of ϵ, $\arg(\epsilon) \approx \arctan(-2\Delta m/\Delta\Gamma)$, is determined by non-perturbative QCD dynamics and is experimentally determined to be about $\pi/4$. The calculation of ϵ benefits from the fact that $\mathcal{I}m(\mathbf{M}_{12})$ is dominated by short distance physics. Consequently, the main sources of uncertainty in theoretical interpretations of ϵ are the values of matrix elements, such as $\langle K^0\,|(\bar{s}d)_{V-A}(\bar{s}d)_{V-A}|\,\overline{K}^0\rangle$. The expression for ϵ' is valid to first order in $|A_2/A_0| \sim 1/20$. The phase of ϵ' is experimentally determined, $\pi/2+\delta_2-\delta_0 \approx \pi/4$, and is independent of the model of electroweak interactions. Note that, accidentally, ϵ'/ϵ is real to a good approximation. Determination of weak phase information from the measurement of $\mathcal{R}e(\epsilon'/\epsilon)$ given in Eq. (13.46) has until now been precluded by uncertainties in the hadronic parameters, but recent advances in lattice QCD calculations and other theoretical approaches [46–48] suggest that it may become possible.

A future measurement of much interest is that of *CP* violation in the rare $K \to \pi\nu\overline{\nu}$ decays. The signal for *CP* violation is simply observing the $K_L \to \pi^0\nu\overline{\nu}$ decay. The effect here is that of interference between decays with and without mixing (type III) [49]:

$$\frac{\Gamma(K_L \to \pi^0\nu\overline{\nu})}{\Gamma(K^+ \to \pi^+\nu\overline{\nu})} = \frac{1}{2}\left[1 + |\lambda_{\pi\nu\overline{\nu}}|^2 - 2\,\mathcal{R}e(\lambda_{\pi\nu\overline{\nu}})\right] \simeq 1 - \mathcal{R}e(\lambda_{\pi\nu\overline{\nu}}) \,, \tag{13.51}$$

where in the last equation we neglect *CP* violation in decay and in mixing (expected, model-independently, to be of order 10^{-5} and 10^{-3}, respectively). Such a measurement is experimentally very challenging but would be theoretically very rewarding [50]. Similar to the *CP* asymmetry in $B^0 \to J/\psi K_S$, the *CP* violation in $K \to \pi\nu\overline{\nu}$ decay is predicted to be large (that is, the ratio in Eq. (13.51) is neither CKM- nor loop-suppressed) and can be very cleanly interpreted. In particular, the independent determinations of the CKM parameters via B-meson and K-meson decays and mixing will over-constrain the unitarity triangle and provide a stringent text of the KM mechanism.

Within the Standard Model, the $K_L \to \pi^0\nu\overline{\nu}$ decay is dominated by an intermediate top quark contribution and, consequently, can be interpreted in terms of CKM parameters [51]. (For the charged mode, $K^+ \to \pi^+\nu\overline{\nu}$, the contribution from an intermediate charm quark is not negligible, and constitutes a source of hadronic uncertainty.) In particular, $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu})$ provides a theoretically clean way to determine the Wolfenstein parameter η [52]:

$$\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) = \kappa_L[X(m_t^2/m_W^2)]^2 A^4\eta^2 \,, \tag{13.52}$$

where the hadronic parameter $\kappa_L \sim 2 \times 10^{-10}$ incorporates the value of the four-fermion matrix element which is deduced, using isospin relations, from $\mathcal{B}(K^+ \to \pi^0 e^+\nu_e)$, and $X(m_t^2/m_W^2)$ is a known function of the top mass. An explicit calculation gives $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) = (3.00 \pm 0.30) \times 10^{-11}$ [53].

Currently the most stringent experimental limit is $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) < 3.0 \times 10^{-9}$ [54, 55], which does not yet reach the bound that can be derived from Eq. (13.51), $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu}) < 4.4 \times \mathcal{B}(K^+ \to \pi^+\nu\overline{\nu})$ [49], with the most precise result for the charged kaon decay being $\mathcal{B}(K^+ \to \pi^+\nu\overline{\nu}) = \left(10.6\,^{+4.0}_{-3.4} \pm 0.9\right) \times 10^{-11}$ [56]. Significant further progress is anticipated from experiments searching for $K \to \pi\nu\overline{\nu}$ decays in the next few years.

13.5 Charm

The existence of D^0–$\overline{D}^0$ mixing is well established [57–61], with the latest experimental constraints giving [62, 63] $x \equiv \Delta m/\Gamma = (0.407 \pm 0.044) \times 10^{-2}$ and $y \equiv \Delta\Gamma/(2\Gamma) = (0.647 \pm 0.024) \times 10^{-2}$. Long-distance contributions make it difficult to calculate Standard Model predictions for the D^0–$\overline{D}^0$ mixing parameters. Therefore, the goal of the search for D^0–$\overline{D}^0$ mixing is not to constrain the CKM parameters, but rather to probe new physics. Here *CP* violation plays an important role. Within the Standard Model, the *CP*-violating effects are predicted to be small, since the mixing and the relevant decays are described, to an excellent approximation, by the physics of the first two generations only. The expectation is that the Standard Model size of *CP* violation in D decays is $\mathcal{O}(10^{-3})$ or less. At present, the most sensitive searches involve the $D^0 \to K^+K^-$, $D^0 \to \pi^+\pi^-$ and $D^0 \to K^\pm\pi^\mp$ modes.

The neutral D mesons decay via a singly-Cabibbo-suppressed transition to the *CP* eigenstates K^+K^- and $\pi^+\pi^-$. These decays are dominated by Standard-Model tree diagrams. Thus, we can write, for $f = K^+K^-$ or $\pi^+\pi^-$,

$$A_f = A_f^T e^{+i\phi_f^T}\left[1 + r_f e^{i(\delta_f+\phi_f)}\right] \,, \tag{13.53a}$$

$$\bar{A}_f = A_f^T e^{-i\phi_f^T}\left[1 + r_f e^{i(\delta_f-\phi_f)}\right] \,, \tag{13.53b}$$

where $A_f^T e^{\pm i\phi_f^T}$ is the Standard Model tree-level contribution, ϕ_f^T and ϕ_f are weak, *CP* violating phases, δ_f is a strong phase difference, and r_f is the ratio between a subleading ($r_f \ll 1$) contribution with a weak phase different from ϕ_f^T and the Standard

Model tree-level contribution. Neglecting r_f, λ_f is universal, and we can define an observable phase ϕ_D via

$$\lambda_f \equiv -|q/p|e^{i\phi_D} \,. \tag{13.54}$$

(In the limit of *CP* conservation, choosing $\phi_D = 0$ is equivalent to defining the mass eigenstates by their *CP* eigenvalue: $|D_\mp\rangle = p|D^0\rangle \pm q|\overline{D}^0\rangle$, with D_- (D_+) being the *CP*-odd (*CP*-even) state; that is, the state that does not (does) decay into K^+K^-.)

We define the time integrated *CP* asymmetry for a final *CP* eigenstate f as follows:

$$a_f \equiv \frac{\int_0^\infty \Gamma(D^0_{\rm phys}(t) \to f)dt - \int_0^\infty \Gamma(\overline{D}^0_{\rm phys}(t) \to f)dt}{\int_0^\infty \Gamma(D^0_{\rm phys}(t) \to f)dt + \int_0^\infty \Gamma(\overline{D}^0_{\rm phys}(t) \to f)dt} \,. \tag{13.55}$$

(This expression corresponds to the D meson being tagged at production, hence the integration goes from 0 to $+\infty$; measurements are also possible with $\psi(3770) \to D^0\overline{D}^0$, in which case the integration goes from $-\infty$ to $+\infty$ giving slightly different results; see the discussion in Section 13.1.3.) We take $x, y, r_f \ll 1$ and expand to leading order in these parameters. We can then separate the contribution to a_f into three parts [64],

$$a_f = a^d_f + a^m_f + a^i_f \,, \tag{13.56}$$

with the following underlying mechanisms:

1. a^d_f signals *CP* violation in decay (similar to Eq. (13.21)):

$$a^d_f = 2r_f \sin\phi_f \sin\delta_f \,. \tag{13.57}$$

2. a^m_f signals *CP* violation in mixing (similar to Eq. (13.30)). With our approximations, it is universal:

$$a^m = -\frac{y}{2}\left(\left|\frac{q}{p}\right| - \left|\frac{p}{q}\right|\right)\cos\phi_D \,. \tag{13.58}$$

3. a^i_f signals *CP* violation in the interference of mixing and decay (similar to Eq. (13.31)). With our approximations, it is universal:

$$a^i = \frac{x}{2}\left(\left|\frac{q}{p}\right| + \left|\frac{p}{q}\right|\right)\sin\phi_D \,. \tag{13.59}$$

In the SM, both a^m and a^i are $\mathcal{O}(10^{-5})$ or less, while a^d could be up to two orders of magnitude larger.

One can isolate the effects of direct *CP* violation by taking the difference between the *CP* asymmetries in the K^+K^- and $\pi^+\pi^-$ modes:

$$\Delta a_{CP} \equiv a_{K^+K^-} - a_{\pi^+\pi^-} = a^d_{K^+K^-} - a^d_{\pi^+\pi^-} \,, \tag{13.60}$$

where we neglected a residual, experiment-dependent, contribution from indirect *CP* violation due to the fact that there may be a decay time-dependent acceptance function that can be different for the K^+K^- and $\pi^+\pi^-$ channels. The current average gives [13,62]:

$$a^d_{K^+K^-} - a^d_{\pi^+\pi^-} = (-0.161 \pm 0.028) \times 10^{-2} \,, \tag{13.61}$$

demonstrating *CP* violation in charm decay. While the asymmetry is somewhat larger than the theoretical predictions that preceded the measurement, it can in principle be explained by non-perturbative QCD effects.

One can also isolate the effects of indirect *CP* violation in the following way. Consider the time-dependent decay rates in Eq. (13.17a) and Eq. (13.17b). The mixing processes modify the time dependence from a pure exponential. However, given the small values of x and y, the time dependences can be recast, to a good approximation, into purely exponential form, but with modified decay-rate parameters [65,66] (given here for the K^+K^- final state):

$$\Gamma_{D^0\to K^+K^-} = \Gamma \times [1 + |q/p|\,(y\cos\phi_D - x\sin\phi_D)] \,, \tag{13.62a}$$

$$\Gamma_{\overline{D}^0\to K^+K^-} = \Gamma \times [1 + |p/q|\,(y\cos\phi_D + x\sin\phi_D)] \,. \tag{13.62b}$$

One can define *CP*-conserving and *CP*-violating combinations of these two observables (normalized to the true width Γ):

$$\begin{aligned} y_{CP} &\equiv \frac{\Gamma_{\overline{D}^0\to K^+K^-} + \Gamma_{D^0\to K^+K^-}}{2\Gamma} - 1 \\ &= (y/2)\,(|q/p| + |p/q|)\cos\phi_D - (x/2)\,(|q/p| - |p/q|)\sin\phi_D \,, \end{aligned} \tag{13.63a}$$

$$\begin{aligned} A_\Gamma &\equiv \frac{\Gamma_{D^0\to K^+K^-} - \Gamma_{\overline{D}^0\to K^+K^-}}{2\Gamma} \\ &= -(a^m + a^i) \,. \end{aligned} \tag{13.63b}$$

In the limit of *CP* conservation (and, in particular, within the Standard Model), $y_{CP} = (\Gamma_+ - \Gamma_-)/2\Gamma = y$ (where $\Gamma_+(\Gamma_-)$ is the decay width of the *CP*-even (-odd) mass eigenstate) and $A_\Gamma = 0$. Indeed, present measurements imply that *CP* violation is small [62],

$$y_{CP} - y_{CP}(K\pi) = (+0.697 \pm 0.028) \times 10^{-2} \,, \tag{13.64a}$$

$$A_\Gamma = (0.009 \pm 0.011) \times 10^{-2} \,, \tag{13.64b}$$

where the correction $y_{CP}(K\pi)$ is necessary at high precision since experimentally the denominator of the relative widths in Eq. (13.63a) is measured with the $D^0 \to K^-\pi^+$ mode [67,68].

The $K^\pm\pi^\mp$ states are not *CP* eigenstates, but they are still common final states for D^0 and $\overline{D}^0$ decays. Since $D^0(\overline{D}^0) \to K^-\pi^+$ is a Cabibbo-favored (doubly-Cabibbo-suppressed) process, these processes are particularly sensitive to x and/or $y = \mathcal{O}(\lambda^2)$. Taking into account that $|\lambda_{K^-\pi^+}|\,, \left|\lambda^{-1}_{K^+\pi^-}\right| \ll 1$ and $x, y \ll 1$, assuming that there is no direct *CP* violation (these are Standard Model tree-level decays dominated by a single weak phase, and there is no contribution from penguin-like and chromomagnetic operators), and expanding the time-dependent rates for $xt, yt \lesssim \Gamma^{-1}$, one obtains

$$\begin{aligned} &\Gamma[D^0_{\rm phys}(t) \to K^+\pi^-] = e^{-\Gamma t}|\overline{A}_{K^-\pi^+}|^2 \\ &\times \left[r_d^2 + r_d\left|\frac{q}{p}\right|(y'\cos\phi_D - x'\sin\phi_D)\Gamma t + \left|\frac{q}{p}\right|^2 \frac{y^2+x^2}{4}(\Gamma t)^2\right] \,, \end{aligned} \tag{13.65a}$$

$$\begin{aligned} &\Gamma[\overline{D}^0_{\rm phys}(t) \to K^-\pi^+] = e^{-\Gamma t}|\overline{A}_{K^-\pi^+}|^2 \\ &\times \left[r_d^2 + r_d\left|\frac{p}{q}\right|(y'\cos\phi_D + x'\sin\phi_D)\Gamma t + \left|\frac{p}{q}\right|^2 \frac{y^2+x^2}{4}(\Gamma t)^2\right] \,, \end{aligned} \tag{13.65b}$$

where

$$y' \equiv y\cos\delta - x\sin\delta \quad \text{and} \quad x' \equiv x\cos\delta + y\sin\delta \,. \tag{13.66}$$

The weak phase ϕ_D is the same as that of Eq. (13.54) (a consequence of neglecting direct *CP* violation) and $r_d = \mathcal{O}(\tan^2\theta_c)$ is the amplitude ratio, $r_d = \left|\overline{A}_{K^-\pi^+}/A_{K^-\pi^+}\right| = \left|A_{K^+\pi^-}/\overline{A}_{K^+\pi^-}\right|$, that is, $\lambda_{K^-\pi^+} = r_d|q/p|e^{-i(\delta-\phi_D)}$ and $\lambda^{-1}_{K^+\pi^-} = r_d|p/q|e^{-i(\delta+\phi_D)}$. The parameter δ is a strong-phase difference for these processes, that can be obtained from measurements of quantum correlated $\psi(3770) \to D^0\overline{D}^0$ decays [69,70]. By fitting to the six coefficients of the various time-dependences, one can determine r_d, $|q/p|$, (x^2+y^2), $y'\cos\phi_D$, and $x'\sin\phi_D$. In particular, finding *CP* violation ($|q/p| \neq 1$ and/or $\sin\phi_D \neq 0$) at a level much higher than 10^{-3} would constitute evidence for new physics. The most stringent constraints to date on *CP* violation in charm mixing have been obtained with this method [71] and from the A_Γ measurement [72].

A fit to all data [62], including also results from time-dependent analyses of $D^0 \to K_S\pi^+\pi^-$ decays, from which x, y, $|q/p|$ and ϕ_D can be determined directly, yields no evidence for indirect *CP* violation:

$$1 - |q/p| = +0.006\,^{+0.015}_{-0.016} \,, \tag{13.67a}$$

$$\phi_D = (-2.6 \pm 1.1)^\circ \,. \tag{13.67b}$$

With the additional assumption of no direct *CP* violation in doubly-Cabibbo-suppressed D decays [73–75], more stringent constraints are obtained:

$$1 - |q/p| = -0.005 \pm 0.007 \,, \tag{13.68a}$$

$$\phi_D = (-0.2 \pm 0.3)^\circ \,. \tag{13.68b}$$

More details on various theoretical and experimental aspects of D^0–$\overline{D}^0$ mixing can be found in Ref. [32].

Searches for *CP* violation in charged $D_{(s)}$ decays have been performed in many modes. Searches in decays mediated by Cabibbo-suppressed amplitudes are particularly interesting, since in other channels effects are likely to be too small to be observable in current experiments. Examples of relevant two-body modes are $D^+ \to \pi^+\pi^0$, $K_S K^+$, $\phi\pi^+$ and $D_s^+ \to K^+\pi^0$, $K_S\pi^+$, ϕK^+. The most precise results are $\mathcal{A}_{D^+\to K_S K^+} = +0.0011 \pm 0.0017$ and $\mathcal{A}_{D_s^+\to K_S\pi^+} = +0.0038 \pm 0.0048$ [62]. The precision of experiments is now sufficient that the effect from *CP* violation in the neutral kaon system can be seen in $D^+ \to K_S\pi^+$ decays [76, 77].

Three- and four-body final states provide additional possibilities to search for *CP* violation, since effects may vary over the phase-space [78]. A number of methods have been proposed to exploit this feature and search for *CP* violation in ways that do not require modelling of the decay distribution [79–82]. Such methods are useful for analysis of charm decays since they are less sensitive to biases from production asymmetries, and are well suited to address the issue of whether or not *CP* violation effects are present. They can also be applied to tagged neutral D meson as well as to charged $D_{(s)}$ decays (flavor tagging is typically achieved from the charge of the pion produced in $D^{*+} \to D^0\pi^+$ decays). The results of all searches to date are consistent with the absence of *CP* violation, with the most significant hint at the level of 2.7σ [83].

13.6 Beauty

13.6.1 *CP violation in mixing of B^0 and B_s^0 mesons*

The upper bound on the *CP* asymmetry in semileptonic B decays [84] implies that *CP* violation in B^0–$\overline{B}^0$ mixing is a small effect (we use $\mathcal{A}_{\rm SL}/2 \approx 1 - |q/p|$, see Eq. (13.23)):

$$\mathcal{A}_{\rm SL}^d = (-2.1 \pm 1.7) \times 10^{-3} \quad \Longrightarrow \quad |q/p| = 1.0010 \pm 0.0008 \,. \tag{13.69}$$

The Standard Model prediction is

$$\mathcal{A}_{\rm SL}^d = \mathcal{O}\left[(m_c^2/m_t^2)\sin\beta\right] \lesssim 0.001 \,. \tag{13.70}$$

An explicit calculation gives $(-4.73 \pm 0.42) \times 10^{-4}$ [36].

The experimental constraint on *CP* violation in B_s^0–$\overline{B}_s^0$ mixing is somewhat weaker than that in the B^0–$\overline{B}^0$ system [84]

$$\mathcal{A}_{\rm SL}^s = (-0.6 \pm 2.8) \times 10^{-3} \quad \Longrightarrow \quad |q/p| = 1.0003 \pm 0.0014 \,. \tag{13.71}$$

The Standard Model prediction is $\mathcal{A}_{\rm SL}^s = \mathcal{O}\left[(m_c^2/m_t^2)\sin\beta_s\right] \lesssim 10^{-4}$, with an explicit calculation giving $(2.06 \pm 0.18) \times 10^{-5}$ [36].

The fit to experimental data that results in the averages quoted above has a χ^2 probability of 4.5% indicating some tension between the different measurements [62]. This originates in part from a result from the D0 collaboration for the inclusive same-sign dimuon asymmetry that deviates from the Standard Model prediction by 3.6σ [85]. As yet, this has not been confirmed by independent studies.

In models where $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is approximately real, such as the Standard Model, an upper bound on $\Delta\Gamma/\Delta m \approx \mathcal{R}e(\mathbf{\Gamma}_{12}/\mathbf{M}_{12})$ provides yet another upper bound on the deviation of $|q/p|$ from one. This constraint does not hold if $\mathbf{\Gamma}_{12}/\mathbf{M}_{12}$ is approximately imaginary. (An alternative parameterization uses $q/p = (1 - \tilde{\epsilon}_B)/(1 + \tilde{\epsilon}_B)$, leading to $\mathcal{A}_{\rm SL} \simeq 4\mathcal{R}e(\tilde{\epsilon}_B)$.)

13.6.2 *CP violation in interference of B^0 decays with and without mixing*

The small deviation (less than one percent) of $|q/p|$ from 1 implies that, at the present level of experimental precision, *CP* violation in B^0 mixing is a negligible effect. Thus, for the purpose of analyzing *CP* asymmetries in hadronic B^0 decays, we can use

$$\lambda_f = e^{-i\phi_{M(B^0)}}(\overline{A}_f/A_f) \,, \tag{13.72}$$

where $\phi_{M(B^0)}$ refers to the phase of $\mathbf{M}_{12}$ appearing in Eq. (13.28) that is appropriate for B^0–$\overline{B}^0$ oscillations. Within the Standard Model, the corresponding phase factor is given by

$$e^{-i\phi_{M(B^0)}} = (V_{tb}^* V_{td})/(V_{tb} V_{td}^*) \,. \tag{13.73}$$

The class of *CP* violation effects in interference between mixing and decay is studied with final states that are common to B^0 and $\overline{B}^0$ decays [86–88]. It is convenient to rewrite Eq. (13.26) for B^0 decays as [89–91]

$$\mathcal{A}_f(t) = S_f \sin(\Delta m t) - C_f \cos(\Delta m t) \,, \tag{13.74}$$

$$S_f \equiv \frac{2\mathcal{I}m(\lambda_f)}{1 + \left|\lambda_f\right|^2} \,, \quad C_f \equiv \frac{1 - \left|\lambda_f\right|^2}{1 + \left|\lambda_f\right|^2} \,, \tag{13.75}$$

where we assume that $\Delta\Gamma = 0$ and $|q/p| = 1$. An alternative notation in use is $A_f \equiv -C_f$ – this A_f should not be confused with the A_f of Eq. (13.1), but in the limit that $|q/p| = 1$ is equivalent with the $\mathcal{A}_f$ of Eq. (13.21).

A large class of interesting processes proceed via quark transitions of the form $\overline{b} \to \overline{q}q\overline{q}'$ with $q' = s$ or d. For $q = c$ or u, there are contributions from both tree (t) and penguin (p^{q_u}, where $q_u = u, c, t$ is the quark in the loop) diagrams (see Fig. 13.2) which carry different weak phases:

$$A_f = \left(V_{qb}^* V_{qq'}\right) t_f + \sum_{q_u = u,c,t} \left(V_{q_u b}^* V_{q_u q'}\right) p_f^{q_u} \,. \tag{13.76}$$

(The distinction between tree and penguin contributions is a heuristic one; the separation by the operator that enters is more precise. A more detailed discussion of the operator product expansion approach, which also includes higher order QCD corrections, can be found in Ref. [92, 93] for example.) Using CKM unitarity, the various decay amplitudes can always be written in terms of just two CKM combinations. For example, for $f = \pi\pi$, which proceeds via a $\overline{b} \to \overline{u}u\overline{d}$ transition, we can write

$$A_{\pi\pi} = \left(V_{ub}^* V_{ud}\right) T_{\pi\pi} + \left(V_{tb}^* V_{td}\right) P_{\pi\pi}^t \,, \tag{13.77}$$

where $T_{\pi\pi} = t_{\pi\pi} + p_{\pi\pi}^u - p_{\pi\pi}^c$ and $P_{\pi\pi}^t = p_{\pi\pi}^t - p_{\pi\pi}^c$. *CP*-violating phases in Eq. (13.77) appear only in the CKM elements, so that

$$\frac{\overline{A}_{\pi\pi}}{A_{\pi\pi}} = \frac{\left(V_{ub} V_{ud}^*\right) T_{\pi\pi} + \left(V_{tb} V_{td}^*\right) P_{\pi\pi}^t}{\left(V_{ub}^* V_{ud}\right) T_{\pi\pi} + \left(V_{tb}^* V_{td}\right) P_{\pi\pi}^t} \,. \tag{13.78}$$

For $f = J/\psi K$, which proceeds via a $\overline{b} \to \overline{c}c\overline{s}$ transition, we can write

$$A_{\psi K} = \left(V_{cb}^* V_{cs}\right) T_{\psi K} + \left(V_{ub}^* V_{us}\right) P_{\psi K}^u \,, \tag{13.79}$$

where $T_{\psi K} = t_{\psi K} + p_{\psi K}^c - p_{\psi K}^t$ and $P_{\psi K}^u = p_{\psi K}^u - p_{\psi K}^t$. A subtlety arises in this decay that is related to the fact that B^0 decays into a final $J/\psi K^0$ state while $\overline{B}^0$ decays into a final $J/\psi \overline{K}^0$ state. A common final state, *e.g.*, $J/\psi K_S$, is reached only via K^0–$\overline{K}^0$ mixing. Consequently, the phase factor (defined in Eq. (13.28)) corresponding to neutral K mixing, $e^{-i\phi_{M(K)}} = (V_{cd}^* V_{cs})/(V_{cd} V_{cs}^*)$, plays a role:

$$\frac{\overline{A}_{\psi K_S}}{A_{\psi K_S}} = -\frac{\left(V_{cb} V_{cs}^*\right) T_{\psi K} + \left(V_{ub} V_{us}^*\right) P_{\psi K}^u}{\left(V_{cb}^* V_{cs}\right) T_{\psi K} + \left(V_{ub}^* V_{us}\right) P_{\psi K}^u} \times \frac{V_{cd}^* V_{cs}}{V_{cd} V_{cs}^*} \,. \tag{13.80}$$

For $q = s$ or d, there are only penguin contributions to A_f, that is, $t_f = 0$ in Eq. (13.76). (The tree $\overline{b} \to \overline{u}u\overline{q}'$ transition followed by $\overline{u}u \to \overline{q}q$ rescattering is included below in the P^u terms.) Again, CKM unitarity allows us to write A_f in terms of two CKM combinations. For example, for $f = \phi K_S$, which proceeds via a $\overline{b} \to \overline{s}s\overline{s}$ transition, we can write

$$\frac{\overline{A}_{\phi K_S}}{A_{\phi K_S}} = -\frac{\left(V_{cb} V_{cs}^*\right) P_{\phi K}^c + \left(V_{ub} V_{us}^*\right) P_{\phi K}^u}{\left(V_{cb}^* V_{cs}\right) P_{\phi K}^c + \left(V_{ub}^* V_{us}\right) P_{\phi K}^u} \times \frac{V_{cd}^* V_{cs}}{V_{cd} V_{cs}^*} \,, \tag{13.81}$$

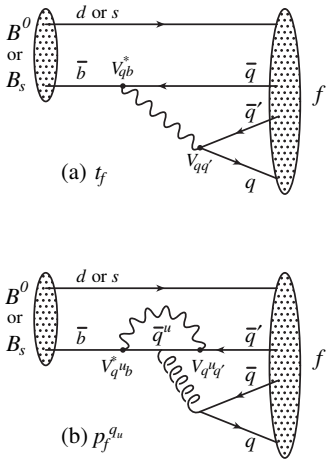

Figure 13.2: Feynman diagrams for (a) tree and (b) penguin amplitudes contributing to $B^0 \to f$ or $B_s^0 \to f$ via a $\bar{b} \to \bar{q}q\bar{q}'$ quark-level process.

where $P^c_{\phi K} = p^c_{\phi K} - p^t_{\phi K}$ and $P^u_{\phi K} = p^u_{\phi K} - p^t_{\phi K}$.

Since in general the amplitude A_f involves two different weak phases, the corresponding decays can exhibit both *CP* violation in the interference of decays with and without mixing, $S_f \neq 0$, and *CP* violation in decay, $C_f \neq 0$. (At the present level of experimental precision, the contribution to C_f from *CP* violation in mixing is negligible, see Eq. (13.69).) If the contribution from a second weak phase is suppressed, then the interpretation of S_f in terms of Lagrangian *CP*-violating parameters is clean, while C_f is small. If such a second contribution is not suppressed, S_f depends on hadronic parameters and, if the relevant strong phase difference is large, C_f is large.

A summary of $\bar{b} \to \bar{q}q\bar{q}'$ modes with $q' = s$ or d is given in Table 13.1. The $\bar{b} \to \bar{d}d\bar{q}$ transitions lead to final states that are similar to those from $\bar{b} \to \bar{u}u\bar{q}$ transitions and have similar phase dependence. Final states that consist of two vector mesons ($\psi\phi$ and $\phi\phi$) are not *CP* eigenstates, and angular analysis is needed to separate the *CP*-even from the *CP*-odd contributions.

The cleanliness of the theoretical interpretation of S_f can be assessed from the information in the last column of Table 13.1. In case of small uncertainties, the expression for S_f in terms of CKM phases can be deduced from the fourth column of Table 13.1 in combination with Eq. (13.73) (and, for $b \to q\bar{q}s$ decays, the example in Eq. (13.80)). Here we consider several interesting examples.

For $B^0 \to J/\psi K_S$ and other $\bar{b} \to \bar{c}c\bar{s}$ processes, we can neglect the P^u contribution to A_f, in the Standard Model, to an approximation that is better than one percent, giving

$$\lambda_{\psi K_S} = -e^{-2i\beta} \;\Rightarrow\; S_{\psi K_S} = \sin(2\beta)\,, \quad C_{\psi K_S} = 0\,. \qquad (13.82)$$

It is important to verify experimentally the level of suppression of the penguin contribution. Methods based on flavor symmetries [94–97] allow limits to be obtained. All are currently consistent with the P^u term being negligible. Explicit calculations [97–100] also support this conclusion.

In the presence of new physics, A_f is still likely to be dominated by the T term, but the mixing amplitude might be modified. Thus, model-independently, $C_f \approx 0$ while S_f cleanly determines the mixing phase $(\phi_M - 2\arg(V_{cb}V_{cd}^*))$. The experimental measurement gave the first precision test of the Kobayashi-Maskawa mechanism. The latest world average [62] is

$$S_{\psi K^0} = +0.709 \pm 0.011\,. \qquad (13.83)$$

(We use K^0 throughout to denote results that combine K_S and K_L modes, but use the sign appropriate to K_S.) The consistency of this measurement with the predictions for $\sin 2\beta$ makes it very likely that this mechanism is indeed the dominant source of *CP* violation in the quark sector.

For $B^0 \to \phi K_S$ and other $\bar{b} \to \bar{s}s\bar{s}$ processes (as well as some $\bar{b} \to \bar{u}u\bar{s}$ processes), we can neglect the subdominant contributions, in the Standard Model, to an approximation that is good to the order of a few percent:

$$\lambda_{\phi K_S} = -e^{-2i\beta} \;\Rightarrow\; S_{\phi K_S} = \sin 2\beta\,, \quad C_{\phi K_S} = 0\,. \qquad (13.84)$$

A review of explicit calculations of the effects of subleading amplitudes can be found in Ref. [101]. In the presence of new physics, both A_f and $\mathbf{M}_{12}$ can have contributions that are comparable in size to those of the Standard Model and carry new weak phases. Such a situation gives several interesting consequences for penguin-dominated $\bar{b} \to \bar{q}q\bar{s}$ decays ($q = u, d, s$) to a final state f:

1. The value of $-\eta_f S_f$ may be different from $S_{\psi K_S}$ by more than a few percent, where η_f is the *CP* eigenvalue of the final state.
2. The values of $\eta_f S_f$ for different final states f may be different from each other by more than a few percent (for example, $S_{\phi K_S} \neq S_{\eta' K_S}$).
3. The value of C_f may be different from zero by more than a few percent.

While a clear interpretation of such signals in terms of Lagrangian parameters will be difficult because, under these circumstances, hadronic parameters play a role, any of the above three options will clearly signal new physics. In addition, flavor symmetry relations, such as those that relate observables in $B \to K\pi$ decays [102,103] can be used to provide further tests of the Standard Model. Fig. 13.3 summarizes the present experimental results: none of the possible signatures listed above is unambiguously established, but there is definitely still room for new physics.

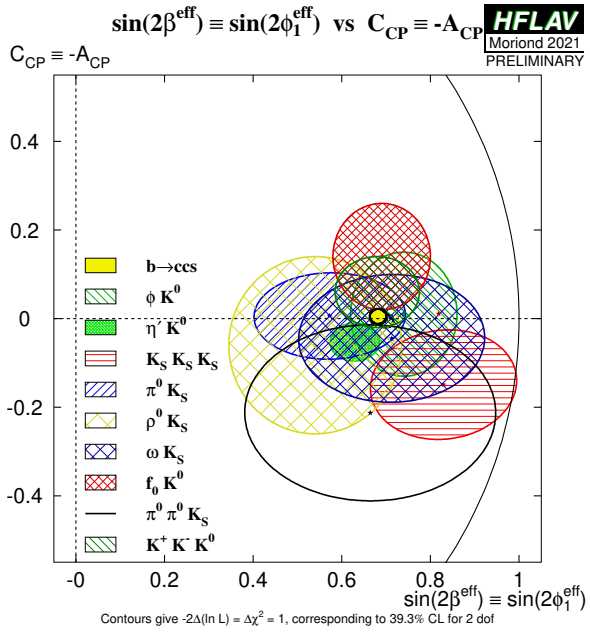

Figure 13.3: Summary of the results [62] of time-dependent analyses of $b \to q\bar{q}s$ decays, which are potentially sensitive to new physics.

For the $\bar{b} \to \bar{u}u\bar{d}$ process $B \to \pi\pi$ and other related channels, the penguin-to-tree ratio can be estimated using SU(3) relations and experimental data on related $B \to K\pi$ decays. The result (for $\pi\pi$) is that the suppression is at the level of $0.2 - 0.3$ and so cannot be neglected. The expressions for $S_{\pi\pi}$ and $C_{\pi\pi}$ to leading order in $R_{PT} \equiv (|V_{tb}V_{td}|\,P^t_{\pi\pi})/(|V_{ub}V_{ud}|\,T_{\pi\pi})$ are:

$$\lambda_{\pi\pi} = e^{2i\alpha}\left[(1 - R_{PT}e^{-i\alpha})/(1 - R_{PT}e^{+i\alpha})\right] \;\Rightarrow \qquad (13.85)$$

$$S_{\pi\pi} \approx \sin 2\alpha + 2\,\mathcal{R}e(R_{PT})\cos 2\alpha \sin\alpha\,, \quad C_{\pi\pi} \approx 2\,\mathcal{I}m(R_{PT})\sin\alpha\,. \qquad (13.86)$$

Table 13.1: Summary of $\bar{b} \to \bar{q}q\bar{q}'$ modes with $q' = s$ or d. The second and third columns give examples of hadronic final states (usually those which are experimentally most convenient to study). The fourth column gives the CKM dependence of the amplitude A_f, using the notation of Eqs. ((13.77), (13.79), (13.81)), with the dominant term first and the subdominant second. The suppression factor of the second term compared to the first is given in the last column. "Loop" refers to a penguin versus tree-suppression factor (it is mode-dependent and roughly $\mathcal{O}(0.2-0.3)$) and $\lambda \simeq 0.23$ is the expansion parameter of Eq. (13.34).

$\bar{b} \to \bar{q}q\bar{q}'$	$B^0 \to f$	$B_s^0 \to f$	CKM dependence of A_f	Suppression
$\bar{b} \to \bar{c}c\bar{s}$	ψK_S	$\psi\phi$	$(V_{cb}^* V_{cs})T + (V_{ub}^* V_{us})P^u$	loop $\times\, \lambda^2$
$\bar{b} \to \bar{s}s\bar{s}$	ϕK_S	$\phi\phi$	$(V_{cb}^* V_{cs})P^c + (V_{ub}^* V_{us})P^u$	λ^2
$\bar{b} \to \bar{u}u\bar{s}$	$\pi^0 K_S$	K^+K^-	$(V_{cb}^* V_{cs})P^c + (V_{ub}^* V_{us})T$	λ^2/loop
$\bar{b} \to \bar{c}c\bar{d}$	D^+D^-	ψK_S	$(V_{cb}^* V_{cd})T + (V_{tb}^* V_{td})P^t$	loop
$\bar{b} \to \bar{s}s\bar{d}$	$K_S K_S$	ϕK_S	$(V_{tb}^* V_{td})P^t + (V_{cb}^* V_{cd})P^c$	$\lesssim 1$
$\bar{b} \to \bar{u}u\bar{d}$	$\pi^+\pi^-$	$\rho^0 K_S$	$(V_{ub}^* V_{ud})T + (V_{tb}^* V_{td})P^t$	loop
$\bar{b} \to \bar{c}u\bar{d}$	$D_{CP}\pi^0$	$D_{CP}K_S$	$(V_{cb}^* V_{ud})T + (V_{ub}^* V_{cd})T'$	λ^2
$\bar{b} \to \bar{c}u\bar{s}$	$D_{CP}K_S$	$D_{CP}\phi$	$(V_{cb}^* V_{us})T + (V_{ub}^* V_{cs})T'$	$\lesssim 1$

Note that R_{PT} is mode-dependent and, in particular, could be different for $\pi^+\pi^-$ and $\pi^0\pi^0$. If strong phases can be neglected, then R_{PT} is real, resulting in $C_{\pi\pi} = 0$. The size of $C_{\pi\pi}$ is an indicator of how large the strong phase is. The present experimental average is $C_{\pi^+\pi^-} = -0.311 \pm 0.030$ [62]. As concerns $S_{\pi\pi}$, it is clear from Eq. (13.86) that the relative size or strong phase of the penguin contribution must be known to extract α. The theoretical uncertainty stemming from $|R_{PT}| \not\ll 1$ is referred to in the literature as penguin pollution.

The cleanest solution involves isospin relations among the $B \to \pi\pi$ amplitudes [104]:

$$\frac{1}{\sqrt{2}} A_{\pi^+\pi^-} + A_{\pi^0\pi^0} = A_{\pi^+\pi^0} \,. \tag{13.87}$$

The method exploits the fact that the penguin contribution to $P_{\pi\pi}^t$ is pure $\Delta I = 1/2$ (this is not true for the electroweak penguins which, however, are expected to be small), while the tree contribution to $T_{\pi\pi}$ contains amplitudes that are both $\Delta I = 1/2$ and $\Delta I = 3/2$. A simple geometric construction then allows one to find R_{PT} and extract α cleanly from $S_{\pi^+\pi^-}$. The key experimental difficulty is that one must measure accurately the separate rates for B^0 and $\overline{B}^0 \to \pi^0\pi^0$.

CP asymmetries in $B \to \rho\pi$ and $B \to \rho\rho$ can also be used to determine α. In particular, the $B \to \rho\rho$ measurements are presently very significant in constraining α. The extraction proceeds via isospin analysis similar to that of $B \to \pi\pi$. There are, however, several important differences. First, due to the finite width of the ρ mesons, a final $(\rho\rho)_{I=1}$ state is possible [105]. The effect is, however, of the order of $(\Gamma_\rho/m_\rho)^2 \sim 0.04$. Second, due to the presence of three helicity states for the two vector mesons, angular analysis is needed to separate the *CP*-even and *CP*-odd components. The theoretical expectation is that the *CP*-odd component is small. This is supported by experiments which find that the $\rho^+\rho^-$ and $\rho^\pm\rho^0$ modes are dominantly longitudinally polarized. Third, an important advantage of the $\rho\rho$ modes is that the penguin contribution is expected to be small due to different hadronic dynamics. This expectation is confirmed by the smallness of $\mathcal{B}(B^0 \to \rho^0\rho^0) = (0.95 \pm 0.16) \times 10^{-6}$ compared to $\mathcal{B}(B^0 \to \rho^+\rho^-) = (24.2 \pm 3.1) \times 10^{-6}$ [62]. Thus, $S_{\rho^+\rho^-}$ is not far from $\sin 2\alpha$. Finally, both $S_{\rho^0\rho^0}$ and $C_{\rho^0\rho^0}$ are experimentally accessible, which may allow a precise determination of α. However, a full isospin analysis should allow that the fractions of longitudinal polarization in B and $\overline{B}$ decays may differ, which has not yet been done by the experiments.

Detailed discussion of the determination of α with these methods can be found in Refs. [106, 107]. The latest world average is

$$\alpha = \left(84.1\,^{+4.5}_{-3.8}\right)^\circ \,. \tag{13.88}$$

The consistency between the range of α determined by the $B \to \pi\pi$, $\rho\pi$ and $\rho\rho$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism.

All modes discussed in this Section so far have possible contributions from penguin amplitudes. As shown in Table 13.1, *CP* violation can also be studied with final states, typically containing charmed mesons, where no such contribution is possible. The neutral charmed meson must be reconstructed in a final state, such as a *CP* eigenstate, common to D^0 and $\overline{D}^0$ so that the amplitudes for the B and $\overline{B}$ meson decays interfere. Although there is a second tree amplitude with a different weak phase, the contributions of the different diagrams can in many cases be separated experimentally (for example by exploiting different decays of the neutral D mesons) making these channels very clean theoretically. The first determination of $\sin(2\beta)$, with significance of *CP* violation over 5σ, with this method has recently been reported [108]. Moreover, the interference between the two tree diagrams gives sensitivity to γ, as will be discussed in Section 13.6.4.

13.6.3 *CP violation in interference of B_s^0 decays with and without mixing*

As discussed in Section 13.6.1, the world average for $|q/p|$ in the B_s^0 system currently deviates from the Standard Model expectation due to an anomalous value of the dimuon asymmetry. Attributing the dimuon asymmetry result to a fluctuation, we again neglect the deviation of $|q/p|$ from 1, and use

$$\lambda_f = e^{-i\phi_M(B_s^0)}(\overline{A}_f/A_f) \,. \tag{13.89}$$

Within the Standard Model,

$$e^{-i\phi_{M(B_s^0)}} = (V_{tb}^* V_{ts})/(V_{tb} V_{ts}^*) \,. \tag{13.90}$$

Note that in the B_s^0 system, and with the sign convention of Eq. (13.8b), $\Delta\Gamma/\Gamma = -0.126 \pm 0.007$ [62] and therefore y should not be put to zero in Eqs. (13.17a) and (13.17b). However, $|q/p| = 1$ is expected to hold to an even better approximation than for B^0 mesons. One therefore obtains

$$\mathcal{A}_f(t) = \frac{S_f \sin(\Delta m t) - C_f \cos(\Delta m t)}{\cosh(\Delta\Gamma t/2) - A_f^{\Delta\Gamma} \sinh(\Delta\Gamma t/2)} \,, \tag{13.91}$$

$$A_f^{\Delta\Gamma} \equiv \frac{-2\,\mathcal{R}e(\lambda_f)}{1 + \left|\lambda_f\right|^2} \,. \tag{13.92}$$

The presence of the $A_f^{\Delta\Gamma}$ term implies that information on λ_f can be obtained from analyses that do not use tagging of the initial flavor, through so-called effective lifetime measurements [109].

The $B_s^0 \to J/\psi\phi$ decay proceeds via the $\bar{b} \to \bar{c}c\bar{s}$ transition. The *CP* asymmetry in this mode thus determines (with angular analysis to disentangle the *CP*-even and *CP*-odd components of the final state) $\sin 2\beta_s$, where β_s is defined in Eq. (13.38) [110]. The $B_s^0 \to J/\psi\pi^+\pi^-$ decay, which has a large contribution from $J/\psi f_0(980)$ and is assumed to also proceed dominantly via the $\bar{b} \to \bar{c}c\bar{s}$ transition, has also been used to determine β_s. In this case no angular analysis is necessary, since the final state has been shown to be dominated by the *CP*-odd component [111]. The combination of measurements yields [62]

$$2\beta_s = 0.049 \pm 0.019 \,, \tag{13.93}$$

consistent with the Standard Model prediction, assuming negligible penguin contributions, $\beta_s = 0.0184 \pm 0.0004$ [20].

A time-dependent *CP* asymmetry was established in $B_s^0 \to K^+K^-$ decay, which proceeds via the $\overline{b} \to \overline{u}u\overline{s}$ transition [112]:

$$C_{KK} = +0.172 \pm 0.031\,, \quad S_{KK} = +0.139 \pm 0.032\,. \qquad (13.94)$$

For both C_{KK} and S_{KK}, the hadronic ratio (T/P^c) plays an important role (see Table 13.1), making a clean theoretical interpretation challenging. First results on the $\overline{b} \to \overline{q}q\overline{s}$ decays $B_s^0 \to \phi\phi$ and $K^{*0}\overline{K}^{*0}$ have also been reported. Parameters of *CP* violation have also been determined from the decay-time distributions of $B_s^0 \to D_s^{\mp}K^{\pm}$ and $D_s^{\mp}K^{\pm}\pi^+\pi^-$ decays, involving interference between $\overline{b} \to \overline{c}u\overline{s}$ and $\overline{b} \to \overline{u}c\overline{s}$ amplitudes.

13.6.4 *Direct CP violation in the B system*

An interesting class of decay modes is that of the tree-level decays $B^{\pm} \to D^{(*)}K^{\pm}$, which allow a theoretically pristine determination of the angle γ [113–118]. The method uses the decays $B^+ \to D^0K^+$, which proceeds via the quark transition $\overline{b} \to \overline{u}c\overline{s}$, and $B^+ \to \overline{D}^0K^+$, which proceeds via the quark transition $\overline{b} \to \overline{c}u\overline{s}$, with the D^0 and $\overline{D}^0$ decaying into a common final state. The decays into common final states, such $(\pi^0K_S)_DK^+$, involve interference effects between the two amplitudes, with sensitivity to the relative phase, $\delta + \gamma$ (δ is the relevant strong phase difference). The *CP*-conjugate processes are sensitive to $\delta - \gamma$. Measurements of branching ratios and *CP* asymmetries allow the determination of γ and δ from amplitude triangle relations. The method suffers from discrete ambiguities but, since all hadronic parameters can be determined from the data, has negligible theoretical uncertainty [119].

Unfortunately, the smallness of the CKM-suppressed $b \to u$ transitions makes it difficult to use the simplest methods alone [113–115] to determine γ. These difficulties are overcome (and the discrete ambiguities are removed) by performing a Dalitz plot analysis for multi-body D decays [116–118]. Detailed discussion of the determination of γ with these methods can be found in Ref. [107].

Constraints on γ from combinations of results on various $B \to D^{(*)}K^{(*)}$ processes have been obtained by experiments [120,121]. The latest world average is [62, 107]

$$\gamma = \left(65.9\,^{+2.9}_{-3.1}\right)^{\circ}\,. \qquad (13.95)$$

The consistency between the range of γ determined by the $B \to DK$ measurements and the range allowed by CKM fits (excluding these direct determinations) provides further support to the Kobayashi-Maskawa mechanism. As more data become available, determinations of γ from $B_s^0 \to D_s^{\mp}K^{\pm}$ [122, 123] and $B^0 \to DK^{*0}$ [124–128] are expected to also give competitive measurements.

Decays to the final state $K^{\mp}\pi^{\pm}$ provided the first observations of direct *CP* violation in both B^0 and B_s^0 systems. The asymmetry arises due to interference between tree and penguin diagrams [129], similar to the effect discussed in Section 13.6.2. In principle, measurements of $\mathcal{A}_{B^0\to K^+\pi^-}$ and $\mathcal{A}_{B_s^0\to K^-\pi^+}$ could be used to determine the weak phase difference γ, but lack of knowledge of the relative magnitude and strong phase of the contributing amplitudes limits the achievable precision. The uncertainties on these hadronic parameters can be reduced by exploiting flavor symmetries, which predict a number of relations between asymmetries in different modes. One such relation is that the partial rate differences for B^0 and B_s^0 decays to $K^{\mp}\pi^{\pm}$ are expected to be approximately equal and opposite [130], which is consistent with current data. It is also expected that the partial rate asymmetries for $B^0 \to K^+\pi^-$ and $B^+ \to K^+\pi^0$ should be approximately equal; however, the experimental results currently show a significant discrepancy [62]:

$$\mathcal{A}_{B^0\to K^+\pi^-} = -0.0836 \pm 0.0032\,, \quad \mathcal{A}_{B^+\to K^+\pi^0} = +0.029 \pm 0.012\,. \qquad (13.96)$$

It is therefore of great interest to understand whether this originates from Standard Model QCD corrections, or whether it is a signature of new dynamics. Improved tests of a more precise relation between the partial rate differences of all four $K\pi$ final states [131–134], currently limited by knowledge of the *CP* asymmetry in $\overline{B}^0 \to K_S\pi^0$ decays, may help to resolve the situation.

It is also of interest to investigate whether similar patterns appear among the *CP* violating asymmetries in B meson decays to final states containing one pseudoscalar and one vector meson. Since the vector resonance decays to two particles, such channels can be studied through Dalitz plot analysis of the three-body final state. Model-independent analyses of $B^+ \to K^+K^-K^+$, $\pi^+\pi^-K^+$, $\pi^+\pi^-\pi^+$ and $K^+K^-\pi^+$ decays have revealed large *CP* violation effects in certain regions of phase space [135]. For the $B^+ \to K^+K^-\pi^+$ decay, an amplitude analysis has established a large *CP* violation effect associated with $\pi\pi \leftrightarrow KK$ S-wave rescattering [136]. In $B^+ \to \pi^+\pi^-\pi^+$ decays, amplitude analysis has established *CP* violation effects in the decay amplitude involving the $f_2(1270)$ resonance, in the $\pi^+\pi^-$ S-wave at low invariant mass, and in the interference between the $\pi^+\pi^-$ S-wave and the P-wave $B^+ \to \rho(770)^0\pi^+$ amplitude [137, 138]. For the other channels it remains to be seen whether the *CP* violation effects are associated to particular resonances or to interference effects, which will be necessary to understand the underlying dynamics.

13.7 Summary and Outlook

CP violation has been experimentally established in K, D and B meson decays. A full list of *CP* asymmetries that have been measured at a level higher than 5σ is given in Section 13.8. In Section 13.1.4 we introduced three types of *CP*-violating effects. Examples of these three types include the following:

1. All three types of *CP* violation have been observed in $K \to \pi\pi$ decays:

$$\begin{aligned}
\mathcal{R}e(\epsilon') &= \frac{1}{6}\left(\left|\frac{\overline{A}_{\pi^0\pi^0}}{A_{\pi^0\pi^0}}\right| - \left|\frac{\overline{A}_{\pi^+\pi^-}}{A_{\pi^+\pi^-}}\right|\right) \\
&= (2.5 \pm 0.4) \times 10^{-6}\,, \qquad \text{(I)} \qquad (13.97a)\\
\mathcal{R}e(\epsilon) &= \frac{1}{2}\left(1 - \left|\frac{q}{p}\right|\right) \\
&= (1.66 \pm 0.02) \times 10^{-3}\,, \qquad \text{(II)} \qquad (13.97b)\\
\mathcal{I}m(\epsilon) &= -\frac{1}{2}\mathcal{I}m(\lambda_{(\pi\pi)_{I=0}}) \\
&= (1.57 \pm 0.02) \times 10^{-3}\,. \qquad \text{(III)} \qquad (13.97c)
\end{aligned}$$

2. For D mesons, *CP* violation in decay has been established in the difference of asymmetries for $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays.

$$\begin{aligned}
\Delta a_{CP} &= \frac{|\overline{A}_{K^+K^-}/A_{K^+K^-}|^2 - 1}{|\overline{A}_{K^+K^-}/A_{K^+K^-}|^2 + 1} - \frac{|\overline{A}_{\pi^+\pi^-}/A_{\pi^+\pi^-}|^2 - 1}{|\overline{A}_{\pi^+\pi^-}/A_{\pi^+\pi^-}|^2 + 1} \\
&= (-0.161 \pm 0.028) \times 10^{-2}\,, \quad \text{(I)}
\end{aligned} \qquad (13.98)$$

3. In the B meson system, *CP* violation in decay has been observed in, for example, $B^0 \to K^+\pi^-$ transitions, while *CP* violation in interference of decays with and without mixing has been observed in, for example, the $B^0 \to J/\psi K_S$ channel:

$$\begin{aligned}
\mathcal{A}_{K^+\pi^-} &= \frac{|\overline{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 - 1}{|\overline{A}_{K^-\pi^+}/A_{K^+\pi^-}|^2 + 1} \\
&= -0.0836 \pm 0.0032\,, \qquad \text{(I)} \qquad (13.99a)\\
S_{\psi K^0} &= \mathcal{I}m(\lambda_{\psi K^0}) \\
&= +0.709 \pm 0.011\,. \qquad \text{(III)} \qquad (13.99b)
\end{aligned}$$

Based on Standard Model predictions, further observations of *CP* violation in B^0, B^+ and B_s^0 decays seem likely in the near future, at both LHCb and its upgrades [139–141] as well as the Belle II experiment [142]. The first observation of *CP* violation in b baryons is also likely to be within reach of LHCb. Further improvements in the sensitivity to *CP* violation effects in the charm sector can also be anticipated, though uncertainty in the Standard Model predictions makes it difficult to forecast whether or

not additional discoveries will be forthcoming. A number of upcoming experiments have potential to make significant progress on rare kaon decays. Observables that are subject to clean theoretical interpretation, such as β from $S_{\psi K_S}$, β_s from $B_s^0 \to J/\psi\phi$, $\mathcal{B}(K_L \to \pi^0\nu\overline{\nu})$ and γ from *CP* violation in $B \to DK$ decays, are of particular value for constraining the values of the CKM parameters and probing the flavor sector of extensions to the Standard Model. Progress in lattice QCD calculations is also needed to complement the anticipated experimental results. Other probes of *CP* violation now being pursued experimentally include the electric dipole moments of the neutron and electron, and the decays of tau leptons. Additional processes that are likely to play an important role in future *CP* studies include top-quark production and decay, Higgs boson decays and neutrino oscillations.

All measurements of *CP* violation to date are consistent with the predictions of the Kobayashi-Maskawa mechanism of the Standard Model. In fact, it is now established that the KM mechanism plays a dominant role in the *CP* violation measured in the quark sector. However, a dynamically-generated matter-antimatter asymmetry of the universe requires additional sources of *CP* violation, and such sources are naturally generated by extensions to the Standard Model. New sources might eventually reveal themselves as small deviations from the predictions of the KM mechanism, or else might not be observable in the quark sector at all, but observable with future probes such as neutrino oscillations or electric dipole moments. The fundamental nature of *CP* violation demands a vigorous search.

A number of excellent reviews of *CP* violation are available [143–150], where the interested reader may find a detailed discussion of the various topics that are briefly reviewed here.

We thank David Kirkby for significant contributions to earlier versions of this review.

13.8 Observed *CP* violation effects

We conclude by listing the observables where *CP* violation has been observed at a level above 5σ [44, 62, 84]:

- Indirect *CP* violation in $K \to \pi\pi$ and $K \to \pi\ell\nu$ decays, and in the $K_L \to \pi^+\pi^- e^+ e^-$ decay, is given by
$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}\,. \tag{13.100}$$
- Direct *CP* violation in $K \to \pi\pi$ decays is given by
$$\mathcal{R}e(\epsilon'/\epsilon) = (1.65 \pm 0.26) \times 10^{-3}\,. \tag{13.101}$$
- *CP* violation in the interference of mixing and decay in the tree-dominated $b \to c\bar{c}s$ transitions, such as $B^0 \to \psi K^0$, is given by:
$$S_{\psi K^0} = +0.709 \pm 0.011\,. \tag{13.102}$$
- *CP* violation in the interference of mixing and decay in modes governed by the tree-dominated $b \to c\bar{u}d$ transitions is given by
$$S_{D^{(*)}h^0} = +0.71 \pm 0.09\,, \tag{13.103}$$
- *CP* violation in the interference of mixing and decay in various modes related to $b \to c\bar{c}d$ transitions is given by
$$\begin{aligned} S_{\psi\pi^0} &= -0.86 \pm 0.14\,, \\ S_{D^+D^-} &= -0.84 \pm 0.12\,, \\ S_{D^{*\pm}D^{\mp}} &= -0.81 \pm 0.06\,, \\ S_{D^{*+}D^{*-}} &= -0.71 \pm 0.09\,. \end{aligned} \tag{13.104}$$
- *CP* violation in the interference of mixing and decay in various modes related to $b \to q\bar{q}s$ (penguin) transitions is given by
$$\begin{aligned} S_{\phi K^0} &= +0.74\,^{+0.11}_{-0.13}\,, \\ S_{\eta' K^0} &= +0.63 \pm 0.06\,, \\ S_{f_0 K^0} &= +0.69\,^{+0.10}_{-0.12}\,, \\ S_{K^+K^-K_S} &= +0.68\,^{+0.09}_{-0.10}\,. \end{aligned} \tag{13.105}$$
- *CP* violation in the interference of mixing and decay in the $B^0 \to \pi^+\pi^-$ mode is given by
$$S_{\pi^+\pi^-} = -0.666 \pm 0.029\,. \tag{13.106}$$
- Direct *CP* violation in the $B^0 \to \pi^+\pi^-$ mode is given by
$$C_{\pi^+\pi^-} = -0.311 \pm 0.030\,. \tag{13.107}$$
- Direct *CP* violation in the $B_s^0 \to K^+K^-$ mode is given by
$$C_{K^+K^-} = 0.172 \pm 0.031\,. \tag{13.108}$$
- Direct *CP* violation in $B^+ \to D_+^{(*)}K^+$ decays ($D_+^{(*)}$ is the *CP*-even neutral $D^{(*)}$ state) are given by
$$\begin{aligned} \mathcal{A}_{B^+\to D_+K^+} &= +0.139 \pm 0.009 \quad \text{and} \\ \mathcal{A}_{B^+\to D_+^*K^+} &= -0.109 \pm 0.019\,, \end{aligned} \tag{13.109}$$
while the corresponding quantity in the case that the neutral D meson is reconstructed in the suppressed $K^-\pi^+$ final state is
$$\mathcal{A}_{B^+\to D_{K^-\pi^+}K^+} = -0.453 \pm 0.026\,, \tag{13.110}$$
- Direct *CP* violation has also been observed in $B^+ \to DK^+$ decays through differences between the phase-space distributions of subsequent $D \to K_S\pi^+\pi^-$ and $D \to K^-\pi^+\pi^+\pi^-$ decays.
- Direct *CP* violation in the $B^0 \to K^+\pi^-$ mode is given by
$$\mathcal{A}_{B^0\to K^+\pi^-} = -0.0836 \pm 0.0032\,. \tag{13.111}$$
- Direct *CP* violation in the $B_s^0 \to K^-\pi^+$ mode is given by
$$\mathcal{A}_{B_s^0\to K^-\pi^+} = +0.225 \pm 0.012\,. \tag{13.112}$$
- Direct *CP* violation in $B^+ \to K^+K^-\pi^+$, $B^+ \to K^+K^-K^+$ and $B^+ \to \pi^+\pi^-\pi^+$ decays is given by
$$\begin{aligned} \mathcal{A}_{B^+\to K^+K^-\pi^+} &= -0.115 \pm 0.008\,, \\ \mathcal{A}_{B^+\to K^+K^-K^+} &= -0.0365 \pm 0.0036\,, \\ \mathcal{A}_{B^+\to \pi^+\pi^-\pi^+} &= 0.076 \pm 0.005\,, \end{aligned} \tag{13.113}$$
- Large *CP* violation effects have been observed model-independently in certain regions of the phase space of $B^+ \to K^+K^-K^+$, $K^+K^-\pi^+$, $\pi^+\pi^-K^+$ and $\pi^+\pi^-\pi^+$ decays. An amplitude analysis has established a large *CP* violation effect associated with $\pi\pi \leftrightarrow KK$ S-wave rescattering in $B^+ \to K^+K^-\pi^+$ decays. In $B^+ \to \pi^+\pi^-\pi^+$ decays, amplitude analysis has established *CP* violation effects in the decay amplitude involving the $f_2(1270)$ resonance, in the $\pi^+\pi^-$ S-wave at low invariant mass, and in the interference between the $\pi^+\pi^-$ S-wave and the P-wave $B^+ \to \rho(770)^0\pi^+$ amplitude.
- Direct *CP* violation has been established in the difference of asymmetries for $D^0 \to K^+K^-$ and $D^0 \to \pi^+\pi^-$ decays
$$\Delta a_{CP} = (-0.161 \pm 0.028) \times 10^{-2}\,. \tag{13.114}$$

14. Neutrino Masses, Mixing, and Oscillations

Revised September 2023 by M.C. Gonzalez-Garcia (YITP, Stony Brook; ICREA, Barcelona; ICC, U. of Barcelona) and M. Yokoyama (UTokyo; Kavli IPMU (WPI), UTokyo).

14.1 Neutrinos in the Standard Model: Massless Neutrinos

The gauge symmetry principle is one of the pillars of the great success of modern particle physics as it establishes an unambiguous connection between local (gauge) symmetries and forces mediated by spin-1 particles. In the Standard Model (SM) of particle physics the strong, weak, and electromagnetic interactions are connected to gauge symmetry under $SU(3)_{\rm C} \times SU(2)_L \times U(1)_Y$ where C stands for colour, L for left-handedness, and Y for hypercharge. The SM gauge symmetry is spontaneously broken to $SU(3)_{\rm C} \times U(1)_{\rm EM}$ where $U(1)_{\rm EM}$ couples to the electromagnetic charge $Q_{\rm EM} = T_{L3} + Y$ (T_{L3} is the weak isospin which is the third generator of $SU(2)_L$). The model explains all the interactions of the known fermions once they are assigned to a well defined representation of the gauge group. The construction and tests of the Standard Model as a gauge theory are covered in Chapter 9 "Quantum chromodynamics" and Chapter 10 "Electroweak model and constraints on new physics" of this *Review*. Here we emphasize that the gauge invariance principle requires that all terms in the Lagrangian, including the mass terms, respect the local symmetry. This has important implications for the neutrino and in particular for the question of the neutrino mass [1].

In the SM, neutrinos are fermions that do not have strong nor electromagnetic interactions. Consequently, they are singlets of the subgroup $SU(3)_C \times U(1)_{\rm EM}$. They are part of the lepton doublets $L_{L\ell} = \begin{pmatrix} \nu_\ell \\ \ell \end{pmatrix}_L$ where f_L is the left-handed component of the fermion f, $f_L = P_L f \equiv \frac{1-\gamma_5}{2} f$. In what follows we will refer as *active* neutrinos to neutrinos that are part of these lepton doublets. In the SM there is one active neutrino for each charged leptons, $\ell = e, \mu, \tau$. $SU(2)_L$ gauge invariance dictates the form of weak charged current (CC) interactions between the neutrinos and their corresponding charged leptons and neutral current (NC) among themselves to be:

$$-\mathcal{L}_{\rm CC} = \frac{g}{\sqrt{2}} \sum_\ell \bar{\nu}_{L\ell} \gamma^\mu \ell_L^- W_\mu^+ + \text{h.c.}\,, \tag{14.1}$$

$$-\mathcal{L}_{\rm NC} = \frac{g}{2\cos\theta_W} \sum_\ell \bar{\nu}_{L\ell} \gamma^\mu \nu_{L\ell} Z_\mu^0\,. \tag{14.2}$$

In the above equations, g is the coupling constant associated with $SU(2)$ and θ_W is the Weinberg angle. Equations(14.1) and (14.2) describe all the neutrino interactions in the SM. In particular, Eq.(14.2) determines the decay width of the Z boson into light ($m_\nu \leq m_Z/2$) left-handed neutrinos states. Thus from the measurement of the total decay width of the Z one can infer the number of such states. At present the measurement implies $N_\nu = 2.984 \pm 0.008$ (see Particle Listing). As a result any extension of the SM should contain three, and only three, light active neutrinos.

Sterile neutrinos are defined as having no SM gauge interactions, that is, they are singlets of the complete SM gauge group. Thus the SM, as the gauge theory able to describe all known particle interactions, contains no sterile neutrinos.

The SM with its gauge symmetry and the particle content required for the gauge interactions, that is, in the absence of SM singlets, respects an accidental global symmetry that is not imposed but appears as a consequence of the gauge symmetry and the representation of the matter fields:

$$G_{\rm SM}^{\rm global} = U(1)_B \times U(1)_{L_e} \times U(1)_{L_\mu} \times U(1)_{L_\tau}\,, \tag{14.3}$$

where $U(1)_B$ is the baryon number symmetry, and $U(1)_{L_e, L_\mu, L_\tau}$ are the three lepton flavour symmetries. The total lepton number, $L_e + L_\mu + L_\tau$, is then also an accidental symmetry since it is a subgroup of $G_{\rm SM}^{\rm global}$. This fact has consequences that are relevant to the question of the neutrino mass as we argue next.

In the SM, the masses of the fermions are generated via a Yukawa coupling of the scalar Higgs doublet ϕ with a fermion right-handed and left-handed component. The former is an $SU(2)_L$ singlet, the latter is part of a doublet. For leptons, we can build such a term coupling the left-handed lepton doublets L_L with the right-handed charged lepton fields E_R:

$$-\mathcal{L}_{\rm Yukawa,lep} = Y_{ij}^\ell \bar{L}_{Li} \phi E_{Rj} + \text{h.c.}\,. \tag{14.4}$$

After spontaneous symmetry breaking these terms lead to charged lepton masses

$$m_{ij}^\ell = Y_{ij}^\ell \frac{v}{\sqrt{2}}\,, \tag{14.5}$$

where v is the vacuum expectation value of the Higgs field. However, since the model does not contain right-handed neutrinos, no such Yukawa interaction can be built for the neutrinos, which are consequently massless at the Lagrangian level.

In principle, a neutrino mass term could be generated at loop level. With the particle content of the SM the only possible neutrino mass term that could be constructed is the bilinear $\bar{L}_L L_L^c$, where L_L^c is the charge conjugated field, $L_L^c = C\bar{L_L}^T$ and C is the charge conjugation matrix. However this term is forbidden in the SM because it violates the total lepton symmetry by two units and therefore it cannot be induced by loop corrections because it breaks the accidental symmetry of the model. Also, because $U(1)_{B-L}$ is a non-anomalous subgroup of $G_{\rm SM}^{\rm global}$, the bilinear $\bar{L}_L L_L^c$, cannot be induced by nonperturbative corrections either since it breaks $B - L$.

We conclude that within the SM neutrinos are precisely massless. Consequently one must go beyond the SM in order to add a mass to the neutrino.

[1] The physics of massive neutrinos has been the subject of excellent books such as [1–5] and multiple review articles. The contents of the present review is built upon the structure and the contents of the review articles [6, 7].

14.2 Extending the Standard Model to Introduce Massive Neutrinos

From the above discussion, we conclude that it is not possible to construct a renormalizable mass term for the neutrinos with the fermionic content and gauge symmetry of the SM. The obvious consequence is that in order to introduce a neutrino mass in the theory one must extend the particle content of the model, depart from gauge invariance and/or renormalizability, or do both.

As a matter of fact, neutrino mass terms can be constructed in different ways. In the following we shall assume to maintain the gauge symmetry and explore the different possibilities to introduce a neutrino mass term adding to the SM an arbitrary number of sterile neutrinos ν_{si} $(i = 1, \dots m)$.

In the SM extended with the addition of m number of sterile neutrinos one can construct two gauge invariant renormalizable operators leading to two types of mass terms

$$-\mathcal{L}_{M_\nu} = M_{D\,ij}\bar{\nu}_{si}\nu_{Lj} + \frac{1}{2}M_{N\,ij}\bar{\nu}_{si}\nu^c_{sj} + \text{h.c.}\,, \tag{14.6}$$

where ν^c is the neutrino charge conjugated field (defined in section 14.1). M_D is a complex matrix of dimension $m \times 3$ and M_N is a symmetric $m \times m$ matrix.

The first term is generated after spontaneous electroweak symmetry breaking from Yukawa interactions,

$$Y^\nu_{ij}\bar{\nu}_{si}\tilde{\phi}^\dagger L_{Lj} \Rightarrow M_{D\,ij} = Y^\nu_{ij}\frac{v}{\sqrt{2}}\,, \tag{14.7}$$

in a similar way to Eqs.(14.4) and (14.5) for the charged fermion masses. It is correspondingly called a Dirac mass term. It conserves total lepton number but it can break the lepton flavour number symmetries.

The second term in Eq.(14.6) is a Majorana mass term and it differs from the Dirac mass terms in several relevant aspects. First, it is a singlet of the SM gauge group and, as such, it can appear as a bare mass term in the Lagrangian. Second, since it involves two neutrino fields (right-handed in this case), it breaks lepton number by two units. In general, such a term is not allowed if the neutrinos carry any additive conserved charge.

It is possible to rewrite Eq.(14.6) as:

$$-\mathcal{L}_{M_\nu} = \frac{1}{2}(\overline{\vec{\nu}^c_L}, \overline{\vec{\nu}_s}) \begin{pmatrix} 0 & M_D^T \\ M_D & M_N \end{pmatrix} \begin{pmatrix} \vec{\nu}_L \\ \vec{\nu}^c_s \end{pmatrix} + \text{h.c.} \equiv \overline{\vec{\nu}^c} M_\nu \vec{\nu} + \text{h.c.}\,, \tag{14.8}$$

where $\vec{\nu} = (\vec{\nu}_L,\, \vec{\nu^c_s})^T$ is a $(3+m)$-dimensional vector. The matrix M_ν is complex and symmetric [2]. Thus it can be diagonalized by a unitary matrix V^ν of dimension$(3+m)$, so

$$(V^\nu)^T M_\nu V^\nu = \text{diag}(m_1, m_2, \dots, m_{3+m})\,. \tag{14.9}$$

One can express the original weak eigenstates in terms of the resulting $3+m$ mass eigenstates

$$\vec{\nu}_{\text{mass}} = (V^\nu)^\dagger \vec{\nu}\,, \tag{14.10}$$

and in terms of the mass eigenstates, Eq.(14.8) takes the form:

$$\begin{aligned} -\mathcal{L}_{M_\nu} &= \frac{1}{2}\sum_{k=1}^{3+m} m_k \left(\bar{\nu}^c_{\text{mass},k}\nu_{\text{mass},k} + \bar{\nu}_{\text{mass},k}\nu^c_{\text{mass},k}\right) \\ &= \frac{1}{2}\sum_{k=1}^{3+m} m_k \bar{\nu}_{Mk}\nu_{Mk}\,, \end{aligned} \tag{14.11}$$

where

$$\nu_{Mk} = \nu_{\text{mass},k} + \nu^c_{\text{mass},k} = (V^{\nu\,\dagger}\vec{\nu})_k + (V^{\nu\,\dagger}\vec{\nu})^c_k\,. \tag{14.12}$$

[2] Notice that Eq.(14.8) corresponds to the tree-level neutrino mass matrix. Corrections are induced at the loop level, which in particular lead to non-vanishing $\bar{\nu}^c_L\nu_L$ entry [8].

So these states obey the Majorana condition

$$\nu_M = \nu^c_M\,, \tag{14.13}$$

and are referred to as Majorana neutrinos. The Majorana condition implies that only one field describes both neutrino and antineutrino states, unlike the case of a charged fermion for which particles and antiparticles are described by two different fields. So a Majorana neutrino can be described by a two-component spinor unlike the charged fermions, which are Dirac particles, and are represented by four-component spinors.

Inverting Eq.(14.12) we can write the weak-doublet components of the neutrino fields as:

$$\nu_{Li} = P_L \sum_{j=1}^{3+m} V^\nu_{ij}\nu_{Mj} \quad i = 1, 2, 3\,, \tag{14.14}$$

where P_L is the left projector.

In the following, we will discuss some interesting particular cases of this general framework: light Dirac neutrinos in Sec.14.2.1, and light Majorana neutrinos and the see-saw mechanism in Sec.14.2.2. A special case of the second example is the possibility of light-sterile neutrinos discussed in Sec.14.2.3. In Sec.14.2.4 we shall discuss the effective generation of neutrino masses from non-renormalizable operators (of which the see-saw mechanism is a particular realization).

14.2.1 *Dirac Neutrinos*

Imposing $M_N = 0$ is equivalent to imposing lepton number symmetry on the model. In doing this only the first term in Eq.(14.6), the Dirac mass term, is allowed. If there are only three sterile ($m = 3$), we can identify them with the right-handed component of a four-spinor neutrino field. In this case the Dirac mass term can be diagonalized with two 3×3 unitary matrices, V^ν and V^ν_R as:

$$V^{\nu\,\dagger}_R M_D V^\nu = \text{diag}(m_1, m_2, m_3)\,. \tag{14.15}$$

The neutrino mass term can be written as:

$$-\mathcal{L}_{M_\nu} = \sum_{k=1}^{3} m_k \bar{\nu}_{Dk}\nu_{Dk}\,, \tag{14.16}$$

where

$$\nu_{D\,k} = (V^{\nu\,\dagger}\vec{\nu}_L)_k + (V^{\nu\,\dagger}_R\vec{\nu}_s)_k\,, \tag{14.17}$$

so the weak-doublet components of the neutrino fields are

$$\nu_{Li} = P_L \sum_{j=1}^{3} V^\nu_{ij}\nu_{Dj}\,. \qquad i = 1, 2, 3\,. \tag{14.18}$$

Let us stress that in this case both the low-energy matter content and the assumed symmetries are different from those of the SM. Consequently, the SM is not even a good low-energy effective theory. Furthermore, this scenario does not explain the fact that neutrinos are much lighter than the corresponding charged fermions, because all of them acquire their mass via the same mechanism.

14.2.2 *The See-saw Mechanism*

If the mass eigenvalues of M_N are much higher than the scale of electroweak symmetry breaking v, the diagonalization of M_ν leads to three light neutrinos, ν_l, and m heavy neutrinos, N:

$$-\mathcal{L}_{M_\nu} = \frac{1}{2}\bar{\nu}_l M^l \nu_l + \frac{1}{2}\bar{N} M^h N\,, \tag{14.19}$$

with

$$M^l \simeq -V_l^T M_D^T M_N^{-1} M_D V_l, \qquad M^h \simeq V_h^T M_N V_h\,, \tag{14.20}$$

and

$$V^\nu \simeq \begin{bmatrix} \left(1 - \frac{1}{2} M_D^\dagger {M_N^*}^{-1} M_N^{-1} M_D\right) V_l & M_D^\dagger {M_N^*}^{-1} V_h \\ -M_N^{-1} M_D V_l & \left(1 - \frac{1}{2} {M_N}^{-1} M_D M_D^\dagger {M_N^*}^{-1}\right) V_h \end{bmatrix} , \tag{14.21}$$

where V_l and V_h are 3×3 and $m \times m$ unitary matrices respectively. From Eq.(14.20) we see that the masses of the heavier states are proportional to M_N while those of the lighter ones to M_N^{-1}, hence the name *see-saw mechanism* [9–13]. Also, as seen from Eq.(14.21), the heavy states are mostly right-handed while the light ones are mostly left-handed. Both the light and the heavy neutrinos are Majorana particles. Two well-known examples of extensions of the SM leading to a see-saw mechanism for neutrino masses are SO(10) Grand Unified Theories [10, 11] and left-right symmetryc models [13].

In this case, the SM is a good effective low energy theory. Indeed the see-saw mechanism is a particular example of a full theory whose low energy effective realization is the SM with three light Majorana neutrinos which we describe in Sec.14.2.4.

14.2.3 *Light Sterile Neutrinos*

If the scale of some $n_s \leq m$ eigenvalues of M_N are not higher than the electroweak scale, the low energy spectrum contains n_s additional light states with a large admixture of sterile component. As in the case with Dirac Neutrinos, the SM is not a good low energy effective theory: there are more than three $(3+n_s)$ light neutrinos, and they are admixtures of doublet and singlet fields. As in the general case, both light and heavy neutrinos are Majorana particles.

14.2.4 *Neutrino Masses from Generic New Physics*

Under the generic hypothesis that new physics (NP) beyond the SM only manifests itself directly above some scale $\Lambda_{\rm NP}$, we can consider that the SM is an effective low energy theory which is valid to describe the physical world at energies well below $\Lambda_{\rm NP}$ with the same gauge group, fermionic spectrum, and the pattern of spontaneous symmetry breaking of the SM. However, this is an effective theory, holding only till energy below $\Lambda_{\rm NP}$, and consequently does not need to be renormalizable. In this case, the low energy Lagrangian can contain non-renormalizable higher dimensional terms whose effect will be suppressed by powers $1/\Lambda_{\rm NP}^{\rm dim-4}$.

In this approach, the least suppressed NP effects at low energy are expected to come from dim= 5 operators. With the SM fields and gauge symmetry one can only construct the following set of dimension-five terms

$$\mathcal{O}_5 = \frac{Z^\nu_{ij}}{\Lambda_{\rm NP}} \left(\bar{L}_{Li} \tilde{\phi}\right) \left(\tilde{\phi}^T L^C_{Lj}\right) + \text{h.c.} . \tag{14.22}$$

This set violates (14.3), which poses no problem since, in general, there is no reason for the NP to respect the accidental symmetries of the SM. In particular, it violates the total lepton number by two units, and after spontaneous symmetry breaking it generates a bilinear neutrino field term:

$$-\mathcal{L}_{M_\nu} = \frac{Z^\nu_{ij}}{2} \frac{v^2}{\Lambda_{\rm NP}} \bar{\nu}_{Li} \nu^c_{Lj} + \text{h.c.} . \tag{14.23}$$

This is a Majorana mass term (see Eq.(14.8)). It is built with the left-handed neutrino fields and with mass matrix:

$$(M_\nu)_{ij} = Z^\nu_{ij} \frac{v^2}{\Lambda_{\rm NP}} . \tag{14.24}$$

We conclude that Eq.(14.24) would arise in a generic extension of the SM and that neutrino masses are very likely to appear if there is NP. Comparing Eq.(14.24) and Eq.(14.5), we also find that the scale of neutrino masses is suppressed by $v/\Lambda_{\rm NP}$ when compared to the scale of charged fermion masses, which provides an explanation for their smallness. Furthermore, both total lepton number and the lepton flavour symmetry $U(1)_e \times U(1)_\mu \times U(1)_\tau$ are broken by Eq.(14.24), which means that, generically, in the absence of additional symmetries on the coefficients Z_{ij}, we can expect lepton flavour mixing and CP violation as we discuss in the next section.

Finally, we notice that, as mentioned in Sec.14.2.2, a theory where the NP is composed of m heavy sterile neutrinos, provides an specific example of a theory which at low energy contains three light mass eigenstates with an effective dim-5 interaction of the form (14.22) with $\Lambda_{\rm NP} = M_N$. In this case, the NP scale is the characteristic mass scale of the heavy sterile neutrinos.

14.3 Lepton Mixing

Let us start by considering $n = 3 + m$ massive neutrino states and denote the neutrino mass eigenstates by $(\nu_1, \nu_2, \nu_3, \ldots, \nu_n)$. The neutrino interaction eigenstates are denoted by $\vec{\nu} = (\nu_{Le}, \nu_{L\mu}, \nu_{L\tau}, \nu_{s1}, \ldots, \nu_{sm})$. We label the corresponding mass and interaction eigenstates for the charged leptons as (e, μ, τ) and (e^I, μ^I, τ^I), respectively. The Lagrangian for the leptonic charged current interactions in the mass basis takes the form:

$$-\mathcal{L}_{\rm CC} = \frac{g}{\sqrt{2}} (\bar{e}_L, \bar{\mu}_L, \bar{\tau}_L) \gamma^\mu U \begin{pmatrix} \nu_1 \\ \nu_2 \\ \nu_3 \\ \vdots \\ \nu_n \end{pmatrix} W^+_\mu + \text{h.c.} , \tag{14.25}$$

where U is a $3 \times n$ matrix [14–16]. It satisfies the unitary condition

$$U U^\dagger = I_{3\times 3} . \tag{14.26}$$

However, in general $U^\dagger U \neq I_{n\times n}$.

In the interaction basis, the mass terms for the leptons are:

$$-\mathcal{L}_M = [(\bar{e}^I_L, \bar{\mu}^I_L, \bar{\tau}^I_L) M_\ell \begin{pmatrix} e^I_R \\ \mu^I_R \\ \tau^I_R \end{pmatrix} + \text{h.c.}] - \mathcal{L}_{M_\nu} , \tag{14.27}$$

with $\mathcal{L}_{M_\nu}$ given in Eq.(14.8). M_ℓ can be diagonalized with two 3×3 unitary matrices V^ℓ and V^ℓ_R which satisfy

$$V^{\ell\dagger} M_\ell V^\ell_R = \text{diag}(m_e, m_\mu, m_\tau) . \tag{14.28}$$

Then for the charged leptons we have

$$-\mathcal{L}_{M_\ell} = \sum_{k=1}^{3} m_{\ell_k} \bar{\ell}_k \ell_k , \tag{14.29}$$

with

$$\ell_k = (V^{\ell\dagger} \ell^I_L)_k + (V^{\ell\dagger}_R \ell^I_R)_k . \tag{14.30}$$

Inverting the equation above we find that the weak-doublet components of the charged lepton fields are

$$\ell^I_{Li} = P_L \sum_{j=1}^{3} V^\ell_{ij} \ell_j . \qquad i = 1, 2, 3 \tag{14.31}$$

From Eqs.(14.14), (14.18) and (14.31) we find that the mixing matrix U can be expressed as:

$$U_{ij} = \mathcal{P}_{\ell,ii} \, V^{\ell\,\dagger}_{ik} \, V^\nu_{kj} \, (\mathcal{P}_{\nu,jj}). \tag{14.32}$$

The matrix $V^{\ell\dagger} V^\nu$ contains a number of phases that are not physical. Three of them are eliminated by the diagonal 3×3 phase matrix $\mathcal{P}_\ell$ that absorbs them in the charged lepton mass eigenstates. If neutrinos are Dirac states, further $n - 1$ are similarly eliminated by absorbing them in the neutrino mass eigenstates with the diagonal $n \times n$ phase matrix $\mathcal{P}_\nu$. For Majorana neutrinos, $\mathcal{P}_\nu = I_{n\times n}$ because one cannot rotate by an arbitrary phase a Majorana field without physical effects. If one rotates a Majorana neutrino by a phase, this phase will appear in its mass term, which will no longer be real. Consequently, the number of phases that can be absorbed by redefining the mass eigenstates

depends on whether the neutrinos are Dirac or Majorana particles. Altogether for $n \geq 3$ Majorana [Dirac] neutrinos, the U matrix contains a total of $6(n-2)$ [$5n-11$] real parameters, of which $3(n-2)$ are angles, and $3(n-2)$ [$2n-5$] can be interpreted as physical phases.

The possibility of arbitrary mixing between massive neutrino states was first discussed in the context of two neutrinos in Ref. [17] (the possibility of two mixed massless flavour neutrino states had been previously considered in the literature [18], and the possibility of mixing between neutrino and antineutrino states even earlier, in the seminal paper of Pontecorvo [19]). For the case where only mixing between two generations is considered with $n = 2$ distinct neutrino masses, the U matrix is 2×2 and contains one mixing angle if the neutrinos are Dirac and an additional physical phase if they are Majorana.

If there are only $n = 3$ Majorana neutrinos, U is a 3×3 matrix analogous to the CKM matrix for the quarks [20, 21], but due to the Majorana nature of the neutrinos it depends on six independent parameters: three mixing angles and three phases. In this case the mixing matrix can be conveniently parameterized as:

$$U = \begin{pmatrix} 1 & 0 & 0 \\ 0 & c_{23} & s_{23} \\ 0 & -s_{23} & c_{23} \end{pmatrix} \cdot \begin{pmatrix} c_{13} & 0 & s_{13} e^{-i\delta_{\rm CP}} \\ 0 & 1 & 0 \\ -s_{13} e^{i\delta_{\rm CP}} & 0 & c_{13} \end{pmatrix} \cdot \begin{pmatrix} c_{12} & s_{12} & 0 \\ -s_{12} & c_{12} & 0 \\ 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} e^{i\eta_1} & 0 & 0 \\ 0 & e^{i\eta_2} & 0 \\ 0 & 0 & 1 \end{pmatrix} , \tag{14.33}$$

where $c_{ij} \equiv \cos\theta_{ij}$ and $s_{ij} \equiv \sin\theta_{ij}$. The angles θ_{ij} can be taken without loss of generality to lie in the first quadrant, $\theta_{ij} \in [0, \pi/2]$ and the phases $\delta_{\rm CP}$, $\eta_i \in [0, 2\pi]$. This is to be compared to the case of three Dirac neutrinos. In this case, the Majorana phases, η_1 and η_2, can be absorbed in the neutrino states so the number of physical phases is one (similar to the CKM matrix). Thus we can write U as:

$$U = \begin{pmatrix} c_{12}\, c_{13} & s_{12}\, c_{13} & s_{13}\, e^{-i\delta_{\rm CP}} \\ -s_{12}\, c_{23} - c_{12}\, s_{13}\, s_{23}\, e^{i\delta_{\rm CP}} & c_{12}\, c_{23} - s_{12}\, s_{13}\, s_{23}\, e^{i\delta_{\rm CP}} & c_{13}\, s_{23} \\ s_{12}\, s_{23} - c_{12}\, s_{13}\, c_{23}\, e^{i\delta_{\rm CP}} & -c_{12}\, s_{23} - s_{12}\, s_{13}\, c_{23}\, e^{i\delta_{\rm CP}} & c_{13}\, c_{23} \end{pmatrix} . \tag{14.34}$$

This matrix is often called the Pontecorvo-Maki-Nakagawa-Sakata (PMNS) mixing matrix.

Notice that when the charged leptons have no other interactions than the SM ones, one can identify their interaction eigenstates with the corresponding mass eigenstates up to phase redefinition. This implies that, in this case, U is just a $3 \times n$ sub-matrix of the unitary neutrino mass diagonalizing matrix V^ν.

Finally, let us point out that for the case of 3 light Dirac neutrinos, the procedure above leads to a unitary U matrix for the light states. But for three light Majorana neutrinos, this is not the case since the full spectrum contains states which are heavy and are not in the low energy spectrum as seen, for example, in Eq.(14.21). This implies that, strictly speaking, the parametrization in Eq.(14.33) is not valid to describe the flavour mixing of the three light Majorana neutrinos in the see-saw mechanism. The violation of unitarity, however, is rather small, of the order $\mathcal{O}(M_D/M_N)$ as seen in Eq.(14.21). It is also severely constrained experimentally [22, 23]. For all these reasons, for all practical purposes, we will consider the U matrix for the 3ν mixing case to be unitary independently of whether neutrinos are Dirac or Majorana particles.

14.4 Mass-Induced Flavour Oscillations in Vacuum

If neutrinos have masses and lepton flavours are mixed in the weak CC interactions, lepton flavour is not conserved in neutrino propagation [19, 24]. This phenomenon is usually referred to as *neutrino oscillations*. In brief, a weak eigenstates, ν_α, which by default is the state produced in the weak CC interaction of a charged lepton ℓ_α, is the linear combination determined by the mixing matrix U

$$|\nu_\alpha\rangle = \sum_{i=1}^{n} U^*_{\alpha i} |\nu_i\rangle \,, \tag{14.35}$$

where ν_i are the mass eigenstates, and here n is the number of light neutrino species (implicit in our definition of the state $|\nu\rangle$ is its energy-momentum and space-time dependence). After traveling a distance L ($L \simeq ct$ for relativistic neutrinos), that state evolves as:

$$|\nu_\alpha(t)\rangle = \sum_{i=1}^{n} U^*_{\alpha i} |\nu_i(t)\rangle \,. \tag{14.36}$$

This neutrino can then undergo a charged-current (CC) interaction producing a charge lepton ℓ_β, $\nu_\alpha(t) N' \to \ell_\beta N$, with a probability

$$P_{\alpha\beta} = |\langle \nu_\beta | \nu_\alpha(t) \rangle|^2 = |\sum_{i=1}^{n} \sum_{j=1}^{n} U^*_{\alpha i} U_{\beta j} \langle \nu_j | \nu_i(t) \rangle|^2 \,. \tag{14.37}$$

Assuming that $|\nu\rangle$ is a plane wave, $|\nu_i(t)\rangle = e^{-i\,E_i t} |\nu_i(0)\rangle$, [3] with $E_i = \sqrt{p_i^2 + m_i^2}$ and m_i being, respectively, the energy and the mass of the neutrino mass eigenstate ν_i. In all practical cases neutrinos are very relativistic ,so $p_i \simeq p_j \equiv p \simeq E$. We can then write

$$E_i = \sqrt{p_i^2 + m_i^2} \simeq p + \frac{m_i^2}{2E} \,, \tag{14.38}$$

and use the orthogonality of the mass eigenstates, $\langle \nu_j | \nu_i \rangle = \delta_{ij}$, to arrive to the following form for $P_{\alpha\beta}$:

$$P_{\alpha\beta} = \delta_{\alpha\beta} - 4 \sum_{i<j}^{n} {\rm Re}[U_{\alpha i} U^*_{\beta i} U^*_{\alpha j} U_{\beta j}] \sin^2 X_{ij} + 2 \sum_{i<j}^{n} {\rm Im}[U_{\alpha i} U^*_{\beta i} U^*_{\alpha j} U_{\beta j}] \sin 2X_{ij} \,, \tag{14.39}$$

where

$$X_{ij} = \frac{(m_i^2 - m_j^2)L}{4E} = 1.267\, \frac{\Delta m^2_{ij}}{{\rm eV}^2}\, \frac{L/E}{\rm m/MeV} \,. \tag{14.40}$$

If we had made the same derivation for antineutrino states, we would have ended with a similar expression but with the exchange $U \to U^*$. Consequently, we conclude that the first term in the right-hand-side of Eq.(14.39) is CP conserving since it is the same for neutrinos and antineutrinos, while the last one is CP violating because it has opposite signs for neutrinos and antineutrinos.

Equation (14.39) is oscillatory in distance with oscillation lengths

$$L^{\rm osc}_{0,ij} = \frac{4\pi E}{|\Delta m^2_{ij}|} \,, \tag{14.41}$$

and with amplitudes proportional to products of elements in the mixing matrix. Thus, neutrinos must have different masses

[3] For a pedagogical discussion of the quantum mechanical description of flavour oscillations in the wave package approach see for example Ref. [3]. A recent review of the quantum mechanical aspects and subtleties on neutrino oscillations can be found in in Ref. [25].

Table 14.1: Characteristic values of L and E for experiments performed using various neutrino sources and the corresponding ranges of $|\Delta m^2|$ to which they can be most sensitive to flavour oscillations in vacuum. SBL stands for Short Baseline, VSBL stands for Very Short Baseline , MBL stands for Medium Baseline, and LBL for Long Baseline.

Experiment		L (m)	E (MeV)	$\|\Delta m^2\|$ (eV^2)
Solar		10^{10}	1	10^{-10}
Atmospheric		$10^4 - 10^7$	10^2–10^5	$10^{-1} - 10^{-4}$
Reactor	VSBL–SBL–MBL	$10 - 10^3$	1	$1 - 10^{-3}$
	LBL	$10^4 - 10^5$		$10^{-4} - 10^{-5}$
Accelerator	SBL	10^2	10^3–10^4	> 0.1
	LBL	$10^5 - 10^6$	$10^3 - 10^4$	$10^{-2} - 10^{-3}$

($\Delta m^2_{ij} \neq 0$) and they must have not vanishing mixing ($U_{\alpha_i} U_{\beta i} \neq 0$) in order to undergo flavour oscillations. Also, from Eq.(14.39) we see that the Majorana phases cancel out in the oscillation probability. This is expected because flavour oscillation is a total lepton number conserving process.

Ideally, a neutrino oscillation experiment would like to measure an oscillation probability over a distance L between the source and the detector, for neutrinos of a definite energy E. In practice, neutrino beams, both from natural or artificial sources, are never monoenergetic but have an energy spectrum $\Phi(E)$. In addition, each detector has a finite energy resolution. Under these circumstances what is measured is an average probability

$$\begin{aligned}\langle P_{\alpha\beta}\rangle &= \frac{\int dE \frac{d\Phi}{dE}\sigma(E)P_{\alpha\beta}(E)\epsilon(E)}{\int dE \frac{d\Phi}{dE}\sigma_{CC}(E)\epsilon(E)} \\ &= \delta_{\alpha\beta} - 4\sum_{i<j}^{n} \mathrm{Re}[U_{\alpha i}U^*_{\beta i}U^*_{\alpha j}U_{\beta j}]\langle \sin^2 X_{ij}\rangle \\ &+ 2\sum_{i<j}^{n} \mathrm{Im}[U_{\alpha i}U^*_{\beta i}U^*_{\alpha j}U_{\beta j}]\langle \sin 2X_{ij}\rangle\,.\end{aligned} \tag{14.42}$$

σ is the cross-section for the process in which the neutrino flavour is detected, and $\epsilon(E)$ is the detection efficiency. The minimal range of the energy integral is determined by the energy resolution of the experiment.

It is clear from the above expression that if $(E/L) \gg |\Delta m^2_{ij}|$ ($L \ll L^{\rm osc}_{0,ij}$) so $\sin^2 X_{ij} \ll 1$, the oscillation phase does not give any appreciable effect. Conversely, if $L \gg L^{\rm osc}_{0,ij}$, many oscillation cycles occur between production and detection, so the oscillating term is averaged to $\langle \sin^2 X_{ij}\rangle = 1/2$.

We summarize in Table 14.1 the typical values of L/E for different types of neutrino sources and experiments and the corresponding ranges of Δm^2 to which they can be most sensitive.

Historically, the results of neutrino oscillation experiments were interpreted assuming two-neutrino states so there is only one oscillating phase; the mixing matrix depends on a single mixing angle θ, and no CP violation effect in oscillations is possible. At present, as we will discuss in Sec.14.7, we need at least the mixing among three-neutrino states to fully describe the bulk of experimental results. However, in many cases, the observed results can be understood in terms of oscillations dominantly driven by one Δm^2. In this limit $P_{\alpha\beta}$ of Eq.(14.39) takes the form [24]

$$P_{\alpha\beta} = \delta_{\alpha\beta} - (2\delta_{\alpha\beta} - 1)\sin^2 2\theta \sin^2 X\,. \tag{14.43}$$

In this effective $2-\nu$ limit, changing the sign of the mass difference, $\Delta m^2 \to -\Delta m^2$, and changing the octant of the mixing angle, $\theta \to \frac{\pi}{2} - \theta$, is just redefining the mass eigenstates, $\nu_1 \leftrightarrow \nu_2$: $P_{\alpha\beta}$ must be invariant under such transformation. So the physical parameter space can be covered with either $\Delta m^2 \geq 0$ with $0 \leq \theta \leq \frac{\pi}{2}$, or, alternatively, $0 \leq \theta \leq \frac{\pi}{4}$ with either sign for Δm^2.

However, from Eq.(14.43) we see that $P_{\alpha\beta}$ is actually invariant under the change of sign of the mass splitting *and* the change of octant of the mixing angle separately. This implies that there is a two-fold discrete ambiguity since the two different sets of physical parameters, $(\Delta m^2, \theta)$ and $(\Delta m^2, \frac{\pi}{2} - \theta)$, give the same transition probability in vacuum. In other words, one could not tell from a measurement of, say, $P_{e\mu}$ in vacuum whether the larger component of ν_e resides in the heavier or in the lighter neutrino mass eigenstate. This symmetry is broken when one considers mixing of three or more neutrinos in the flavour evolution and or when the neutrinos traverse regions of dense matter as we describe in Sec.14.7.1 and Sec.14.5, respectively.

14.5 Propagation of Massive Neutrinos in Matter

Neutrinos propagating in a dense medium can interact with the particles in the medium. The probability of an incoherent inelastic scattering is very small. For example the characteristic cross section for ν-proton scattering is of the order

$$\sigma \sim \frac{G_F^2 s}{\pi} \sim 10^{-43}\ \mathrm{cm}^2 \left(\frac{E}{\mathrm{MeV}}\right)^2, \tag{14.44}$$

where G_F is the Fermi constant and s is the square of the center of mass energy of the collision.

But when neutrinos propagate in dense matter, they can also interact coherently with the particles in the medium. By definition, in coherent interactions, the medium remains unchanged so it is possible to have interference of the forward scattered and the unscattered neutrino waves which enhances the effect of matter in the neutrino propagation. In this case, the effect of the medium is not on the intensity of the propagating neutrino beam, which remains unchanged, but on the phase velocity of the neutrino wave, and for this reason the effect is proportional to G_F, instead of the G_F^2 dependence of the incoherent scattering. Coherence also allows decoupling the evolution equation of the neutrinos from those of the medium. In this limit, the effect of the medium is introduced in the evolution equation for the neutrinos in the form of an effective potential which depends on the density and composition of the matter [26].

As an example, let us consider the evolution of ν_e in a medium with electrons, protons, and neutrons with corresponding n_e, n_p, and n_n number densities. The effective low-energy Hamiltonian describing the relevant neutrino interactions at point x is given by

$$H_W = \frac{G_F}{\sqrt{2}}\left[J^{(+)\alpha}(x)J^{(-)}_\alpha(x) + \frac{1}{4}J^{(N)\alpha}(x)J^{(N)}_\alpha(x)\right], \tag{14.45}$$

where the J_α's are the standard fermionic currents

$$J^{(+)}_\alpha(x) = \bar\nu_e(x)\gamma_\alpha(1-\gamma_5)e(x)\,, \tag{14.46}$$

$$J^{(-)}_\alpha(x) = \bar e(x)\gamma_\alpha(1-\gamma_5)\nu_e(x)\,, \tag{14.47}$$

$$\begin{aligned}J^{(N)}_\alpha(x) &= \bar\nu_e(x)\gamma_\alpha(1-\gamma_5)\nu_e(x) \\ &- \bar e(x)[\gamma_\alpha(1-\gamma_5) - 4\sin^2\theta_W\gamma_\alpha]e(x) \\ &+ \bar p(x)[\gamma_\alpha(1-g^{(p)}_A\gamma_5) - 4\sin^2\theta_W\gamma_\alpha]p(x) \\ &- \bar n(x)\gamma_\alpha(1-g^{(n)}_A\gamma_5)n(x)\,,\end{aligned} \tag{14.48}$$

and $g^{(n,p)}_A$ are the axial couplings for neutrons and protons, respectively.

Let us focus first on the effect of the charged current interactions. The effective CC Hamiltonian due to electrons in the medium is

$$H_C^{(e)} = \frac{G_F}{\sqrt{2}} \int d^3p_e f(E_e,T) \times \left\langle \langle e(s,p_e) \,|\, \bar{e}(x)\gamma^\alpha(1-\gamma_5)\nu_e(x)\bar{\nu}_e(x)\gamma_\alpha(1-\gamma_5)e(x) \,|\, e(s,p_e)\rangle \right\rangle$$
$$= \frac{G_F}{\sqrt{2}} \bar{\nu}_e(x)\gamma_\alpha(1-\gamma_5)\nu_e(x) \int d^3p_e f(E_e,T) \left\langle \langle e(s,p_e) \,|\, \bar{e}(x)\gamma_\alpha(1-\gamma_5)e(x) \,|\, e(s,p_e)\rangle \right\rangle . \tag{14.49}$$

In the above equation, we denote by s the electron spin, and by p_e its momentum, and $f(E_e,T)$ is the energy distribution function of the electrons in the medium which is assumed to be homogeneous and isotropic and is normalized as

$$\int d^3p_e f(E_e,T) = 1 . \tag{14.50}$$

We denote by $\left\langle \ldots \right\rangle$ the averaging over electron spinors and summing over all electrons in the medium. Coherence dictates that s, p_e are the same for initial and final electrons. The axial current reduces to the spin in the non-relativistic limit and therefore averages to zero for a background of non-relativistic electrons. The spatial components of the vector current cancel because of isotropy. Therefore, the only non-trivial average is

$$\int d^3p_e f(E_e,T) \left\langle \langle e(s,p_e) \,|\, \bar{e}(x)\gamma_0 e(x) \,|\, e(s,p_e)\rangle \right\rangle = n_e(x) , \tag{14.51}$$

which gives a contribution to the effective Hamiltonian

$$H_C^{(e)} = \sqrt{2} G_F n_e \bar{\nu}_{eL}(x)\gamma_0\nu_{eL}(x) . \tag{14.52}$$

This can be interpreted as a contribution to the ν_{eL} potential energy

$$V_C = \sqrt{2} G_F n_e . \tag{14.53}$$

Should we have considered antineutrino states, we would have ended up with $V_C = -\sqrt{2}G_F n_e$ For a more detailed derivation of the matter potentials see, for example, Ref. [3].

With an equivalent derivation, we find that for ν_μ and ν_τ, the potential due to its CC interactions is zero for most media since neither μ's nor $\tau's$ are present, while the effective potential for any active neutrino due to the neutral current interactions is found to be

$$V_{NC} = \frac{\sqrt{2}}{2} G_F \left[-n_e(1-4\sin^2\theta_w) + n_p(1-4\sin^2\theta_w) - n_n \right] . \tag{14.54}$$

In neutral matter, $n_e = n_p$ and the contribution from electrons and protons cancel each other. So we are left only with the neutron contribution

$$V_{NC} = -1/\sqrt{2} G_F n_n . \tag{14.55}$$

After including these effects, the evolution equation for n ultrarelativistic neutrinos propagating in matter written in the mass basis is (see for instance Ref. [27–29] for the derivation):

$$i\frac{d\vec{\nu}}{dx} = H\,\vec{\nu}, \qquad H = H_m + U^{\nu\,\dagger}\, V\, U^\nu . \tag{14.56}$$

Here $\vec{\nu} \equiv (\nu_1, \nu_2, \ldots, \nu_n)^T$, H_m is the the kinetic Hamiltonian,

$$H_m = \frac{1}{2E}\,\mathrm{diag}(m_1^2, m_2^2, \ldots, m_n^2), \tag{14.57}$$

and V is the effective neutrino potential in the interaction basis. U^ν is the $n\times n$ submatrix of the unitary V^ν matrix corresponding to the n ultrarelativistic neutrino states. For the three SM active neutrinos with purely SM interactions crossing a neutral medium with electrons, protons and neutrons, the evolution equation takes the form (14.56) with $U^\nu \equiv U$, and the effective potential:

$$V = \mathrm{diag}\left(\pm\sqrt{2}G_F n_e(x),\, 0,\, 0\right) \equiv \mathrm{diag}\,(V_e,\, 0,\, 0) . \tag{14.58}$$

The sign + (−) in Eq.(14.58) applies to neutrinos (antineutrinos), and $n_e(x)$ is the electron number density in the medium, which in general is not constant along the neutrino trajectory so the potential is not constant. The characteristic value of the potential at the Earth core is $V_e \sim 10^{-13}$ eV, while at the solar core $V_e \sim 10^{-12}$ eV. Since the neutral current potential Eq.(14.55) is flavour diagonal, it can be eliminated from the evolution equation as it only contributes to an overall unobservable phase.

The instantaneous mass eigenstates in matter, ν_i^m, are the eigenstates of the Hamiltonian H in (14.56) for a fixed value of x, and they are related to the interaction basis by

$$\vec{\nu} = \tilde{U}(x)\nu^{\vec{m}} . \tag{14.59}$$

The corresponding instantaneous eigenvalues of H are $\mu_i(x)^2/(2E)$ with $\mu_i(x)$ being the instantaneous effective neutrino masses.

Let us take for simplicity a neutrino state which is an admixture of only two neutrino species $|\nu_\alpha\rangle$ and $|\nu_\beta\rangle$, so the two instantaneous mass eigenstates in matter ν_1^m and ν_2^m have instantaneous effective neutrino masses

$$\mu_{1,2}^2(x) = \frac{m_1^2+m_2^2}{2} + E[V_\alpha + V_\beta]$$
$$\mp \frac{1}{2}\sqrt{[\Delta m^2\cos 2\theta - A]^2 + [\Delta m^2 \sin 2\theta]^2} , \tag{14.60}$$

and $\tilde{U}(x)$ is a 2x2 rotation matrix with the instantaneous mixing angle in matter given by

$$\tan 2\theta_m = \frac{\Delta m^2 \sin 2\theta}{\Delta m^2\cos 2\theta - A} . \tag{14.61}$$

In the Eqs.(14.60) and (14.61) A is

$$A \equiv 2E(V_\alpha - V_\beta) , \tag{14.62}$$

and its sign depends on the composition of the medium and on the flavour composition of the neutrino state considered. From the expressions above, we see that for a given sign of A the mixing angle in matter is larger(smaller) than in vacuum if this last one is in the first (second) octant. We see that the symmetry about $\theta = 45^\circ$ which exists in vacuum oscillations between two neutrino states is broken by the matter potential in propagation in a medium. The expressions above show that signficant effects are present when A, is close to $\Delta m^2\cos 2\theta$. In particular, as seen in Eq.(14.61), the tangent of the mixing angle changes sign if, along its path, the neutrino passes by some matter density region satisfying, for its energy, the *resonance condition*

$$A_R = \Delta m^2 \cos 2\theta . \tag{14.63}$$

This implies that if the neutrino is created in a region where the relevant potential satisfies $A_0 > A_R$ (A_0 here is the value of the relevant potential at the production point), then the effective mixing angle in matter at the production point is such that $\mathrm{sgn}(\cos 2\theta_{m,0}) = -\,\mathrm{sgn}(\cos 2\theta)$. So the flavour component of the mass eigenstates is inverted as compared to their composition in vacuum. In particular, if at the production point we have $A_0 = 2A_R$, then $\theta_{m,0} = \frac{\pi}{2} - \theta$. Asymptotically, for $A_0 \gg A_R$, $\theta_{m,0} \to \frac{\pi}{2}$. In other words, if in vacuum the lightest (heaviest) mass eigenstate has a larger projection on the flavour α (β), inside a matter with density and composition such that $A > A_R$,

the opposite holds. So if the neutrino system is traveling across a monotonically varying matter potential, the dominant flavour component of a given mass eigenstate changes when crossing the region with $A = A_R$. This phenomenon is known as *level crossing*.

Taking the derivative of Eq.(14.59) with respect to x and using Eq.(14.56), we find that in the instantaneous mass basis the evolution equation reads:

$$i\frac{d\vec{\nu}^m}{dx} = \\ = \left[\frac{1}{2E}\,\mathrm{diag}\left(\mu_1^2(x),\,\mu_2^2(x),\,\ldots,\,\mu_n^2(x)\right) - i\,\tilde{U}^\dagger(x)\,\frac{d\tilde{U}(x)}{dx}\right]\vec{\nu}^m\,. \tag{14.64}$$

The presence of the last term, Eq.(14.64) implies that this is a system of coupled equations. So, in general, the instantaneous mass eigenstates, ν_i^m are not energy eigenstates. For constant or slowly enough varying matter potential this last term can be neglected and the instantaneous mass eigenstates, ν_i^m, behave approximately as energy eigenstates, and they do not mix in the evolution. This is the *adiabatic* transition approximation. On the contrary, when the last term in Eq.(14.64) cannot be neglected, the instantaneous mass eigenstates mix along the neutrino path. This implies there can be *level-jumping* [30–33], and the evolution is *non-adiabatic*.

For adiabatic evolution in matter, the oscillation probability take a form very similar to the vacuum oscillation expression, Eq.(14.39). For example, neglecting CP violation:

$$P_{\alpha\beta} = \left|\sum_i \tilde{U}_{\alpha i}(0)\tilde{U}_{\beta i}(L)\exp\left(-\frac{i}{2E}\int_0^L \mu_i^2(x')dx'\right)\right|^2 . \tag{14.65}$$

To compute $P_{\alpha\beta}$ in a varying potential, one can always solve the evolution equation numerically. Also, several analytic approximations for specific profiles of the matter potential can be found in the literature [34].

14.5.1 *The Mikheyev-Smirnov-Wolfenstein Effect for Solar Neutrinos*

The matter effects discussed in the previous section are of special relevance for solar neutrinos. As the Sun produces ν_e's in its core, we consider the propagation of a $\nu_e - \nu_X$ neutrino system (X is some superposition of μ and τ, which is arbitrary because ν_μ and ν_τ have only and equal neutral current interactions) in the matter density of the Sun.

The density of solar matter is a monotonically decreasing function of the distance R from the center of the Sun, and it can be approximated by an exponential for $R < 0.9R_\odot$

$$n_e(R) = n_e(0)\exp\left(-R/r_0\right)\,, \tag{14.66}$$

with $r_0 = R_\odot/10.54 = 6.6\times10^7$ m $= 3.3\times10^{14}$ eV^{-1}.

As mentioned above, the nuclear reactions in the Sun produce electron neutrinos. After crossing the Sun, the composition of the neutrino state exiting the Sun will depend on the relative size of $\Delta m^2\cos2\theta$ versus $A_0 = 2\,E\,G_F\,n_{e,0}$ (where 0 refers to the neutrino production point, which is near but not exactly at the center of the Sun, $R = 0$).

If the relevant matter potential at production is well below the resonant value, $A_R = \Delta m^2\cos2\theta \gg A_0$, matter effects are negligible. With the characteristic matter density and energy of the solar neutrinos, this condition is fulfilled for values of Δm^2 such that $\Delta m^2/E \gg L_{\mathrm{Sun-Earth}}$. So the propagation occurs as in vacuum with the oscillating phase averaged to 1/2 and the survival probability at the exposed surface of the Earth is

$$P_{ee}(\Delta m^2\cos2\theta \gg A_0) = 1 - \frac{1}{2}\sin^2 2\theta > \frac{1}{2}\,. \tag{14.67}$$

If the relevant matter potential at production is only slightly below the resonant value, $A_R = \Delta m^2\cos2\theta \gtrsim A_0$, the neutrino does not cross a region with resonant density, but matter effects are sizable enough to modify the mixing. The oscillating phase is averaged in the propagation between the Sun and the Earth. This regime is well described by an adiabatic propagation, Eq.(14.65). Using that $\tilde{U}(0)$ is a 2x2 rotation of angle $\theta_{m,0}$ – the mixing angle in matter at the neutrino production point–, and $\tilde{U}(L)$ is the corresponding rotation with vacuum mixing angle θ, we get

$$P_{ee}(\Delta m^2\cos2\theta \geq A_0) = \cos^2\theta_{m,0}\cos^2\theta + \sin^2\theta_{m,0}\sin^2\theta \\ = \frac{1}{2}\left[1 + \cos2\theta_{m,0}\cos2\theta\right]\,. \tag{14.68}$$

This expression reflects that an electron neutrino produced at A_0 is an admixture of ν_1 with fraction $P_{e1,0} = \cos^2\theta_{m,0}$ and ν_2 with fraction $P_{e2,0} = \sin^2\theta_{m,0}$. On exiting the Sun, ν_1 consists of ν_e with fraction $P_{1e} = \cos^2\theta$, and ν_2 consists of ν_e with fraction $P_{2e} = \sin^2\theta$ so $P_{ee} = P_{e1,0}P_{1e} + P_{e2,0}P_{2e} = \cos^2\theta_{m,0}\cos^2\theta + \sin^2\theta_{m,0}\sin^2\theta$ [35–37], exactly as given in Eq.(14.68). Since $A_0 < A_R$ the resonance is not crossed so $\cos2\theta_{m,0}$ has the same sign as $\cos2\theta$ and still $P_{ee} \geq 1/2$.

Finally, in the case that $A_R = \Delta m^2\cos2\theta < A_0$, the neutrino can cross the resonance on its way out. In the convention of $\Delta m^2 > 0$ this occurs if $\cos2\theta > 0$ ($\theta < \pi/4$). which means that in vacuum ν_e is a combination of ν_1 and ν_2 with a larger ν_1 component, while at the production point ν_e is a combination of ν_1^m and ν_2^m with larger ν_2^m component. In particular, if the density at the production point is much higher than the resonant density, $\Delta m^2\cos2\theta \ll A_0$,

$$\theta_{m,0} = \frac{\pi}{2} \quad\Rightarrow\quad \cos2\theta_{m,0} = -1\,, \tag{14.69}$$

and the produced ν_e is purely ν_2^m.

In this regime, the evolution of the neutrino ensemble can be adiabatic or non-adiabatic depending on the particular values of Δm^2 and the mixing angle. The oscillation parameters (see Secs.14.6.1 and 14.7) happen to be such that the transition is adiabatic in all ranges of solar neutrino energies. Thus the survival probability at the exposed surface of the Earth is given by Eq.(14.68) but now with mixing angle (14.69) so

$$P_{ee}(\Delta m^2\cos2\theta < A_0) = \frac{1}{2}\left[1 + \cos2\theta_{m,0}\cos2\theta\right] = \sin^2\theta\,. \tag{14.70}$$

So, in this case, P_{ee} can be much smaller than 1/2 because $\cos2\theta_{m,0}$ and $\cos2\theta$ have opposite signs. This is referred to as the Mihheev-Smirnov-Wolfenstein (MSW) effect [26, 38], which plays a fundamental role in the interpretation of the solar neutrino data.

The resulting energy dependence of the survival probability of solar neutrinos is shown in Fig.14.3 (together with a compilation of data from solar experiments). The plotted curve corresponds to $\Delta m^2 \sim 7.5\times10^{-5}$ eV^2 and $\sin^2\theta \sim 0.3$ (the so-called large mixing angle, LMA, solution). The figure illustrates the regimes described above. For these values of the oscillation parameters, neutrinos with $E \ll 1$ MeV are in the regime with $\Delta m^2\cos2\theta \gg A_0$ so the curve represents the value of vacuum averaged survival probability, Eq.(14.67), and therefore $P_{ee} > 0.5$. For $E > 10$ MeV, on the contrary, $\Delta m^2\cos2\theta \ll A_0$ and the survival probability is given by Eq.(14.70), so $P_{ee} = \sin^2\theta \sim 0.3$. In between, the survival probability is given by Eq.(14.68) with θ_0 changing rapidly from its vacuum value to the asymptotic matter value (14.69), 90°.

14.6 Experimental Study of Neutrino Oscillations

Neutrino flavour transitions, or neutrino oscillations, have been experimentally studied using various neutrino sources and detection techniques. Intense sources and large detectors are mandatory because of a large distance necessary for observable oscillation effects in addition to the tiny cross-sections. Also, the relevant neutrino flux before oscillations should be known with sufficient precision for a definitive measurement. Here, the experimental status of neutrino oscillations with the different neutrino sources: the Sun, Earth's atmosphere, accelerators, and nuclear reactors are reviewed.

14.6.1 *Solar Neutrinos*

14.6.1.1 *Solar neutrino flux*

In the Sun, electron neutrinos are produced in the thermonuclear reactions which generate solar energy. These reactions occur via two main chains, the *pp* chain and the CNO cycle. The *pp* chain includes reactions $p+p \to d+e^+ +\nu$ (*pp*), $p+e^- +p \to d+\nu$ (*pep*), $^3\mathrm{He}+p \to {}^4\mathrm{He}+e^+ +\nu$ (*hep*), $^7\mathrm{Be}+e^- \to {}^7\mathrm{Li}+\nu(+\gamma)$ (^{7}Be), and $^8\mathrm{B} \to {}^8\mathrm{Be}^* + e^+ + \nu$ (^{8}B). The CNO cycle involves $^{13}\mathrm{N} \to {}^{13}\mathrm{C}+e^+ +\nu$ (^{13}N), $^{15}\mathrm{O} \to {}^{15}\mathrm{N}+e^+ +\nu$ (^{15}O), and $^{17}\mathrm{F} \to {}^{17}\mathrm{O}+e^+ +\nu$ (^{17}F). Those reactions result in the overall fusion of protons into ^{4}He, $4p \to {}^4\mathrm{He}+2e^+ +2\nu_e$, where the energy released in the reaction, $Q = 4m_p - m_{^4\mathrm{He}} - 2m_e \sim 26$ MeV, is mostly radiated through the photons and only a small fraction is carried by the neutrinos, $\langle E_{2\nu_e} \rangle = 0.59$ MeV. In addition, electron capture on ^{13}N, ^{15}O, and ^{17}F produces line spectra of neutrinos called ecCNO neutrinos. Dividing the solar luminosity by the energy released per neutrino production, the total neutrino flux can be estimated. At Earth, the *pp* solar neutrino flux is about 6×10^{10} cm^{-2}s^{-1}.

The solar neutrino flux has been calculated based on the Standard Solar Model (SSM). The SSM describes the structure and evolution of the Sun based on a variety of inputs such as the mass, luminosity, radius, surface temperature, age, and surface elemental abundances. In addition, the knowledge of the absolute nuclear reaction cross sections for relevant fusion reactions and radiative opacities are necessary. John Bahcall and his collaborators continuously updated the SSM calculations over several decades [39,40]. Figure 14.1 shows the solar neutrino fluxes predicted by the SSM calculation in [41] and ecCNO neutrinos in [42].

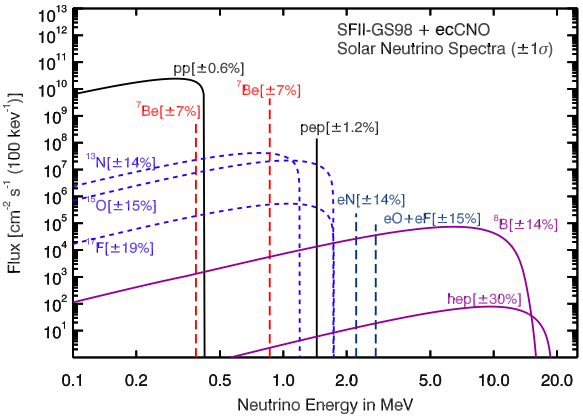

Figure 14.1: Spectrum of solar neutrino fluxes predicted by SSM calculation in [41]. In addition to standard fluxes, ecCNO neutrinos have been added based on [42]. Electron capture fluxes are given in cm^{-2}s^{-1}. Taken from [43].

14.6.1.2 *Detection of solar neutrinos and the solar neutrino problem*

Experiments that observed solar neutrinos are summarized in Table 14.2. A pioneering solar neutrino experiment was carried out by R. Davis, Jr. and collaborators at Homestake starting in the late 1960s [44]. The Davis' experiment utilizes the reaction $\nu_e + {}^{37}\mathrm{Cl} \to e^- + {}^{37}\mathrm{Ar}$. Because this process has an energy threshold of 814 keV, the most relevant fluxes are the ^{7}Be and ^{8}B neutrinos. The detector contained ~ 615 t of C_2Cl_4. The produced ^{37}Ar, which has a half-life of 34.8 days, was chemically extracted and introduced into a low-background proportional chamber every few months. The Auger electrons from electron capture of ^{37}Ar were counted to determine the reaction rate.

From the beginning, the observed number of neutrinos in the Homestake mine experiment was significantly smaller than the prediction by SSM — it was almost one-third. After thorough checks of both experimental and theoretical work, the discrepancy remained. This became to be known as the solar neutrino problem. The final result from the Homestake experiment is $2.56 \pm 0.16 \pm 0.16$ SNU [45], where SNU (solar neutrino unit) is a unit of event rate, 1 SNU $= 10^{-36}$ captures/(s atom). On the other hand, prediction based on SSM is $8.46^{+0.87}_{-0.88}$ SNU [46].

The detection of neutrinos from other production processes was recognized as an important input to investigate the origin of the solar neutrino problem. In particular, the *pp* neutrino is most abundant, and its flux prediction has the smallest uncertainty. Using the radiochemical technique with gallium, the reaction $\nu_e + {}^{71}\mathrm{Ga} \to e^- + {}^{71}\mathrm{Ge}$ has an energy threshold of 233 keV and can be used for the *pp* neutrino detection. According to the SSM, more than half of the events on ^{71}Ga are due to the *pp* neutrinos, with the second dominant contribution coming from the ^{7}Be neutrinos. ^{71}Ge decays via electron capture with a half-life of 11.4 days. The SAGE experiment in Baksan [47] used about 50 t of liquid metallic gallium as a target. The GALLEX experiment in LNGS [48] used 101 t of $GaCl_3$, containing 30.3 t of gallium. Both experiments used natural gallium, containing 39.9% of ^{71}Ga isotope. GALLEX was followed by its successor GNO experiment. The measured capture rate is $69.3 \pm 4.1 \pm 3.6$ SNU for GALLEX+GNO [49] and $65.4^{+3.1+2.6}_{-3.0-2.8}$ SNU for SAGE [50]. A SSM prediction is $127.9^{+8.1}_{-8.2}$ SNU [46].

The radiochemical detectors measure the reaction rate integrated between extractions. The real-time measurement of solar neutrinos was realized by the Kamiokande experiment [51]. The Kamiokande detector was a 3,000-t water-Cherenkov detector in the Kamioka mine. Super-Kamiokande, the successor of Kamiokande, started operation in 1996. It is a large upright cylindrical water Cherenkov detector containing 50 kt of pure water [4]. An inner detector volume corresponding to 32 kt water mass is viewed by more than 11,000 inward-facing 50 cm diameter photomultiplier tubes (PMTs). Kamiokande and Super-Kamiokande can observe solar neutrinos using ν-e elastic scattering (ES), $\nu_x + e^- \to \nu_x + e^-$. The ES reaction occurs via both charged and neutral current interactions. Consequently, it is sensitive to all active neutrino flavours, although the cross-section for ν_e, which is the only flavour to interact via charged current, is about six times larger than that for ν_μ or ν_τ. Because the energy threshold is 6.5 MeV for Kamiokande and 3.5 MeV for the present Super-Kamiokande (for the kinetic energy of recoil electron), these experiments are sensitive to primarily to ^{8}B neutrinos.

The results from Kamiokande [52] and Super-Kamiokande [53] showed significantly smaller numbers of observed solar neutrinos compared to the prediction. The latest solar neutrino flux observed by Super-Kamiokande is $(2.345 \pm 0.014 \pm 0.036) \times 10^6$ cm^{-2}s^{-1} [54], while a prediction based on the SSM is $(5.46 \pm 0.66) \times 10^6$ cm^{-2}s^{-1} [55]. In addition, no significant zenith angle variation nor spectrum distortion were observed in the initial phase of Super-Kamiokande, which placed strong constraints on the solution of the solar neutrino problem [56].

14.6.1.3 *Solution of the solar neutrino problem*

The SNO experiment in Canada used 1,000 t of heavy water (D_2O) contained in a spherical acrylic vessel which was surrounded by an H_2O shield. An array of PMTs installed on a stainless steel structure detected Cherenkov radiation produced in both the D_2O and H_2O. The SNO detector observed ^{8}B neutrinos via three different reactions. In addition to the ES scattering with an electron, with D_2O target the CC $\nu_e + d \to e^- + p + p$ and the NC $\nu_x + d \to \nu_x + p + n$ interactions are possible. The CC reaction is sensitive to only ν_e, while NC reaction is sensitive to all active flavours of neutrinos with equal cross-sections. Therefore, by comparing the measurements of different reactions, SNO could provide a model-independent test of the neutrino flavour change [57].

In 2001, SNO reported the initial result of CC measurement [60]. Combined with the high statistics measurement of ν-e elastic scattering from Super-Kamiokande [61], it provided a direct evidence for the existence of non-ν_e component in solar neutrino flux. The result of the NC measurement in 2002 [62] established it with 5.3σ of statistical significance. Figure 14.2 shows the fluxes of electron neutrinos ($\phi(\nu_e)$) and muon and tau

[4] Recently, gadolinium (0.01% by weight in 2020, 0.03% in 2022) is loaded in the water.

Table 14.2: List of solar neutrino experiments

Name	Target material	Energy threshold (MeV)	Mass (ton)	Years
Homestake	C_2Cl_4	0.814	615	1970–1994
SAGE	Ga	0.233	50	1989–
GALLEX	$GaCl_3$	0.233	100 [30.3 for Ga]	1991–1997
GNO	$GaCl_3$	0.233	100 [30.3 for Ga]	1998–2003
Kamiokande	H_2O	6.5	3,000	1987–1995
Super-Kamiokande	H_2O	3.5	50,000	1996–
SNO	D_2O	3.5	1,000	1999–2006
KamLAND	Liquid scintillator	0.5/5.5	1,000	2001–
Borexino	Liquid scintillator	0.19	300	2007–2021

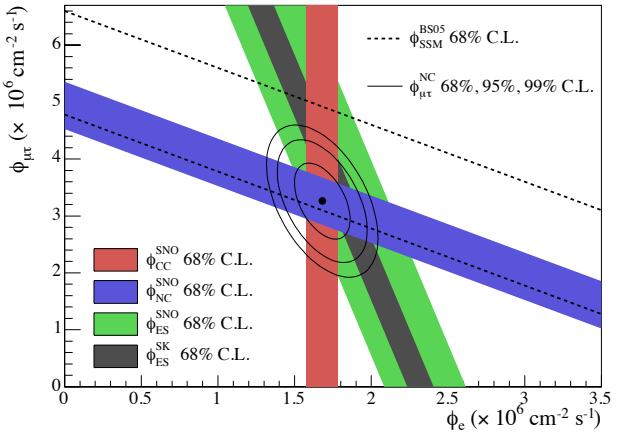

Figure 14.2: Fluxes of ^{8}B solar neutrinos, $\phi(\nu_e)$, and $\phi(\nu_{\mu,\tau})$, deduced from the SNO's CC, ES, and NC results [58]. The Super-Kamiokande ES flux is from [59]. The BS05(OP) standard solar model prediction [40] is also shown. The bands represent the 1σ error. The contours show the 68%, 95%, and 99% joint probability for $\phi(\nu_e)$ and $\phi(\nu_{\mu,\tau})$. The figure is from [58].

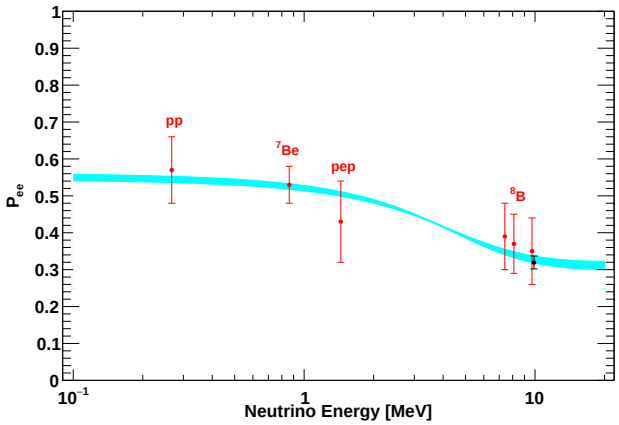

Figure 14.3: Electron neutrino survival probability as a function of neutrino energy. The points represent, from left to right, the Borexino pp, ^{7}Be, pep, and ^{8}B data (red points) and the SNO+SK ^{8}B data (black point). The three Borexino ^{8}B data points correspond, from left to right, to the low-energy (LE) range, LE+HE range, and the high-energy (HE) range. The electron neutrino survival probabilities from experimental points are determined using a high metallicity SSM from [55]. The error bars represent the $\pm1\sigma$ experimental + theoretical uncertainties. The curve corresponds to the $\pm1\sigma$ prediction of the MSW-LMA solution using the parameter values given in [64]. This figure is provided by A. Ianni.

neutrinos ($\phi(\nu_{\mu,\tau})$) with the 68%, 95%, and 99% joint probability contours obtained with the SNO data. Finally, together with the reactor neutrino experiment KamLAND (see Sec.14.6.4), the solution of solar neutrino problem was found to be the MSW adiabatic flavour transitions in the solar matter, the so-called large mixing angle (LMA) solution. From a combined result of three phases of SNO [63], the total flux of ^{8}B solar neutrino is found to be $(5.25 \pm 0.16^{+0.11}_{-0.13})$ cm^{-2}s^{-1}, consistent with the SSM prediction. This consistency is one of the major accomplishments of SSM.

In order to understand the SSM as well as to study the MSW effect for the solar neutrino, measurements of solar neutrinos other than ^{8}B are important. The Borexino experiment at Gran Sasso detected solar neutrino via ν-e scattering in real-time with a low energy threshold. The Borexino detector consisted of 300 t of ultra-pure liquid scintillator, which achieved 0.19 MeV of energy threshold and 5% energy resolution at 1 MeV. Borexino reported the first real-time detection of ^{7}Be solar neutrinos [65]. They also measured the fluxes of *pep* [66], *pp* [67], and CNO [68] neutrino for the first time. Together with ^{8}B [69] neutrino measurement, Borexino provides important data to study the MSW effect. The KamLAND experiment also measured solar neutrinos [70, 71].

Figure 14.3 shows the survival probability of solar ν_e as a function of neutrino energy. The data points are from the Borexino results [72, 73] and the SNO+SK ^{8}B data. The theoretical curve shows the prediction of the MSW-LMA solution. All the data shown in this plot are consistent with the theoretically calculated curve. This indicates that these solar neutrino measurements are consistent with the MSW-LMA solution of the solar neutrino problem.

The matter effects can also be relevant to the propagation of solar neutrinos through the Earth. Because solar neutrinos go through the Earth before interaction in the detector during the nighttime, a comparison of measured event rate between daytime and nighttime provides a clean and direct test of matter effects on neutrino oscillations. Super-Kamiokande reported the indication of the day/night asymmetry in ^{8}B solar neutrinos [54]. The measured asymmetry, defined as the difference of the average day rate and average night rate divided by the average of those two rates, is $(-3.3 \pm 1.0 \pm 0.5)\%$, corresponding to a statistical significance of 2.9σ.

14.6.2 *Atmospheric Neutrinos*

14.6.2.1 *Atmospheric neutrino flux*

Atmospheric neutrinos are produced by the decays of pions and kaons generated in the interaction of cosmic rays and nucleons in the Earth's atmosphere. They have a broad range of energy (∼0.1 GeV to >TeV) and long travel distances before detection (∼10 to ∼ 10^4 km), and contain all the flavours of neutrinos and antineutrinos.

Considering their dominant production modes, some generic relations for flux ratios of different flavours of neutrinos can be derived without detailed calculations. From the decay chain of a charged pion $\pi^+ \to \mu^+\nu_\mu$ followed by $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$ (and the charge conjugate for π^-), the ratio $(\nu_\mu+\bar{\nu}_\mu)/(\nu_e+\bar{\nu}_e)$ is expected to be around 2 at low energies (∼ 1 GeV), where most muons decay in the atmosphere. For higher energies, some muons reach the Earth before they decay and the ratio increases. One can also

expect that the zenith angle distributions of atmospheric neutrinos are symmetric between upward-going and downward-going neutrinos. It is true for the energy above 1 GeV, but at lower energies, the Earth's geomagnetic field induces up-down asymmetries in the primary cosmic ray. The zenith angle corresponds to the flight length of atmospheric neutrinos. Vertically upward-going neutrinos come from the other side of the Earth with flight lengths of $\sim 10^4$ km, while downward-going neutrinos produced just above the experimental site travel ∼10 km before detection.

The atmospheric neutrino fluxes are calculated in detail based on the energy spectrum and composition of primary cosmic rays and their hadronic interactions in the atmosphere. The effects of solar activity and geomagnetic field are also taken into account. Results of calculations by several groups are available [74–77]. A typical uncertainty of the absolute flux is 10–20%, while the ratio of fluxes between different flavour has much smaller uncertainty ($< 5\%$).

14.6.2.2 *Observation of atmospheric neutrino oscillations*

The first detection of atmospheric neutrinos was reported in the 1960's by the underground experiments in the Kolar Gold Field experiment in India [78] and in South Africa [79]. In the 1980's, experiments searching for nucleon decays started operation. They used large underground detectors which could also observe atmospheric neutrinos that were studied as backgrounds to nucleon decays. Among the early experiments were Kamiokande [80] and IMB [81] using water Cherenkov detectors, and Frejus [82] and NUSEX [83] using iron tracking calorimeters.

The flavour of an atmospheric neutrino can be identified in charged current interaction with nuclei, which produces the corresponding charged lepton. Those detectors originally designed for nucleon decay search had the capability to distinguish muons and electrons. For example, a water Cherenkov detector can utilize the information from Cherenkov ring patterns for particle identification; e-like particles ($e^{\pm}$, γ) produce more diffuse ring than μ-like particles ($\mu^{\pm}$, $\pi^{\pm}$) because of electromagnetic cascades and multiple Coulomb scattering effects.

To reduce the uncertainty, in early results the flux ratio $\nu_\mu/\nu_e \equiv (\nu_\mu + \bar{\nu}_\mu)/(\nu_e + \bar{\nu}_e)$ was measured, and the double ratio between observation and expectation $(\nu_\mu/\nu_e)_{\rm obs}/(\nu_\mu/\nu_e)_{\rm exp}$ was reported. The Kamiokande experiment reported an indication of a deficit of $(\nu_\mu + \bar{\nu}_\mu)$ flux [80]. IMB also observed a similar deficit [81], but measurements by Frejus [82] and NUSEX [83] were consistent with the expectations. This was called the atmospheric neutrino anomaly. Kamiokande reported studies with an increased data set of the sub-GeV (< 1.33 GeV) [84] as well as the multi-GeV (> 1.33 GeV) [85] samples. In the latter, they reported an analysis of zenith angle distributions, which showed an indication that the muon disappearance probability is dependent on the zenith angle, hence the travel length of neutrinos. However, the statistical significance was not sufficient to provide a conclusive interpretation.

The solution to the atmospheric neutrino anomaly was brought by Super-Kamiokande, which reported compelling evidence for neutrino oscillations in atmospheric neutrinos in 1998 [86]. The zenith angle (θ_z, with $\theta_z = 0$ for vertically downward-going) distributions of μ-like events showed a clear deficit of upward-going events, while no significant asymmetry was observed for e-like events. The asymmetry is defined as $A = (U-D)/(U+D)$, where U is the number of upward-going ($-1 < \cos\theta_z < -0.2$) events and D is the number of downward-going ($0.2 < \cos\theta_z < 1.0$) events. With multi-GeV (visible energy > 1.33 GeV) μ-like events alone, the measured asymmetry was $A = -0.296 \pm 0.048 \pm 0.001$, deviating from zero by more than 6σ. The sub-GeV (< 1.33 GeV) μ-like, upward through going, and upward stopping μ samples which correspond to different energy ranges of neutrinos, showed the consistent behaviour which strengthens the credibility of the observation. Super-Kamiokande's results were confirmed by other atmospheric neutrino observations MACRO [87] and Soudan2 [88].

Although the energy and zenith-angle-dependent muon neutrino disappearance observed with atmospheric neutrinos could be consistently explained by the neutrino oscillations predominantly between ν_μ and ν_τ, other exotic explanations such as neutrino decay [89] or decoherence [90] were not initially ruled out. By using a selected sample from Super-Kamiokande's atmospheric data with good L/E resolution, the L/E dependence of the survival probability was measured [91]. The observed dip in the L/E distribution was consistent with the expectation from neutrino oscillation, while alternative models were strongly disfavored.

As an experimental proof of ν_μ-ν_τ oscillation, an appearance signal of ν_τ was searched for in the atmospheric neutrino data. Because of the high energy threshold (> 3.5 GeV) of ν_τ CC interaction and the short lifetime of τ lepton (0.3 ps), identifying the appearance of ν_τ experimentally is challenging. Super-Kamiokande reported evidence of tau neutrino appearance using atmospheric neutrino data with 4.6σ significance [92]. The definitive observation of ν_τ appearance was made by the long-baseline experiment, OPERA (See Sec.14.6.3.3), and recently IceCube also reported the ν_τ appearance analysis [93] using atmospheric neutrinos.

14.6.2.3 *Neutrino oscillation measurements using atmospheric neutrinos*

Figure 14.4 shows the zenith angle distributions of atmospheric neutrino data from Super-Kamiokande. For a wide range of neutrino energy and path length, the observed distributions are consistent with the expectation from neutrino oscillation. Atmospheric neutrinos in the energy region of a few to ∼10 GeV provide information for the determination of the neutrino mass ordering [94].

The neutrino telescopes primarily built for high-energy neutrino astronomy such as ANTARES and IceCube can also measure neutrino oscillations with atmospheric neutrinos. ANTARES consists of a sparse array of PMTs deployed under the Mediterranean Sea at a depth of about 2.5 km to instrument a 10^5 m^3 volume. IceCube is a detector deployed in ice in Antarctica at the South Pole, at a depth between 1.45 and 2.45 km. In the bottom center of IceCube there is a region of $\sim 10^7$ m^3 volume with denser PMT spacing called DeepCore to extend the observable energies to the lower energy region. By observing the charged current interaction of up-going ν_μ, they measure the ν_μ disappearance. ANTARES reported a measurement of ν_μ disappearance with 20 GeV threshold [95]. The ν_μ disappearance measurements from IceCube DeepCore [96] provided a precision comparable to the measurements by Super-Kamiokande and long-baseline accelerator neutrino experiments.

There are several projects for atmospheric neutrino observations either proposed or under preparation. The atmospheric neutrino observation program is included in the plans for future neutrino telescopes such as ORCA in the KM3NeT project [97] in the Mediterranean Sea and the IceCube Upgrade [98]. In India, a 50 kt magnetized iron tracking calorimeter ICAL is planned at the INO [99]. Future large underground detectors, Hyper-Kamiokande in Japan [100] and DUNE in US [101] can also study the atmospheric neutrinos.

14.6.3 *Accelerator Neutrinos*

14.6.3.1 *Accelerator neutrino beams*

A comprehensive description of the accelerator neutrino beams is found in [102]. Conventional neutrino beams from accelerators are produced by colliding high-energy protons onto a target, producing π and K, which then decay into neutrinos. Undecayed mesons and muons are stopped in a beam dump and soil. Because pions are the most abundant product of the high energy collisions, a conventional neutrino beam contains a dominant amount of muon-type neutrinos (or antineutrinos).

Focusing devices called magnetic horns are used to concentrate the neutrino beam flux towards the desired direction [103]. A magnetic horn is a pulsed electromagnet with toroidal magnetic fields to focus charged particles that are parents of neutrinos. One can choose the dominant component of the beam to be either neutrinos or antineutrinos by selecting the direction of current in the magnetic horns. Even with the focusing with horns, *wrong sign* neutrinos contaminate in the beam. Also, there is a small amount of contamination of ν_e and $\bar{\nu}_e$ coming primarily from kaon and muon decays.

In order to maximize the sensitivity of the experiment, the ratio of baseline and neutrino energy (L/E) should be chosen to match the oscillation effects to be studied. In addition to maximizing the flux of neutrinos with relevant energy, neutrinos with irrele-

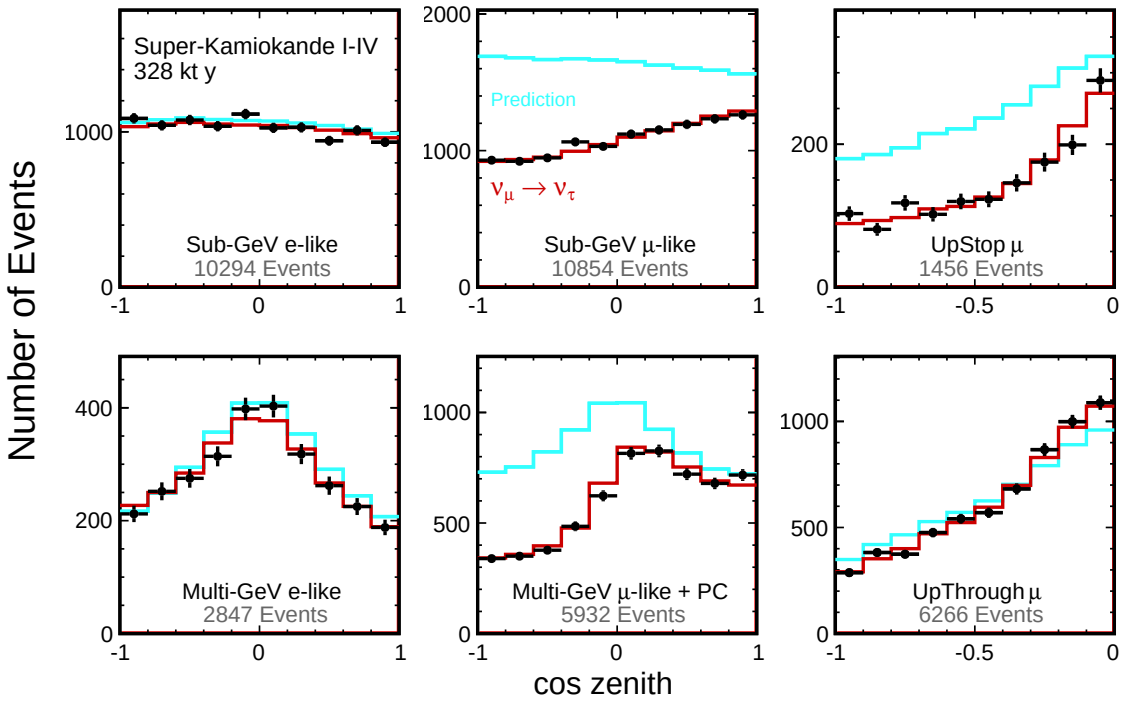

Figure 14.4: The zenith angle distributions of Super-Kamiokande atmospheric neutrino events. A data set corresponding to 328 kton-years of exposure is used. Fully contained 1-ring e-like and μ-like events with visible energy < 1.33 GeV (sub-GeV) and > 1.33 GeV (multi-GeV), as well as upward stopping and upward through going μ samples are shown. Partially contained (PC) events are combined with multi-GeV μ-like events. The blue histograms show the non-oscillated Monte Carlo events, and the red histograms show the best-fit expectations for neutrino oscillations. (This figure is provided by the Super-Kamiokande Collaboration)

vant energy that result in unwanted background process should be suppressed. The energy of a neutrino from a pion decay is

$$E_\nu = \frac{[1-(m_\mu/m_\pi)^2]E_\pi}{1+\gamma^2\theta^2}, \qquad (14.71)$$

where E_ν and E_π are the energy of neutrino and pion, respectively, θ is the angle between the pion and neutrino direction, and $\gamma = E_\pi/m_\pi$. For $\theta = 0$, the energy of neutrino is linearly proportional to the energy of pion. In this case, a narrow band beam can be made by selecting the momentum of pions. On the other hand, for $\theta \neq 0$, the energy of neutrino is not strongly dependent on the parent energy for a wide range of pion energy, but dependent on the off-axis angle θ. Using this relation, a neutrino beam with narrow energy spectrum, around the energy determined by θ, can be produced. This off-axis beam method was first introduced for BNL E889 proposal [104] and adopted in T2K and NOvA experiments. For a list of neutrino beamlines, see also Chapter 33 of this *Review*, "Neutrino Beam Lines at High-Energy Proton Synchrotrons."

As indicated in Table 14.1, there are two different scales of baselines for accelerator-based experiments to study different ranges of Δm^2. The atmospheric mass splitting $\Delta m^2 \sim 2.5 \times 10^{-3}$ eV^2 gives rise to the first oscillation maximum at $L/E \sim 500$ GeV/km. In order to study this parameter region with a ~ 1 GeV accelerator neutrino beam, a long baseline of a few hundred to a thousand km is necessary. On the other hand, there have been reports of possible neutrino oscillations at the ~ 1 eV^2 scale, which can be studied at ~ 1 km baseline with neutrinos from accelerators. These experiments are called short-baseline oscillation experiments.

The flux of a neutrino beam is calculated using Monte Carlo simulation based on the configuration of the beamline. An important ingredient of the neutrino flux prediction is the hadron production cross-section. Data from dedicated hadron production experiments [105–108] are used to tune the beam simulation and constrain the uncertainty. The uncertainty of predicted neutrino flux for the most relevant energy region is 5–10% with the latest hadron production data [109–111].

14.6.3.2 *Near detectors and neutrino interaction cross sections*

Many long-baseline experiments use two detectors to reduce the systematic uncertainties arising from neutrino flux and neutrino-nucleus interactions. The near detectors either use the same technology as the far detector or consist of sub-detectors with complementary functions to obtain detailed information of the neutrino beam and interactions. The near detectors provide information for the neutrino flux, energy spectrum, and the interaction cross-sections, which is used as input to make predictions of observables at the far detector. However, even with the two-detector configuration, one should note that the neutrino flux is inevitably different between the near and the far detectors. In addition to the fact that the neutrino source looks like a line source for the near detector while it looks like a point source for the far detector, the neutrino oscillations alter the flavour composition of the neutrino beam quite significantly, as the design of a neutrino oscillation experiment requires.

For the precision measurements of neutrino oscillations with long-baseline experiments, the understanding of the neutrino-nucleus interaction becomes crucial. Because heavy nuclei are used as the interaction target, the nuclear effects complicate the understanding of the neutrino-nucleus interaction. For more information on the neutrino cross-sections, see also Chapter 52 of this *Review*, "Neutrino Cross Section Measurements."

14.6.3.3 *Long-baseline experiments*

Long-baseline neutrino oscillation experiments are summarized in Table 14.3. The first long-baseline experiment was the K2K experiment which used a neutrino beam from the KEK 12 GeV proton synchrotron directed towards Super-Kamiokande with a baseline of 250 km. The beam had an average energy of 1.3 GeV. The K2K near detectors, located 300 m downstream of the production target, consisted of a combination of a 1 kt water Cherenkov detector and a set of fine-grained detectors. K2K confirmed the muon neutrino disappearance originally reported by Super-Kamiokande atmospheric neutrino observation [112].

The MINOS experiment used a beam from Fermilab and a de-

Table 14.3: List of long-baseline neutrino oscillation experiments

Name	Beamline	Far Detector	L (km)	E_ν (GeV)	Year
K2K	KEK-PS	Water Cherenkov	250	1.3	1999–2004
MINOS	NuMI	Iron-scintillator	735	3	2005–2013
MINOS+	NuMI	Iron-scintillator	735	7	2013–2016
OPERA	CNGS	Emulsion hybrid	730	17	2008–2012
ICARUS	CNGS	Liquid argon TPC	730	17	2010–2012
T2K	J-PARC	Water Cherenkov	295	0.6	2010–
NOvA	NuMI	Liquid scint. tracking calorimeter	810	2	2014–
DUNE	LBNF	Liquid argon TPC	1300	2–3	
Hyper-Kamiokande	J-PARC	Water Cherenkov	295	0.6	

tector in the Soudan mine 735 km away. The neutrino beam is produced in the NuMI beamline with a 120 GeV proton beam from the Main Injector. The MINOS detectors were both iron-scintillator tracking calorimeters with toroidal magnetic fields. The far detector was 5.4 kt, while the near detector had a total mass of 0.98 kt and was located 1 km downstream of the production target. The energy spectrum of the NuMI beamline can be varied by changing the relative position of the target and horns. Most of MINOS data were taken with the "low energy" configuration with a peak energy of around 3 GeV. Since 2013, NuMI was operated with a "medium energy" configuration with the peak neutrino energy of around 7 GeV. The experiment for this period was called MINOS+. MINOS and MINOS+ combined accelerator and atmospheric neutrino data in both disappearance and appearance modes to measure oscillation parameters [113, 114].

In Europe, the CNGS neutrino beamline provided a beam with mean energy of 17 GeV from CERN to LNGS for long-baseline experiments with about 730 km of baseline. The beam energy was chosen so that CC interaction of ν_τ can occur for direct confirmation of ν_τ appearance. There was no near detector in CNGS because it was not necessary for the ν_τ appearance search. The OPERA experiment used a detector consisting of an emulsion/lead target with about 1.25 kt total mass, complemented by electronic detectors. The excellent spatial resolution of the emulsion enabled the event-by-event identification of τ leptons. OPERA observed ten ν_τ CC candidate events with 2.0±0.4 expected background [115] and confirmed $\nu_\mu \to \nu_\tau$ oscillation in appearance mode with a statistical significance of 6.1σ. Another neutrino experiment, ICARUS [116], which used 600 t liquid argon time projection chambers (TPCs), was operated in Gran Sasso from 2010 to 2012.

The first generation of long-baseline experiments confirmed the existence of neutrino oscillation. The major initial goal of second-generation experiments was the observation of $\nu_\mu \to \nu_e$ oscillation. Using this appearance mode, and by comparison of neutrino and antineutrino oscillation probabilities, search for CP violation in the neutrino mixing and measurement of the mass ordering and the octant of θ_{23} become possible.

The T2K experiment started in 2010 using a newly constructed high-intensity proton synchrotron J-PARC and the Super-Kamiokande detector. It is the first long-baseline experiment to employ the off-axis neutrino beam. The off-axis angle of 2.5° was chosen to set the peak of the neutrino energy spectrum at 0.6 GeV, matching the first maximum of oscillation probability at the 295 km baseline for $\Delta m^2 \sim 2.5 \times 10^{-3}$ eV^2. T2K employs a set of near detectors at about 280 m from the production target. In 2011, T2K reported the first indication of $\nu_\mu \to \nu_e$ oscillation with a statistical significance of 2.5σ [117]. In the framework of 3ν mixing, it corresponds to detecting non-zero amplitude generated by the mixing angle θ_{13} (see Eq.14.33). Later $\nu_\mu \to \nu_e$ oscillation was established by T2K with more than 7σ in 2014 [118]. Figure 14.5 shows the observed kinematic distributions from T2K, for neutrino and antineutrino beam mode and also for muon and electron candidates. By a combined analysis of the neutrino and antineutrino data, T2K reported a hint of CP violation at the 2σ level [119].

The NOvA experiment uses the upgraded NuMI beamline with an off-axis configuration. The 14 kt NOvA far detector is located near Ash River, Minnesota, 810 km away from the source. At 14.6 mrad off-axis from the central axis of the NuMI beam, the neutrino energy spectrum at the far detector has a peak of around 2 GeV. The near detector, located around 1 km from the source, has a functionally identical design to the far detector with a total mass of 290 t. Both detectors are tracking calorimeters consisting of planes of polyvinyl chloride cells alternating in vertical and horizontal orientation filled with liquid scintillator. The physics run of NOvA was started in 2014. After confirmation of ν_e appearance from ν_μ beam [120], NOvA started data taking with antineutrino beam in 2016. Using the antineutrino beam data, NOvA has reported the observation of $\bar{\nu}_e$ appearance from $\bar{\nu}_\mu$ beam with 4.4σ significance [121]. Figure 14.6 shows the reconstructed neutrino energy distributions from NOvA [122]. The NOvA data do not show a strong asymmetry in the rate of ν_e versus $\bar{\nu}_e$ appearance, excluding $\delta_{\rm CP} = 90°$ for the inverted mass ordering ($m_3 < m_2 < m_1$, see Sec.14.7 for definitions) with $> 3\sigma$ and disfavouring $\delta_{\rm CP} = 270°$ for the case of normal mass ordering ($m_1 < m_2 < m_3$, see Sec.14.7 for definitions) with $> 2\sigma$.

Two large-scale long-baseline experiments are under construction. DUNE [101] will be a 1,300 km long-baseline experiment based in the US. The DUNE far detector will consist of four modules of at least 10 kt fiducial mass liquid argon time projection chambers, located 1.5 km underground at the Sanford Underground Research Facility in South Dakota. The beamline for DUNE, 1.2 MW at start and upgradable to 2.4 MW, as well as the facility for near detectors will be newly constructed at Fermilab. The Hyper-Kamiokande detector [100] in Japan will be the successor of the Super-Kamiokande detector. It will be a water Cherenkov detector with 260 kt total water mass. With upgrades to the existing accelerator and beamline, J-PARC will provide a 1.3 MW neutrino beam to Hyper-Kamiokande with a baseline of 295 km. Both DUNE and Hyper-Kamiokande will have a rich physics program besides the long-baseline experiment, such as searches for nucleon decays and study of supernova neutrinos.

14.6.3.4 *Short-baseline experiments*

The LSND experiment searched for neutrino oscillation using neutrinos from stopped pions at Los Alamos. A 800 MeV linac was used to produce pions that stopped in the target. Most of π^-s are absorbed by the nuclei inside the target, while π^+s and their daughter μ^+s decay and produce neutrinos. Therefore, the produced neutrinos are mostly ν_μ, $\bar{\nu}_\mu$, and ν_e with minimal contamination of $\bar{\nu}_e$. The detector was a tank filled with 167 t of diluted liquid scintillator, located about 30 m from the neutrino source. LSND searched for $\bar{\nu}_\mu \to \bar{\nu}_e$ appearance using the inverse beta decay process, $\bar{\nu}_e + p \to e^+ + n$, and found an excess of $87.9 \pm 22.4 \pm 6.0$ events over the expected background [123].

The KARMEN experiment was performed at the neutron spallation facility ISIS of the Rutherford Appleton Laboratory. The KARMEN 2 detector was a segmented liquid scintillation calorimeter with a total volume of 65 m^3 located at a mean distance of 17.7 m from the ISIS target. KARMEN found a number of events consistent with the total background expectation, showing no signal for $\bar{\nu}_\mu \to \bar{\nu}_e$ oscillations [124]. The resulting limits exclude large regions of the parameter area favored by LSND.

The MiniBooNE experiment at Fermilab used a conventional neutrino beam to search for ν_e and $\bar{\nu}_e$ appearance in the same

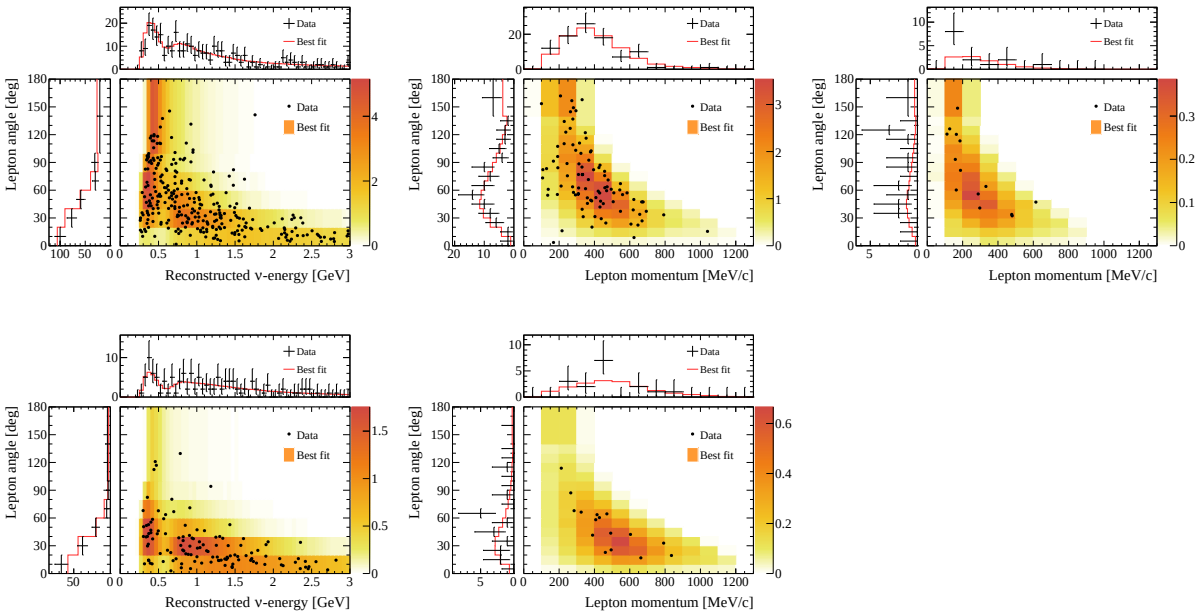

Figure 14.5: Observed kinematic distributions from T2K compared to the expectations with the best-fit parameters [119]. Top and bottom panels correspond to data from neutrino and antineutrino beam mode, respectively. Left, middle, and right panels show distributions for single ring μ-like events, single ring e-like events with no associated decay electron, and single ring e-like events with one associated decay electron (only for neutrino beam mode data), respectively.

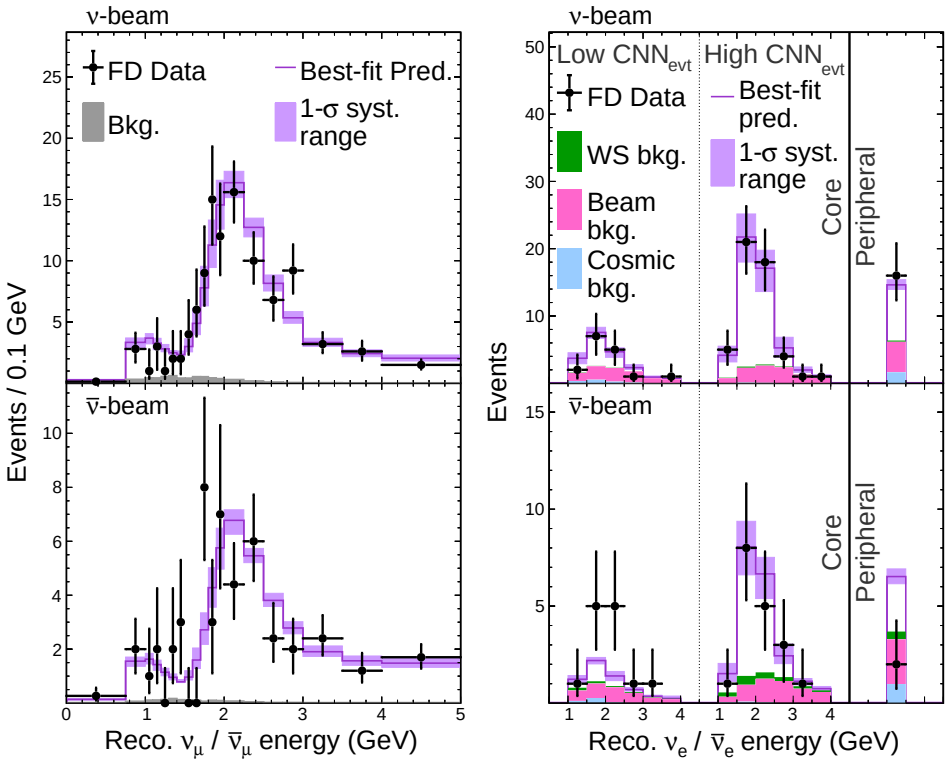

Figure 14.6: Reconstructed neutrino energy distributions from the NOvA far detector [122]. Top plots are for neutrino beam mode, and bottom plots are for antineutrino beam mode. Left: muon-type candidates. Right: electron-type candidates, split into a low and high purity sample as well as the event counts in the peripheral sample which occurred near the edge of the detector.

parameter region as LSND. The booster neutrino beamline (BNB) with a single magnetic horn uses an 8 GeV proton beam from the Fermilab booster to produce a neutrino (antineutrino) beam with an energy spectrum peak of 600 (400) MeV. The MiniBooNE detector consists of a 12.2 m diameter sphere filled with 818 t of mineral and oil located 541 m from the target. MiniBooNE reported ν_e and $\bar{\nu}_e$ event excess in both neutrino and antineutrino running modes. In total, $638.0 \pm 52.1 \pm 122.2$ excess events are observed over the expected backgrounds, corresponding to 4.8σ significance [125].

Both LSND and MiniBooNE are single detector experiments. The short-baseline neutrino (SBN) program at Fermilab BNB [126] is further investigating the reported excess with a multi-detector configuration. The SBN program comprises three liquid argon time projection chambers at different baselines in the same neutrino beamline. The 85 t MicroBooNE detector was operated at 470 m from the target. The 112 t Short-Baseline Near Detector is located at 110 m from the target. The ICARUS detector was transported from Europe after refurbishment at CERN and is located at a baseline of 600 m as the SBN Far Detector. As of the writing of this review, MicroBooNE is the only experiment that has presented results from SBN, observing no excess of ν_e events [127] and no evidence of light sterile neutrino oscillations [128].

JSNS^2 experiment at J-PARC has started the search for neutrino oscillations with $\Delta m^2 \sim 1$ eV^2 [129]. 1MW proton beam from the 3 GeV Rapid Cycling Synchrotron of J-PARC produces neutrinos from muon decay at rest. With a detector filled with a gadolinium-loaded liquid scintillator of 17 t fiducial mass at 24 m from the target, JSNS^2 is aiming to provide a direct test of the LSND anomaly. The second phase with an additional second detector at 48 m is under preparation.

14.6.4 *Reactor Antineutrinos*

14.6.4.1 *Reactor antineutrino flux*

Nuclear reactors are very intense sources of $\bar{\nu}_e$'s in the MeV energy region, which are generated in nuclear fission of heavy isotopes (mainly ^{235}U, ^{238}U, ^{239}Pu, and ^{241}Pu). The $\bar{\nu}_e$ flux from a reactor can be estimated based on the thermal power output and fuel composition as a function of time. On average, about six $\bar{\nu}_e$'s are emitted, and about 200 MeV of energy is released per fission. Therefore, a 1 GW$_{\rm th}$ (thermal power) reactor produces about 2×10^{20} $\bar{\nu}_e$'s per second.

The detailed estimate of $\bar{\nu}_e$ flux and energy spectrum can be obtained by either summing up the spectra of beta decays involved using available nuclear data information of each fission fragment and its decays, or by using measurements of cumulative electron spectra associated with the beta decays of fission fragments. Because the fission of four main fuel isotopes involves thousands of beta-decay branches, a complete *ab initio* calculation is challenging. The cumulative electron spectra for ^{235}U, ^{239}Pu, and ^{241}Pu were measured at the Institut Laue-Langevin (ILL) reactor in Grenoble, France in the 1980s [130–132]. For the prediction of $\bar{\nu}_e$ flux from ^{238}U, a summation calculation in [133] was often used together with the ILL results.

A recent calculation of the reactor $\bar{\nu}_e$ flux [134] uses an improved *ab initio* approach for ^{238}U and combined information from nuclear databases and electron spectra measured at ILL for ^{235}U, ^{239}Pu, and ^{241}Pu. Another calculation [135] is provided for ^{235}U, ^{239}Pu, and ^{241}Pu based on the ILL measurement of electron spectra, taking into account higher-order corrections and minimizing the use of nuclear databases. Both calculations predict a few percent higher normalization for the energy-averaged antineutrino fluxes of ^{235}U, ^{239}Pu, and ^{241}Pu compared to the original analyses of ILL data. However, the reactor antineutrino flux measurement at Daya Bay [136] is consistent with the old flux predictions and the flux measurement results. Also, an excess of $\bar{\nu}_e$ flux around 5 MeV, compared to the prediction, has been observed by recent reactor experiments [137–139].

14.6.4.2 *Reactor antineutrino oscillation experiments*

Charged current interaction cannot happen if a reactor $\bar{\nu}_e$ changes its flavour to $\bar{\nu}_\mu$ or $\bar{\nu}_\tau$, because its energy is not sufficient to produce heavier charged leptons. Thus, $\bar{\nu}_e$ disappearance is the only channel to study neutrino flavour change with reactor experiments. The inverse beta decay $\bar{\nu}_e + p \rightarrow e^+ + n$ provides a way to detect $\bar{\nu}_e$ in the relevant energy region. The energy of prompt signal from e^+, E_p, is related to the energy of $\bar{\nu}_e$, $E_{\bar{\nu}} \sim E_p + 0.8$ MeV. The delayed coincidence with the signal from γ ray emitted by neutron capture on nucleus after thermalization very efficiently suppresses the backgrounds. A liquid scintillator is often used to realize large detectors containing hydrogen as the target of inverse beta decay. In order to increase the neutron detection efficiency, a liquid scintillator is sometimes loaded with gadolinium because of a large neutron capture cross-section and higher energy of emitted γ rays, the total energy of about 8 MeV, by gadolinium, in contrast to 2.2 MeV for the capture by hydrogen.

Table 14.4 shows a list of reactor antineutrino experiments measuring neutrino oscillations. As was also shown in Table 14.1, experiments are designed with different baselines because of the different scale of mass splittings found by solar and atmospheric neutrino experiments. Experiments with O(100) km baseline are sensitive to Δm^2 of 10^{-4}–10^{-5} eV^2, while ~ 1 km of baseline results in a sensitivity in the range of 10^{-2}–10^{-3} eV^2.

The KamLAND detector consists of 1,000 t of ultra-pure liquid scintillator contained in a 13-m diameter spherical balloon [140]. The detector is located in the original Kamiokande cavern, where the $\bar{\nu}_e$ flux was dominated by a few reactors at an average distance of ∼180 km until 2011. KamLAND reported the first results in 2002 showing that the ratio of the observed number of $\bar{\nu}_e$ events and expectation without disappearance is $0.611 \pm 0.085 \pm 0.041$, evidence for reactor $\bar{\nu}_e$ disappearance at the 99.95% confidence level [140]. It confirmed a large value of the mixing angle corresponding to the LMA solution, which was reported by solar neutrino experiments. KamLAND also showed the evidence of $\bar{\nu}_e$ spectrum distortion consistent with the expectation from neutrino oscillations [141]. Figure 14.7 shows the ratio of observed $\bar{\nu}_e$ spectrum to the expectation for no-oscillation as a function of L_0/E ($L_0 = 180$ km) for the KamLAND data. A clear oscillatory signature can be seen.

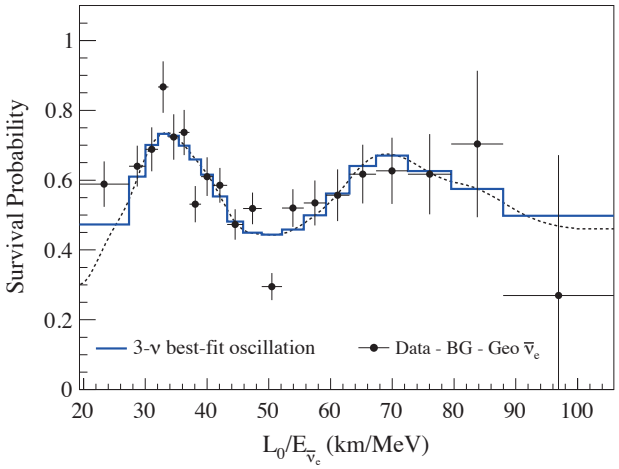

Figure 14.7: Ratio of the observed $\bar{\nu}_e$ spectrum to the expectation for no-oscillation versus L_0/E for the KamLAND data. $L_0 = 180$ km is the flux-weighted average reactor baseline. The 3-ν histogram is the best-fit survival probability curve from the three-flavour unbinned maximum-likelihood analysis using only the KamLAND data. This figure is taken from [142].

Following the establishment of neutrino oscillations with atmospheric, solar, accelerator, and reactor experiments, the measurement of the remaining mixing angle θ_{13} was recognized as the next major milestone. A reactor neutrino experiment with a baseline of ∼1 km can make an almost pure measurement of $\sin^2 2\theta_{13}$ from the disappearance of $\bar{\nu}_e$. To be sensitive to a small value of θ_{13}, experiments with two detectors were proposed. Among several proposals, three experiments have been realized: Double Chooz

Table 14.4: List of reactor antineutrino oscillation experiments

Name	Reactor power (GW_{th})	Baseline (km)	Detector mass (t)	Year
KamLAND	various	180 (ave.)	1,000	2001–

RENO	2.8×6	1.38	16	2011–
JUNO	26.6 (total)	53	20,000	

in France, Daya Bay in China, and RENO in Korea.

These three experiments employ a similar detector design optimized for the precise measurement of a reactor antineutrino. An antineutrino detector consists of a cylindrical stainless steel vessel that houses two nested acrylic cylindrical vessels. The innermost vessel is filled with gadolinium-doped liquid scintillator as the primary antineutrino target. It is surrounded by a liquid scintillator layer to contain γ rays from the target volume. A buffer layer of mineral oil is placed outside to shield inner volumes from radioactivity of PMTs and surrounding rock. The light from liquid scintillator is detected by an array of PMTs mounted on the stainless steel vessel. Optically separated by the stainless steel vessel, the outside region is instrumented as a veto detector with either liquid scintillator (Double Chooz) or water Cherenkov (Daya Bay and RENO) detector.

The Double Chooz detector has a gadolinium-doped liquid scintillator with a mass of 8.3 t. The far detector at a baseline of ∼1050 m from the two 4.25 GW_{th} reactors started physics data taking in 2011. The near detector, located at ∼400 m from the reactors, was completed in the end of 2014. Double Chooz finished data taking in early 2018. Daya Bay has two near (flux-weighted baseline 470 m and 576 m), and one far (1648 m) underground experimental halls near six reactors with 2.9 GW_{th} each. Daya Bay has eight antineutrino detectors in total; two detectors in each of the near detector halls, and four detectors in the far detector hall. Each detector contains 20 t of gadolinium-loaded liquid scintillator. RENO has two identical detectors located at 294 m and 1383 m from the center of an array of six 2.8 GW_{th} reactors. The mass of the gadolinium-loaded liquid scintillator is 16 t per detector. RENO started data taking with both near and far detectors in August 2011.

All three reactor neutrino experiments published their first results in 2012. First, Double Chooz reported an indication of reactor electron antineutrino disappearance with the ratio of observed to expected events of $R = 0.944 \pm 0.016 \pm 0.04$, ruling out the no-oscillation hypothesis at the 94.6% CL [143]. Daya Bay observed $R = 0.940 \pm 0.011 \pm 0.004$, corresponding to 5.2σ significance of non-zero value of θ_{13} [144]. RENO also reported $R = 0.920 \pm 0.009 \pm 0.014$, indicating a non-zero value of θ_{13} with a significance of 4.9σ [145]. These results established a non-zero value of θ_{13}.

Both Daya Bay [146] and RENO [137] report results constraining mass-squared difference as well as the mixing angle by using both relative $\bar{\nu}_e$ rate and energy spectra information. Double Chooz has reported the analysis based on both far and near detectors [138] for the mixing angle, using neutron capture on any elements (primarily gadolinium and hydrogen) to increase the effective target mass. Figure 14.8 shows the energy spectra of the prompt signals observed in the far detector of three experiments.

In all three experiments, an excess of $\bar{\nu}_e$ events over the expected energy spectrum has been observed around 5 MeV, as mentioned earlier. This excess is observed in both near and far detectors and scales with the reactor power. Thanks to the cancellation between the near and far detectors, the neutrino oscillation measurements are not affected in a multi-detector setup.

With a baseline of ∼50 km and an excellent energy measurement, reactor antineutrino experiments have significant sensitivity to the mass ordering. The JUNO detector, which is under construction, will consist of a 20 kt liquid scintillator and be located at 53 km from two nuclear power plants in China [147]. The JUNO experiment aims to determine the mass ordering with this technique as its primary goal. It can also provide precision

measurements of neutrino mixing parameters as well as a broad non-oscillation science program.

14.6.4.3 *Reactor experiments sensitive to O(1) eV² oscillations*

Possible hints of neutrino oscillation at a scale of $\Delta m^2 \sim 1$ eV² (see Sec.14.8) have motivated reactor experiments at a distance of ∼10 m from the core. Recent experiments searching for ∼1 eV² oscillation at reactors are summarized in Table 14.5.

As the antineutrino source, some use commercial reactors, which can provide a large flux leading to high statistical preci-

Table 14.5: List of reactor antineutrino experiments for O(eV^2) oscillations

Name	Reactor power (MW_{th})	Baseline (m)	Detector mass (t)	Detector technology	σ_E/E @1 MeV(%)	S/B
NEOS	2,800	24	1	Gd-LS	5	22
DANSS	3,100	10–13	0.9	Gd-PS	34	∼30
STEREO	57	9–11	1.7	Gd-LS	10	0.9
PROSPECT	85	7–9	4	^{6}Li-LS	4.5	1.3
NEUTRINO-4	100	6–12	1.5	Gd-LS	16	0.5
SoLid	80	6–9	1.6	^{6}Li-PS	14	

sion. On the other hand, though the flux is orders of magnitude smaller, a research reactor could have favorable conditions such as relatively easier access to a short baseline, simpler fuel composition, and compact core size.

The detectors are based on organic scintillators, either liquid scintillator (LS) or solid plastic scintillator (PS), which contain hydrogen as the target for inverse beta decay ($\bar{\nu}_e + p \to e^+ + n$). To identify the signal, neutron capture on either gadolinium (Gd) or ^{6}Li is detected with delayed coincidence. When a neutron is captured by Gd, γ rays with a total energy of 8 MeV are emitted. After neutron capture, ^{6}Li decays into triton and α. The effect of neutrino oscillation appears as a distortion of energy spectrum. To be independent from the reactor neutrino spectrum uncertainties, some experiments compare the spectra at different baselines by using a segmented detector or moving the detector.

NEOS [139,148] uses about 1 t of gadolinium-loaded liquid scintillator in an unsegmented detector. It is located at 23.7 m from the center of a commercial reactor and covered by an overburden of about 20 meters of water equivalent.

DANSS [149] is another experiment using a commercial reactor. The detector is highly segmented, consisting of 2,500 plastic scintillator strips, each with the size of $1\times4\times100$ cm^3 and coated with a thin gadolinium-loaded reflective layer. The detector is placed on a movable platform below the reactor core, which varies the distance to the core from 10.7 to 12.7 m.

The STEREO detector [150, 151] has six identical target cells of 37 cm length, ~ 2m^3 of volume in total, filled with gadolinium-loaded liquid scintillator. They are placed from 9.4 to 11.1 m from the compact (80 cm high, 40 cm diameter) core of the ILL research reactor.

The PROSPECT detector [152] consists of a segmented 4 t ^{6}Li-doped liquid scintillator detector. It covers a baseline range of 7–9 m from the highly ^{235}U enriched reactor core of the High Flux Isotope Reactor (HFIR) at Oak Ridge National Laboratory. Thin reflecting panels divide the LS volume into an 11×14 two-dimensional array of 154 optically isolated rectangular segments ($14.5 \times 14.5 \times 117.6$ cm^3).

NEUTRINO-4 [153, 154] uses a gadolinium-loaded liquid scintillator detector segmented in 10×5 sections with a total volume of 1.8 m^3. The detector is installed on a movable platform and moved to various positions with baselines of 6–12 m from the SM-3 reactor core in Russia.

The SoLid detector [155] is a finely segmented detector made of $5 \times 5 \times 5$ cm^3 plastic scintillator cubes and ^{6}LiF:ZnS sheets. Using the difference of time constant of scintillation between ZnS and the plastic scintillator a n-γ separation capability is achieved. A detector with 1.6 t of active volume is installed at a distance of 6–9 m from the research reactor core in the BR2 reactor, Belgium.

14.7 Combined Analysis of Experimental Results: The 3ν Paradigm

From the experimental situation described in Sec.14.6 we conclude that

- Atmospheric ν_μ and $\bar{\nu}_\mu$ disappear most likely converting to ν_τ and $\bar{\nu}_\tau$. The results show an energy and distance dependence perfectly described by mass-induced oscillations.
- Accelerator ν_μ and $\bar{\nu}_\mu$ disappear over distances of $\sim$ 200 to 800 km. The energy spectrum of the results show a clear oscillatory behavior also in accordance with mass-induced oscillations with a wavelength in agreement with the effect observed in atmospheric neutrinos.
- Accelerator ν_μ and $\bar{\nu}_\mu$ appear as ν_e and $\bar{\nu}_e$ at distances $\sim$ 200 to 800 km.
- Solar ν_e convert to ν_μ and/or ν_τ. The observed energy dependence of the effect is well described by massive neutrino conversion in the Sun matter according to the MSW effect
