For X-ray detection, a major effort is made to find high-Z materials with a bandgap that is sufficiently large to allow for room-temperature operation while still providing good energy resolution. Compound semiconductors, *e.g.* CZT, can allow this but typically suffer from charge collection problems, which are characterised by the product $\mu\tau$ of mobility and carrier lifetime; this is the depth per field strength that generated carriers can drift before being trapped, *i.e.* in this context the distance over which photon absorption can still be detected.

In Si and Ge $\mu\tau$ is orders of magnitude larger than in compound semiconductors for both electrons and holes (see Tab. 35.10). Since for holes $\mu\tau$ is typically much smaller than for electrons, detector configurations where the electron contribution to the charge signal near the readout electrode dominates—*e.g.* strip or pixel structures with electron collection—usually provide better performance (see also next section).

35.8.1.2 *Signal formation*

The signal and its pulse shape depend on the instantaneous carrier velocity $\vec{v}(\vec{x}) = \mu\vec{E}(\vec{x})$, μ = mobility, and the electrode configuration and its geometry which determine the distribution of induced current according to the Shockley-Ramo theorem

$$i_S(t) = Ne\,\vec{E}_w(\vec{x})\,\vec{v}(\vec{x}(t))\,, \qquad (35.20)$$

where Ne represents a drifting charge cloud of N elementary charges, $\vec{E}_w(\vec{x})$ is the "weighting field", which accounts for the coupling of the charge to a specific electrode and depends on the electrode configuration; $\vec{v}$ is the drift velocity. Note the difference between the electric field $\vec{E}$ and the weighting field $\vec{E}_w$ and take account of the fact that the mobility is, in general, field-dependent, $\mu = \mu(E)$, with $v \approx const$ at high fields (velocity saturation, for electrons in Si approaching 10^7cm/s at $E > 10^4$ V/cm). Both, electron and hole movements contribute to an electrode's signal. Hence, if the carrier mobility is very different for electrons and holes, like *e.g.* in CdTe where $\mu_h \ll \mu_e$ (Tab. 35.10), a photon signal, for example, becomes absorption-point dependent.

Integration of the induced current signal on an electrode yields the "collected charge". The average time to collect the created charge decreases with increasing bias voltage (*i.e.* field strength) until velocity saturation occurs at field strengths of about 10^4 V/cm in Si.

For a simple parallel-plate geometry with two electrodes the weighting field is constant, whereas for structured electrode geometries, like for example strips or pixels, E_w is position dependent which for small electrodes (compared to the sensor dimensions) strongly enhances the contribution of the movement close to the electrode ("small-pixel effect"). More details and practical accounts of the Shockley-Ramo theorem and its usage can be found in [1, 8] and references therein.

Position resolution is ultimately limited by transverse diffusion of the moving charge cloud (typically 3–5 µm for 200–300 µm thickness) and by the emission of δ electrons. The performance then depends on optimal usage of charge sharing between neighbouring electrodes and on noise. In magnetic fields, Lorentz drift deflects the electron and hole trajectories thus increasing the spatial spreading. The total spreading and hence charge sharing between electrodes can be tuned (increased or decreased) by tilting the detector relative to the incoming (average) particle direction. Overall spatial resolutions of 2–4 µm (rms) have been obtained.

35.8.2 *Junction detectors*

Si and Ge detector substrates must be—others like CdTe, GaAs should be and CZT can be—depleted from free charge carriers by operating them as reverse-bias junctions (p-n or Schottky) to be sensitive to the charge created by impinging particles. A typical cross-section of a junction detector is shown in Fig. 35.24, here with structured electrodes at the top. A p-n junction—even without external voltage—forms a sensitive space-charge region across itself depleted of mobile charges, hence also called "depletion region". The space charge establishes an electric field corresponding to a "built-in" voltage V_{bi}. Additional reverse-bias voltage V applied externally increases the space-charge region such that in-

jected charge liberated by radiation is swept to the electrodes by the existing field. Detectors typically use an asymmetric structure, for example, a thin and highly doped p^+ electrode[6] region and a lightly doped n^- substrate region – or vice versa, so that the depletion region extends predominantly into the more lightly doped bulk volume.

In such planar Si (or Ge) devices, the thickness of the depleted region is

$$d = \sqrt{2\epsilon\,(V + V_{bi})/Ne} = \sqrt{2\rho\mu\epsilon\,(V + V_{bi})} \qquad (35.21)$$

$$\approx \frac{0.5}{\mu\text{m}} \times \sqrt{\frac{\rho\,V}{\Omega\,\text{cm}\cdot\text{V}}} \qquad \text{for } n\text{-type Si bulk}$$

$$\approx \frac{0.3}{\mu\text{m}} \times \sqrt{\frac{\rho\,V}{\Omega\,\text{cm}\cdot\text{V}}} \qquad \text{for } p\text{-type Si bulk}$$

with (values for Si)

V = external bias voltage
V_{bi} = "built-in" voltage (≈ 0.5 V for typ. used resistivities)
N = doping concentration
e = elementary charge
ϵ = dielectric constant = $11.9\,\epsilon_0 \approx 1$ pF/cm
ρ = resistivity (typically 1–10 kΩ cm)
μ = charge carrier mobility
($\sim$ 1450 cm^2/Vs (electrons), $\sim$ 500 cm^2/Vs (holes) [360])

The conductive p and n regions together with the depleted volume form a capacitor with capacitance per unit area

$$C' = \frac{\epsilon}{d} \approx \frac{1\,\text{pF/cm}}{d} \qquad \text{in Si.} \qquad (35.22)$$

The depletion depth d becomes as large as the sensor's thickness at the "full depletion voltage" $V = V_{fd}$ for which the sensor capacitance reaches a minimum (about 35 pF/cm^2 for $d = 300$ µm). In strip and pixel detectors (see next section) the capacitance is dominated by the fringing capacitance to neighbouring electrodes as the electrode pitch is typically much smaller than the sensor thickness. For example, the strip-to-strip Si fringing capacitance is about 1–1.5 pF per cm of strip length at a strip pitch of 25–50 µm.

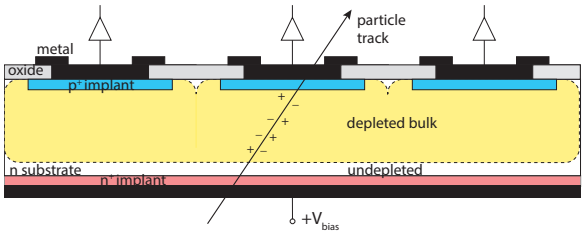

Figure 35.24: Reverse-biased junction detector with planar readout electrodes at the top in a standard sensor configuration (p$^+$-in-n): lightly doped n-type substrate with p^+ implants forming the diode junction at the top side. Electrons move to the bottom electrode and holes to the top. Both movements contribute to the (induced) signal at the top electrodes with amounts as specified by the weighting field (see Sec. 35.8.1.2). The n^+ implant at the bottom side forms an ohmic contact between bulk and metal.

The electric field strength and shape inside the semiconductor bulk are important for efficient signal charge collection. Governed not only by the applied external voltage but also by the space charge inside the semiconductor bulk, leads (for constant space charge) to a linear field-strength decrease from its maximum at the junction's boundary into the depleted semiconductor bulk. Space charge can also occur from ionised lattice defects

[6] $n^{+/++}$, $p^{+/++}$ as well as n^-, p^- qualitatively denote relative doping-concentration levels.

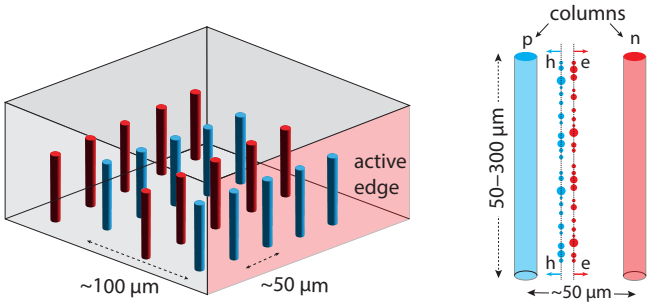

Figure 35.25: Junction detector with vertical electrodes, n (red) and p (blue), and "active" edges called 3D-Si. Dimensions given are typical. This electrode configuration provides short drift paths for moving charges while keeping a large sensing thickness. An active edge minimises dead areas at the sensor boundaries. This geometry has also been employed in CVD diamond substrates.

which either naturally exist for example in GaAs or can be created by irradiation in any semiconductor material. This can lead to low-field regions as well as to changes in the field's shape (deviating from linear), both of which usually deteriorate the charge collection properties of a detector.

In partial depletion (*i.e.* $V < V_{fd}$) the field decreases to zero at the end of the depletion zone. Overbias ($V > V_{fd}$) adds a constant electric field component which avoids a vanishing field region and also provides faster charge collection as long as the carrier drift velocity has not yet saturated. At an average field of $E = 10^4$ V/cm, the onset of velocity saturation, where $\mu_e \approx 7{\times}10^3$ cm^2/Vs, $\mu_h \approx 3.5{\times}10^3$ cm^2/Vs, the collection times for Si are about 15 ps/µm for electrons and 30 ps/µm for holes. In typical fully-depleted detectors, 100–300 µm thick, electrons are collected within less than about 5 ns, and holes within less than about 10 ns.

Large volume ($\sim 10^2 - 10^3$ cm^3) germanium detectors, especially for γ-ray detection, are commonly configured in cylindrical or hexagonal rod shapes, for example, a 10 cm long cylindrical n-type crystal with 5–10 cm diameter with an inner 5–10 mm diameter n^+ electrode and an outer p^+ layer forming the diode junction. Germanium can be grown with fairly low impurity levels, 10^9–10^{10} cm^{-3} (HPGe, high-purity germanium), so these large volumes can be depleted with several kilovolts.

Diamond, featuring free charge carrier densities close to zero, needs no further depletion and is operated as a parallel plate capacitor with an insulator dielectric inside. Still, a substantial bias voltage is required to overcome charge trapping.

35.8.3 *Detectors with structured electrodes*

35.8.3.1 *Microstrip-, Si-drift- and hybrid-pixel detectors*

In HEP experiments semiconductor detectors usually aim at good position resolution achieved with electrodes patterned in "strips" or "pixels" with typical dimension scales (electrode pitch) of 50–100 µm, or in "pads" (mm^2–cm^2) if coarser granularity is affordable for the benefit of fewer channels.

Electrodes are usually placed "planar", *i.e.*, at the surface of the sensing Si bulk (Fig. 35.24). In an alternative, but more elaborate way, electrodes can be shaped as columns or trenches running orthogonally to the surface and hence parallel to the average direction of impinging particles (Fig. 35.25) [361]. This geometry (termed "3D-Si", but is also exercised with diamond) enhances the radiation tolerance due to shorter drift distances of charges at the same thickness (see also Sec. 35.8.5).

In strip detectors, the strip ends are connected to dedicated readout ICs where the signals are amplified and processed. Two-dimensonal readout is realised either by angled double-layers of strip detectors or by "double-sided" strip sensors structured by readout strips on either side (see *e.g.* [1, 358] and references therein). For the latter, one electrode surface features n^+n or p^+p strip junctions (rather than pn), respectively, which require dedicated measures, *e.g.* intermediate strips or special doping profiles to break the electron accumulation layer that occurs at an

n^+n interface. For p^+p, intermediate n strips or similar are not necessary, thanks to positive oxide charges residing at the Si/SiO_2 interface.

As for gaseous driftchambers, silicon driftchambers provide the position of a hit orthogonal to a strip's coordinate from a measurement of the charge cloud's drift time, drifting over centimeter-long paths inside the silicon bulk. For this to work the bulk is "sidewards depleted" by using junction strip implants of the same polarity on both sides of the sensor (p in n or n in p, respectively), different to standard double-sided strip detectors (see *e.g.* [1]). This way a quadratic potential minimum for electrons is created, confining them amid the sensor bulk, on which a linear electric potential in drift direction is superimposed; holes, instead, drift to the sides. In comparison to strip detectors, much fewer electrodes are necessary for the same active area coverage. Low rate capability is a drawback caused by the long drift path of created charges. Arranged with only one small electrode with low capacitance in the center of a cylindrical disk, so-called silicon-drift diodes (SDD) are low-noise single-channel devices with large area coverage, used for example in X-ray fluorescence analysis and electron microscopy.

Very small pixel structures for particle detection were first realised with CCDs [362]. Most current applications, particularly those for high-rate applications such as at the LHC, employ the "hybrid-pixel" concept in which both, the sensing diode structure as well as the readout IC, have equal electrode structures and patterns (pixels). The connection is made by two-dimensional arrays of solder or indium bumps that mate the two parts by employing flip-chip technology (Fig. 35.26, usually chip-to-chip or chip-to-sensor; more details *e.g.* in [358, 363]). Further advancements in bonding techniques especially address chip-to-wafer or even wafer-to-wafer placements, such as SLID (Solid Liquid Interface Diffusion) employing a very thin liquid metal layer (Sn) in between metals with higher melting points (e.g. Cu). Also, Cu–Cu, Cu–Sn, or oxide–oxide (SiO_2) diffusion bonding without solder is feasible.

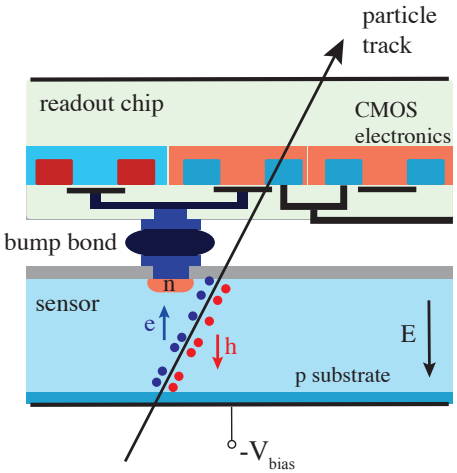

Figure 35.26: Cross-sectional view of a hybrid-pixel detector cell (one pixel) consisting of sensor (bottom) and readout chip (top) with CMOS circuitry illustrated by three transistors (red and blue implant areas plus metal lines). The sensor is a depleted diode structure (here p substrate with n electrode). Both parts are mated by a microbond (bump bond), typically solder or indium.

The hybrid approach excels in optimally utilising chip and sensor technologies for radiation hardness and rate capability (see *e.g.* [364]). It is, therefore, the technology of choice for pixel trackers in high-rate, high-radiation environments optimised for the purpose by employing very thin modules ($\mathcal{O}(300\,\mu m)$ total). A disadvantage is the complex and cost-intensive module assembly.

35.8.3.2 *Monolithic pixels*

Partially or fully monolithic pixel detectors directly connect the generated signal charge with an embedded active electronics device (*i.e.* one or several transistors). An example of a partially monolithic device is the DEPFET (depleted p-channel FET) pixel sensor (see *e.g.* [365]), employed, for example, in the pixel tracker of the Belle-II detector. A single transistor (pMOSFET) is implemented in every pixel (Fig. 35.27 (a)). The sensor substrate is "sidewards depleted", as similarly done in Si driftchambers (Sec. 35.8.3.1), by means of the backside p-contact and several p regions near the transistor. Depletion is provided by the n^+ *clear* contact (see below) plus a bulk n-implant outside the matrix. In addition, the structure features a deep n-implant located a few micrometers underneath the transistor channel on floating potential. This implant becomes the most positive point of the structure, hence being an electron accumulation point, which acts as an "internal gate" of the transistor. The gate voltage changes by an amount $\alpha q_S/C$, with q_S = signal charge, gate-oxide capacitance $C = C_{ox}\,WL$ with $W \times L$ = gate area, and $\alpha \lesssim 1$ accounting for stray capacitance. The gate voltage changes due to an accumulated signal charge q_S and leads to a detectable change in drain current (in saturation):

$$I_D = \frac{W}{2L}\,\mu C_{ox}\left(V_G + \frac{\alpha\, q_S}{C} - V_{th}\right)^2 . \qquad (35.23)$$

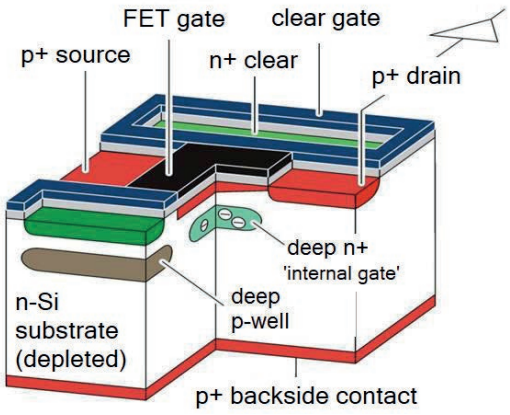
Other elements in Fig. 35.27 (a) like the external FET gate and the *clear* implant provide control and reset of the structure. The device gain $g_q = dI_D/dq_S \approx \alpha g_m/C$, with transconductance $g_m = \mu C_{ox}\frac{W}{L}(V_G - V_{th})$, is of order $500\,pA/e^-$. The small capacitance of the internal gate (few fF) enables very low noise operation ($\lesssim 2e^-$) when operating with long shaping times (see Sec. 35.9).

Fully monolithic pixels combine the sensing task and the complete readout circuitry, *i.e.* the two separated parts of hybrid pixels, in one chip. Both functions must be properly shielded against each other, which is achieved by exploiting multi-well IC technology. Realised as MAPS (monolithic active pixel sensors) standard CMOS wafers can be used for pixel detector fabrication. CMOS wafers often feature a Si epitaxial layer where the transistors are implanted. It is possible to use this epi-layer as a sensitive detection volume for particle detection. However, in such detectors, only the immediate regions near the collection nodes (see Fig. 35.27(b)) are depleted. Outside these confined regions there is no or little electric field and charge collection is dominantly governed by slow and non-directional charge diffusion, a problem for high-rate applications. Depleted MAPS (DMAPS) exploit non-standard high resistivity wafers or high-ohmic epi-layers, typically with resistivities $>1\,k\Omega\,cm$, as well as high bias voltage (up to $\gtrsim 300\,V$) resulting in charge collection by directed drift motion. Charge collecting electrodes are deep wells (n-wells in Fig. 35.27(b)), either formed as large (typ. $50\times100\mu m^2$) structures to fully contain the CMOS circuitry (Fig. 35.27(b), top) or as small nodes, set aside the electronics (Fig. 35.27(b), bottom), with obvious pros and cons resulting from shorter average drift distance (large electrode) versus much smaller capacitance (small electrode). The former benefits radiation tolerance, whereas the latter allows for smaller pixels and benefits from small sensor capacitance in noise and rise time. However, in both approaches radiation tolerance levels of $\gtrsim 10^{15}\,n_{eq}/cm^2$ (fluence) and 1 MGy (ion. dose) have been demonstrated.

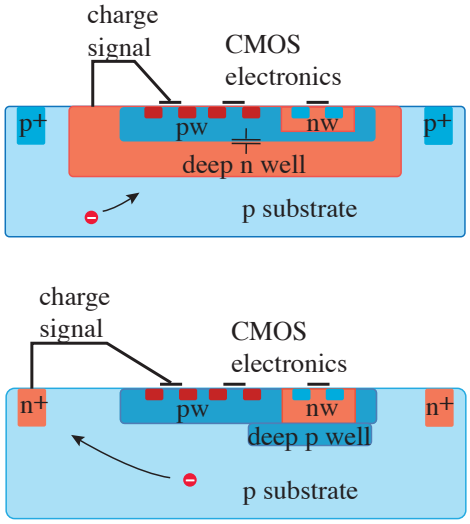
A variant of the monolithic approach are SOI (silicon on insulator) pixels providing high spatial resolution, but less radiation tolerance: A high-resistivity supporting wafer, employed for particle sensing, connects through an embedded insulator (a buried oxide layer, BOX) to the CMOS readout circuitry. The BOX separates the sensing volume from the electronics layer and provides shielding. Because the area between BOX and the transistor layer acts as a "back-gate", transistor operation can be affected requiring dedicated cures (see *e.g.* [366]).

35.8.4 *Precise timing with silicon detectors*

Typical time scales for silicon detector output signals are several tens of nanoseconds (*e.g.* rise times, shaping times, etc.) accompanied by a typical time mark precision in the order of nanoseconds. Essential for achieving precision timing ($<100\,ps$) are steep signal rise and low noise according to eq. (35.38) in Sec. 35.9. This,



(a) DEPFET pixel structure.



(b) DMAPS pixel structures.

Figure 35.27: Partially (a) and fully (b) monolithic pixels: (a) DEPFET pixel structure with an embedded pMOSFET transistor; source and drain are p implants (red), gate metal (black), oxide (grey), deep-n internal gate (light green), other metal (blue), clear contact (green), and deep p-well (brown). (b) Depleted MAPS with joint sensing and electronics volumes: (top) charge collection by a *large-electrode* housing the electronics in a deep-n well; (bottom) charge collection by a *small electrode* set aside from the electronics area.

in turn, requires fast charge collection, *e.g.* in thin planar or 3D-Si detectors with high E-fields, as well as fast and strong amplification, both together yielding large slew rates (dS/dt, with S="signal", *e.g.* an induced current or a voltage). Important parameters that influence timing precision are the detector capacitance (including stray contributions) and the amplification gain.

Detectors that have achieved precise time measurement are so-called LGADs (low gain avalanche diodes, Fig. 35.28). They have planar electrode geometry that includes an implanted low-gain ($g = 10$–50) amplification structure on either the top or bottom electrode side to maximise the slew rate. Electrons created from ionising traversing particles are accelerated towards a very high field created by an amplification layer near the (here) top electrode, where impact ionisation creates a multitude of e-h pairs. They induce a very fast and large signal rise, mainly governed by the holes' movement away from the amplification layer. Sufficiently low amplification gain minimises excess noise contributions and avoids the creation of hole-induced avalanches moving in the opposite direction to electron avalanches.

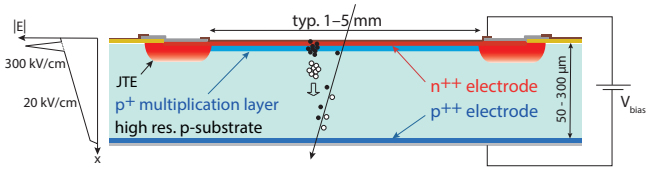


Figure 35.28: LGAD amplification structure for precision timing. Amplification (typ. $\times$ 20–50) occurs at the structure boundary in a highly doped p-n junction near the (here: top) surface (JTE = Junction Termination Extension, deep n-well).

The achievable time resolution has several contributions:

$$\sigma_t^2 \approx \left(\frac{\sigma_S^{thr}}{dS/dt}\right)^2 + \left(\frac{\sigma_n}{dS/dt}\right)^2 + \sigma^2_{\text{arrival}} + \sigma^2_{\text{dist}} + \sigma^2_{\text{TDC}} \,. \quad (35.24)$$

The first term represents "time walk" coming from Landau fluctuations, defined as originating from number and energy-transfer fluctuations in the energy-loss process with σ_S^{thr} being the signal-height variations at discriminator threshold. This term can be kept minimal, *e.g.*, by employing constant fraction discrimination or by applying corrections using amplitude information. The second term is the contribution of noise to the time jitter, which can be approximated by $(t_r/\text{SNR})^2$ with $t_r =$ rise time, SNR = signal-to-noise ratio. Both first terms are kept small by large signal slew rates. An irreducible contribution comes from fluctuations in non-uniform depositions of charge along the particle path (including fluctuations in the amplification process) which causes an intrinsic jitter in the arrival time (third term)[7]. The thinner the detector the less disturbing is this effect. The fourth contribution is signal distortion due to non-uniform weighting field regions and variations in (non-saturated) drift velocities. "Junction Termination Extensions" (JTE, see Fig. 35.28) serve to lower this term. The final term denotes time fluctuations due to uncertainties in digitization, which can, however, be made negligible with GHz TDCs. Timing precision of order 30 ps has been reached. Structural and operational variants to improve charge collection and position resolution are "resistive AC-coupled LGADs", "deep junction LGADs", "trench-isolated LGADs" and others. More details on LGADs are given in [367] and [368].

Columnar electrode geometries such as shown in Fig. 35.25 with small diameter and small pitch are by design a very suitable choice for precision timing due to short collection paths and strong fields. Employing an optimised trench-like column shape field- and weighting-field distortions are minimised and time resolutions in the order of 10 ps have been achieved in prototypes [369].

High precision timing can also be approached by exploiting the benefits of SiGe BiCMOS technology: strain mismatch of Si-Ge alloy layers results in a smaller bandgap as well as higher mobility and hence larger transconductance. This benefits the speed in hetero-junction bipolar transistors (HBTs) which also feature less 1/f noise than MOS transistors. Resolutions of order 20 ps have been reached in a monolithic pixel matrix using this technology [370]. More elaborate discussions on timing in silicon detectors can be found *e.g.* in [371].

35.8.5 *Radiation damage in silicon detectors*

High channel density and response times in the nanosecond range render micro-patterned semiconductor detectors particularly suited for high particle rates. This is usually accompanied by high radiation causing damage of sensors and front-end electronics. We restrict ourselves here to damage in Si detectors and their electronics. Radiation damage occurs in semiconductor detectors through two basic mechanisms:

[7] In LGAD literature these fluctuations are sometimes also referred to as "Landau fluctuations".

1. *Bulk damage* due to displacement of atoms from their lattice sites resulting in defect energy levels inside the band gap. This leads to increased leakage current, carrier trapping, and build-up of space charge that changes the required operating voltage. Displacement damage results from non-ionizing energy loss (NIEL). The energy imparted to the recoil atoms can initiate a chain of subsequent displacements including "damage clusters". For a description, it is critical to consider both, particle type and energy. Conventionally, for silicon, the received NIEL is normalised to the damage level caused by 1 MeV neutrons and specified in units of neutron-equivalent fluence Φ_{eq} with units n_{eq}/cm^2.
2. *Surface damage* due to charge build-up in surface layers and formation of interface traps at *e.g.* Si–SiO_2 boundaries. These influence transistor currents and thresholds or cause thin charge carrier layers at a silicon surface, leading to increased surface leakage currents in sensors or circuits and affecting electrodes' isolation and/or transistor characteristics. The effects of charge build-up are strongly dependent on the device structure and on fabrication details. The damage is dominantly due to ionising energy loss (IEL) and hence proportional to the absorbed total ionisation dose (TID) measured in Gy (or rad), independent of the particle type.

The increase in reverse bias generation current (leakage current) due to bulk damage is $\Delta I_L = \alpha \Phi_{eq} V$, where V is the volume under an electrode and $\alpha \simeq 4 \times 10^{-17}$ A/cm, a universal constant when normalised to temperature (conventionally 20 °C), and measured after annealing for 80 min at 60 °C. Note that for devices with intrinsic amplification, generation current is amplified accordingly. Reverse bias leakage current depends strongly on temperature

$$I_L(T) \propto T^2 \exp\left(-\frac{E_a}{2kT}\right) , \qquad (35.25)$$

where $E_a \approx 1.2$ eV (activation energy), so rather modest cooling can reduce the current substantially (∼6-fold reduction in cooling from room temperature to 0 °C).

For bulk damage in silicon, the *NIEL hypothesis* is a good first-order description of the observed damage (especially regarding I_L). It states that all lattice radiation damage in silicon linearly scales with NIEL and can be traced back to the abundance of primary defects (point defects and clusters), irrespective of their initial distribution over energy and space, that is, regardless of the damage's topology and origin. Under the NIEL hypothesis, the observed differences in damage caused by neutrons, protons, pions and electrons are hence usually scaled to each other.

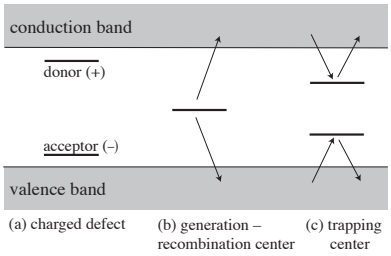

Figure 35.29: Characteristic locations of energy levels caused by bulk radiation damage and their main action effects.

Three main bulk displacement damage effects are sketched in Fig. 35.29: (a) defects acting as charged donors/acceptors, (b) deep defects (near the middle of the bandgap) causing increased leakage current, and (c) carrier trapping centers. Damage effects are not constant with time; for example in n-type bulk, radiation-induced negative space charge anneals at first, reaching a stable damage minimum (beneficial annealing), but later electrically active defects (negative space charge from acceptor-type damage) build up over the time scale of months (reverse annealing).

Acceptor- (usually dominant) or donor-like (deep) defect states, when ionised, build up space charge (dominantly negative), which in turn normally requires an increase in the applied voltage to sweep signal charge through the detector thickness. For n-type bulk starting material, however, donor (*e.g.* phosphorous) removal by forming electrically inactive vacancy-phosphor (V-P) complexes induced by the incipient radiation, leads to a faster decrease in depletion voltage (faster than only by the compensation of donors through generated deep acceptors) until positive and negative space charges effectively balance; only little bias voltage then is required for operation (point of effective space charge inversion, also called "type inversion" (Fig. 35.30)). At larger fluences the negative space charge dominates, and the required operating voltage increases proportional to the increasing effective space charge density N_{eff}, also called effective doping concentration. Also the space-charge distribution can no longer be regarded as constant and homogeneous over the detector volume, thus destroying the linear slope of the electric field from the junction to the backside as was introduced in Sec. 35.8.2; instead "double-junction"-like field distributions typically occur.

Today, p-type silicon with n^+ electrode-implants is the preferred choice for sensors operating in high-radiation environments for reasons of cost-effectiveness in production as well as high radiation hardness due to fast (high mobility) electron collection in high electric- and high weighting-field regions at small segmented n^+ electrodes. Space charge inversion is usually not observed since the initial space charge is negative already (Fig. 35.30).

Removal of acceptors (*i.e.* substitution of electrically active boron at its lattice site) in p material is found to be dominantly caused by interstitial silicon replacing boron on its lattice position. The highly active interstitial boron then can cause the formation of other defects such as interstitial oxygen-boron complexes (B_iO_i, subscript i for "interstitial") which absorb boron atoms into electrically active defects, dominantly as donors, that means that space charge is changed twice.

Various techniques have been explored to neutralise radiation damage effects by defect engineering. For n-type material, oxygen enrichment with a larger abundance than phosphorus, introduced during the Si growth, successfully reduces the formation of multi-vacancy, acceptor-like complexes which are dominantly produced by charged hadrons, because it enhances instead the formation of electrically neutral V-O complexes. Carbon enrichment, on the other hand, reduces acceptor removal in p-type Si by building stable C_i-S_i complexes, thus trapping the Si interstitials which could else remove boron as described above.

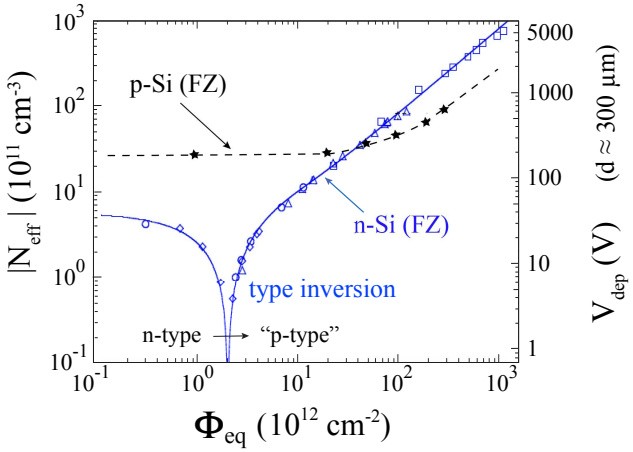

Figure 35.30: Effective space charge concentration N_{eff} (left axis) and required voltage for full depletion V_{dep} (right axis) of approximately 300 µm thick Si sensors as a function of neutron-equivalent radiation fluence for typical n-type (blue) and p-type (black) silicon float zone (FZ) material before annealing. While initial n-type Si inverts to effectively p-type Si, this is not observed for initial p-type silicon. Bias voltage supply for large systems is usually limited to less than 600–1000 V. Figure adapted using [372, 373] and [374].

Dopant removal plays a particularly important role in more

complex sensor structures such as, for example, DMAPS or LGADs. In particular, the high p-doping concentration in LGAD's gain layer is vulnerable to acceptor removal causing a drastic gain decrease with increasing fluence.

Deep level defects (Fig. 35.29(b)) typically are the origin of leakage current increase, whereas trapping centers (Fig. 35.29(c)) dominate carrier lifetime and signal loss at high fluences beyond $10^{15}\,\mathrm{n_{eq}/cm^2}$. The safe limit on the operating voltage ultimately limits the detector lifetime. Strip and pixel detectors, specifically designed for high voltages, have been extensively operated at bias voltages of 500–600 V. Sensors with columnar electrodes normal to the surface (3D-Si, Fig. 35.25) need significantly lower voltages for full depletion and are prime contenders for radiation-hard sensors.

Synthetic CVD diamond has proven strong against radiation damage due to its large bandgap (see Tab. 35.10) and strong lattice binding with a roughly twice higher threshold ($\sim 40\,\mathrm{eV}$) for a displacement of lattice atoms than silicon (see *e.g.* [354]). Even for polycrystalline material, charge collection distances (CCD = sum of the mean free paths $\mu\tau E$ of e and h over which charges reach the electrodes) of 300–400 µm have been achieved. Diamond wafer cost, however, is comparatively very high. Smaller scale trackers acting *e.g.* as beam monitors have been built.

GaAs has received interest as a potentially radiation-hard material in the 1990ies. For particle detection it must still be depleted from charge carriers despite comparatively small intrinsic carrier densities (see Tab. 35.10). It suffers from a strong loss in charge collection efficiency when irradiated, dominantly because of electron trapping. Other semiconductor materials such as SiC or GaN feature wider bandgaps (3.26 eV and 3.39 eV, respectively) than Si (but smaller than diamond) and possess other suitable properties relevant to high-fluence operation, such as density, e-h ionisation energy, and displacement energies. They have regained attention after the material quality has improved much due to an industrial push coming from power devices and LEDs. So far, charge collection degrades faster with radiation fluence than for Si and diamond, however.

Strip and pixel detectors have remained functional in large detectors even at particle fluences well beyond $10^{15}\,\mathrm{n_{eq}/cm^2}$ where charge loss due to recombination and trapping becomes significant. Thin planar ($\sim$100 µm) and 3D silicon detectors have been successfully operated at fluences of 2 and $3 \times 10^{16}\,\mathrm{n_{eq}/cm^2}$, respectively, and measurements indicate that operation above $10^{17}\,\mathrm{n_{eq}/cm^2}$ does not seem impossible. The large SNR obtainable with low capacitance pixel structures extends the detector lifetime. The higher mobility of electrons makes them less sensitive to carrier lifetime than holes, so detector configurations that emphasize the electron contribution to the charge signal are advantageous, *i.e.* n^+ strips or pixels on p- or n-substrates. The occupancy of the defect charge states is strongly temperature dependent; competing processes can increase or decrease space charge and the required operating voltage. It is critical to choose the operating temperature judiciously ($-30\,^\circ\mathrm{C}$ to $0\,^\circ\mathrm{C}$ in typical collider detectors) and to limit warm-up periods during maintenance. Detailed discussions of radiation damage and its effects on semiconductor detectors can be found e.g. in [373, 375]; an introduction to the subject can be found in [1].

Tolerance against surface damage, especially in SiO_2 layers as in gates and in oxide trenches of CMOS transistor structures, largely depends on the feature size of a technology and on appropriately designed circuitry. Deep submicron technology nodes of 130 nm and 65 nm sustain total ionisation doses of up to 5 MGy (500 Mrad), corresponding to fluences of up to $5 \times 10^{15}\,\mathrm{cm^{-2}}$ of minimum ionising pions or protons.

35.9 Low-noise detector readout

Revised November 2021 by N. Wermes (Bonn U.), revised November 2013 by H. Spieler (LBNL).

Many detectors rely critically on low-noise readout electronics, for best energy resolution or to allow low thresholds for high detection efficiencies. A typical detector front-end is shown in Fig. 35.31.

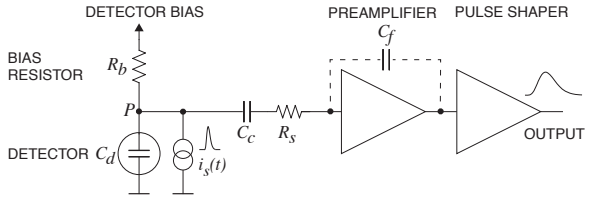

Figure 35.31: Typical detector front-end. The dashed circuit part is a charge-sensitive amplifier (CSA) realization.

In a model relevant to most readout applications, the detector, represented by a capacitance C_d, delivers a delta-function-shaped current signal, represented by a current source in parallel. Bias voltage is applied through resistor R_b and the signal is (often) coupled to the amplifier through a blocking capacitor C_c. The series resistance R_s represents the sum of all resistances present in the input signal path, *e.g.* the electrode resistance, any input protection network, and parasitic resistances in the input transistor. The amplification stage contains the preamplifier providing gain and a pulse shaper (characterized by a shaping time τ), which tailors the overall frequency response to optimize the signal-to-noise ratio (SNR) while limiting the duration of the signal pulse to accommodate the signal-pulse rate. For a given input signal, purely random noise leads to a gaussianly smeared signal distribution behind the shaper. Even if not explicitly stated, all amplifiers provide some form of pulse shaping due to their limited frequency response.

It is useful to distinguish between noise inherent to a detector's signal amplification and processing circuitry (per channel) on the one hand, depending on the detector specifics and the experimental environment (*e.g.* the data rate), and — on the other hand — external noise sources introduced *e.g.* by systems external to a specific readout circuit often resulting in "common-mode" noise, *i.e.* common to all channels. External noise can be introduced from power supplies, digital signal switching, RF pick-up, or from effects due to "common grounding" allowing noise to couple to the current loop connecting the detector to the preamplifier. These noise sources differ from setup to setup and must be dealt with – and should at best be eliminated – individually. In the following, therefore, only the noise inherent to typical detector signal processing is discussed.

35.9.1 *Principal noise origins*

As principal noise origins in circuit elements we mainly distinguish *thermal noise* resulting from velocity fluctuations of charge carriers (Brownian motion), as well as *shot noise* and $1/f$ *noise*, both resulting from charge carrier number fluctuations. Shot noise is due to emission statistics of electrons crossing a barrier, $1/f$ noise is often — especially in MOSFETs — due to charge trapping–detrapping processes leading to a spectral behaviour as $1/f^\alpha$ with $\alpha = 0.5 \ldots 2$. Further noise nomenclature, like for example RTS (random telegraph signal) noise, also called "burst noise' or "popcorn noise", is in its origin usually related to trapping/detrapping processes, like $1/f$ noise. The popping-up nature of individual RTS bursts eventually leads to the $1/f$ noise spectral density when the noise of several traps with (very) different trapping times are superimposed. RTS noise is omitted in the following for simplicity reasons.

35.9.2 *Equivalent noise analysis*

The equivalent circuit for noise analysis (Fig. 35.32) shows contributions of the mentioned noise sources at several circuit points. Originating from fluctuations, noise is expressed as the variance $\langle i^2 \rangle$ or $\langle v^2 \rangle$ of a noise current or voltage distribution. Shot noise, such as that produced in a semiconductor detector by leakage current fluctuations, is represented by a current noise generator in parallel with the detector and the amplifier input. The statistical fluctuations in a charge measurement will scale with the square root of the total number of recorded charges, so this noise contribution increases with the measurement (shaping) time. Thermal noise in resistors produces a white noise, *i.e.* a noise power density independent of frequency. Hence limiting the bandwidth by

a shaper, *i.e.* increasing the shaping time, will decrease the noise at the expense of slowing down the detector response. Usually, resistors shunting the input act as noise current sources and resistors in series with the amplifier input act as noise voltage sources, so that they are often referred to as "parallel" and "series" noise. Thermal fluctuations in the bias resistor result in fluctuations of the voltage at point P in Fig. 35.31 and its noise current source $\langle i_b^2 \rangle$ has the same effect as the shot noise current $\langle i_d^2 \rangle$ from the detector. Conversely, the series resistor R_s acts as a voltage noise generator $\langle v_s^2 \rangle$ for the amplifier input.

Shot noise and thermal noise have a "white" frequency distribution, *i.e.* the (power) spectral densities (f = frequency) $d\langle i^2 \rangle/df$ and $d\langle v^2 \rangle/df$ are constant with magnitudes

$$\begin{aligned} d\langle i_d^2 \rangle &= 2eI_d\, df\,, \\ d\langle i_b^2 \rangle &= \frac{4kT}{R_b}\, df\,, \\ d\langle v_s^2 \rangle &= 4kTR_s\, df\,, \end{aligned} \tag{35.26}$$

where e is the elementary charge, I_d the detector leakage current, and k,T Boltzmann constant and temperature. Hence, in a 1 kΩ resistor at room temperature, for example, one finds a current-independent thermal noise of $\sqrt{d\langle i^2 \rangle/df} = 4\,\mathrm{pA}/\sqrt{\mathrm{Hz}}$ or $\sqrt{d\langle v^2 \rangle/df} = 4\,\mathrm{nV}/\sqrt{\mathrm{Hz}}$, respectively. For $1/f$ noise, by contrast, the spectral power density is proportional to $1/f^\alpha$ ($\alpha = 0.5$–2) with a device specific proportionality constant. In what follows, we will assume $\alpha = 1$ for simplicity reasons, noting though that more complex models exist.

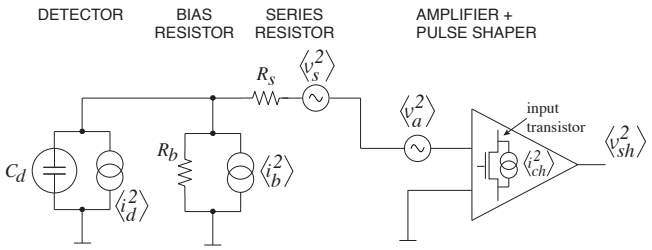

Figure 35.32: Equivalent circuit diagram for noise analysis.

An important noise source is the preamplifier input stage, very often dominated by the first amplification transistor. In what follows we assume a MOSFET at this point, as the large majority of amplification circuits is based on MOS transistors. Noise sources in bipolar amplification is shortly mentioned at the end of this section. A MOS transistor's channel features thermal noise with "resistance" $1/g_m$, where $g_m = \partial I/\partial V$ is the transconductance. Correction factor(s) for parametrization depend on the transistor operation point. Conventionally, a factor γ is applied varying between 0.5 and 1 when temperature dependence is implicit, but is commonly taken as $\gamma \approx 2/3$ for operation in strong inversion and 0.5 in weak inversion.

In addition, especially in MOSFETs, there is $1/f$ noise originating from trapping/detrapping processes of charge carriers at the channel's Si–SiO_2 interface. The channel's current noise is equivalent to a voltage noise at the transistor input (the gate) via

$$\langle i_{ch}^2 \rangle = \langle (g_m v_a)^2 \rangle \tag{35.27}$$

leading to respective noise power spectral densities of

$$\frac{d\langle v_a^2 \rangle}{df} = 4kT\gamma \frac{1}{g_m} + K_f \frac{1}{C'_{ox} WL} \frac{1}{f}\,, \tag{35.28}$$

where the individual (uncorrelated) noise contributions add in quadrature. The "$1/f$ noise constant" K_f has magnitude in the order of 10^{-24}–10^{-26}J depending on the device type and the technology[8]. C'_{ox} is the oxide capacitance per unit area, and W, L are width and length of the gate.

[8] Other $1/f$ noise parametrizations also exist with correspondingly different numerical values for K_f.

Particle and radiation detectors typically convert the deposited energy into charge (usually e-ion or e-h pairs) which can be measured by integrating the current induced on an electrode by the drifting charge pairs (see *e.g.* Sec. 35.8) employing a "charge-sensitive (pre)amplifier" (CSA), realized by feeding back the preamp's output to the input through capacitor C_f (dashed circuit part of Fig. 35.31). The feedback capacitance must be discharged for the next pulse to appear, for example by a resistor, a (constant) current source or a switch. Noise contributions from such components can usually be kept small in comparison.

For a CSA the noise output voltage after the preamplifier $\langle v_{pa}^2 \rangle$ relates to the input (current or voltage) noise sources via the transimpedance $1/\omega C_f$ as

$$\left\langle v_{pa}^2 \right\rangle = \left\langle i_{in}^2 \right\rangle \left(\frac{1}{\omega C_f} \right)^2 \quad \text{or} \quad \left\langle v_{pa}^2 \right\rangle = \left\langle v_{in}^2 \right\rangle \left(\frac{\omega C_D}{\omega C_f} \right)^2 \tag{35.29}$$

with $\omega = 2\pi f$. The capacitance C_D includes the detector capacitance C_d plus all capacitances shunting the input. Considering only the (usually) dominant noise sources, being the detector shot noise as well as the transistor channel noise, and neglecting the resistor parallel and serial noise sources of (35.26) by choosing R_b large and keeping R_s small, one obtains

$$\frac{d\left\langle v_{pa}^2 \right\rangle}{d\omega} = \sum_{k=-2}^{0} c_k\, \omega^k \tag{35.30}$$

with

$$c_{-2} = \frac{e}{\pi} I_d \frac{1}{C_f^2}\,, \quad c_{-1} = K_f \frac{1}{C'_{ox} WL} \frac{C_D^2}{C_f^2}\,, \quad c_0 = \frac{2\gamma}{\pi} kT \frac{1}{g_m} \frac{C_D^2}{C_f^2}\,, \tag{35.31}$$

which correspond to the discussed main noise components, c_{-2}: shot noise, c_{-1}: $1/f$ noise, c_0: thermal noise, respectively.

The filtering effect of the shaper limits the bandwidth of the system and is generally described by a transfer function $H(\omega)$ for $\langle v_{pa}^2 \rangle$ integrated over the full bandwidth

$$\left\langle v_{\mathrm{sh}}^2 \right\rangle = \int_0^\infty \frac{d\langle v_{\mathrm{pa}}^2 \rangle}{d\omega}\, |H(\omega)|^2\, d\omega \tag{35.32}$$

with $\langle v_{sh}^2 \rangle$ being the shaper output voltage noise. $H(\omega)$ depends on the filter circuit, *i.e.* the shape of the pulse formed by the shaper, and is characterized by a characteristic time τ, the shaping time, which can, for example, be the peaking time of a semi-gaussian pulse or the sampling interval in a correlated double-sampler (see *e.g.* [8]). The peaking time is an important quantity for readout systems since for peaking times large compared to the duration of the input signal the amplitude at peaking time corresponds to the total input charge.

For a simple time-invariant CR–RC filter, consisting of a high-pass followed by a low-pass filter with equal time constants, the transfer function is

$$|H(\omega)|^2 = A^2 \left(\frac{\omega\tau}{1 + \omega^2\tau^2} \right)^2 \tag{35.33}$$

and (35.30) becomes

$$\left\langle v_{\mathrm{sh}}^2 \right\rangle = \frac{\pi}{4} A^2 \left(c_{-2}\,\tau + \frac{2}{\pi} c_{-1} + c_0 \frac{1}{\tau} \right) \tag{35.34}$$

with A being an overall gain factor.

The system noise for a charge measurement is conveniently expressed as an equivalent noise charge (ENC) referring the noise to the equivalent signal of one electron at the input:

$$\mathrm{ENC}^2 = \frac{\langle v_{\mathrm{sh}}^2 \rangle}{v_{\mathrm{signal}}^2 (1e^-)}\,. \tag{35.35}$$

While being dimensionless by definition, ENC is commonly expressed as an equivalent number of electrons (e^-) at the input or alternatively as equivalent Coulombs (C) when multiplying by the

elementary charge or as equivalent deposited energy (eV), where $1e^-$ equivalent charge corresponds to 3.65 eV of equivalent deposited energy in Si (see Tab. 35.10 in Sec. 35.8).

A charge of one electron at the input yields a voltage signal (peak) behind the shaper of $v_{\rm signal} = \dfrac{A}{2.71}\dfrac{e}{C_f}$. Hence with (35.35) and (35.34) one obtains:

$$\mathrm{ENC}^2\,(e^{-2}) = \frac{(2.71)^2}{4e^2}\left(eI_d\tau + 2C_D^2\,K_f\,\frac{1}{C'_{ox}WL} + \gamma\frac{2kT}{g_m}\,\frac{C_D^2}{\tau}\right)$$
$$= a_{\rm shot}\,\tau + a_{1/\rm f}\,C_D^2 + a_{\rm therm}\,\frac{C_D^2}{\tau}\,, \qquad (35.36)$$

where 2.71 is Euler's number resulting from the amplitude peak value behind the (CR–RC) shaper (for $t = \tau$), while e is the elementary charge and (e^-) explicitly denotes the equivalent number of electrons at the input.

Equation (35.36) accentuates the main noise dependencies of the system. The contribution from parallel current shot noise (*i.e.* detector leakage) increases with shaping time, *i.e.* with pulse duration, whereas thermal noise (here serial voltage noise at the gate, originating from transistor channel noise) decreases with increasing shaping time, *i.e.* with reduced bandwidth. Noise with a $1/f$ spectrum depends only on the ratio of upper to lower cutoff frequencies (low pass to high pass time constants) and is hence independent of τ for a given shaper topology. Furthermore, the contribution of serial noise voltage ($1/f$ and thermal noise) to ENC increases with input (detector) capacitance C_D. Pulse shapers can be designed to optimize the noise performance of a system or to mitigate operation variations with time (*e.g.* due to radiation damage) deteriorating the performance, at the expense of loss of simplicity. For example, a shaper with one high-pass filter followed by four cascaded low-pass filters, increases the pulse symmetry and tends to decrease the current noise, but increases the voltage noise contributions for the circuit of Fig. 35.32, if the same peaking time is assured by adjusting the individual time constants of the filter stages. If instead the low-pass filters cause the peaking time of the pulse to increase, the opposite can be true. More details about shaping filters can be found *e.g.* in [8, 376–378].

Figure 35.33 shows a typical example of eq. (35.36) displaying ENC as a function of shaping time τ for a system. At short shaping times, thermal noise dominates, whereas for longer shaping times the shot noise contribution takes over. The total noise has a minimum at a shaping time where shot and thermal noise contributions are equal. The minimum is flattened by the presence of $1/f$ noise. Increasing the detector capacitance increases the thermal and $1/f$ contributions and shifts the noise minimum to larger shaping times. One can hence exploit the shaping time dependence of the total noise to determine the individual noise contributions of a system.

For quick estimates (35.36) is cast into a useful equation for a typical CSA-shaper system [1]:

$$\mathrm{ENC}^2\,(e^{-2}) = 11\,\frac{I_d}{\rm nA}\,\frac{\tau}{\rm ns} + 740\,\frac{1}{WL/(\mu\mathrm{m}^2)}\,\frac{C_D^2}{(100\,\mathrm{fF})^2}$$
$$+\,4000\,\frac{1}{g_m/\mathrm{mS}}\,\frac{C_D^2/(100\,\mathrm{fF})^2}{\tau/\mathrm{ns}}\,, \qquad (35.37)$$

where $\gamma = 2/3$, $K_f = 33 \times 10^{-25}$J, and $C'_{ox} = 6$ fF/μm^2 has been used, the latter being typical for CMOS technologies as employed for example for the detector readout chips of the LHC experiments and their upgrades. Generally, noise performance is improved by reducing the detector capacitance and the leakage current, judiciously selecting all resistances in the input circuit, and by choosing the optimum shaping time constant τ. Another noise contribution to consider is the fact that noise can cross-couple from the neighbouring front-ends in detectors with structured electrodes through the inter-electrode capacitance.

As mentioned, the noise parameters of the amplifier depend primarily on the input device (input transistor(s)). In field-effect transistors, the input noise current contribution of the transistor itself is very small. Hence, if the experiment's time structure permits, reducing the detector leakage current and increasing the bias resistance will allow long shaping times with correspondingly lower noise. For amplifiers employing bipolar transistors, shot noise sources originate from both, base-emitter and collector-base, junctions and from the series resistance at the base which is especially important for small structures optimized for radiation hardness. For the shot-noise contribution, the input base current I_B sets a lower bound on the noise current, such that these devices are best at short shaping times.

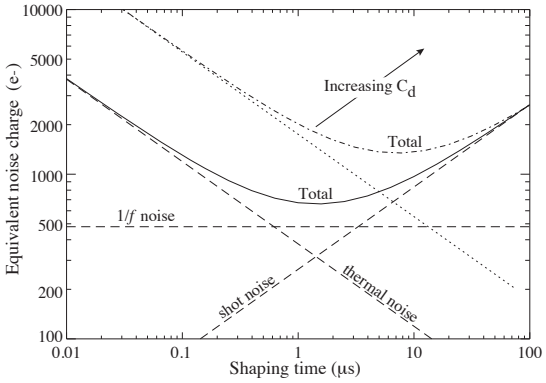

Figure 35.33: Equivalent noise charge *vs* shaping time. Changing the detector capacitance C_D affects thermal and $1/f$ noise contributions and moves the noise minimum as indicated by the dotted and dash-dotted lines. The $1/f$ noise contribution is small for the chosen parameters ($C_D = 20$ pF, $I_d = 10$ nA, $g_m = 1$ mS) in this example.

35.9.2.0.1 Examples Using (35.37) one finds for a typical pixel detector (before heavy irradiation) with $C_D = 200$ fF, $I_d = 1$ nA, $\tau = 50$ ns, $W = 20$ μm, $L = 0.5$ μm, $g_m = 0.5$ mS:

$$\mathrm{ENC}^2 \approx (24\,e^-)^2\Big|_{\rm shot} + (17\,e^-)^2\Big|_{1/\rm f} + (25\,e^-)^2\Big|_{\rm therm} \approx (40\,e^-)^2\,.$$

For a typical silicon microstrip detector after radiation damage (fluence $\gtrsim 10^{14}\mathrm{n_{eq}/cm^2}$, assuming no degradation of the front-end electronics due to radiation) one obtains for $C_D = 20$ pF, $I_d = 1$ μA, $\tau = 50$ ns, $W = 2000$ μm, $L = 0.4$ μm, $g_m = 5$ mS:

$$\mathrm{ENC}^2 \approx (750\,e^-)^2\Big|_{\rm shot} + (200\,e^-)^2\Big|_{1/\rm f} + (800\,e^-)^2\Big|_{\rm therm} \approx (1100\,e^-)^2\,.$$

Apart from the larger leakage current, the larger capacitance of strips compared to pixels leads to a much worse noise performance which can only be partially compensated by allowing more power in the amplification transistor, *i.e.* by increasing g_m.

A liquid argon calorimeter cell is a suitable example of a detector with a large electrode capacitance with typical parameters (similar to the ATLAS central electromagnetic calorimeter, see Sec. 35.10). Using $C_D = 1.5$ nF, $I_d = < 2$ μA, $\tau = 50$ ns, $W = 3000$ μm, $L = 0.25$ μm, $g_m = 100$ mS, one obtains:

$$\mathrm{ENC}^2 \approx (1000\,e^-)^2\Big|_{\rm shot} + (15000\,e^-)^2\Big|_{1/\rm f} + (13500\,e^-)^2\Big|_{\rm therm}$$
$$\approx (20200\,e^-)^2\,.$$

Here only a small (negligible) parallel shot noise (leakage current) contribution is assumed, which is typical for liquid argon calorimeters.

Practical noise levels range from $\sim 1e^-$ for CCD's at long shaping times to $\sim 10^4\,e^-$ in high-capacitance liquid argon calorimeters. Gaseous micropattern detectors like GEMs or MicroMegas (see Sec. 35.6.4) typically feature noise levels between $1000\,e^-$ and $1500\,e^-$, depending on the ability to correct for common-mode noise. Silicon strip detectors typically operate at levels of $\sim 10^3\,e^-$, whereas pixel detectors with fast readout typically have noise levels below about 100 electrons.

35.9.3 *Timing measurements*

In timing measurements, the slope-to-noise ratio must be optimized, rather than the signal-to-noise ratio alone, so the rise time t_r of the pulse is important. The "jitter" σ_t of the timing distribution is

$$\sigma_t = \frac{\sigma_n}{(dS/dt)_{\rm trig}} \approx \frac{t_r}{SNR}, \tag{35.38}$$

where σ_n is the rms noise, SNR the signal-to-noise ratio and the "slew rate" dS/dt, *i.e.* the derivative of the signal, is evaluated at the trigger level. The rise-time of a CSA again depends on the detector and feedback capacitances and on the amplifier transconductance

$$t_r \propto \frac{C_D}{C_f \cdot g_m}\,. \tag{35.39}$$

To increase dS/dt without incurring excessive noise, the amplifier bandwidth should match the rise time of the detector signal. The 10% to 90% rise time of an amplifier with bandwidth f_U is $0.35/f_U$. For example, an oscilloscope with 350 MHz bandwidth has a 1 ns rise time. For cascaded amplifiers, the individual rise times add in quadrature to first order.

As increasing SNR also improves the time resolution, minimizing the total input capacitance is extremely important for timing measurements (see also Sec. 35.8). At high signal-to-noise ratios, the time jitter can be much smaller than the rise time. The time-mark distribution of pulses may shift with the signal level ("time walk"), but this can be corrected by various means, either in hardware or in software.

For applications aiming at extreme time resolution charge-sensitive (integrating) amplification can be less optimal. Transimpedance or voltage amplifiers converting current/voltage to voltage are usually preferred. Also, when aiming for picosecond timing using voltage amplifiers, *e.g.*, with LGAD detectors having C_D of $\mathcal{O}$(pF) (see Sec. 35.8), not only the preamplifier rise time t_r but also the signal pulse duration t_d at the preamplifier input is important, *i.e.*, the preamplifier must react draining the charge from C_D before the input voltage $v_{in} = Q_S/C_D$ (Q_S = signal charge) reaches its peak. Both times must reasonably match, $t_r \approx t_d$, resulting in a time jitter of [379]

$$\sigma_t^2 \approx \frac{C_D^2}{Q_S^2}\frac{d\langle v_n^2\rangle}{df}\; t_d\,, \tag{35.40}$$

where $d\langle v_n^2\rangle/df$ is the voltage noise spectral density.

35.9.4 *Digital signal processing*

The filtering principles apply to both analog and digital signal processing. In digital signal processing the pulse shaper shown in Fig. 35.31 is replaced by an analog to digital converter (ADC) followed by a digital processor that determines the pulse shape. Digital signal processing allows great flexibility in implementing filtering functions. The software can be changed readily to adapt to a wide variety of operating conditions and it is possible to implement filters that are impractical or even impossible using analog circuitry. However, this comes at the expense of increased circuit complexity and increased demands on the ADC compared to analog shaping.

If the sampling rate of the ADC is too low, high frequency components will be transferred to lower frequencies ("aliasing"). The sampling rate of the ADC must be high enough to capture the maximum frequency component of the input signal. Apart from missing information on the fast components of the pulse, undersampling introduces spurious artifacts. If the frequency range of the input signal is much larger than the sampling rate, the noise at the higher frequencies will be transferred to lower frequencies and will increase the noise level in the frequency range of pulses formed in the subsequent digital shaper. The Nyquist criterion states that the sampling frequency must be at least twice the maximum relevant input frequency. This requires that the bandwith of the circuitry preceding the ADC must be limited. The most reliable technique is to insert a low-pass filter.

The digitization process also introduces inherent noise, since the voltage range ΔV corresponding to a minimum bit step introduces quasi-random fluctuations relative to the exact amplitude

$$\sigma_n = \frac{\Delta V}{\sqrt{12}}\,. \tag{35.41}$$

When the Nyquist condition is fulfilled the noise bandwidth Δf_n is spread nearly uniformly and extends to 1/2 the sampling frequency f_S, so the spectral noise density is

$$\frac{\sigma_n}{\sqrt{\Delta f_n}} = \frac{\Delta V}{\sqrt{12}} \cdot \frac{1}{\sqrt{f_S/2}} = \frac{\Delta V}{\sqrt{6 f_S}}\,. \tag{35.42}$$

Sampling at a higher frequency spreads the total noise over a larger frequency range, so oversampling can be used to increase the effective resolution. In practice, this quantization noise is increased by the ADC's differential non-linearity (DNL). Furthermore, the equivalent input noise of ADCs is often rather high, so the overall gain of the stages preceding the ADC must be sufficiently large for the preamplifier to override the ADC input noise.

35.9.5 *What to use when?*

When implemented properly, digital signal processing provides significant advantages in systems where the shape of detector signal pulses changes greatly, for example in large semiconductor detectors for gamma rays or in gaseous detectors (*e.g.* TPCs) where the duration of the current pulse varies with drift time, which can range over orders of magnitude. Analog signal processing is best or most efficient in systems that require fast time response, but the high power requirements of high-speed ADCs are prohibitive. Systems that are not sensitive to pulse shape can use fixed shaping time constants and rather simple filters (like CR–RC), which can be either continuous or sampled. In high-density systems that require small circuit area and low power (*e.g.*, in strip and pixel detectors), analog filtering often yields the required response and tends to be most efficient.

As stressed already in the introduction, it is important to consider that additional noise is often introduced externally. Recognizing additional noise sources and minimizing cross-coupling to the detector current loop is often essential to obtain the best overall noise performance. Understanding basic physics and its practical effects is important in forming a broad view of the detector system and recognizing potential problems (*e.g.* modified data), rather than merely following standard recipes.

More comprehensive treatments of low noise detector readout and signal processing can be found, for example, in [8, 376, 378] and in [1, 363].

35.10 Calorimeters

35.10.1 *Introduction*

Revised August 2023 by F. Sefkow (DESY, Hamburg) and F. Simon (KIT).

A calorimeter measures the energy and direction of particles by absorption in the detector material and registration of the energy deposited in an (ideally) contained electromagnetic (EM) or hadronic shower. Calorimeters are central components of modern high energy physics experiments, due to their ability to measure not only the energy of charged particles (with the exception of muons), but also of photons and neutral hadrons, thus enabling the reconstruction of π^0 and η decays and of exclusive final states involving long-lived neutral kaons, or neutrons. They are indispensable for the measurement of particle jets and for the reconstruction of total event properties, which, via the measurement of missing energy (or missing transverse energy in hadron colliders). enable the detection of the presence of "invisible" particles such as neutrinos and hypothetical particles such as dark-matter candidates. Calorimeters are also important for the identification of particle species, using information on the longitudinal and transverse shape of the energy deposition to separate electrons, photons, hadrons and muons. While the performance of calorimeters is typically assessed by the quality of their energy measurements, position resolution, both for EM and hadronic showers, is also

highly relevant, for example for the reconstruction of effective jet masses. The capability to measure high-level observables that serve to classify events, such as particle and jet energies, missing energy and isolated leptons, makes calorimeters central components of the trigger systems in high-energy physics experiments.

In collider experiments, the importance of calorimeters tends to increase with increasing collision energies since the relative energy resolution improves with increasing particle energy while the depth required for full containment of the showers shows only logarithmic growth with energy. This is in contrast to the precision of track-based measurements, which is decreasing with increasing momentum. With recent advances in timing capabilities calorimeters are also contributing to the rejection of pile-up from multiple interactions within the same bunch crossings at colliders.

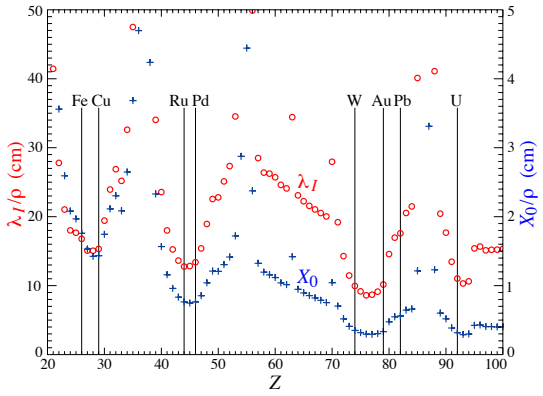

Figure 35.34: Nuclear interaction length λ_I/ρ (circles) and radiation length X_0/ρ (+'s) in cm for the chemical elements with $Z > 20$ and $\lambda_I < 50$ cm.

The characteristic length scale for EM showers is the radiation length X_0, which ranges from 1.8 cm (13.8 g cm^{-2}) in iron to 3.2 mm (6.0 g cm^{-2}) in uranium for materials used to generate showers in calorimeters.[9] Similarly, the characteristic nuclear interaction length λ_I varies from 16.8 cm (132.1 g cm^{-2}) (Fe) to 11.0 cm (209 g cm^{-2}) (U).[10] There is a premium on small λ_I/ρ and X_0/ρ (both with units of length). These quantities are shown for elements with $Z > 20$ in Fig. 35.34. The minima for both X_0 and λ_I correspond to elements between W and Au. Some of these elements are very difficult to work with (e.g. W) or expensive (e.g. Au), so, depending on the application (size of the required calorimeter) other materials, such as Fe, Cu, Pb, and different alloys like brass and CuW are often chosen. For EM calorimeters high Z is preferred; here Pb is a popular choice, while W provides even higher density and is generally affordable due to the limited volume of EM systems.

Most existing calorimeters are subdivided into a front EM section (ECAL) and a hadronic part (HCAL) behind; electrons and photons are measured in the ECAL, while hadrons and jets are measured in the combined ECAL and HCAL system. The detailed design depends on energy range and performance requirements as well as on size and cost constraints for the entire system. EM calorimeters tend to be 15–30 X_0 deep, while hadronic calorimeters are usually optimised for cost and performance at 5–8 λ_I. The depth of the ECAL typically corresponds to approximately 1 λ_I, with the exact value depending on the material. This means that approximately 70% of all hadronic showers will already begin in the electromagnetic calorimeter, making its response to a hadronic cascade highly relevant for the overall performance of the system. The choice of the calorimeter technology for the ECAL is thus a result of simultaneous optimisation for EM and hadronic performance of the overall system.

Sampling calorimeters consist of a high-density, normally metallic absorber sandwiched (or threaded) with an active material which generates a signal in response to shower particles. The active medium may be a scintillator, a noble liquid, a gas, silicon, or a Cherenkov radiator. These active media all have a relatively low Z, a significantly lower density, and larger X_0 and λ_I values than typical absorber materials. The average radiation and interaction lengths in the full detector are thus larger than those of the absorber alone.

There are also *homogeneous calorimeters*, in which the entire volume contributes to the signal. Homogeneous calorimeters may be built with inorganic heavy scintillating crystals or non-scintillating Cherenkov radiators such as lead glass and lead fluoride. Nuclear interaction lengths in inorganic crystals range from 17.8 cm ($LuAlO_3$) to 42.2 cm (NaI). Materials with low X_0 used in large systems are for example BGO with $\lambda_I = 22.3$ cm and $X_0 = 1.12$ cm, and $PbWO_4$ (20.3 cm and 0.89 cm). Properties of these and other commonly used inorganic crystal scintillators can be found in Table 35.4. Cryogenic noble liquids, where scintillation light and/or inonization can be detected, are also suitable materials for homogeneous detectors.

Homogeneous calorimeters at colliders are usually only used for the EM section. For the use of homogeneous calorimeters for hadron energy measurement, the large differences in the response to EM and hadronic parts of the shower are a significant challenge, as is the three-dimensional segmentation. This is still requiring substantial R&D, including the search for affordable materials. In non-accelerator physics experiments or at neutrino beams, homogeneous calorimeters, where the sensitive medium can be water or ice, scintillator, a noble liquid or the atmosphere itself, are used to detect both EM and hadronic showers.

Comprehensive tables of particle-physics calorimeters are given as Appendix C in Ref. [380].

35.10.1.1 *Energy Resolution and System Performance*

The energy resolution of calorimeters is a complex observable, due to the variety of contributing processes with different energy dependencies, and response functions often not perfectly Gaussian. Nevertheless, a simplified picture is useful in practice, and in particular for EM calorimeters also numerically accurate. For hadronic calorimeters additional complications must be taken into account. In such a simplified picture, due to the stochastic nature of shower evolution, the intrinsic calorimeter energy resolution, σ, is proportional to $\sqrt{E}$, as the number of charged particles, or the total ionising track length in a shower are on average proportional to the incident particle energy E. The relative resolution σ/E therefore improves with $A/\sqrt{E}$, where A denotes the so-called *stochastic term*. The readout system of the active medium will contribute noise to the resolution, $\sigma_N = B$, which in general is not energy-dependent. Effects that are proportional to the total deposited energy result in a *constant term*, $\sigma_C = C \cdot E$. Different sources contribute to this term, depending on the type of calorimeter. For both EM and hadronic calorimeters, imperfections of the detector, inhomogeneities such as density variations or those introduced by the detector mechanics, instabilities in time, imperfections of the readout or incorrect calibration of channels contribute. Shower leakage, which depends on particle energy, also contributes to the resolution with approximately linear dependence on energy. In non-compensating hadronic calorimeters, fluctuations of the EM fraction f_{em} from shower to shower, together with the energy dependence of the average f_{em} value, can lead to a significant constant term that often dominates over the instrumental effects. Adding up all contributions in quadrature yields the standard parameterisation of the relative energy resolution of a calorimeter:

$$\frac{\sigma}{E} = \frac{A}{\sqrt{E}} \oplus \frac{B}{E} \oplus C\,. \qquad (35.43)$$

In particular the effects specific to hadronic showers give rise to non-Gaussian distributions of the energy response. Therefore care must be used in performance comparisons, as different parameterisations of the line shape and different definitions of the resolution are in use. In some cases, a linear rather than a quadratic addition of the stochastic and constant term may provide a better description of the energy resolution as a function of energy. It should be noted that the individual terms then lose the simplified

[9] $X_0 = 120\ \mathrm{g\,cm^{-2}}\ Z^{-2/3}$ to better than 5% for $Z > 23$.
[10] $\lambda_I = 37.8\ \mathrm{g\,cm^{-2}}\ A^{0.312}$ to within 0.8% for $Z > 15$.
See https://pdg.lbl.gov/current/AtomicNuclearProperties for actual values.

interpretation discussed above, and care has to be taken when comparing performance based on fits to the energy dependence of the resolution.

Typically, primarily the stochastic term — which is determined by the calorimeter design in terms of material and geometry — is considered in order to describe the overall properties of a calorimeter. For the calorimeters of the multi-purpose experiments at the LHC, the stochastic terms are $3-10\%$ for electromagnetic and $50-80\%$ for hadronic calorimeters. In practice, the energy resolution of a calorimeter at high energies is limited by the constant term C, which in the EM case mainly reflects the precision and stability of the mechanical construction, electronic readout system and calibration. Typical constant terms are a few per-mil for EM and a few percent for hadronic calorimeters. For concrete examples and references see Tables 35.11 and 35.13.

For sampling calorimeters, the stochastic term depends on the *sampling fraction* $f_{\rm samp}$, i.e. the ratio of energies deposited in the active and passive material. Also the *sampling frequency* enters, which is determined by the number N of different sampling elements present in the region in which the shower develops. The stochastic term A scales approximately with $1/\sqrt{f_{\rm samp}}$, and for given $f_{\rm samp}$ and total depth, with $1/\sqrt{N}$.

While the energy resolution for single hadrons (most commonly pions) is often used as the key performance criterion for a hadronic calorimeter, it has to be noted that this value is only of limited relevance in high-energy physics experiments. In most experiments, the calorimetric measurement of hadrons is based on the combined system consisting of ECAL and HCAL. Moreover, for the physics capabilities of a detector at a high-energy particle collider, also the combined calorimetric resolution for single hadrons is not a sufficient criterion to fully characterise hadronic performance, but rather the jet energy resolution, the resolution for missing (transverse) energy, and the capability to cope with high background and pile-up levels. These quantities cannot be measured directly with prototypes in beam tests, and strongly depend on overall system aspects and reconstruction tools. However, the performance in these observables can be reliably inferred from system simulations once the simulated response to single particles and the simulated topology of showers has been validated in detail by beam tests.

Besides energy resolution, response linearity is an important factor in the design of calorimeters. While a non-linear response for single particles can be corrected for if appropriate calibration measurements exist, such corrections deteriorate the energy resolution, in particular in the case of superposition of several showers, as it often occurs in jets. Sources for non-linearities can be intrinsic to the design, for example due to saturation effects in the active medium with increasing energy density, due to leakage, or connected to shower physics as discussed in section 35.10.3.

The energy resolution for hadrons is intrinsically limited by large event-to-event fluctuations of the shower evolution and of "invisible" components not contributing to the detector signal. It remains the limiting factor for single particles and for the high-level performance for jets and total event properties. This has motivated intense research in the past decades. One direction aims at improving the hadronic resolution by extracting additional signals to disentangle the shower composition, e.g.with so-called dual read-out methods, and is explained in the hadron calorimeter section 35.10.3. Another, so-called "particle flow" approach described below optimises the combination of measurements of individual particles in different detector components. Ideally, both methods can be combined.

35.10.1.2 *Role of Simulations*

Simulations have become indispensable for the design of detectors and the development of reconstruction algorithms. Since event-to-event fluctuations drive calorimeter performance, Monte Carlo techniques that accurately model the evolution of particle cascades in material are required. By far the most common computer code in use today is the *GEANT4* toolkit [381, 382], which provides a step-based simulation of the passage of particles through matter. Thanks to the relative simplicity of EM cascades, simulations of EM showers are typically highly accurate. The modelling of hadronic showers is more complex, and suffers from larger uncertainties. Significant improvement has been achieved in this area, moving from simpler parameterised models to physics-driven interaction models. From early on, detailed codes and data describing nuclear break-up and neutron transport like *CALOR* [383] or *FLUKA* [384, 385] contributed crucially to the understanding of hadron calorimetry. The simulations reproduce the general features of the substructure of hadronic showers, characterised by dense shower activity and sparser ionising track segments, and their accuracy is adequate for most purposes of quantitative design optimisations. Details of the implementation of physics models in *GEANT4* are discussed in [386].

35.10.1.3 *Particle flow approach*

In a typical collider experiment, the EM and hadronic calorimeter system surrounds a charged-particle tracking volume devised for momentum measurement in a magnetic field. Matching tracks to calorimetric energy deposits provides corrections for the magnetic deflection of the charged particles, necessary for the reconstruction of invariant masses in multi-jet final states, or of the total momentum imbalance. Furthermore, for charged particles the track-based measurements are far more precise for particles in jets with energies of up to several hundred GeV, so using these instead of calorimeter energies may optimise the jet energy resolution. This so-called "particle flow" approach aims at reconstructing each particle individually, using a combination of the best measurements from the detector.

About 60% of the energy in a typical jet is carried by charged particles, predominantly hadrons, 30% by photons and only 10% by long-lived neutral hadrons (K_L^0 and n), for which hadronic calorimetry is unavoidable. Assuming, as motivated by detector designs proposed for a future Higgs factory, $15\%/\sqrt{E(\mathrm{GeV})}$ for photons and $55\%/\sqrt{E(\mathrm{GeV})}$ for hadrons, then, in the ideal case, where each particle is resolved, a jet energy resolution of $19\%/\sqrt{E(\mathrm{GeV})}$ could be obtained. Here the dominant part ($18\%/\sqrt{E(\mathrm{GeV})}$) is still due to the calorimeter resolution for neutral hadrons.

The particle flow method places high demands on the imaging capabilities of the calorimeters, and on the pattern recognition performance of the reconstruction algorithms. Only energy deposits not associated with charged particles and not identified as photons, will be interpreted as neutral hadrons. In practice, this cannot always be done unambiguously, and mis-assignments give rise to an additional measurement uncertainty, which is called *confusion*. For simulated detectors at proposed future Higgs factories jet energy resolutions of 3-4% have been demonstrated, significantly larger than in the ideal case, but sufficient for the required efficient separation of W and Z hadronic final states.

Particle flow-like techniques were first applied in the ALEPH detector [387], which achieved a jet energy resolution of $60\%/\sqrt{E}$, or 6.2 GeV for hadronic Z decays. More recently, particle flow techniques are successfully used in the CMS experiment [388], for example improving the missing energy resolution by one third over a wide range.

The Pandora particle flow algorithm (PFA) [389] is the most developed and best performing today in the context of future lepton colliders. The algorithms make use of topological information, including the sub-structure of showers, as well as the compatibility of calorimetric and track-based measurements. In this way the purely calorimetric performance for the jet is either retained or improved. In the framework of studies for CLIC [390], it was shown that the required jet energy resolution of 3.5% can be achieved with the PF technique for jet energies up to 1500 GeV.

For the use of energy-momentum matching in the assignment of energy depositions, and for energy flow treatment of dense jets, particle flow calorimeters with their emphasis on imaging must still feature a good energy resolution. Furthermore, the neutral hadron energy uncertainty is the dominant contribution to the jet resolution for low energy jets, where particles are well separated, while at higher energies the confusion effects take over.

High granularity in all three space dimensions comparable to or smaller than the length scales of particle showers given by X_0

and ρ_M for both ECAL and HCAL brings additional advantages; for example it offers ideal conditions for the application of software compensation methods, which improves the intrinsic resolution and also reduces "confusion" [391]. A particular strength is the possibility to use topological information such as the reconstructed starting point of the shower for the estimation of leakage. Moreover, the combination of fine-grained topological reconstruction and cuts on cluster-wise timing with a precision of few tens of pico-seconds allows for powerful pile-up rejection. This extends the application range of particle flow methods towards collider environments with less benign background conditions, like multi-TeV e^+e^- collisions, and it is an asset on its own for high-intensity hadron colliders, even if particle flow methods are difficult to apply.

The performance of highly granular calorimeters depends, among others, on the particle separation and pattern recognition capabilities and on the single particle energy and timing resolution. They are thus not only optimised for energy measurement, but also for multi-dimensional shower reconstruction and particle separation in space and time. The potential of such calorimeters can be further enhanced by combining a fine spatial segmentation with maximised information on energy, time, and possibly the nature of the energy deposition, for example by using dual-readout methods. This may be achieved, for example, by combining multiple optical materials sensitive to different components in the shower in finely segmented sandwich calorimeters, or by using timing information to extract the position of the energy deposition along a fibre. For future collider experiments, different approaches based on silicon, scintillator, noble liquid, fibre and crystal readout are being pursued [392]. They all foresee, with different level of emphasis, high granularity to enable the application of particle flow methods, and in some cases to further enhance their performance by additional information not exploited in current algorithms. One such example is the proposal [393] to benefit from the superior electromagnetic energy performance of crystals to pair photons from π^0 decays and thereby resolve jet finding ambiguities to improve the jet energy resolution.

35.10.2 *Electromagnetic calorimeters*

Revised August 2023 by C.L. Woody (BNL) and R.-Y. Zhu (HEP California Inst. of Technology).

The development of electromagnetic showers is discussed in the section on "Passage of Particles Through Matter" (Sec. 34 of this *Review*). Formulae are given which approximately describe average showers, but since the physics of electromagnetic showers is well understood, a detailed and reliable Monte Carlo simulation is possible. EGS4 [394] and GEANT [381] have emerged as the standards.

Electromagnetic calorimeters are devices that are designed to measure the total energy of electrons and photons by total absorption. They come in two general categories: homogeneous and sampling. In a homogeneous calorimeter, all of the particle's energy is deposited in the active detector volume and is used to produce a measurable signal (either scintillation light, Cherenkov light or charge). Homogeneous electromagnetic calorimeters are typically constructed using high density, high Z inorganic scintillating crystals such as BaF_2, BGO, CsI, CsI(Tl), LYSO, NaI(Tl) and PWO, non-scintillating Cherenkov radiators such as lead glass and lead fluoride (PbF_2), or ionizing noble liquids such as liquid argon, liquid krypton or liquid xenon. The properties of some commonly used inorganic crystal scintillators can be found in Table 35.4. Total absorption homogeneous calorimeters such as those built with heavy crystal scintillators provide the best energy resolution for measuring electromagnetic showers and are generally used when the best possible performance is required, particularly at lower energies. Attention, however, needs to be paid to radiation damage in inorganic scintillators when exposed to the typical environment of high luminosity proton colliders, as discussed below and in Section 35.4.

A sampling calorimeter consists of an active medium which generates a signal and a passive medium which functions as an absorber. In this case, most of the particle's energy is deposited in the absorber and only a fraction of the energy is detected in the active medium. The ratio of energy in the sampling medium to the total enegy in calorimeter is called the sampling fraction. The active medium may be a scintillator, an ionizing noble liquid, a semiconductor, or a gas ionization detector. The absorber is typically a heavy metal with a high Z such as lead, tungsten, iron, copper, or depleted uranium. The active material is interspersed with the passive absorber in a variety of ways, e.g. by using alternating plates of active material and absorber or embedding the active material, such as scintillating fibers, into the absorber. The main difficulty in this approach is extracting the signal from the active material. One possibility is a simple stack of alternating absorber and active material, which, however, usually leads to gaps for services and hence non-uniformities. This can be improved by using a so-called "spaghetti" design, where scintillating fibers are brought to the front or back of the detector and read out. This can also be done with either wavelength shifting plates or fibers, such as in a so-called "shashlik" design where wavelength shifting fibers run through the stack of alternating scintillator and absorber plates and are read out at end, or embedding wavelength shifting fibers in the scintillating plates which are then brought out to the edges or back of the detector and read out. For ionization detectors, there is also an "accordion" design which avoids all gaps for services and where the absorber plates are folded into an accordion shape along with interspersed electrodes to collect the ionization charge [395]. While these readout schemes are generally more complicated than those for homogeneous calorimeters, the sampling calorimeter design allows the construction of large calorimeters at much lower cost than homogeneous calorimeters.

The energy resolution σ_E/E of a calorimeter can be parameterized as $a/\sqrt{E} \oplus b \oplus c/E$, where $\oplus$ represents addition in quadrature and E and σ_E are in GeV. The stochastic term a represents statistics-related fluctuations such as intrinsic shower fluctuations, photoelectron statistics, dead material at the front of the calorimeter, and sampling fluctuations for minimum ionizing particles. For a fixed number of radiation lengths, the stochastic term a for a sampling calorimeter is expected to be proportional to $\sqrt{t/f}$, where t is plate thickness and f is sampling fraction [396–398]. The stochastic term a is typically of the order of a few percent for a homogeneous calorimeter, and is generally in the range of 8 to 20% for sampling calorimeters, depending on the sampling fraction.

The main contributions to the systematic, or constant, term b are detector non-uniformity and calibration uncertainties. In the case of hadronic cascades discussed below, non-compensation also contributes deviations from $\sqrt{E}$ scaling. Another important contribution to the energy resolution of calorimeters that are used in high radiation environments such as high lumnosity colliders is radiation damage of the active medium. Radiation damage can induce optical absorption in scintillating materials which reduces the measured light output and produces non-uniformities in light collection. This can be mitigated by developing radiation-hard active media [399], by reducing the signal path length [400] and by frequent *in situ* calibration and monitoring [75, 398]. With effort, the constant term b can be reduced to below one percent. The term c is due mainly to electronic noise summed over the readout channels required to measure the shower energy (typically a few Molière radii).

The position resolution depends on the effective Molière radius and the transverse granularity of the calorimeter. Like the energy resolution, it can be factored as $a/\sqrt{E} \oplus b$, where a is the stochastic term, typically of the order of a few mm to 20 mm, and b can be as small as a fraction of mm for a dense calorimeter with fine granularity. Fine granularity also helps particle flow analysis discussed in the hadron calorimeters section below.

Electromagnetic calorimeters may also provide angular measurements for electrons and photons. This is particularly important for photon-related physics to identify the correct primary vertex, since photons are not detected by the tracking system of the overall experiment. The typical photon angular resolution is about 45 mrad/$\sqrt{E}$, which can be achieved by implementing longitudinal segmentation [395] for a sampling calorimeter or by adding a preshower detector [401] for a homogeneous calorimeter

Table 35.11: Resolution of typical electromagnetic calorimeters. E is in GeV.

Technology (Experiment)	Depth	Energy resolution	Date
NaI(Tl) (Crystal Ball)	$20X_0$	$2.7\%/\mathrm{E}^{1/4}$	1983
$Bi_4Ge_3O_{12}$ (BGO) (L3)	$22X_0$	$2\%/\sqrt{E} \oplus 0.7\%$	1993
CsI (KTeV)	$27X_0$	$2\%/\sqrt{E} \oplus 0.45\%$	1996
CsI(Tl) (BaBar)	16–$18X_0$	$2.3\%/E^{1/4} \oplus 1.4\%$	1999
CsI(Tl) (BELLE)	$16X_0$	1.7% for $E_\gamma > 3.5$ GeV	1998
CsI(Tl) (BES III)	$15X_0$	2.5% for $E_\gamma = 1$ GeV	2010
$PbWO_4$ (PWO) (CMS)	$25X_0$	$3\%/\sqrt{E} \oplus 0.5\% \oplus 0.2/E$	1997
$PbWO_4$ (PWO) (ALICE)	$19X_0$	$3.6\%/\sqrt{E} \oplus 1.2\%$	2008
Lead glass (OPAL)	$20.5X_0$	$5\%/\sqrt{E}$	1990
Liquid Kr (NA48)	$27X_0$	$3.2\%/\sqrt{E} \oplus 0.42\% \oplus 0.09/E$	1998
Scintillator/depleted U (ZEUS)	20–$30X_0$	$18\%/\sqrt{E}$	1988
Scintillator/Pb (CDF)	$18X_0$	$13.5\%/\sqrt{E}$	1988
SciFi/Pb spaghetti (KLOE)	$15X_0$	$5.7\%/\sqrt{E} \oplus 0.6\%$	1995
SciFi/W (sPHENIX)	$20X_0$	$13\%/\sqrt{E}$	2022
Liquid Ar/Pb (NA31)	$27X_0$	$7.5\%/\sqrt{E} \oplus 0.5\% \oplus 0.1/E$	1988
Liquid Ar/Pb (SLD)	$21X_0$	$8\%/\sqrt{E}$	1993
Liquid Ar/Pb (H1)	20–$30X_0$	$12\%/\sqrt{E} \oplus 1\%$	1998
Liquid Ar/depl. U (DØ)	$20.5X_0$	$16\%/\sqrt{E} \oplus 0.3\% \oplus 0.3/E$	1993
Liquid Ar/Pb accordion (ATLAS)	$25X_0$	$10\%/\sqrt{E} \oplus 0.4\% \oplus 0.3/E$	1996

without longitudinal segmentation.

There have been many electromagnetic calorimeters built and used in particle physics experiments for a variety of applications. Table 35.11 provides a short list of the major ones used in some of the larger experiments. Also listed are calorimeter depths in radiation lengths (X_0) and the achieved energy resolution. Whenever possible, the performance of the calorimeters *in situ* is quoted, which is usually in good agreement with prototype test beam results as well as EGS or GEANT simulations, provided that all systematic effects are properly included. Details about detector design and performance can be found in Appendix C of reference [398] and Proceedings of the International Conference series on Calorimetry in High Energy Physics.

35.10.3 *Hadronic calorimeters*

Revised August 2021 by F. Sefkow (DESY, Hamburg) and F. Simon (KIT).

Hadronic calorimetry [380, 402, 403] is considerably more complex than electromagnetic (EM) calorimetry due to the wider range and different nature of physical processes contributing to shower development and energy deposition, which in turn are characterised by different length and time scales. Hadronic showers are initiated by inelastic strong interactions of highly-energetic charged and neutral hadrons with atomic nuclei. These interactions result in the production of secondary particles, which drive the development of the shower. Among these are energetic hadrons, as well as lower-energy nucleons, photons and nuclear fragments. Energy transferred to nuclear break-up, excitation or recoil does not, in general, produce a signal, but remains *invisible*, and event-to-event fluctuations of this invisible energy deposit ultimately limit the resolution of hadronic calorimeters (HCALs).

The length scale of the interaction of relativistic hadrons is given by the nuclear interaction length λ_I. As discussed in Section 35.10.1, λ_I is a factor 10 to 30 larger than X_0 for common materials used in the construction of calorimeters. HCALs thus require a significantly larger geometrical depth for full containment than electromagnetic calorimeters (ECALs), albeit not by the factor suggested by the ratio of λ_I/X_0 due to the different nature of the showers. A key role is played by the production of π^0s and their subsequent decay into two photons. These result in the formation of electromagnetic sub-showers which evolve on the scale given by the radiation length X_0, and thus require sufficiently fine sampling of the shower activity to capture also this electromagnetic component. The two different length scales occurring in hadronic showers, and the large fluctuations of hadronic, electromagnetic and invisible activity, result in significant event-to-event variations of the energy response and of the shower topology. This topology is characterized by a lumpy structure, with compact regions of high local energy density originating from electromagnetic sub-showers, and sparser hadronic activity with minimum-ionizing hadrons.

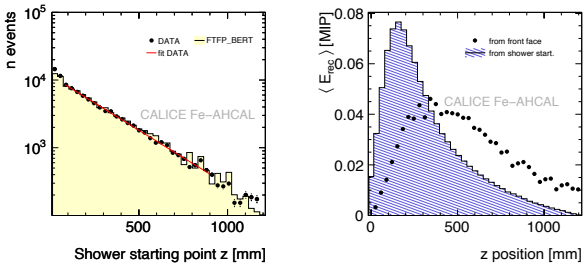

Figure 35.35: Longitudinal profile of hadronic showers induced by 45 GeV negative pions measured in he CALICE highly-granular steel-scintillator sampling calorimeter [404]. Left: Reconstructed position of the first inelastic interaction, compared to simulations (GEANT4 9.4p03, FTFP_BERT), and an exponential fit yielding a slope consistent with the expected pion interaction length. Right: Longitudinal shower profile measured from the front face of the calorimeter (dots, without corrections for dead cells) and relative to the position of the shower start given by the first inelastic interaction (filled histogram). The visible energy is given in units of the most probable energy loss of a minimum-ionizing particle (MIP). The integrals of the distributions are normalized to unity.

Figure 35.35 (left) shows the distribution of the longitudinal position of the first inelastic interaction measured for pion-induced hadronic showers with the highly-granular scintillator-steel HCAL of the CALICE collaboration [404]. The figure illustrates the exponential distribution, with a slope consistent with the pion interaction length expected from the geometry and material composition of the calorimeter. This distribution is well reproduced by simulations using GEANT4 [381, 386]. Figure 35.35 (right) shows the mean longitudinal shower profile, given by the mean energy deposition in each calorimeter layer, both relative to the front face of the calorimeter (dots, without corrections for dead

cells) and relative to the measured shower starting point given by the first inelastic interaction (filled histogram). The latter is much more compact than the former, which is a convolution of the latter with the distribution of shower starting point shown in the left panel of the figure. This shows that the detector depth required for adequate shower containment is significantly influenced by the fluctuations of the position of the first hadronic interaction. Detection of this position allows for an estimate of leakage from a finite calorimeter volume, and it enables stringent tests of shower evolution models. In the past years, motivated by precision needs at the next generation of e^+e^- colliders, the CALICE collaboration has constructed a number of prototypes with high 3-dimensional spatial granularity and recorded large sets of data at test beams, allowing for studies of shower evolution processes in unprecedented detail. The refined simulations support the trend to proceed from research focused on understanding the global intrinsic properties of showers, e.g. for the purpose of compensation, towards the study of detailed information, in space, time, and energy deposition type, through many and multiple readout channels.

In an inelastic hadronic collision a significant fraction f_{em} of the energy is removed from further hadronic interaction by the production of secondary π^0/η's, whose decay photons generate high-energy electromagnetic showers. Charged secondaries ($\pi^\pm$, p, ...) deposit energy via ionization and excitation, but also interact with nuclei, producing evaporation neutrons, spallation protons and neutrons, and heavier spallation fragments. The charged collision products produce detectable ionization, as do the showering γ-rays from the prompt de-excitation of highly excited nuclei. The recoiling nuclei generate little or no detectable signal, as mentioned previously. The neutrons lose kinetic energy in elastic collisions which generate ionization signals via recoiling protons, thermalize on a time scale of several μs, and are finally captured, with the production of more γ-rays—usually outside the acceptance gate of the electronics. Between endothermic spallation losses, nuclear recoils, and late neutron capture, a significant fraction of the hadronic energy (20%–40%, depending on the absorber and energy of the incident particle) is used to overcome nuclear binding energies and is therefore lost or "invisible."

In a hadron-nucleus collision a large fraction of the incident energy is carried by a "leading particle" with the same quark content as the incident hadron. If the projectile is a charged pion, the leading particle is usually a pion, which can be neutral and hence contributes to the EM sector. This is not true for incident protons. The result is an increased mean hadronic fraction for incident protons.

The complexity of hadronic showers also has a significant impact on the energy measurement. In contrast to EM showers, hadronic cascade processes are characterised by the production of relatively few high-energy particles. The number multiplicity of these particles produced in hadronic interactions increases only logarithmically with energy. The lost energy and f_{em} are highly variable from event to event, and on average increase with increasing energy [405]. Electromagnetic sub-showers typically result in a higher response than the hadronic parts of the cascade, where undetectable energy loss due to nuclear dissociation, the long time scales and the material dependence of neutron signals, as well as other effects reduce the measured signal. This difference in response is often expressed by the $\langle h/e \rangle$ ratio, a calorimeter-dependent quantity which is smaller than unity for many, but not all, HCALs. The increase of the electromagnetic fraction with energy thus introduces a non-linear contribution to the response. Combined with the significant event-by-event fluctuations between electromagnetic and hadronic fractions of the showers and between different hadronic processes the non-equality of h and e deteriorates the energy resolution of HCALs. Different strategies to address this exist, as discussed further below.

Most large HCALs are parts of complex 4π detectors at colliding beam facilities. To date, all these HCALs are sampling calorimeters. This choice is imposed by the physics of hadronic showers, both by the required depth for containment which favours high-density materials with short λ_I, and by the differences in response to electromagnetic and hadronic parts of the cascade, which are particularly severe for homogeneous calorimeters. Common absorber materials are Fe, Cu, Pb, and U, with W also used occasionally. A large variety of different active materials are used, depending on application and optimisation, from plastic scintillators (plates, tiles, bars, fibers), crystals and Cherenkov media, silicon, liquid argon (LAr), to gaseous detectors. The energy loss of particles in the active medium is either detected directly by collecting charge, or via scintillation or Cherenkov light observed with conventional photomultipliers (PMTs), photodiodes or silicon photomultipliers (SiPMs). The choice of both active and passive materials is driven by different, sometimes conflicting, constraints, including performance requirements, space and other mechanical boundary conditions, radiation tolerance, and cost considerations.

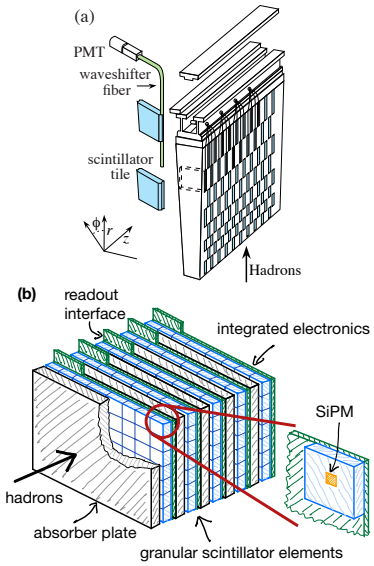

Figure 35.36: Two examples of geometrical structures of scintillator-based HCALs. (a) A wedge of the ATLAS central tile calorimeter consisting of scintillator tiles in iron, read out via wavelength-shifting fibers and PMTs [406]. The coordinate system is that of the ATLAS calorimeter within the experiment, with the z axis along the beam direction, r pointing radially outward, and ϕ being the azimuthal angle. (b) An illustration of the "SiPM-on-tile" structure used in the CALICE analogue HCAL prototype, and in the CMS High-Granularity Calorimeter (HGCAL), highly granular calorimeters with steel absorbers and small scintillator tiles directly read out via SiPMs with embedded electronics [403, 407–409].

A wide range of different geometries of absorbers and sensors is used, with design choices depending on the chosen priorities of addressing these constraints, also considering the need to bring the signals to the outside of the detector while achieving a hermetic coverage and other constraints. In this context it is important to note that a classic sandwich structure with absorber plates and active elements approximately perpendicular to the particle incidence is not required, and arbitrary orientations are viable for good calorimetric measurements, as long as channelling, meaning the extended passage of primary particles through low-density active regions, is excluded. Figure 35.36 shows two examples of plastic scintillator-based calorimeters to illustrate differences in design between coarsely-segmented and highly-granular calorimeters. The ATLAS tile calorimeter [406] uses scintillator tiles coupled to wavelength-shifting fibers which collect the light from the tiles and guide them to PMTs outside of the active region of the calorimeter. The calorimeter is segmented in ϕ (azimuthal angle) and η (pseudorapidity, defined as $\eta = -\ln\tan(\theta/2)$, where θ is the angle relative to the beam axis), with coarse longitudinal segmentation. The technological prototype of the CALICE analog HCAL, a highly granular SiPM-on-tile calorimeter is based on scintillator tiles directly coupled to SiPMs, which, together with

the front-end electronics, are embedded inside of the the active volume of the calorimeter. The CMS HGCAL [409] uses the same concept in part of the detector, and in addition embeds elements for digital data concentration and power distribution in the active volume. Other detector solutions include scintillating fibres threading an absorber [410], liquid-argon-filled tubes [411] and the "accordion" LAr detector [412]. The latter has zig-zag absorber plates to minimize channeling effects; the calorimeter is hermetic (no cracks), and plates are oriented so that cascades cross the same plate repeatedly.

In particular, but not exclusively, the combination of heavy absorber materials (Pb, U) with plastic scintillators allows the construction of HCALs that have a near-equal response to electromagnetic and hadronic parts of the cascade, so-called compensating calorimeters [413]. In this first study, it was recognized that nuclear fission can amplify the hadronic signal when using uranium absorbers. However, the key drivers of compensation are the reduction of the electromagnetic response with high-Z absorbers and an increased sensitivity to neutrons, which are strongly correlated to otherwise invisible energy loss due to nuclear dissociation, with a hydrogeneous active medium [414–418]. Since the electromagnetic cross section increases, and the critical energy decreases with Z, and since most of the energy of an electromagnetic shower is deposited by low-energy, short-range electrons, a disproportionate fraction of the total electromagnetic energy is deposited in the absorber in the high-Z case. Hydrogenous active media, such as organic scintillators, have a high sensitivity to spallation neutrons via elastic $n-p$ scattering. The number of produced neutrons is highly correlated with the invisible energy of the hadronic cascade. Increasing the sensitivity to these particles can thus boost the visible hadronic signal. Achieving compensation requires carefully-chosen sampling fractions and frequencies, with the response to the hadronic parts of the shower also sensitive to the integration time of the electronics due to the time structure of the neutron component of the signal.

Since Cherenkov light, for example in quartz plates or fibers, or in crystals, is produced only by relativistic particles in the cascade and thus predominantly by the electromagnetic component of the shower, such media are less common in hadronic than in ECALs. Notable exceptions are applications that require high radiation tolerance, and dual-readout calorimeters which specifically exploit this feature, as discussed below.

Silicon offers high compactness, high granularity, high radiation tolerance, long-term stability and fast charge collection, and is thus an interesting active material for sampling calorimeters. A thorough overview of the development and of the features of this technology can be found in a recent review paper [419]. The first silicon-based calorimeter in a collider experiment was a HCAL, the H1 PLUG calorimeter [420] covering the very forward region of the H1 experiment at HERA. The SICAPO collaboration has demonstrated the conceptual possibility of constructing compensating HCALs using silicon sensors [421]. Silicon is currently the technology of choice for several ECALs for future Higgs factories [422–424]. It is also being used extensively in the CMS HGCAL [409] in both electromagnetic and hadronic sections, complemented by scintillator tiles with on-tile SiPM readout where the radiation levels allow.

More generally, high-granularity calorimeters play an increasingly important role, in particular motivated by the use of particle-flow algorithms for global event reconstruction (see Section 35.10.1). The associated technologies for both electromagnetic and HCALs have been pioneered by the CALICE collaboration, which has built and tested an increasingly sophisticated series of "imaging" calorimeters with a highly granular readout [425]. In the area of HCALs, this includes the scintillator-based analog HCAL [426] with the latest SiPM-on-tile technological prototype with fully-integrated electronics having approximately $22,000$ channels [407, 408], as well as digital [427] and semidigital [428] calorimeters using gas detectors, such as RPCs (Sec. 35.6.7) and micropattern gas detectors (Sec. 35.6.4), with channel counts of up to $500,000$. The large numbers of channels of high-granularity calorimeters presents a significant integration challenge for full detector systems, and requires the full integration of the front-end electronics inside of the active volume of the detector, as well as very compact data concentration and interface units. The first such detector in construction for a collider experiment is the CMS HGCAL [409]. Beam tests with a combined prototype using both silicon and scintillator-SiPM instrumented active layers have confirmed simulation-based expectations [429]. The total silicon area of the full HGCAL amounts to about 600 m^2, and about 240,000 SiPMs are foreseen. The calibration of such calorimeters requires the monitoring of a large number of cells, which is achieved in-situ using reconstructed track segments within hadronic showers [409, 430] or externally identified muons. For this method, the capability to detect the most probable energy loss of a minimum-ionizing particle in a single cell is essential. This is required over the full lifetime of the detector, also after the active elements have received significant radiation damage, resulting in increased noise and reduced charge or signal collection efficiency. Due to the large number of cells contributing to the measurement of one shower, the requirements on the precision of the calibration of individual cells is relaxed relative to the global energy calibration of the calorimeter.

The energy resolution of HCALs is severely affected by fluctuations between different components of the cascade, exacerbated by differences in response to purely hadronic and to electromagnetic sub-showers. In many detectors, fluctuations in the electromagnetic energy fraction, $f_{\rm em}$, and the related, consequential variations in nuclear energy dissociation losses, represent the biggest single contribution to the hadron energy resolution. One strategy to address this problem is the construction of intrinsically-compensating calorimeters, which imposes stringent constraints on materials and geometries as discussed above. Compensating calorimeters are not used in current large collider experiments, and are at the moment not considered for future collider detectors. Two different strategies are presently followed to improve the energy resolution in non-compensating calorimeters: Offline weighting or software compensation in longitudinally-segmented or in highly-granular calorimeters; and dual-readout calorimetry.

Software compensation techniques exploit the fact that electromagnetic sub-showers typically have a higher spatial density than the purely hadronic parts of the cascade. Amplitude (or energy-density) dependent weights are applied in the reconstruction to reduce the effects of shower-to-shower fluctuations. These techniques were pioneered by the CDHS collaboration for a longitudinally segmented steel-plastic scintillator calorimeter [431], where an improvement of the energy resolution of 10% (at 10 GeV) to 30% (at 140 GeV) for charged pion showers was achieved. Similar techniques were successfully applied in the H1 [432] liquid argon calorimeter system resulting in a stochastic term of $51\%/\sqrt{E}$, and in the ATLAS [433] endcap calorimeters, also based on liquid argon, with an energy resolution of $84\%/\sqrt{E}$. Inspired by these approaches, a software compensation technique using the detailed spatial information provided by highly-granular calorimeters of the CALICE collaboration has been developed, achieving up to 25% improvement of the energy resolution compared to the resolution without software compensation, resulting in a stochastic term of $45\%/\sqrt{E}$ [434] in a scintillator tile calorimeter with steel absorbers. This technique has also been successfully transferred to particle-flow reconstruction [435], resulting in an improvement of the jet-energy resolution in simulated events by 8% - 15%, depending on jet energy. Highly-granular calorimeters with software compensation and particle-flow reconstruction are currently studied as the baseline configuration for several Higgs-factory detectors.

The *dual-readout method*, originally proposed by Mockett in 1983 [436], measures $f_{\rm em}$ event by event in parallel to the total deposited energy. It uses the fact that most of the relativistic particles in the shower originate from the electromagnetic part, and that only those produce Cherenkov light, while the signal of the hadronic part is mostly due to non-relativistic protons. In practice either two different active media, e.g. scintillator and quartz, are used to register scintillation and Cherenkov light, respectively, or the optical signals from the two processes occurring in heavy crystals are disentangled, using their different spectral, directional or timing properties.

The Cherenkov and scintillation signals, normalised to the response for electrons, are given by

$$C = [f_{\rm em} + (h/e)_C(1 - f_{\rm em})]E\,, \tag{35.44}$$
$$S = [f_{\rm em} + (h/e)_S(1 - f_{\rm em})]E\,, \tag{35.45}$$

respectively, which can be solved for the fraction $f_{\rm em}$ and the energy

$$E = (\xi S - C)/(\xi - 1)\,, \tag{35.46}$$

where $\xi = [1 - (h/e)_C]/[1 - (h/e)_S]$ and $(h/e)_{C,S}$ denote the average ratios of hadronic to electromagnetic response in the Cherenkov and scintillator parts, respectively. This is illustrated in Figure 35.37, which shows their correlation for a set of simulated negative pion events [437] using FLUKA [385].

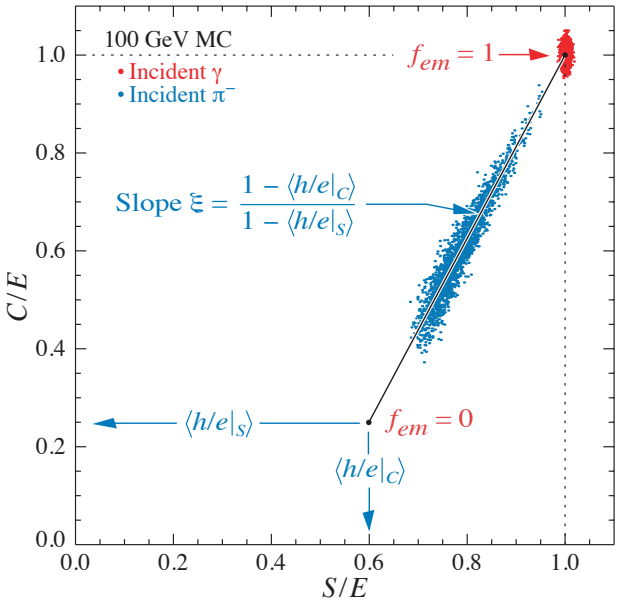

Figure 35.37: Scatter plot of Monte Carlo C/E (Cherenkov) vs S/E (scintillator) signals for individual events in a dual-readout calorimeter for 100 GeV negative pions and photons. Hadronic events are shown in blue, and scatter about the indicated event locus. Electromagnetic events cluster about $(C/E, S/E) = (1,1)$. In this case worse resolution (fewer p.e.'s) was assumed for the Cherenkov events, leading to the "elliptical" distribution.

It was noted that the method demands a steep slope ξ, which implies that the scintillator read-out should be as compensating as possible, which however reduces the room for improvement by adding Cherenkov information.

The method was tested by the DREAM/RD52 collaboration [438,439], using a 1 ton copper matrix with embedded quartz and scintillating fibers. The value of ξ was about 3 in this detector. With this detector, a resolution of $70\%/\sqrt{E(GeV)}$ was obtained for single hadrons [440]. Due to the small size of the module, this includes contributions from transverse leakage which prevent the full exploitation of key features of dual readout, and thus underestimates the potential of the method.

The separate Cherenkov read-out evidently provides excellent pion-electron separation for particle identification. In another RD52 prototype, each fiber is read out individually by SiPMs, giving also a superior transverse granularity. A fiber-based calorimeter with full solid-angle coverage requires a pointing geometry due to the limited or missing longitudinal segmentation. The resulting challenges for a mechanical design are studied in the framework of the IDEA detector concept [441].

Table 35.12 shows selected examples of the energy resolution of HCALs for single charged pions achieved in beam tests. The examples are selected to illustrate the performance achieved with different designs ranging from intrinsic compensation to software compensation and dual readout, with a focus on results by R&D projects. It should be noted that the exact values of the different resolution terms depend on the functional form used in the fit, here the addition in quadrature is used for the cases where more than just the stochastic term is quoted. The results shown in the table illustrate that (close to) compensating calorimeters with optimized sampling fraction and frequency, such as HELIOS (U-plastic scintillator) and SPACAL (Pb-plastic scintillator), achieve a very good energy resolution. The comparison with Bernardi *et al.*, which has the same Pb/scintillator ratio by volume as SPACAL, but coarser sampling in a sandwich structure, illustrates the importance of the geometrical details. Beyond the examples shown in the table, liquid argon has also been explored as an active medium, for example in the context of the SLD detector with different absorber options [446]. Due to the reduced sensitivity to neutrons in the shower, not the same resolution as for plastic-scintillator-based systems is achieved. This technology has also been used in the D0 experiment, as discussed below. The dual-readout method has the potential to reach or surpass this performance, but would require a prototype sufficiently large for full longitudinal and transverse shower containment for an experimental demonstration. The two CALICE calorimeters shown, which use the same active elements (5 mm thick scintillator tiles) but different absorbers (21.4 mm Fe vs 10 mm W + 4 mm Fe) per layer, illustrate the impact of the absorber choice on energy resolution and reconstruction possibilities. While the tungsten-based W-AHCAL setup is very close to compensating, the steel-based AHCAL achieves a better energy resolution when software compensation is applied, profiting from the finer sampling of the electromagnetic parts of the cascade and the correction for shower-to-shower fluctuations of the electromagnetic fraction in the reconstruction. In the case of tungsten, software compensation does not significantly improve the energy resolution, as expected. The comparison of the CALICE AHCAL performance with the one of CDHS illustrates the benefits of higher granularity for software compensation techniques, but it should be noted that the absorber thickness of the latter is 25 mm, with the same scintillator thickness as in the case of CALICE.

As explained in the introduction, in most high-energy physics experiments, the HCAL follows after an ECAL, making the response of the latter to hadronic cascades highly relevant for the overall performance of the combined ECAL HCAL system. For scenarios where the electromagnetic and the HCAL have very different $\langle h/e \rangle$, as is typically the case for crystal-based ECALs, the fluctuations of the fraction of the hadronic shower contained within the ECAL result in a significant deterioration of the energy resolution for hadrons. A deterioration of the hadronic performance also results from larger amounts of not-instrumented material, e.g. supports and services, between electromagnetic and hadronic sections. In particle-flow calorimeters, a large value of the λ_I/X_0 ratio of the absorber material, like in tungsten, maximises the longitudinal separation of electromagnetic and hadronic showers. This is reflected in the design of particle-flow-based detector concepts for future Higgs Factories.

Table 35.13 summarizes the single hadron energy resolution obtained from test beams of the combined ECAL and HCAL systems of the large multi-purpose experiments at HERA, the Tevatron and at the LHC. These systems are examples of different optimization strategies. D0 and ZEUS are near-compensating systems with the same technology in ECAL and HCAL emphasizing hadronic performance. ATLAS and H1 use sampling ECALs with good electromagnetic resolution and weighting techniques exploiting longitudinal and transverse shower information for hadronic energy reconstruction. CMS, with a crystal ECAL and a scintillator-brass HCAL, prioritizes electromagnetic performance, with very different $\langle h/e \rangle$ in the electromagnetic and hadronic system. Of the detectors shown in the table, CMS has the best electromagnetic resolution by a comfortable margin, but consequently the weakest hadronic resolution. The best hadronic performance is achieved with the compensating calorimeter of ZEUS, which however has a weaker electromagnetic performance than the other calorimeter systems shown here. It should be noted that an excellent single-hadron resolution in general does not fully propagate into the jet-energy performance. Inactive material in

CMS	$PbWO_4$, brass/plastic scintillator	$84.7\%/\sqrt{E} \oplus 7.4\%$	[452]

front of the calorimeter can significantly worsen the energy resolution for jets, with an impact in particular on lower-energy particles. For example, the core of the invariant mass distribution of hadronically-decaying Z^0 bosons measured in ZEUS, which had a superconducting coil in front of the calorimeter, is well described by a Gaussian with a σ of 6 GeV [453], approximately 40% wider than would be expected for a jet-energy resolution that is identical to the single-hadron performance.

35.10.4 *Free electron drift velocities in liquid ionization chambers*

Revised August 2009 by W. Walkowiak (Siegen U.).

Drift velocities of free electrons in LAr [259] are given as a function of electric field strength for different temperatures of the medium in Fig. 35.38. The drift velocites in LAr have been measured using a double-gridded drift chamber with electrons produced by a laser pulse on a gold-plated cathode. The average temperature gradient of the drift velocity of the free electrons in LAr is described [259] by

$$\frac{\Delta v_d}{\Delta T\, v_d} = (-1.72 \pm 0.08)\ \%/\mathrm{K}. \qquad (35.47)$$

Previous measurements [454, 455, 457, 458] range from 13% higher [455] to 18% lower [457] than these measurements. They used different techniques and show drift velocities for free electrons which cannot be explained by the temperature dependence mentioned above.

Drift velocities of free electrons in LXe [454] as a function of electric field strength are also displayed in Fig. 35.38. The drift velocity saturates for $|E| > 3$ kV/cm, and decreases with increasing temperature for LXe as well as measured e.g. by [459].

The addition of small concentrations of other molecules like N_2, H_2 and CH_4 in solution to the liquid typically increases the drift velocities of free electrons above the saturation value [454, 457], see example for CH_4 admixture to LAr in Fig. 35.38. Therefore, actual drift velocities are critically dependent on even small additions or contaminations.

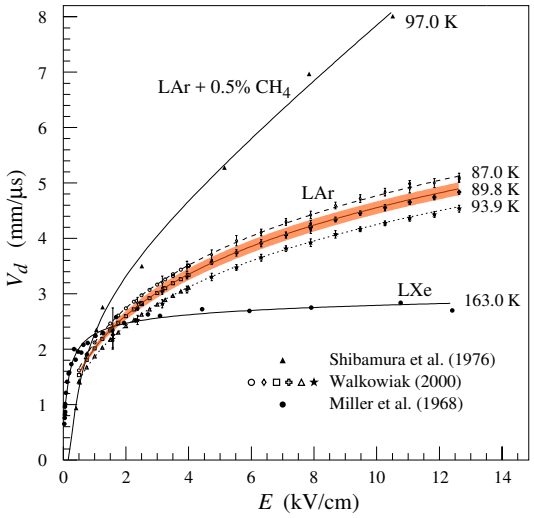

Figure 35.38: Drift velocity of free electrons as a function of electric field strength for LAr [259], LAr + 0.5% CH_4 [454] and LXe [455]. The average temperatures of the liquids are indicated. Results of a fit to an empirical function [456] are superimposed. In case of LAr at 91 K the error band for the global fit [259] including statistical and systematic errors as well as correlations of the data points is given. Only statistical errors are shown for the individual LAr data points.

35.11 Accelerator-based neutrino detectors

Written by M.O. Wascko (Imperial Coll. London). Minor revision in August 2023 by A. Fava (FNAL) and F. Pietropaolo (CERN;

INFN, Padova).

35.11.1 *Introduction*

Accelerator-based neutrino experiments span many orders of magnitude in neutrino energy, from a few MeV to hundreds of GeV. This wide range of neutrino energy is driven by the many physics applications of accelerator-based neutrino beams. Foremost among them is neutrino oscillation, which varies as the ratio L/E_ν, where L is the neutrino baseline (distance traveled), and E_ν is the neutrino energy. But accelerator-based neutrino beams have also been used to study the nature of the weak interaction, to probe nucleon form factors and structure functions, and to study nuclear structure.

The first accelerator-based neutrino experiment used neutrinos from the decays of high energy pions in flight to show that the neutrinos emitted from pion decay are different from the neutrinos emitted by beta decay [460]. The field of accelerator-based neutrino experiments would likely not have expanded beyond this without Simon van der Meer's invention of the magnetic focusing horn [461], which significantly increased the flux of neutrinos aimed toward the detector. In this mini-review, we focus on experiments employing decay-in-flight beams—pions, kaons, charmed mesons, and taus—producing fluxes of neutrinos and antineutrinos from $\sim$ 10 MeV to $\sim$ 100 GeV.

Neutrino interactions with matter proceed only through the weak interaction, making the cross section extremely small and requiring high fluxes of neutrinos and large detector masses in order to achieve satisfactory event rates. Therefore, neutrino detector design is a balancing act taking into account sufficient numbers of nuclear targets (often achieved with inactive detector materials), adequate sampling/segmentation to ensure accurate reconstruction of the tracks and showers produced by neutrino-interaction secondary particles, and practical readout systems to allow timely analysis of data.

35.11.2 *Signals and Backgrounds*

The neutrino interaction processes available increase with increasing neutrino energy as interaction thresholds are crossed; in general neutrino-interaction cross sections grow with energy; for a detailed discussion of neutrino interactions see [462]. The multiplicity of secondary particles from each interaction process grows in complexity with neutrino energy, while the forward-boost due to increasing E_ν compresses the occupied phase space in the lab frame, impacting detector designs. Because decay-in-fight beams produce neutrinos at well-defined times, leading to very small duty factors, the predominant backgrounds usually stem from unwanted beam-induced neutrino interactions, i.e. neutrinos interacting via other processes than the one being studied. A noteworthy exception is time projection chambers, wherein the long drift times can admit substantially more cosmic backgrounds than most other detection methods. Cosmic backgrounds are more rare at higher energies because the secondary particles produced by neutrino interactions yield detector signals that resemble cosmic backgrounds less and less.

Below, we describe a few of the dominant neutrino interaction processes, with a focus on the final state particle content and topologies.

35.11.2.1 *Charged-Current Quasi-Elastic Scattering and Pion Production*

Below $\sim$ 2 GeV neutrino energy, the dominant neutrino-nucleus interaction process is quasi-elastic (QE) scattering. In the charged current (CC) mode, the CCQE base neutrino reaction is $\nu_\ell\, n \to \ell^-\, p$, where $\ell = e, \mu, \tau$, and similarly for antineutrinos, $\overline{\nu}_\ell\, p \to \ell^+\, n$. The final state particles are a charged lepton, and perhaps a recoiling nucleon if it is given enough energy to escape the nucleus. Detectors designed to observe this process should have good single-particle track resolution for muon neutrino interactions, but should have good μ/e separation for electron neutrino interactions. Because the interaction cross section falls sharply with Q^2, the lepton typically carries away more of the neutrino's kinetic energy than the recoiling nucleon. The fraction of backward-scattered leptons is large, however, so detectors with 4π coverage are desirable. The dominant backgrounds in this channel tend to come from single pion production events in which the pion is not detected.

Near 1 GeV, the quasi-elastic cross section is eclipsed by pion production processes. A typical single pion production (CC1π) reaction is $\nu_\ell\, n \to \ell^-\, \pi^+\, n$, but many more final state particle combinations are possible. Single pion production proceeds through the coherent channel and many incoherent processes, dominated by resonance production. With increasing neutrino energy, higher-order resonances can be excited, leading to multiple pions in the final state. Separating these processes from quasi-elastic scattering, and indeed from each other, requires tagging, and ideally reconstructing, the pions. Since these processes can produce neutral pions, electromagnetic (EM) shower reconstruction is more important here than it is for the quasi-elastic channel. The predominant backgrounds for pion production change with increasing neutrino energy. Detection of pion processes is also complicated because near threshold the quasi-elastic channel creates pion backgrounds through final state interactions of the recoiling nucleon, and at higher energies backgrounds come from migration of multiple pion events in which one or more pions is not detected.

35.11.2.2 *Deep Inelastic Scattering*

Beyond a few GeV, the neutrino has enough energy to probe the nucleon at the parton scale, leading to deep inelastic scattering (DIS). In the charged-current channel, the DIS neutrino reaction is $\nu_\ell\, N \to \ell^-\, X$, where N is a nucleon and X encompasses the entire recoiling hadronic system. The final state particle reconstruction revolves around accurate reconstruction of the lepton momentum and containment and reconstruction of the hadronic shower energy. Because of the high neutrino energies involved, DIS events are very forward boosted, and can have extremely long particle tracks. For this reason, detectors measuring DIS interactions must be large to contain the hadronic showers in the detector volume.

35.11.2.3 *Neutral Currents*

Neutrino interactions proceeding through the neutral current (NC) channel are identified by the lack of a charged lepton in the final state. For example, the NC elastic reaction is $\nu_l\, N \to \nu_l\, N$, and the NC DIS reaction is $\nu_l\, N \to \nu_l\, X$. NC interactions are suppressed relative to CC interactions by a factor involving the weak mixing angle; the primary backgrounds for NC interactions come from CC interactions in which the charged lepton is misidentified.

35.11.3 *Instances of Neutrino Detector Technology*

Below we describe many of the actual detectors that have been built and operated for use in accelerator-based neutrino beams.

35.11.3.1 *Spark Chambers*

In the first accelerator-based neutrino beam experiment, Lederman, Schwartz, and Steinberger [460] used an internally-triggered spark chamber detector, filled with 10 tons of Al planes and surrounded by external scintillator veto planes, to distinguish muon tracks from electron showers, and hence muon neutrinos from electron neutrinos. The inactive Al planes served as the neutrino interaction target and as radiators for EM shower development. The detector successfully showed the presence of muon tracks from neutrino interactions. It was also sensitive to the hadronic showers induced by NC interactions, which were unknown at the time. In 1963, CERN also built and ran a large (20 ton) Al plane spark chamber in a wideband beam based on the PS accelerator [463]. More than a decade later, the Aachen-Padova [464] experiment at CERN employed a 40 ton Al spark chamber in the PS-WBB.

35.11.3.2 *Bubble Chambers*

Several large bubble chamber detectors were employed as accelerator neutrino detectors in the 1970s and 80s, performing many of the first studies of the properties of the weak interaction. Bubble chambers provide exquisite granularity in the reconstruction of secondary particles, allowing very accurate separation of interaction processes. However, the extremely slow and labor-intensive acquisition and analysis of the data from photographic film led to them being phased out in favor of electronically read out detectors.

The Gargamelle [465] detector at CERN used Freon and propane gas targets to make the first observation of neutrino-induced NC interactions and more. The BEBC [466] detector at CERN was a bubble chamber that was alternately filled with liquid hydrogen, deuterium, and a neon-hydrogen mixture; BEBC was also outfitted with a track-sensitive detector to improve event tagging, and sometimes used with a small emulsion chamber. The SKAT [467] Freon bubble chamber was exposed to wideband neutrino and antineutrino beams at the Serpukhov laboratory in the former Soviet Union. A series of American bubble chambers in the 1970's and 1980's made measurements on free nucleons that are still crucial inputs for neutrino-nucleus scattering predictions. The 12-foot bubble chamber at ANL [468] in the USA used both deuterium and hydrogen targets, as did the 7-foot bubble chamber at BNL [469]. Fermilab's 15 foot bubble chamber [470] used deuterium and neon targets.

35.11.3.3 *Iron Tracking Calorimeters*

Because of the forward boost of high energy interactions, long detectors made of magnetized iron interspersed with active detector layers have been very successfully employed. The long magnetized detectors allow measurements of the momentum of penetrating muons. The iron planes also act as shower-inducing layers, allowing separation of EM and hadronic showers; the large number of iron planes provide enough mass for high statistics and/or shower containment. Magnetized iron spectrometers have been used for studies of the weak interaction, measurements of structure functions, and searches for neutrino oscillation. Non-

magnetized iron detectors have also been successfully employed as neutrino monitors for oscillation experiments and also for neutrino-nucleus interaction studies.

The Caltech-Fermilab counter (CITF) [468] combined a 92 ton iron-scintillator target-calorimeter detector with a downstream toroidal magnet to perform early studies of weak interactions—including observations of neutral currents. The CDHS [471] detector used layers of magnetized iron modules interspersed with wire drift chambers, with a fiducial mass of 1250 t, to detector neutrinos in the range 10–200 GeV. Within each iron module, 5 cm (or 15 cm) iron plates were interspersed with scintillation counters. The MINOS [472] detectors, a near detector of 980 t at FNAL and a far detector of 5500 t in the Soudan Underground Laboratory (SUL), were functionally identical magnetized iron calorimeters, comprised of iron plates interleaved with layers of 4 cm wide plastic scintillator strips in alternating orientations. The T2K [473] on-axis detector, INGRID, consists of 16 non-magnetized iron scintillator sandwich detectors, each with nine 6.5 cm iron plane (7.1 t total) interspersed between layers of 5 cm wide plastic scintillator strips readout out by multi-pixel photon counters (MPPCs) coupled to WLS fibers. Fourteen of the INGRID modules are arranged in a cross-hair configuration centered on the neutrino beam axis.

35.11.3.4 *Cherenkov Detectors*

Open volume water Cherenkov detectors were originally built to search for proton decay. Large volumes of ultra-pure water were lined with photomultipliers to collect Cherenkov light emitted by the passage of relativistic charged particles. See Sec. 36.3.1 for a detailed discussion of deep liquid detectors for rare processes. The Cherenkov light, which has significant production in the visible range, appears on the walls of the detectors in distinctive ring patterns, and topological characteristics of the rings are employed to separate muon-induced rings from electron-induced with very high accuracy. As neutrino detectors, Cherenkov detectors optimize the design balance since the entire neutrino target is also active detector medium.

When used to detect $\sim$ GeV neutrinos, the detector medium acts as a natural filter for final state particles below the Cherenkov threshold; this feature has been exploited successfully by the K2K, MiniBooNE (using mineral oil instead of water), and T2K neutrino oscillation experiments. This makes event reconstruction simple and robust since electrons and muons have very different signatures, but does require making assumptions when inferring neutrino energy since not all final state particles are observed. At higher energies Cherenkov detectors become less accurate because the overlapping rings from many final state particles become increasingly difficult to resolve.

The second-generation Cherenkov detector in Japan, Super-Kamiokande [86] (Super-K), comprises 22.5 kt of water viewed by 50 cm photomultiplier tubes with 40% photocathode coverage; it is surrounded by an outer detector region viewed by 20 cm photomultipliers. Super-K is the far detector for K2K and T2K, and is described in greater detail elsewhere in this review. The K2K experiment also employed a 1 kt water Cherenkov detector in the suite of near detectors [474], with 40% photocathode coverage. The MiniBooNE detector at FNAL was a 0.8 kt [475] mineral oil Cherenkov detector, with 20 cm photomultipliers giving 10% photocathode coverage, surrounded by a veto detector also with 20 cm photomultipliers. The ANNIE detector also at FNAL consists of a 26-ton water Cherenkov detector loaded with gadolinium sulfate (Gd2O12S3), complemented by a muon range detector and a veto wall. In addition to traditional PMTs, it exploits novel Large Area Picosecond Photodetectors (LAPPDs) for the detection of the Cherenkov light.

35.11.3.5 *Scintillation Detectors*

Liquid and solid scintillator detectors also employ fully (or nearly fully) active detector media. Typically organic scintillators, which emit into the ultraviolet range, are dissolved in mineral oil or plastic and read out by photomultipliers coupled to wavelength shifters (WLS). Open volume scintillation detectors lined with photomultipliers are conceptually similar to Cherenkov detectors, although energy reconstruction is calorimetric in nature as opposed to kinematic (see also Sec. 36.3.1). For higher energies and higher particle multiplicities, it becomes beneficial to use segmented detectors to help distinguish particle tracks and showers from each other.

The HWPF collaboration [476] employed a 2 t liquid scintillator total-absorption hadron calorimeter followed by a magnetic spectrometer to observe neutral current events in the early days of Fermilab. The LSND [477] detector at LANL was a 130 t open volume liquid scintillator detector employed to detect relatively low energy (<300 MeV) neutrinos. The NOvA [478] detectors use segmented volumes of liquid scintillator in which the scintillation light is collected by WLS fibers in the segments that are coupled to avalanche photodiodes (APDs) at the ends of the volumes. The NOvA far detector, located in Ash River, MN, is comprised of 896 layers of 15.6 m long extruded PVC scintillator cells for a total mass of 14 kt; the NOνA near detector is comprised of 214 layers of 4.1 m scintillator volumes for a total mass of of 300 t. Both are placed in the NuMI beamline at 0.8° off-axis. The SciBar (Scintillation Bar) detector was originally built for K2K at KEK in Japan and then re-used for SciBooNE [479] at FNAL. SciBar used plastic scintillator strips with 1.5 cm×2.5 cm rectangular cross section, read out by multianode photomultipliers (MAPMTs) coupled to WLS fibers, arranged in alternating horizontal and vertical layers. Both SciBooNE and K2K employed an EM calorimeter downstream of SciBar and a muon range detector (MRD) downstream of that.

The Coherent Captain Mills (CCM) detector is an upright cylindrical cryostat 2.58 m in diameter and 2.25 m high that holds 10 tons of LAr and is designed to be movable for distances between 20 m to 40 m from the neutrino source. It is instrumented with 120 8-inch PMTs, out of which 96 are coated with Tetraphenyl Butadiene (TPB) wavelength shifter.

35.11.3.6 *Liquid Argon Time Projection Chambers*

Liquid argon time projection chambers (LAr-TPCs) were conceived in the 1970s as a way to achieve a fully active detector with sub-centimeter track reconstruction [480]. A massive volume of purified liquid argon is put under a strong electric field (hundreds of V/cm), so that the liberated electrons from the paths of ionizing particles can be drifted to the edge of the volume and read out, directly by collecting charge from wire planes or non-destructively through charge induction in the wire planes. Dual-phase readout methods have also been developed, in which the charge is drifted vertically and then passed through an amplification region inside a gas volume above the liquid volume; the bottom of the liquid volume is equipped with a PMT array for detecting scintillation photons form the liquid argon. The first large scale LAr-TPC was the ICARUS T-600 module [481], comprising 760 t of liquid argon with a charge drift length of 1.5 m read out by wires with 3 mm pitch, which operated in LNGS, both standalone and also exposed to the CNGS high energy neutrino beam. The ICARUS detector has been transported to Fermilab and installed and presently operated in an on-axis position in the Booster Neutrino Beamline at 600 m from target, where it is also exposed to off-axis neutrinos from the NuMI beamline. It will be complemented by the SBND detector(100 m from BNB target, 112 t fiducial mass), currently in the final phases of installation to search for possible anomalies in short baseline neutrino oscillation in the context of the SBN Program.

The ArgoNeuT [482] detector at FNAL, with fiducial mass 25 kg of argon read out with 4 mm pitch wires, was exposed to the NuMI neutrino and antineutrino beams. The MicroBooN [483] detector at FNAL comprises 170 t (85t active) of liquid Ar, read out with 3 mm wire pitch, which began collecting data in the Booster Neutrino Beam Oct 2015. A LAr-TPC has also been chosen as the multi-kton detector design for the future DUNE [484] neutrino oscillation experiment, from FNAL to Sanford Underground Research Facility. The design choices for the first two DUNE far detector modules (each with a total LAr mass of 17 kt) are being validated in the NP04 (horizontal drift) and the NP02 (vertical drift) experiments at the CERN Neutrino Platform facility [485, 486].

35.11.3.7 *Emulsion Detectors*

Photographic film emulsions have been employed in particle physics experiments since the 1940s [487]. Thanks to advances in scanning technology and automation [488], they have been successfully employed as neutrino detectors. Emulsions are used for experiments observing CC tau neutrino interactions, where the short lifetime of the tau, $\tau_\tau = 2.90 \times 10^{-13}$s, leading to the short mean path length, $c \times \tau = 87\mu$m, requires extremely precise track resolution. They are employed in hybrid detectors in which the emulsion bricks are embedded inside fine-grained tracker detectors. In the data analysis, the tracker data are used to select events with characteristics typical of a tau decay in the final state, such as missing energy and unbalanced transverse momentum. The reconstructed tracks are projected back into an emulsion brick and used as the search seed for a neutrino interaction vertex.

E531 [489] at Fermilab tested many of the emulsion-tracker hybrid techniques employed by later neutrino experiments, in a detector with approximately 9 kg of emulsion target. The CHORUS [488] experiment at CERN used 1,600 kg of emulsion, in a hybrid detector with a fiber tracker, high resolution calorimeter, and muon spectrometer, to search for $\nu_\mu \to \nu_\tau$ oscillation. The DONuT [490] experiment at FNAL used a hybrid detector, with 260 kg of emulsion bricks interspersed with fiber trackers, followed by a magnetic spectrometer, and calorimeter, to make the first direct observation of tau neutrino CC interactions. The OPERA [491] [492] [493] experiment used an automated hybrid emulsion detector, with 1,25x0 t of emulsion, to make the first direct observation of the appearance of ν_τ in a ν_μ beam. Recently, the NINJA collaboration has developed an emulsion cloud chamber detector to observe neutrinos in the J-PARC neutrino beam [494].

FASERν [495] (a sub-detector of the FASER [496] experiment) is designed to detect and study all neutrino flavors produced at the LHC in the far-forward region of the ATLAS interaction point at the TeV energies scale. It consists of emulsion films interleaved with tungsten plates with a total target mass of 1.2 tons, enabling the identification of the leptons in charged current ν interactions. Placed 480m downstream of ATLAS, FASERν will measure neutrino cross sections at energies where they are currently unconstrained and will bound models of forward particle production.

35.11.3.8 *Hybrid Detectors*

In the previous neutrino detector examples, one can point to a specific detection technology or configuration that defines a category of detectors. In this section we look at detectors that combine multiple elements or techniques, without one facet being specifically dominant or crucial; we call these detectors hybrids.

The CHARM detector [497] at CERN was built to study neutral-current interactions and search for muon neutrino oscillation. It was a fine-grained ionization calorimeter tracker with approximately 150 t of marble as neutrino target, surrounded by a magnetized iron muon system for tagging high angle muons, and followed downstream by a muon spectrometer. The CHARM II detector [498] at CERN comprised a target calorimeter followed by a downstream muon spectrometer. Each target calorimeter module consists of a 4.8 cm thick glass plate followed by a layer of plastic streamer tubes, with spacing 1 cm, instrumented with 2 cm wide pickup strips. Every fifth module is followed by a 3 cm thick scintillator layer. The total mass of the target calorimeter was 692 t.

The Brookhaven E-734 [499] detector was a tracking calorimeter made up of 172 t liquid scintillator modules interspersed with proportional drift tubes, followed by a dense EM calorimeter and a muon spectrometer downstream of that. The detector was exposed to a wideband horn-focused beam with peak neutrino energy near 1 GeV. The Brookhaven E-776 [500] experiment comprised a finely segmented EM calorimeter, with 2.54 cm concrete absorbers interspersed with planes of drift tubes and acrylic scintillation counters, with total mass 240 t, followed by a muon spectrometer.

The FNAL Lab-E neutrino detector was used by the CCFR [501] and NuTeV [502] collaborations to perform a series of experiments in the Fermilab high energy neutrino beam (50 GeV$<$ E_ν $<$ 300 GeV). The detector was comprised of six iron target calorimeter modules, with 690 t total target mass, followed by three muon spectrometer modules, followed by two drift chambers. Each iron target calorimeter module comprised 5.2 cm thick steel plates interspersed with liquid scintillation counters and drift chambers.

The NOMAD [503] detector at CERN consisted of central tracker detector inside a 0.4 T dipole magnet (the magnet was originally used by the UA1 experiment at CERN) followed by a hadronic calorimeter and muon detectors downstream of the magnet. The main neutrino target is 3 t of drift chambers followed downstream by transition radiation detectors which are followed by an EM calorimeter. NOMAD was exposed to the same wideband neutrino beam as was CHORUS.

MINERvA [504] is a hybrid detector based around a central plastic scintillator tracker: 8.3 t of plastic scintillator strips with triangular cross section read out by MAPMTs coupled to WLS fibers. The scintillator tracker is surrounded by electromagnetic and hadronic calorimetry, which is achieved by interleaving thin lead (steel) layers between the scintillator layers for the ECAL (HCAL). MINERvA is situated upstream of the MINOS near detector which acts as a muon spectrometer. Upstream of the scintillator tracker is a nuclear target region containing inactive layers of C (graphite), Pb, Fe (steel), and O (water). MINERvA's physics goals span a wide range of neutrino-nucleus interaction studies, from form factors to nuclear effects.

T2K [473] in Japan employs two near detectors at 280 m from the neutrino beam target, one centered on the axis of the horn-focused J-PARC neutrino beam and one placed 2.5° off-axis. The on-axis detector, INGRID, is described above. The 2.5° off-axis detector, ND280, employs the UA1 magnet (at 0.2 T) previously used by NOMAD. Inside the magnet volume are three separate detector systems: the trackers, the Pi0 Detector (P0D), and several ECal modules. The tracker detectors comprise two fine-grained scintillator detectors (FGDs), read out by MPPCs coupled to WLS fibers, interleaved between three gas TPCs read out by micromegas planes. The downstream FGD contains inactive water layers in addition to the scintillators. Upstream of the tracker is the P0D, a sampling tracker calorimeter with active detector materials comprising plastic scintillator read out by MPPCs and WLS fibers, and inactive sheets of brass radiators and refillable water modules. Surrounding the tracker and P0D, but still inside the magnet, are lead-scintillator EM sampling calorimeters.

The COHERENT collaboration aims to measure CEvNS (Coherent Elastic Neutrino-Nucleus Scattering) using the high-quality pion-decay-at-rest neutrino source at the Spallation Neutron Source in Oak Ridge, Tennessee. For doing so, it is deploying a suite of detector systems in a hallway in the basement of the SNS target hall with a phased approach. This includes CsI[Na] crystal, LAr scintillation detector, NaI[Tl], interwoven EJ200 scintillator and gadolinium-doped Mylar, thorium-232 metal plates and Germanium detectors.

The SND@LHC experiment [505] will perform measurements with high-energy neutrinos (100 GeV–1 TeV) produced at the LHC in the pseudo-rapidity region $7.2 < \eta < 8.6$. It allows the identification of all neutrino flavours with high efficiency. It is located 480 m downstream and off-axis with respect to the ATLAS interaction point and consists of a target region followed by a muon identification system. The target (810 kg) is instrumented with nuclear emulsions and Scintillating Fibre (SciFi) planes. The muon identification system is made of iron slabs interleaved with scintillating bars planes. SND@LHC is complementary to FASERν as it intercepts different components of the neutrino flux from LHC collisions, mainly those produced in heavy flavour decays, mostly charm.

35.11.4 *Outlook*

Detectors for accelerator-based neutrino beams have been in use, and constantly evolving, for six decades now. The rich program of neutrino oscillation physics and attendant need for newer and better neutrino-nucleus scattering measurements means that more neutrino detectors with broader capabilities will be needed in the coming decades.

One of the most intriguing prospects is a large volume, high pressure gas time projection chamber (HPTPC). With the

prospect of megawatt power accelerator-based neutrino beams, it is entirely feasible to collect high statistics data sets with a gas target. The low momentum thresholds for particle detection, and excellent momentum resolution and particle identification capabilities, of an HPTPC would open a new window into the physics of neutrino-nucleus scattering. Moreover, the ability to change the gas mixtures in the HPTPC would allow measurements in the same detector on multiple nuclear targets, which would, in turn, allow unprecedentedly accurate constraints and tuning of neutrino-nucleus interaction models.

35.12 Superconducting magnets for collider detectors

Revised March 2024 by Y. Makida (KEK).

35.12.1 *Solenoid Magnets*

In all cases SI unit are assumed, so that the magnetic field, B, is in Tesla, the stored energy, E, is in joules, the dimensions are in meters, and vacuum permeability of $\mu_0 = 4\pi \times 10^{-7}$.

The magnetic field (B) in an simple solenoid with a flux return iron yoke, in which the magnetic field is lower than magnetic saturation of < 2 T, is given by

$$B = \frac{\mu_0\, n\, I}{L} \tag{35.48}$$

where n is the number of turns, I is the current and L is the coil length.

In an air-core solenoid case, the central field is given by

$$B(0,0) = \mu_0\, n\, I \frac{1}{\sqrt{L^2 + 4R^2}} \ , \tag{35.49}$$

where R is the coil radius.

In most cases, momentum analysis is made by measuring the circular trajectory of the passing particles according to $p = mv = qrB$, where p is the momentum, m the mass, q the charge, r the bending radius. The sagitta, s, of the trajectory is given by

$$s = q\, B\, \ell^2/8p \ , \tag{35.50}$$

where ℓ is the path length in the magnetic field as shown in Fig. 35.39 .

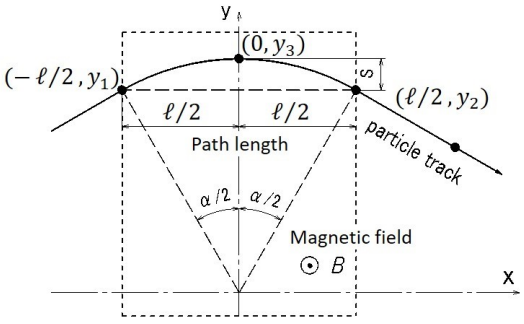

Figure 35.39: Geometric relation of sagitta between path length.

In a practical momentum measurement in colliding beam detectors, it is more effective to increase the magnetic volume than the field strength, since

$$dp/p \propto p/B\,\ell^2 \ , \tag{35.51}$$

where ℓ corresponds to the solenoid coil radius R. The energy stored in the magnetic field of any magnet is calculated by integrating B^2 over all space:

$$E = \frac{1}{2\mu_0} \int B^2 dV \tag{35.52}$$

If the coil thin and inside an iron return yoke , (which is the case if it is to superconducting coil), then

$$E \approx (B^2/2\mu_0)\pi R^2 L \ . \tag{35.53}$$

For a detector in which the calorimetry is outside the aperture of the solenoid, the coil must be transparent in terms of radiation and absorption lengths. This usually means that the superconducting solenoid and its cryostat is of minimum real thickness and is made of a material with long radiation length. There are two major contributors to the thickness of a thin solenoid:

1. The conductor consisting of the current-carrying superconducting material (usually Nb-Ti/Cu) and the quench protecting stabilizer (usually aluminum) are wound on the inside of a structural support cylinder (usually aluminum alloy). The coil thickness scales as B^2R, so the thickness in radiation lengths (X_0) is

$$t_{\rm coil}/X_0 = (R/\sigma_h X_0)(B^2/2\mu_0) \ , \tag{35.54}$$

where $t_{\rm coil}$ is the physical thickness of the coil, X_0 the average radiation length of the coil/stabilizer material, and σ_h is the hoop stress in the coil [506]. $B^2/2\mu_0$ is the magnetic pressure. In large detector solenoids, the aluminum stabilizer and support cylinders dominate the thickness; the superconductor (Nb-TI/Cu) contributes a smaller fraction. The main coil and support cylinder components typically contribute about 2/3 of the total thickness in radiation lengths.

2. Another contribution to the material comes from the outer cylindrical shell of the vacuum vessel. Since this shell is susceptible to buckling collapse, its thickness is determined by the diameter, length and the modulus of the material of which it is fabricated. The outer vacuum shell represents about 1/3 of the total thickness in radiation length.

35.12.2 *Properties of collider detector magnets*

The physical dimensions, central field stored energy and thickness in radiation lengths normal to the beam line of the superconducting solenoids associated with the major collider are given in Table 35.15 [507]. Fig. 35.40 shows thickness in radiation lengths as a function of B^2R in various collider detector solenoids.

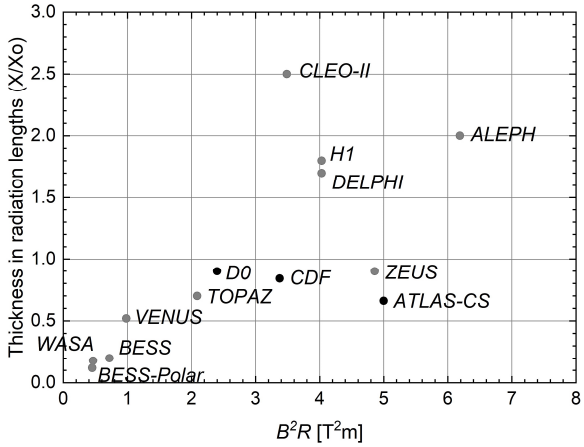

Figure 35.40: Magnet wall thickness in radiation length as a function of B^2R for various detector solenoids. Gray entries are for magnets no longer in use.

The ratio of stored energy to cold mass (E/M) is a useful performance measure. It can also be expressed as the ratio of the stress, σ_h, to twice the equivalent density, ρ, in the coil [506]:

$$\frac{E}{M} = \frac{E}{\rho\, 2\pi t_{\rm coil} RL} \approx \frac{\sigma_h}{2\rho} \tag{35.55}$$

The E/M ratio in the coil is approximately equivalent to H,¶¶

¶¶The enthalpy, or heat content, is called H in the thermodynamics literature. It is not to be confused with the magnetic field intensity B/μ.

Table 35.15: Progress of superconducting magnets for particle physics detectors.

* No longer in service
** Conceptual design in future
† EM calorimeter is inside solenoid, so small X/X_0 is not a goal

the enthalpy of the coil, and it determines the average coil temperature rise after energy absorption in a quench:

$$E/M = H(T_2) - H(T_1) \approx H(T_2) \tag{35.56}$$

where T_2 is the average coil temperature after the full energy absorption in a quench, and T_1 is the initial temperature. E/M ratios of 5, 10, and 20 kJ/kg correspond to ∼65, ∼80, and ∼100 K, respectively. The E/M ratios of various detector magnets are shown in Fig. 35.41 as a function of total stored energy. One would like the cold mass to be as small as possible to minimize the thickness, but temperature rise during a quench must also be minimized. An E/M ratio as large as 12 kJ/kg is designed into the CMS solenoid, with the possibility that about half of the stored energy can go to an external dump resistor. Thus the coil temperature can be kept below 80 K if the energy extraction system works well. The limit is set by the maximum temperature that the coil design can tolerate during a quench. This maximum local temperature should be <130 K (50 K + 80 K), so that thermal expansion effects, which are remarkable beyond 80 K, in the coil are manageable less than 50 K.

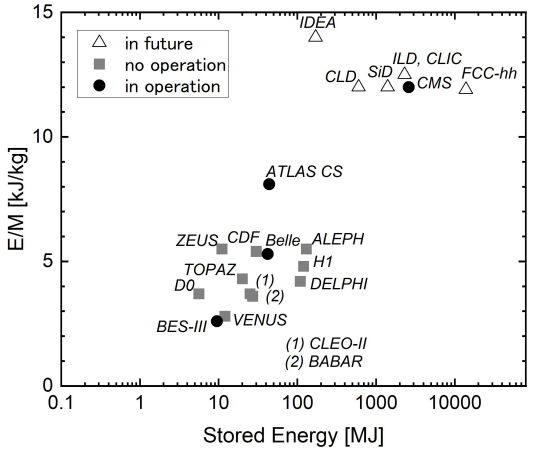

Figure 35.41: Ratio of stored energy to cold mass for major detector solenoids. Gray indicates magnets no longer in operation.

35.12.3 *Toroidal magnets*

Toroidal coils uniquely provide a closed magnetic field without the necessity of an iron flux-return yoke. Because no field exists at the collision point and along the beam line, there is, in principle, no effect on the beam. On the other hand, the field profile generally has $1/r$ dependence. The particle momentum may be determined by measurements of the deflection angle combined with the sagitta. The deflection (bending) power BL is

$$BL \approx \int_{R_i}^{R_0} \frac{B_i R_i \, dR}{R \sin\theta} = \frac{B_i \, R_i}{\sin\theta} \ln(R_0/R_i) \ , \tag{35.57}$$

where R_i is the inner coil radius, R_0 is the outer coil radius, and θ is the angle between the particle trajectory and the beam line axis . The momentum resolution given by the deflection may be expressed as

$$\frac{\Delta p}{p} \propto \frac{p}{BL} \approx \frac{p \sin\theta}{B_i R_i \ln(R_0/R_i)} \ . \tag{35.58}$$

The momentum resolution is better in the forward/backward (smaller θ) direction. The geometry has been found to be optimal when $R_0/R_i \approx 3$–4. In practical designs, the coil is divided into 6–12 lumped coils in order to have reasonable acceptance and accessibility. This causes the coil design to be much more complex. The mechanical structure needs to sustain the decentering force between adjacent coils, and the peak field in the coil is 3–5 times higher than the useful magnetic field for the momentum analysis [508].

35.13 Measurement of particle momenta in a uniform magnetic field

The trajectory of a particle with momentum p (in GeV/c) and charge ze in a constant magnetic field $\vec{B}$ is a helix, with radius of curvature R and pitch angle λ. The radius of curvature and momentum component perpendicular to $\vec{B}$ are related by

$$p \cos\lambda = 0.3 \, z \, B \, R \ , \tag{35.59}$$

where B is in tesla and R is in meters.

The distribution of measurements of the curvature $k \equiv 1/R$ is approximately Gaussian. The curvature error for a large number

of uniformly spaced measurements on the trajectory of a charged particle in a uniform magnetic field can be approximated by

$$(\delta k)^2 = (\delta k_{\rm res})^2 + (\delta k_{\rm ms})^2, \quad (35.60)$$

where δk = curvature error
$\delta k_{\rm res}$ = curvature error due to finite measurement resolution
$\delta k_{\rm ms}$ = curvature error due to multiple scattering.

If many (≥ 10) uniformly spaced position measurements are made along a trajectory in a uniform medium,

$$\delta k_{\rm res} = \frac{\epsilon}{L'^2}\sqrt{\frac{720}{N+4}}, \quad (35.61)$$

where N = number of points measured along track
L' = the projected length of the track onto the bending plane
ϵ = measurement error for each point, perpendicular to the trajectory.

If a vertex constraint is applied at the origin of the track, the coefficient under the radical becomes 320.

For arbitrary spacing of coordinates s_i measured along the projected trajectory and with variable measurement errors ϵ_i the curvature error $\delta k_{\rm res}$ is calculated from:

$$(\delta k_{\rm res})^2 = \frac{4}{w}\,\frac{V_{ss}}{V_{ss}V_{s^2s^2} - (V_{ss^2})^2}, \quad (35.62)$$

where V are covariances defined as $V_{s^m s^n} = \langle s^m s^n - \rangle s^m \langle s^n$ with $\rangle s^m = w^{-1}\sum({s_i}^m/{\epsilon_i}^2)$ and $w = \sum {\epsilon_i}^{-2}$.

The contribution due to multiple Coulomb scattering is approximately

$$\delta k_{\rm ms} \approx \frac{(0.016)({\rm GeV}/c)z}{Lp\beta\cos^2\lambda}\sqrt{\frac{L}{X_0}}, \quad (35.63)$$

where p = momentum (GeV/c)
z = charge of incident particle in units of e
L = the total track length
X_0 = radiation length of the scattering medium (in units of length; the X_0 defined elsewhere must be multiplied by density)
β = the kinematic variable v/c.

More accurate approximations for multiple scattering may be found in the section on Passage of Particles Through Matter (Sec. 34 of this *Review*). The contribution to the curvature error is given approximately by $\delta k_{\rm ms} \approx 8 s^{\rm rms}_{\rm plane}/L^2$, where $s^{\rm rms}_{\rm plane}$ is defined there.

36. Particle Detectors for Non-Accelerator Physics

Revised 2024. See the various sections for authors.

36.1 Introduction

Non-accelerator experiments have become increasingly important in particle physics and astrophysics. From them comes the evidence of physics beyond the SM, with the discovery of neutrino oscillations and adiabatic flavor conversion. Explored energies range from the meV scale to above the EeV, some 24 orders of magnitude. The physics and the design of the detectors vary as a consequence. Some experiments look at astrophysical high-energy phenomena using the atmosphere as a detector in the fluorescence and Cherenkov observatories or the polar ice and the ocean water in neutrino telescopes. Experiments on extremely rare events, such as neutrino-less double beta decay, solar neutrinos and dark matter induced scattering, need dedicated fully equipped deep underground laboratories, existing in different countries. Critical is the research to push back the ultra-low radioactive background frontier, with dedicated facilities in these laboratories. Detectors range from hyper-pure liquid scintillators, both organic and not, to thermalized and ballistic phonon detectors at the sub-Kelvin temperature, to dual phase noble fluid TPCs, etc. Space-based detectors also use some unique instrumentation, but these are beyond the present scope of this review. Gravitational wave detectors are not included as well.

36.2 High-energy cosmic-ray hadron and gamma-ray detectors

36.2.1 *Atmospheric fluorescence detectors*

Revised March 2024 by L.R. Wiencke (Colorado School of Mines).

Cosmic-ray fluorescence detectors (FDs) use the atmosphere as a giant calorimeter to measure isotropic scintillation light that traces the development profiles of extensive air showers. An extensive air shower (EAS) is produced by the interactions of ultra high-energy ($E > 10^{17}$ eV) subatomic particles in the stratosphere and upper troposphere. The amount of scintillation light generated by an EAS is proportional to the energy deposited in the atmosphere and nearly independent of the primary species. With energies extending beyond 10^{20} eV, ultra high energy cosmic rays (UHECRs) are the highest energy subatomic particles known to exist. In addition to particle arrival directions, energy spectra and primary composition, the astroparticle science investigated with FDs also includes multi-messenger studies, searches for high energy photons, neutrinos, monopoles and deeply penetrating forms of dark matter. The Pierre Auger Observatory FD also measures UV scintillation that traces the development of ring-shaped atmospheric transient luminous events, called Elves, in the ionosphere that are initiated by strong lightning [1].

Previous experiments with FDs included the pioneering Fly's Eye [2, 3], and the High Resolution Fly's Eye (HiRes and HiRes prototype) [4]. The history of the fluorescence technique includes earlier studies in the 1950's and 1960's [5, 6]. The current generation of experiments include the Telescope Array (TA) [7] in the northern hemisphere, and the larger Pierre Auger Observatory (Auger) [8] in the southern hemisphere. (Discussion, with extensive references, of current and possible future UHECR experiments can be foundx[in [9].) Auger and TA are hybrid observatories. Their FD telescopes overlook sparse arrays of particle detectors on the ground. Select parameters are listed in Table 36.1. TA and Auger have each one FD site populated with additional telescopes that view up to 60° in elevation to measure lower EASs using a combination of scintillation and direct Cherenkov light. As part of a fourfold coverage upgrade of TA (TAx4), 12 HiRes refurbished telescopes have been installed at the north and south-east sites of TA. A set of prototype FD telescopes, dubbed FAST [10], have observed EASs at the TA site using design that features wide field of view PMTs, fast timing and economical optics for a next-generation ground-based observatory. A second prototype has been installed at the Pierre Auger Observatory.

The fluorescence light is emitted primarily between 290 and 430 nm (Figure 36.1) with major lines at 337, 357, and 391 nm, when relativistic charged particles, primarily electrons and positrons, excite nitrogen molecules in air, resulting in transitions of the 1P and 2P systems. Reviews and references for the pioneering and recent laboratory measurements of fluorescence yield, $Y(\lambda, P, T, u)$, including dependence on wavelength (λ), temperature (T), pressure (p), and humidity (u) may be found in Refs. [11–13]. The results of various laboratory experiments have been combined (Figure 36.2) to obtain an absolute average and uncertainty for Y(337 nm, 800 hPa, 293 K, dry air) of 7.04 ± 0.24 ph/ MeV after corrections for different electron beam energies and other factors. The units of ph/ MeV correspond to the number of fluorescence photons produced per MeV of energy deposited in the atmosphere by the electromagnetic component of an EAS.

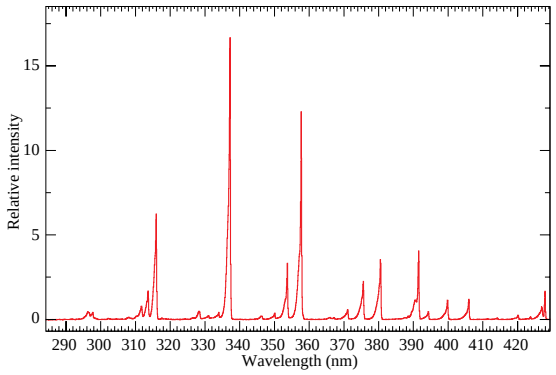

Figure 36.1: Measured fluorescence spectrum excited by 3 MeV electrons in dry air at 800 hPa and 293 K. Airfly experiment. Figure from Ref [14].

An FD element (telescope) consists of a non-tracking spherical mirror of less than astronomical quality, a"camera" of photomultiplier tubes (PMTs) near the focal plane, and a flash ADC readout system with a pulse and track-finding trigger scheme [8, 16]. The major experiments listed in Table 36.1 all use conventional PMTs (for example, Hamamatsu R9508 or Photonis XP3062) with

Table 36.1: Parameters of major fluorescence detectors. Note 1: Year when all FD sites were operational. Note 2: At TA 1 of the 3 FD sites features 24 telescopes from the HiRes experiment. Note 3: A-C for one telescope where A is the full area and C the area obscured by the camera and support structures. Thus A-C is the effective light collecting area. For the modified Schmidt design at Auger, the area of the entrance pupil, A, is listed because the pupil is smaller than the mirror and thus defines the entrance aperture. For the other experiments, the area of the mirror, A, is listed

Figure from Ref [15].

grounded cathodes and AC coupled readout. Segmented mirrors have been fabricated from slumped or slumped/polished glass with an anodized aluminum coating or fabricated using shaped aluminum that was then chemically anodized with $AlMgSiO_5$. A broadband UV filter (custom fabricated, BG-3, or Schott MUG-6) reduces background light such as starlight, airglow, man-made light pollution, and airplane strobe-lights.

At 10^{20} eV, where the flux drops below 1 EAS/km^{2}century, the aperture for an eye of adjacent FD telescopes that span the horizon can reach 10^4 km^2 sr. FD operation requires (nearly) moonless nights and clear atmospheric conditions, which typically imposes a duty cycle of about 10%. Arrangements of LEDs, calibrated diffuse sources [17], pulsed UV lasers [18], LIDARs [1] and IR detectors that are sensitive to clouds are used for photometric calibration, atmospheric calibration [19], and determination of exposure [20]. For purposes of optical transmission, the atmosphere is treated as having a dominant molecular component and a secondary aerosol component. The latter is well described [21] by molecular scattering theory and models derived from radiosonde measurements. The aerosol component can include dust, haze and pollution and the aerosol optical depth profile must be measured on site in the UV during FD data taking.

The EAS generates a track consistent with a light source moving at $v = c$ across the FOV. The number of photons (N_γ) as a function of atmospheric depth (X) can be expressed as [12]

$$\frac{\mathrm{d}N_\gamma}{\mathrm{d}X} = \frac{dE^{\mathrm{tot}}_{\mathrm{dep}}}{dX} \int Y(\lambda, P, T, u) \cdot \tau_{\mathrm{atm}}(\lambda, X) \cdot \varepsilon_{\mathrm{FD}}(\lambda)\mathrm{d}\lambda, \quad (36.1)$$

where $\tau_{atm}(\lambda, X)$ is the atmospheric transmission, including wavelength (λ) dependence, and $\varepsilon_{\mathrm{FD}}(\lambda)$ is the FD efficiency. $\varepsilon_{\mathrm{FD}}(\lambda)$ includes geometric factors and collection efficiency of the optics, quantum efficiency of the PMTs, and other throughput factors. The typical systematic uncertainties, τ_{atm} (10%) and $\varepsilon_{\mathrm{FD}}$ (photometric calibration 10%), currently dominate the systematic uncertainty the absolute EAS energy scale. FD energy resolution, defined as event-to-event statistical uncertainty, is typically less than 10% for final data samples used for science analysis.

Analysis methods to reconstruct the EAS profile and deconvolve the contributions of re-scattered scintillation light, and direct and scattered Cherenkov light are described in [2] and more recently in [23]. The EAS energy is typically obtained by integrating over the Gaisser-Hillas function [24]

$$E_{\mathrm{cal}} = \int_0^\infty [w_{\mathrm{max}} \left(\frac{X - X_0}{X_{\mathrm{max}} - X_0} \right)^{(X_{\mathrm{max}} - X_0)/\lambda} e^{(X_{\mathrm{max}} - X)/\lambda}] \mathrm{d}X, \quad (36.2)$$

where E_{cal} is the energy of electromagnetic energy component of the EAS and X_{max} is the atmospheric slant depth at which the shower reaches its maximum energy deposit rate. This maximum dE/dX is denoted as w_{max}. X_0 and λ are two shape parameters. The energy of the primary cosmic ray is obtained by correcting E_{cal} upward by about 10% to account for the invisible energy carried by particles that do not interact in the atmosphere. Auger reported a data-driven method to estimate the invisible energy from the muon number at ground level and Xmax to reduce systematic uncertainties [25]. Energy resolution, $\Delta E/E$, of 15-20% is achievable, provided the geometric fit of the EAS axis is constrained, typically by multi-eye stereo projection or hybrid observations, and the profile fit of EAS development along the track is constrained by the observed rise and fall about X_{max}. An example of a recorded EAS light profile and its corresponding dE/dX development profile are shown in Fig. 36.3. The EAS generates a track consistent with a light source moving at $v = c$ across the FOV. The number of photons (N_γ) as a function of atmospheric depth (X) can be expressed as [12] In 2023 the Pierre Auger Collaboration published a public data release [26] of the 100 highest energy cosmic ray events collected over a 17-year span through 2020 with an additional 9 energetic hybrid events used in the calibration proceedure. In 2024 the collabaration reported the first comparision of X_{max} measurements [27] between fluorescence and radio detectors at the same location. This comparision includes a subset of 53 airshowers that were observed by the two detectors simultaneously.

[1] LIDAR stands for "Light Detection and Ranging" and refers here to systems that measure atmospheric properties from the light scattered backwards from laser pulses directed into the sky.

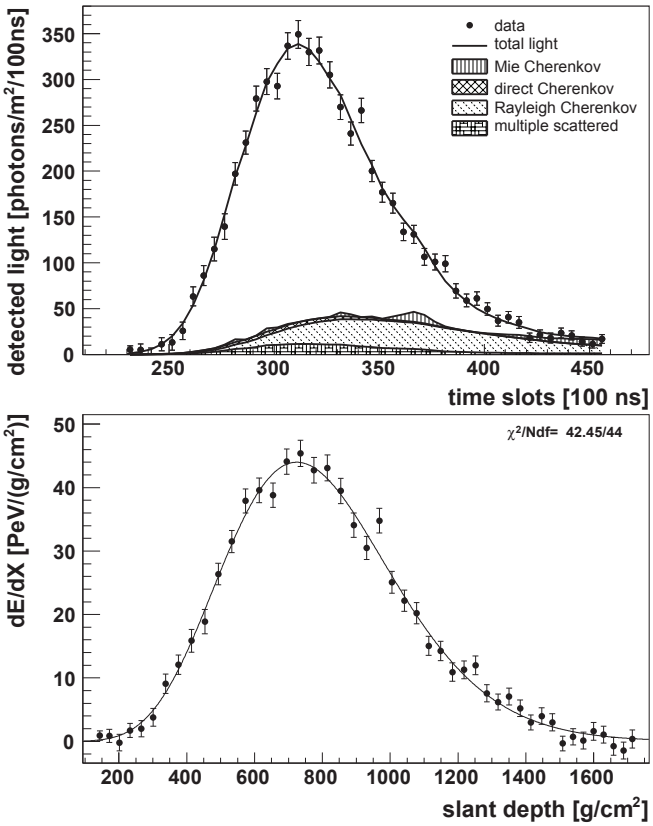

Figure 36.3: Example light profile (left) of one EAS recorded by the Pierre Auger FD and the corresponding profile (right) of energy deposited in the atmosphere vs atmospheric slant depth. The light profiles include the estimated components of Cherenkov light that have been scattered out of the forward beam by the molecular and aerosol (Mie) components of the atmosphere. The reconstructed energy of this EAS was $3.0 \pm 0.2 \times 10^{19}$ eV. Figure from Ref [22].

An FD that would look down on the earth's atmosphere from space orbit to view a much larger area than ground based instruments is an active area of R&D. Prototypes that have been built and flown in orbit include the pioneering TUS instrument [28], [29] operated 2016-2018 onboard the Lomonosov satellite. The JEM-EUSO collabration has flown prototype FD telescopes on stratospheric balloon flights in 2014 (EUSO-Balloon) [30], 2017 (EUSO-SPB1) [31] and 2023 (EUSO-SPB2) [32]. The Mini-EUSO [33] FD continues recording terrestial UV emission by looking down through a 25 cm diameter UV-transmitting window inside the International Space Station since 2019. The Probe of Extreme Multimessenger Astrophysics (POEMMA) project has completed a detailed conceptual design study for a twin-satellite mission [34] that would observe UHECRs and PeV scale cosmogenic tau neutrinos.

36.2.2 *Atmospheric Cherenkov telescopes for high-energy gamma ray astronomy*

Revised October 2023 by J. Holder (Delaware U.; Delaware U., Bartol Inst.).

A wide variety of astrophysical objects are now known to produce high-energy γ-ray photons. Leptonic or hadronic particles, accelerated to relativistic energies in the source, produce γ-rays typically through inverse Compton boosting of ambient photons or through the decay of neutral pions produced in hadronic interactions. At energies below ∼30 GeV, γ-ray emission can be efficiently detected using satellite or balloon-borne instrumentation, with an effective area approximately equal to the size of the detector (typically < 1 m^2). At higher energies, a technique with much larger effective collection area is desirable to measure astrophysical γ-ray fluxes, which decrease rapidly with increasing energy. Atmospheric Cherenkov detectors achieve effective collection areas of $>10^5$ m^2 by employing the Earth's atmosphere as an intrinsic part of the detection technique.

As described in Chapter 30, a hadronic cosmic ray or high energy γ-ray incident on the Earth's atmosphere triggers a particle cascade, or air shower. Relativistic charged particles in the cascade generate Cherenkov radiation, which is emitted along the shower direction, resulting in a light pool on the ground with a radius of ∼130 m. Cherenkov light is produced throughout the cascade development, with the maximum emission occurring when the number of particles in the cascade is largest, at an altitude of ∼10 km for primary energies of 100 GeV–1 TeV. Following absorption and scattering in the atmosphere, the Cherenkov light at ground level peaks at a wavelength, $\lambda \approx 300$–350 nm. The photon density is typically ∼100 photons/m^2 for a 1 TeV primary, arriving in a brief flash of a few nanoseconds duration. This Cherenkov pulse can be detected from any point within the light pool radius by using large reflecting surfaces to focus the Cherenkov light on to fast photon detectors (Fig. 36.4).

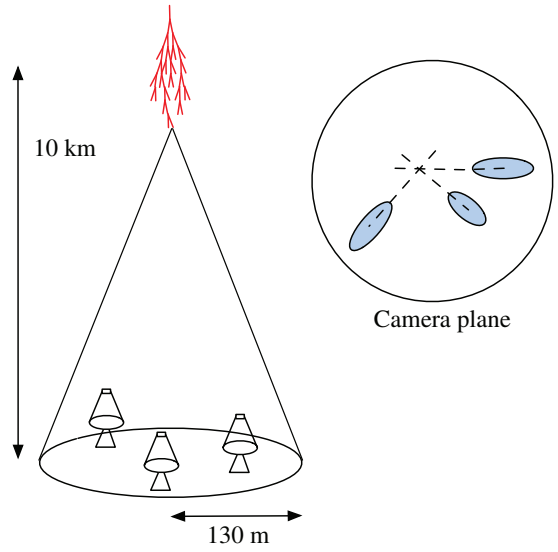

Figure 36.4: A schematic illustration of an imaging atmospheric Cherenkov telescope array. The primary particle initiates an air shower, resulting in a cone of Cherenkov radiation. Telescopes within the Cherenkov light pool record elliptical images; the intersection of the long axes of these images indicates the arrival direction of the primary, and hence the location of a γ-ray source in the sky

Modern atmospheric Cherenkov telescopes, such as those built and operated by the VERITAS [35], H.E.S.S. [36] and MAGIC [37] collaborations, consist of large (> 100 m^2) segmented mirrors on steerable altitude-azimuth mounts. A camera made from an array of photosensors is placed at the focus of each mirror and used to record a Cherenkov image of each air shower. In these imaging atmospheric Cherenkov telescopes, single-anode photomultipliers tubes (PMTs) have traditionally been used (2048, in the case of H.E.S.S. II), but silicon devices now feature in more modern designs. The telescope cameras typically cover a field-of-view of $3 - 10^\circ$ in diameter. Images are recorded at kHz rates, the vast majority of which are due to showers with hadronic cosmic-ray primaries. The shape and orientation of the Cherenkov images are used to discriminate γ-ray photon events from this cosmic-ray background, and to reconstruct the photon energy and arrival direction. γ-ray images result from purely electromagnetic cascades and appear as narrow, elongated ellipses in the camera plane. The long axis of the ellipse corresponds to the vertical extension of the air shower, and points back towards the source position in the field-of-view. If multiple telescopes are used to view the same shower ("stereoscopy"), the source position is simply the in-

tersection point of the various image axes. Cosmic-ray primaries produce secondaries with large transverse momenta, which initiate sub-showers. Their images are consequently wider and less regular than those with γ-ray primaries and, since the original charged particle has been deflected by Galactic magnetic fields before reaching the Earth, the images have no preferred orientation.

The measurable differences in Cherenkov image orientation and morphology provide the background discrimination which makes ground-based γ-ray astronomy possible. For point-like sources, such as distant active galactic nuclei, modern instruments can reject over 99.999% of the triggered cosmic-ray events, while retaining up to 50% of the γ-ray population. In the case of spatially extended sources, such as Galactic supernova remnants, the background rejection is less efficient, but the technique can be used to produce γ-ray maps of the emission from the source. The angular resolution depends upon the number of telescopes which view the image and the energy of the primary γ-ray, but is typically less than 0.1° per event (68% containment radius) at energies above a few hundred GeV.

The total Cherenkov yield from the air shower is proportional to the energy of the primary particle. The image intensity, combined with the reconstructed distance of the shower core from each telescope, can therefore be used to estimate the primary energy. The energy resolution of this technique, also energy-dependent, is typically 15–20% at energies above a few hundred GeV. Energy spectra of γ-ray sources can be measured over a wide range, depending upon the instrument characteristics, source properties (flux, spectral slope, elevation angle, *etc.*), and exposure time. The effective energy range is typically from 30 GeV to 100 TeV and peak sensitivity lies in the range from 100 GeV to a few TeV.

The first astrophysical source to be convincingly detected using the imaging atmospheric Cherenkov technique was the Crab Nebula [38], with an integral flux of 2.1×10^{-11} photons cm^{-2} s^{-1} above 1 TeV [39]. Modern imaging atmospheric Cherenkov telescopes have sensitivity sufficient to detect sources with less than 1% of the Crab Nebula flux in a few tens of hours. The TeV source catalog now consists of over 200 sources (see e.g. Ref. [40]). A large fraction of these were detected by scanning the Galactic plane from the southern hemisphere with the H.E.S.S. telescope array [41]. Recent reviews of the field include [42] and [43], and a historical overview can be found in [44].

Major upgrades of the existing telescope arrays include the 2012 addition of a 28 m diameter central telescope to H.E.S.S. (H.E.S.S. II). Cherenkov telescopes also play an important role in hybrid air-shower detector systems such as TAIGA [45] and LHAASO [46]. Development for the next generation instrument, the Cherenkov Telescope Array Observatory (CTAO), is now at an advanced stage. CTAO will consist of a northern and a southern hemisphere observatory, with a combined total of more than 60 telescopes [47]. Telescopes of three different sizes are planned, spread over an area of > 1 km^2, providing wider energy coverage, improved angular and energy resolutions, and an order of magnitude improvement in sensitivity relative to existing imaging atmospheric Cherenkov telescopes. A number of prototype telescopes are already operating, exploiting technological developments in telescope structural design and high-speed data acquistion. Novel features of some designs include dual mirror optics and silicon photo-detectors. In particular, the first 23 m diameter "Large Size Telescope" is now operating regularly on La Palma, and is producing scientific results [48]. The wide range of physics questions that CTAO will adress is summarized in [49].

36.3 Large neutrino detectors

36.3.1 *Deep liquid detectors for rare processes*

Revised October 2023 by K. Scholberg (Duke U.) and C.W. Walter (Duke U.).

Deep, large detectors for rare processes tend to be multi-purpose with physics reach that includes not only solar, reactor, supernova and atmospheric neutrinos, but also searches for baryon number violation and lepton number violation, searches for exotic particles and beyond-the-standard-model physics, and neutrino and cosmic-ray astrophysics in different energy regimes. The detectors may also serve as targets for long-baseline neutrino beams for neutrino oscillation physics studies. In general, detector design considerations can be divided into high- and low-energy regimes, for which background and event reconstruction issues differ. The high-energy regime, from about 100 MeV to a few hundred GeV, is relevant for proton decay searches, atmospheric neutrinos and high-energy astrophysical neutrinos. The low-energy regime (a few tens of MeV or less) is relevant for supernova, solar, reactor and geological neutrinos.

Large water Cherenkov and scintillator detectors (see Table 36.2) usually consist of a volume of transparent liquid viewed by photomultiplier tubes (PMTs) (see Sec 35.2); the liquid serves as active target. PMT hit charges and times are recorded and digitized, and triggering is usually based on coincidence of PMT hits within a time window comparable to the detector's light-crossing time. Because photosensors lining an inner surface represent a driving cost that scales as surface area, very large volumes can be used for comparatively reasonable cost. Some detectors are segmented into subvolumes individually viewed by PMTs, and may include other detector elements (*e.g.*, tracking detectors). Devices to increase light collection, *e.g.*, reflectors or waveshifter plates, may be employed. A common configuration is to have at least one concentric outer layer of liquid material separated from the inner part of the detector to serve as shielding against ambient background. If optically separated and instrumented with PMTs, an outer layer may also serve as an active veto against entering cosmic rays and other background events. The PMTs for large detectors typically range in size from 20 cm to 51 cm diameter, and typical quantum efficiencies are in the 20–25% range for scintillation and water-Cherenkov photons. PMTs with higher quantum efficiencies, 35% or higher, are now available. The active liquid volume requires purification and there may be continuous recirculation of liquid. For large homogeneous detectors, the event interaction vertex is determined using relative timing of PMT hits, and energy deposition is determined from the number of recorded photoelectrons. A "fiducial volume" is usually defined within the full detector volume, some distance away from the PMT array. Inside the fiducial volume, enough PMTs are illuminated per event that reconstruction is considered reliable, and furthermore, entering background from the enclosing walls is suppressed by a buffer of self-shielding. PMT and detector optical parameters are calibrated using laser, LED, or other light sources. Quality of event reconstruction typically depends on photoelectron yield, pixelization and timing.

Because in most cases one is searching for rare events, large detectors are usually sited underground to reduce cosmic-ray-related background (see Chapter 30). The minimum depth required varies according to the physics goals [50].

36.3.1.1 *Liquid scintillator detectors*

Past and current large underground detectors based on hydrocarbon scintillators include LVD, MACRO, BUST (Baksan), Borexino, KamLAND and SNO+; JUNO is a future detector. Experiments at nuclear reactors include CHOOZ, Double CHOOZ, Daya Bay, and RENO. Organic liquid scintillators (see Section 35.3) for large detectors are chosen for high light yield and attenuation length, good stability, compatibility with other detector materials, high flash point, low toxicity, appropriate density for mechanical stability, and low cost. They may be doped with waveshifters and stabilizing agents. Popular choices are pseudocumene (1,2,4-trimethylbenzene) with a few g/L of the PPO (2,5-diphenyloxazole) fluor, and linear alkylbenzene (LAB), with light yield $\sim 10^4$ photons/MeV. In a typical detector configuration there will be active or passive regions of undoped scintillator, non-scintillating mineral oil or water surrounding the inner neutrino target volume. A thin vessel or balloon made of nylon, acrylic or other material transparent to scintillation light may contain the inner target; if the scintillator is buoyant with respect to its buffer, ropes may hold the balloon in place. For phototube surface coverages in the 20–40% range, yields in the few hundreds of photoelectrons per MeV of energy deposition can be obtained.

Table 36.2: Properties of large detectors for rare processes. If total target mass is divided into large submodules, the number of subdetectors is indicated in parentheses. Projects with first data expected in 2024 or later are indicated in italics.

Detector	Mass, kton (modules)	PMTs (diameter, cm)	ξ	p.e./MeV	Dates

*Indicates typical fiducial mass used for data analysis; this may vary by physics topic.
†Measurements made before 2003 only considered data from the 43 cm PMTs.
‡SNO+ ran with water fill from May 2017 to July 2019.
§The effective Daya Bay coverage is 12% with top and bottom reflectors.
¶The effective Kamiokande III coverage was 25% with light collectors.
‖A second staged module is being investigated.
**Additional photosensor modules and PMTs are planned.
††The effective SNO coverage was 54% with light collectors.
‡‡Photodetector technology and coverage varies according to TPC type and is not yet fully determined.
§§Modules will be constructed in a phased approach.

Typical energy resolution is about $5-7\%/\sqrt{E(\mathrm{MeV})}$ [51,52], and typical position reconstruction resolution is a few tens of cm at $\sim$ 1 MeV, scaling as $\sim N^{-1/2}$, where N is the number of photoelectrons detected.

Shallow detectors for reactor neutrino oscillation experiments require excellent muon veto capabilities. For $\bar{\nu}_e$ detection via inverse beta decay on free protons, $\bar{\nu}_e + p \to n + e^+$, the neutron is captured by a proton on a $\sim$180 μs timescale, resulting in a 2.2 MeV γ ray, observable by Compton scattering and which can be used as a tag in coincidence with the positron signal. The positron annihilation γ rays may also contribute. Inverse beta decay tagging may be improved by addition of Gd at $\sim$0.1% by mass, which for natural isotope abundance has a $\sim$49,000 barn cross-section for neutron capture (in contrast to the 0.3 barn cross-section for capture on free protons). Gd capture takes $\sim$30 μs, and is followed by a cascade of γ rays adding up to about 8 MeV. Gadolinium doping of scintillator requires specialized formulation to ensure adequate attenuation length and stability.

Scintillation detectors have an advantage over water Cherenkov detectors in the lack of Cherenkov threshold and the high light yield. However, scintillation light emission is nearly isotropic, and therefore directional capabilities are relatively weak. Liquid scintillator is especially suitable for detection of low-energy events. Radioactive backgrounds are a serious issue, and include long-lived cosmogenics such as ^{14}C. To go below a few MeV, very careful selection of materials and purification of the scintillator is required (see Section 36.6). Fiducialization and tagging can reduce background. One can also dissolve neutrinoless double beta decay ($0\nu\beta\beta$) isotopes in scintillator. This has been realized by KamLAND-Zen, which deployed a 1.5 m-radius balloon containing enriched Xe dissolved in scintillator inside KamLAND, and ^{130}Te is planned for SNO+.

36.3.1.2 *Water Cherenkov detectors*

Very large imaging water detectors reconstruct ten-meter-scale Cherenkov rings produced by charged particles (see Section 35.5). The first such large detectors were IMB and Kamiokande. The only currently existing instance of this class of detector, with fiducial mass of 22.5 kton and total mass of 50 kton, is Super-Kamiokande (Super-K, SK). Hyper-Kamiokande (Hyper-K) plans at least one, and possibly two, detectors with 187-kton fiducial mass. For volumes of this scale, absorption and scattering of Cherenkov light are non-negligible, and a wavelength-dependent factor $\exp(-d/L(\lambda))$ (where d is the distance from emission to the sensor and $L(\lambda)$ is the attenuation length of the medium) must be included in the integral of Eq. (35.6) for the photoelectron yield. Attenuation lengths on the order of 100 meters have been achieved.

Cherenkov detectors are excellent electromagnetic calorimeters, and the number of Cherenkov photons produced by an e/γ is nearly proportional to its kinetic energy. For massive particles, the number of photons produced is also related to the energy, but not linearly. For any type of particle, the *visible energy* E_{vis} is defined as the energy of an electron which would produce the same number of Cherenkov photons. The number of collected photoelectrons depends on the scattering and attenuation in the water along with the photo-cathode coverage, quantum efficiency and the optical parameters of any external light collection systems or protective material surrounding them. Event-by-event corrections are made for geometry and attenuation. For a typical case, in water $N_{\mathrm{p.e.}} \sim 15\,\xi\,E_{\mathrm{vis}}(\mathrm{MeV})$, where ξ is the effective fractional photosensor coverage. Cherenkov photoelectron yield per MeV of energy is relatively small compared to that for scintillator, *e.g.*, $\sim$ 6 pe/MeV for Super-K with a PMT surface coverage of $\sim$ 40%. In spite of light yield and Cherenkov threshold issues, the intrinsic directionality of Cherenkov light allows individual particle tracks

to be reconstructed. Vertex and direction fits are performed using PMT hit charges and times, requiring that the hit pattern be consistent with a Cherenkov ring.

High-energy (∼100 MeV or more) neutrinos from the atmosphere or beams interact with nucleons; for the nucleons bound inside the ^{16}O nucleus, nuclear effects must be considered both at the interaction and as the particles leave the nucleus. Various event topologies, with final-state particles contained, exiting, or entering the detector, can be distinguished by their timing and fit patterns, and by presence or absence of light in a veto. At high energies, multi-photoelectron hits are likely and the charge collected by each PMT (rather than the number of PMTs firing) must be used; the energy resolution in this case is approximately $2\%/\sqrt{\xi\, E_{\rm vis}({\rm GeV})}$. The absolute energy scale in this regime can be known to ∼2–3% using cosmic-ray muon energy deposition, Michel electrons and π^0 from atmospheric neutrino interactions. Typical vertex resolutions for GeV energies are a few tens of cm [53]. Angular resolution for determination of the direction of a charged particle track is a few degrees. For a neutrino interaction, because some final-state particles are usually below Cherenkov threshold, knowledge of direction of the incoming neutrino direction itself is generally worse than that of the lepton direction, and dependent on neutrino energy.

Multiple particles in an interaction (so long as they are above Cherenkov threshold) may be reconstructed, allowing for the exclusive reconstruction of final states. In searches for proton decay, multiple particles can be kinematically reconstructed to form a decaying nucleon. High-quality particle identification is also possible: γ rays and electrons shower, and electrons scatter, which results in fuzzy rings, whereas muons, pions and protons make sharp rings. These patterns can be quantitatively separated with high reliability using maximum likelihood methods [54]. Sources of background for high energy interactions include misidentified cosmic muons and anomalous light patterns when the PMTs sometimes "flash" and emit photons themselves. The latter class of events can be removed using its distinctive PMT signal patterns, which may be repeated. More information about high energy event selection and reconstruction may be found in reference [55].

In spite of the fairly low light yield, large water Cherenkov detectors may be employed for reconstructing low-energy events, down to *e.g.* ∼ 4-5 MeV for Super-K [56]. Low-energy neutrino interactions of solar neutrinos in water are predominantly elastic scattering off atomic electrons; single electron events are then reconstructed. At solar neutrino energies, the visible energy resolution ($\sim 30\%/\sqrt{\xi\, E_{\rm vis}({\rm MeV})}$) is about 20% worse than photoelectron counting statistics would imply. Using an electron LINAC and/or nuclear sources, approximately 0.5% determination of the absolute energy scale has been achieved at solar neutrino energies. Angular resolution is limited by multiple scattering in this energy regime (25–30°). At these energies, radioactive backgrounds become a dominant issue. These backgrounds include radon in the water itself or emanated from detector materials, and γ rays from the rock and detector materials. In the few to few tens of MeV range, radioactive products of cosmic-ray-muon-induced spallation are troublesome, and are removed by proximity in time and space to preceding muons, at some cost in dead time. Gadolinium doping using 0.2% $Gd_2(SO_4)_3$ has now been initiated for Super-K to improve selection of low-energy $\bar{\nu}_e$ and other events with accompanying neutrons [57].

The Sudbury Neutrino Observatory (SNO) detector [58] was the only instance of a large heavy water detector. In addition to an outer 1.7 kton of light water, SNO contained 1 kton of D_2O, giving it unique sensitivity to neutrino neutral current ($\nu_x + d \to \nu_x + p + n$), and charged current ($\nu_e + d \to p + p + e^-$) deuteron breakup reactions. The neutrons were detected in three ways: via capture on deuterons, via capture on dissolved ^{35}Cl, and via specialized ^{3}He counters.

36.3.1.3 *Noble liquid detectors*

Noble liquids scintillate and can be used as the active medium for particle detection. Detectors employing argon and xenon are also used as time-projection chambers (TPCs), either as dual-phase low-energy recoil detectors, or as track-imaging detectors. Noble-liquid detectors with low energy (few to few tens of keV) capability for detecting electronic and nuclear recoils are employed for dark matter and other rare event searches and are described in Sec. 36.4. These detectors can also be employed for some of the same physics (baryon number violation, astrophysical neutrino transient searches, etc.) as for the other large detectors described here, especially as they approach tens of ton scale and higher (e.g., DARWIN, DarkSide-20, ARGO). Track-imaging time-projection chambers, which are described in detail Section 36.4, have a dynamic range reaching down to the few to few tens of MeV scale, enabling sensitivity to e.g., solar and supernova burst neutrinos. Surface LArTPCs have significant cosmic backgrounds, but may still have sensitivity to astrophysical transients such as supernova burst neutrinos. DUNE will be sufficiently deep to have sensitivity to steady-state low-energy neutrino sources such as solar neutrinos.

36.3.2 *Neutrino telescopes*

Revised February 2024 by U.F. Katz (Erlangen U.) and C. Spiering (DESY, Zeuthen).

The primary goal of neutrino telescopes (NTs) is the detection of astrophysical neutrinos, in particular those which are expected to accompany the production of high-energy cosmic rays in astrophysical accelerators. NTs in addition address a variety of other fundamental physics issues like the indirect search for dark matter, studies of neutrino oscillations, searches for exotic particles like magnetic monopoles or study of cosmic rays and their interactions [59–61]. Electromagnetic radio frequency detectors for high energy neutrinos are discussed in "Radio emission from (ultra-) high energy particle showers" section 36.3.3.

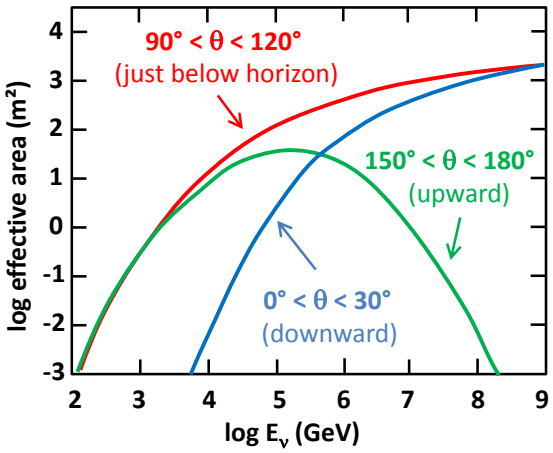

Figure 36.5: Average over the effective ν_μ and $\overline{\nu}_\mu$ areas for IceCube as an example of a cubic-kilometre NT, as a function of neutrino energy for three intervals of the zenith angle θ. The values shown here correspond to a specific event selection for point source searches.

NTs are large-volume arrays of "optical modules" (OMs) installed in open transparent media like water or ice, at depths that completely block the daylight. The OMs are sensitive to individual photons of the Cherenkov light induced by charged secondary particles produced in reactions of high-energy neutrinos in or around the instrumented volume. The time of photon-induced signals ("hits") is registered with a precision of a few nanoseconds. The neutrino energy, E_ν, and direction can be reconstructed from the hit pattern recorded. NTs typically target an energy range $E_\nu \gtrsim 100\,{\rm GeV}$; sensitivity to lower energies is achieved in dedicated setups with denser instrumentation.

In detecting cosmic neutrinos, three sources of backgrounds have to be considered: (i) *atmospheric neutrinos* from cosmic-ray interactions in the atmosphere, which can be separated from cosmic neutrinos on a statistical basis, or, for down-going neutrinos, by vetoing accompanying muons; (ii) down-going punch-through *atmospheric muons* from cosmic-ray interactions, which are sup-

pressed by several orders of magnitude with respect to the ground level due to the large detector depths and can be further reduced by selecting upward-going or high-energy neutrinos or by self-veto methods; (iii) random backgrounds due to photomultiplier (PMT) dark counts, ^{40}K decays (mainly in sea water) or bioluminescence (only water). Atmospheric neutrinos and muons allow for investigating neutrino oscillations and cosmic ray anisotropies, respectively. Since 2012, it has become obvious that a precise measurement of the energy-zenith-distribution of atmospheric neutrinos in the energy range from a few to about 100 GeV may allow for determining the neutrino mass hierarchy by exploiting matter-induced oscillation effects in the Earth [62, 63].

Neutrinos can interact with target nucleons N through charged current ($\overset{(-)}{\nu}_\ell N \to \ell^\mp X$, CC) or neutral current ($\overset{(-)}{\nu}_\ell N \to \overset{(-)}{\nu}_\ell X$, NC) processes. A CC reaction of a $\overset{(-)}{\nu}_\mu$ produces a muon track and a hadronic particle cascade, whereas all NC reactions and CC reactions of $\overset{(-)}{\nu}_e$ produce particle cascades only. CC interactions of $\overset{(-)}{\nu}_\tau$ can have either signature, depending on the τ decay mode. Of particular interest is the so-called double-bang signature, where the τ decays sufficiently far away from the primary interaction to create a second, distinguishable cascade (typically at PeV energies and above). In most astrophysical models, neutrinos are expected to be produced through the $\pi/K \to \mu \to e$ decay chain, *i.e.*, with a flavour ratio $\nu_e : \nu_\mu : \nu_\tau \approx 1 : 2 : 0$. For sources outside the solar system, neutrino oscillations turn this ratio to $\nu_e : \nu_\mu : \nu_\tau \approx 1 : 1 : 1$ upon arrival on Earth.

The total neutrino-nucleon cross section is about $10^{-34}\,\mathrm{cm}^2$ at $E_\nu = 20$ TeV and rises roughly linearly with E_ν below this energy and as $E_\nu^{0.3-0.5}$ above, flattening out towards high energies. The CC:NC cross-section ratio is about 2:1. At energies above several TeV, neutrino absorption in the Earth becomes noticeable; for vertically upward-moving neutrinos (zenith angle $\theta = 180°$), the survival probability is 74 (27, < 2)% for 10 (100, 1000) TeV. The energy transferred to the final-state lepton varies between 0 and 100% of E_ν, with a mean of 50% (65%) for neutrinos (antineutrinos) at 100 GeV and 75% for both neutrinos and antineutrinos at 10 PeV.

The final-state lepton follows the initial (anti)neutrino direction with an average mismatch angle of about $\langle\phi_{\nu\ell}\rangle \approx 1°/(E_\nu/\mathrm{TeV})^{0.55}$, with a steeper decrease beyond 10 TeV, reaching 0.005° at 1 PeV [64]. These values indicate the intrinsic kinematic limit to the angular resolution of NTs. For CC $\overset{(-)}{\nu}_\mu$ reactions at energies above about 10 TeV, the angular resolution is dominated by the muon reconstruction accuracy of a few times 0.1° at most. For muon energies $E_\mu \gtrsim 1$ TeV, the increasing light emission due to radiative processes allows for reconstructing E_μ from the measured Cherenkov light intensity with an accuracy of $\sigma(\log E_\mu) \approx 0.3$; at lower energies, E_μ can be estimated from the length of the muon track if it is contained in the detector. These properties make CC $\overset{(-)}{\nu}_\mu$ reactions the prime channel for the identification of individual astrophysical neutrino sources.

Hadronic and electromagnetic particle cascades at the relevant energies are 5–20 m long, *i.e.*, short compared to typical OM spacings. The total amount of Cherenkov light provides a direct measurement of the cascade energy with an accuracy of about 20% at energies above 10 TeV and 10% beyond 100 TeV for events contained in the instrumented volume. Except for double-bang events, the neutrino flavour and reaction mechanism can, however, be determined on a statistical basis at best, and neutrinos from NC reactions or τ decays may carry away significant "invisible" energy. Above 100 TeV, the average directional reconstruction accuracy of cascades is better than 10 (2) degrees in polar ice (sea water), the difference being due to the inhomogeneity of the ice and stronger light scattering in ice. These features, together with the small background of atmospheric $\overset{(-)}{\nu}_e$ and $\overset{(-)}{\nu}_\tau$ events, makes the cascade channel particularly interesting for searches for a diffuse, high-energy excess of extraterrestrial over atmospheric neutrinos. Cascade events can also be used to complement the muon channel in searches for point sources or transient signals, albeit with inferior angular accuracy compared to muon tracks.

The detection efficiency of a NT is quantified by its effective area, *e.g.*, the fictitious area for which the full incoming neutrino flux would be recorded (see Figure 36.5). The increase with E_ν is due to the rise of neutrino cross section and muon range, while neutrino absorption in the Earth causes the decrease at large θ for large E_ν. Identification of downward-going neutrinos requires stringent event selection to suppress atmospheric muons, hence the cut-off towards low E_ν at low θ. Due to the small cross section, the effective area is many orders of magnitude smaller than the geometrical dimension of the detector; a $\overset{(-)}{\nu}_\mu$ with 1 TeV can, *e.g.*, be detected with a probability of the order 10^{-6} if the NT is on its path.

Due to the long muon range, CC interactions of up-going $\overset{(-)}{\nu}_\mu$ can be detected from far outside the instrumented volume. This method also works for horizontal neutrinos up to about 10° above the horizon (depth dependent), where the background from atmospheric muons become prohibitive. Alternatively, one can select events that start inside the instrumented volume and thus remove incoming muons that generate early hits in the outer layers of the detector. Such a veto-based event selection is sensitive to neutrinos of all flavours from all directions, albeit with a reduced efficiency since a part of the instrumented volume is sacrificed for the veto. Such a muon veto, or vetoing events with a coincident signal in the surface array, also rejects down-going atmospheric neutrinos that are accompanied by muons from the same air shower and thus reduces the atmospheric-neutrino background. Actually, the breakthrough in detecting high-energy cosmic neutrinos was first achieved with this technique.

Note that the fields of view of NTs at the South Pole and in the Northern hemisphere are complementary for each reaction channel and neutrino energy.

36.3.2.1 *The Projects*

Table 36.3 lists past, present and future neutrino telescope projects and their main parameters.

36.3.2.2 *Properties of media*

The efficiency and quality of event reconstruction depend strongly on the optical properties (absorption and scattering length, intrinsic optical activity) of the medium in the spectral range of bialkali photocathodes (300–550 nm). Large absorption lengths result in a better light collection, large scattering lengths in superior angular resolution. Deep-sea sites typically have effective scattering lengths of > 100 m and, at their peak transparency around 450 nm, absorption lengths of 50–65 m. The absorption length for Lake Baikal is 22–24 m. The properties of South Polar ice vary strongly with depth; at the peak transparency wave length (400 nm), the scattering length is between 5 and 75 m and the absorption length between 15 and 250 m, with the best values in the depth region 2200–2450 m and the worst ones in the layer 1950–2100 m.

Noise rates measured by PMTs with a diameter of 25 cm in deep polar ice are about 0.5 kHz per PMT and almost entirely due to radioactivity in the OM components. The corresponding rates in sea water are typically 60 kHz, mostly due to ^{40}K decays. Bioluminescence activity can locally cause rates on the MHz scale for seconds; the frequency and intensity of such "bursts" depends strongly on the sea current, the season, the geographic location, and the geometry of the detector elements. Experience from ANTARES shows that these backgrounds are manageable without a major loss of efficiency or experimental resolution.

36.3.2.3 *Technical realisation*

Optical modules (OMs) and PMTs: An OM is a pressure-tight glass sphere housing one or several PMTs with a time resolution in the nanosecond range, and in most cases also electronics for control, high-voltage generation, operation of calibration LEDs, time synchronisation and signal digitisation.

Hybrid PMTs with 37 cm diameter have been used for NT-200, conventional hemispheric PMTs with 20 cm diameter for AMANDA and with 25 cm diameter for ANTARES, IceCube and Baikal-GVD. A novel concept has been chosen for KM3NeT. Each OM (43 cm) is equipped with 31 PMTs (7.5 cm), plus control, calibration and digitisation electronics. Advantages are that (i) the overall photocathode area exceeds that of a 25 cm PMT by more than a factor of 3; (ii) the individual readout of the PMTs results in a very good separation between one- and two-photoelectron

Table 36.3: Past, present and future NT projects and their main parameters. The milestone years give the times of project start, of first data taking with partial configurations, of detector completion, and of project termination. Projects with first data expected past 2024 are indicated in italics. The size refers to the largest instrumented volume reached during the project development. The status of projects under construction is reported as of February 2024. See [61] for references to the different projects where unspecified.

Experiment	Milestones	Location	Size (km^3)	Remarks
DUMAND	1978/–/–/1995	Pacific Ocean		Terminated due to technical/funding problems
NT-200	1980/1993/1998/2015	Lake Baikal	10^{-4}	First proof of principle
GVD [65]	2012/2015/–/–	Lake Baikal	ca. 1	High-energy ν astronomy first 12 clusters installed
AMANDA	1990/1996/2000/2009	South Pole	0.015	First deep-ice NT
IceCube [66]	2001/2005/2010/–	South Pole	1.0	First km^3-sized detector
IceCube-Gen2 [67, 68]	2014/–/–/–	South Pole	5–10	Planned future extension of IceCube covering low and high energies, a surface array and radio detection
NESTOR	1991/–/–/–	Med. Sea		2004 data taking with prototype
NEMO	1998/–/–/–	Med. Sea		R&D project, prototype tests
ANTARES	1997/2006/2008/2022	Med. Sea	0.010	First deep-sea NT
KM3NeT/ARCA [63]	2013/2021/–/–	Med. Sea	ca. 1	High-energy configuration for neutrino astronomy. Under construction, data taking with 28 strings
KM3NeT/ORCA [63]	2014/2020/–/–	Med. Sea	0.007	Low-energy configuration for neutrino mass hierarchy. Under construction, data taking with 18 strings
KM3NeT Phase 3	2013/–/–/–	Med. Sea	ca. 3	Possible future extension, 6 ARCA blocks + ORCA
P-ONE [69]	2018/–/–/–	Pacific Ocean	$\mathcal{O}(1)$	Planned future NT, R&D phase
TRIDENT [70]	2021/–/–/–	South China Sea	$\mathcal{O}(10)$	Planned future NT, R&D phase

signals which is essential for online data filtering and random background suppression; (iii) the hit pattern on an OM provides directional information; (iv) no mu-metal shielding against the Earth magnetic field is required. Figure 36.6 shows the OM designs of IceCube and KM3NeT.

Readout and data filtering: In current NTs the PMT data are digitised in situ: for ANTARES and Baikal-GVD in special electronics containers close to the OMs, for IceCube and KM3NeT inside the OMs. For IceCube, data are transmitted via electrical cables of up to 3.3 km length, depending on the location of the strings and the depth of the OMs; for ANTARES, KM3NeT and Baikal-GVD optical fibre connections have been chosen (several 10 km for the first two and 4 km for GVD).

The full digitised waveforms of the IceCube OMs are transmitted to the surface for pulses appearing in local coincidences on a string; for other pulses, only time and charge information is provided. For ANTARES (time and charge) and KM3NeT (time and time over threshold), all PMT signals above an adjustable threshold are sent to shore.

The data are subsequently processed on online computer farms, where multiplicity- and topology-driven filter algorithms are applied to select event candidates. The filter output data rate is about 10 GByte/day for ANTARES and of the order 1 TByte/day for IceCube (100 GByte/day transferred via satellite) and KM3NeT.

Calibration: For efficient event recognition and reconstruction, the OM timing must be synchronised at the few-nanosecond level and the OM positions and orientations must be known to a few 10 cm and a few degrees, respectively. Time calibration is achieved by sending synchronisation signals to the OM electronics and also by light calibration signals emitted in situ at known times by LED or laser flashers (ANTARES, KM3NeT). Precise position calibration is achieved by measuring the travel time of light calibration signals sent from OM to OM (IceCube) or acoustic signals sent from transducers at the sea floor to receivers on the detector strings (ANTARES, KM3NeT, Baikal-GVD). Absolute pointing and angular resolution can be determined by measuring the "shadow of the moon" (*i.e.*, the directional depletion of muons generated in cosmic-ray interactions). IceCube and ANTARES have both shown that they have angular resolution below 1°, confirming MC calculations which indicate a precision of $\approx 0.5°$ for energies above 10 TeV. For KM3NeT, simulations indicate that sub-degree precision in the absolute pointing can be reached within a few weeks of operation.

Detector configurations: IceCube [66] (see Figure 36.7) consists of 5160 Digital OMs (DOMs) installed on 86 strings at depths of 1450 to 2450 m in the Antarctic ice; except for the DeepCore region, string distances are 125 m and vertical distances between OMs 17 m. 324 further DOMs are installed in IceTop, an array of detector stations on the ice surface above the strings. DeepCore is a high-density sub-array at large depths (*i.e.*, in the best ice layer) at the centre of IceCube.

The NT200 detector in Lake Baikal at a depth of 1100 m consisted of 8 strings attached to an umbrella-like frame, with 12 pairs of OMs per string. The diameter of the instrumented volume was 42 m, its height 70 m. Meanwhile (February 2024), the Baikal collaboration has installed the first 12 clusters of a future cubic-kilometre array, GVD [65]. It will consist of 18 clusters, each with 288 OMs at 8 strings, plus several single strimgs between the clusters; its completion is scheduled for 2027.

The operation of ANTARES (see [61] and references therein) was terminated in 2022. It comprised 12 strings with lateral distances of 60–70 m, each carrying 25 triplets of OMs at vertical distances of 14.5 m, located at depths of 2.1–2.4 km, starting 100 m above the sea floor. An additional string held devices for calibration and environmental monitoring. A system to investigate the feasibility of acoustic neutrino detection was also implemented.

KM3NeT will consist of building blocks of 115 strings each, with 18 OMs per string. Operation of the first strings deployed has successfully verified the KM3NeT technology and sensitivity. In the upcoming phase of its staged implementation, KM3NeT

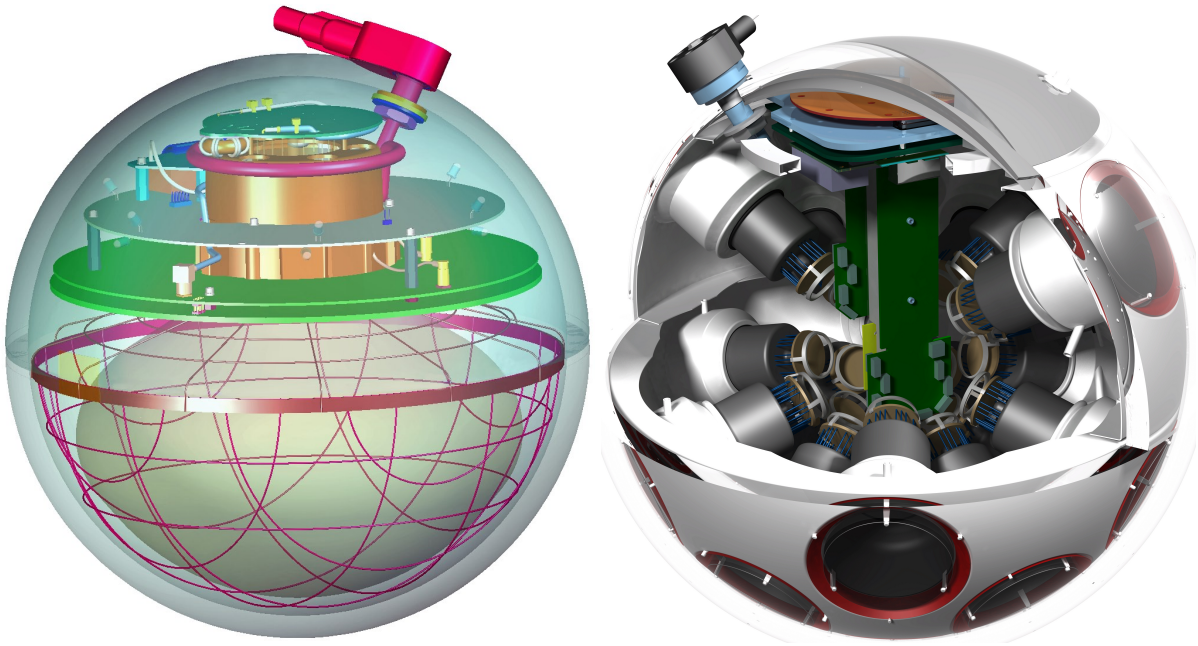

Figure 36.6: Schematic views of the digital OMs of IceCube (left) and KM3NeT (right).

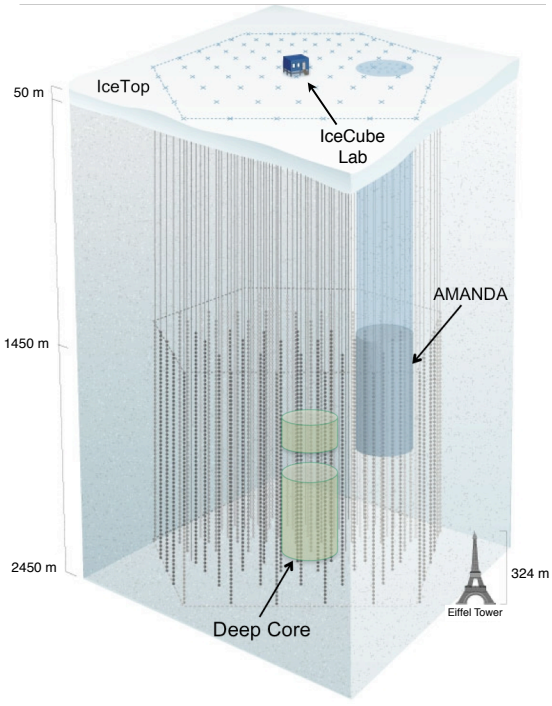

Figure 36.7: Schematic view of the IceCube neutrino observatory comprising the deep-ice detector including its nested dense part DeepCore, and the surface air shower array IceTop. The IceCube Lab houses data acquisition electronics and the computer farm for online processing. Operation of AMANDA was terminated in 2009.

aims at two building blocks for neutrino astronomy, with vertical distances between OMs of 36 m and a lateral distance between adjacent strings of 90 m (ARCA, for *Astroparticle Research with Cosmics in the Abyss*) and at one block for the measurement of the neutrino mass hierarchy, with vertical distances between OMs of 9 m and a lateral distance between adjacent strings of about 20 m (ORCA, for *Oscillation Research with Cosmics in the Abyss*) [63]. The installation of ARCA near Capo Passero, East of Sicily (depth 3440 m) and of ORCA near Toulon (depth 2450 m) is ongoing and as of now (February 2024) 28/18 strings have been deployed for ARCA/ORCA and are continuously operated. Completion of the full ARCA and ORCA arrays is planned for 2028.

P-ONE (*Pacific Ocean Neutrino Experiment*) [69] is a new initiative in its R&D phase, envisaging a large NT in the Pacific Ocean off the Canadian coast. It is intended to use an existing deep-sea cable infrastructure and to optimise the sensitivity for horizontal neutrinos with energies of about 100 TeV and beyond.

TRIDENT (Tropical Deep-Sea Neutrino Telescope) is a proposed future neutrino telescope in the South China Sea with an instrumented volume of 7.5 km^3. R&D and site exploration efforts are ongoing and a pathfinder (TRIDENT Phase-1) is planned to be commissioned around 2026 [71].

36.3.2.4 *Results*

See Sect. 30.4 for a summary of the results from neutrino telescopes.

36.3.2.5 *Plans beyond 2023*

Within the future IceCube-Gen2 project, it is planned to extend the sensitivity of IceCube towards both higher and lower energies. To increase the detector sensitivity at high energies, a large-volume extension is envisaged, combined with a radio array for highest-energy neutrinos and a surface array providing also a powerful veto against atmospheric events [67, 68]. A substantially denser instrumentation of a sub-volume of DeepCore will be achieved with 7 closely spaced strings to be deployed in 2025/26 (the IceCube Upgrade), aiming to cover a low-energy program, to better calibrate the existing IceCube detector and the archival data, and to test new technologies. More information on the future extensions of GVD and KM3NeT and on P-ONE and TRIDENT are given above and in Table 36.3.

36.3.3 *Radio emission from (ultra-)high energy particle showers*

Revised August 2023 by S.R. Klein (NSD LBNL; UC Berkeley) and A. Nelles (DESY, Zeuthen; Erlangen U.).

Coherent radio-frequency (RF) electromagnetic radiation is an attractive signature to search for particle cascades produced by interactions of high-energy particles. RF signatures have been used to study both cosmic-ray air showers and to search for neutrino-induced showers. This article will discuss the radio signal generation, the relevant energy regime and the application in de-

tectors. Air showers are discussed in more detail in two recent reviews [72, 73]. At lower energies, incoherent optical Cherenkov radiation is frequently used, as discussed in "Neutrino telescopes" section 36.3.2. This article uses the general definitions and properties of neutrino telescopes as described in 36.3.2.

36.3.3.1 *Signal generation and its characteristics*

As discussed in the "Passage of Particles Through Matter" review Sec. 34 the electromagnetic component of a high energy shower gives rise to radio emission. For the signal generation itself the type of primary particle is irrelevant. However, the signal medium is important. It must be non-conducting (and non-absorptive at RF frequencies). The different shower length scales (radiation length, X_0) between air and the solid materials used for neutrino searches leads to surprisingly large differences in shower development. Due to the interaction with the medium the shower contains more electrons than positrons, which results in a net charge excess and leads to coherent Cherenkov emission, also known as Askaryan effect [74–76]. In air, during propagation through the geomagnetic field, the relative motion of electrons and positrons is affected, which leads to a varying transverse current, usually referred to as the geomagnetic effect [72]. Both effects may be described more generally as being due to radiation from a time-varying net charge [77]. Their relative importance is governed by the density of the medium, as the electric field scales as the net charge excess, and a lower density allows the geomagnetic effect to gain importance. Thus, in solid materials the emission from the Askaryan effect dominates, but it is a $< 20\%$ correction in air showers.

Coherent radiation is possible at wavelengths longer than the instantaneous thickness of the shower along an observer's line of sight. Since air showers have a larger extent than showers in solid media, their coherent radiation appears at lower frequencies [78].

High-frequency radiation is concentrated around the Cherenkov angle θ_C. Viewed directly on the Cherenkov cone, the electric field strength, $\epsilon_{\rm Ch}$ at a frequency f from an electromagnetic shower from a ν_e with energy E_ν in ice may be roughly parameterized as [79, 80]

$$\epsilon_{\rm Ch}(V/{\rm mMHz}) = 2.53 \times 10^{-7} \frac{E_\nu}{1{\rm TeV}} \frac{f}{f_c} \left[\frac{1}{1 + (f/f_c)^{1.44}} \right]. \quad (36.3)$$

The electric field strength increases linearly with frequency, up to a cut-off frequency f_c, which is set by the transverse size of the shower [81, 82]. The maximum wavelength c/f_c is roughly the Moliere radius divided by $\cos(\theta_C)$ where θ_C is the Cherenkov angle. The cutoff frequencies depend on the density (which affects the Moliere radius). They are about 1 GHz in ice, about 3 GHz in the lunar regolith, and below 100 MHz in air.

Near f_c, radiation is narrowly concentrated around θ_C [81, 82]. At lower frequencies, the limited length of the emitting region leads to a broadening in emission angle around the Cherenkov cone. Away from θ_C, the electric field from Eq. (36.3) is reduced by [79],

$$\frac{\epsilon}{\epsilon_{\rm Ch}} = \exp\left(-\frac{1}{2} \frac{(\theta - \theta_C)^2}{(2.2^\circ \times [1{\rm GHz}/f])^2} \right). \quad (36.4)$$

The angular distribution of the signal around θ_C can be parameterized by a Gaussian peak modulated by a $\sin\theta$. In both ice and the lunar regolith, θ_C is about 56°, in air only 1°. Close to θ_C, the 1 GHz maximum frequency in ice/regolith leads to a generated pulse width of ≈ 1 nsec.

These equations are appropriate for ice. More general parameterizations can be found in [80, 83].

More accurate calculations of the predicted radio signal, in particular air showers are not easily parameterized, but require detailed Monte Carlo simulations. For air showers, these are built on microscopic air shower simulations, calculate the emission from all individual particles in the shower development and add them for different observer positions [72]. For neutrinos, most approaches calculate (directly or from a parameterization) the Askaryan signal from a shower profile. The signal is then propagated through the medium and into an antenna model [80].

At energies above 10^{16} eV in ice, the Landau-Pomeranchuk-Migdal effect lengthens electromagnetic showers, by reducing the cross-sections for bremsstrahlung and pair production [84]. The lengthening of the shower leads to a narrowing of the radio emission around the Cherenkov cone, and a reduction in high-frequency emission away from the cone [80]. At higher energies, this leads to two separate components of the Askaryan radiation from a neutrino interaction: an un-altered component from the hadronic portion of the shower and an angularly narrowed component from the LPM-lengthened electromagnetic shower. The width of the narrowed component scales as $E_\nu^{1/3}$. If these two components can be observed separately, they could, in principle, be combined to determine the inelasticity of the neutrino interaction [85], allowing for improved measurements of low$-x$ parton distributions and searches for beyond-standard-model interactions.

Similarly, energetic outgoing $\mu^\pm$ and $\tau^\pm$ from neutrino interactions will dominantly lose energy via stochastic pair production and photonuclear interactions. These secondary particles will produce electromagnetic showers that can be detected by radio detectors, if they are above threshold energy. This will enable multiple detections of the same particle track and thus present interesting reconstruction opportunities [86].

At still higher energies, above 10^{20} eV, the LPM effect strengthens, and the electromagnetic shower splits into multiple subshowers with significant separation. When these separations become large enough, the subshowers will effectively become independent radiators, with the total emission showing substantial event-by-event variation, depending on the division into subshowers [84]. Because of this, many experiments that study higher energy (well above 10^{20} eV) neutrinos focus on the hadronic shower from the struck nucleus. This contains an average of only about 20% of the energy, but with fewer large fluctuations.

36.3.3.2 *Energy regime of radio detectors*

The electric field amplitude is linearly proportional to the shower energy. Since the signal is a radio wave, the field amplitude decreases as $1/R$, plus potential absorption in the intervening medium, while the energy fluence decreases as $1/R^2$, again, plus potential absorption. The detection threshold depends on the distance to the antenna and the bandwidth and noise characteristics of the antenna and detector. For an antenna located in the detection medium, at a distance of 1 km the typical threshold is around 10^{17} eV. For stand-off (remote sensing) detectors, the threshold rises roughly linearly with the distance. These thresholds can be reduced by using directional antennas and/or combining the signals from multiple antennas using beam-forming techniques.

RF detectors are used to search for energetic neutrinos from three types of sources: astrophysical objects (*i.e.* extending measurements of the neutrino energy spectrum observed at TeV to PeV energies upward in energy), cosmogenic neutrinos associated with cosmic-ray-cosmic microwave background radiation (CMBR) interactions, and neutrinos from beyond-standard-model physics. These types are very roughly associated with energies below 10^{18} eV, the energy range 10^{18} to 10^{20} eV, and above 10^{20} eV.

Cosmogenic neutrinos are produced when ultra-high energy (UHE) protons with energy $E > 5\times10^{19}$ eV interact with photons from the CMBR, infrared light from old stars, and other extragalactic background light. These protons are excited to a Δ^+ resonance which may decay via $\Delta^+ \to n\pi^+$, leading to neutrinos with energies above 10^{18} eV [87, 88]. The cosmogenic neutrino signal depends heavily on the fraction of UHE cosmic-rays that are protons. For a 100% proton composition (disfavored by most data [89]), observing a cosmogenic neutrino signal of at least a few events per year requires a solid or liquid detector with an active volume of about 100 km^3.

To reach the effective volumes necessary to observe the expected low fluxes of UHE neutrinos, common, naturally occurring, non-conducting solid (or potentially liquid) media, with a long absorption length for radio waves are needed. Optical Cherenkov and acoustical detectors are limited by short (< 100 m) attenuation lengths [90] so would require a prohibitively expensive number of sensors. The radio detection technique has been used to detect air

showers, targeting neutrinos as well as cosmic rays, and to search for neutrino showers in ice, salt domes and the lunar regolith.

36.3.3.3 *Reconstruction of particle energy and direction and background suppression*

Since radio detectors view the interaction from afar, the reconstruction techniques differ from optical neutrino telescopes.

Radio detection is a calorimetric measurement, thus provides good energy estimates of the shower energy. The energy fluence (integrated pulse power) of the signal scales quadratically with shower energy. It also depends on the distance to the shower, through potential attenuation losses and the usual $1/R$ loss in electric field amplitude. The arrival times in antennas and a spherical wave approximation can be used to determine the interaction vertex, although some uncertainty due to the viewing angle with respect to the Cherenkov angle may remain, if not corrected for by using the frequency information. If the radio signal travels through media where the index of refraction varies (like the firn of glacial ice), then ray-tracing techniques may be required to follow the signal back to the interaction point. For buried antennas, the bending of the signal trajectories due to the index of refraction creates an opportunity. For some geometries, there may be two paths to the detector: a 'direct' path, with minor bending, and a second where the signal is bent beyond horizontal, bouncing off the surface before reaching the antenna. By measuring the time difference between the two paths, the distance to the interaction vertex may be determined; this greatly simplifies the energy determination [91,92]. For most neutrino interactions (except for ν_e charged-current interactions), the shower energy is less than the neutrino energy. The uncertainty on the interaction inelasticity is a major contributor to the uncertainty in the neutrino energy, along with uncertainties on the distance between the antenna(s) and the interaction vertex [93].

Reconstruction of the neutrino arrival direction depends on several aspects of the signal. First, the direction from the antenna to the interaction site must be determined. This can be done by using the relative timing from separated antennas, or using beamforming techniques with multi-element arrays. For air showers, the signal arrival direction is (almost) equal to the particle arrival direction, with corrections being obtainable by fitting a hyperbolic wavefront [72, 73].

For showers in solid/liquid media, the arrival direction with respect to the interaction point - antenna vector is determined from two additional angles. The frequency spectrum can be used to determine the angle between signal arrival direction and Cherenkov cone according to Eq. (36.4) [94]. The second angle can be determined from the polarization of the signal. The radio signal is produced with a linear polarization in the plane containing both the particle direction and the radio wave direction. These two angles can be combined to determine the direction, subject to a (usually) four-fold ambiguity, due to uncertainty as to whether the antenna is inside or outside the Cherenkov cone, and because the particle direction can be flipped 180° without affecting the observed signal. Often, some of these solutions can be rejected because they correspond to long path lengths through the Moon or the Earth, where the neutrino would be absorbed.

Spectral information is crucial for the reconstruction and background rejection. However, large bandwidth antennas typically disperse (i.e. broaden) the pulses. As long as the dispersion can be compensated for and backgrounds controlled, a large bandwidth detector is the most sensitive.

All radio experiments must contend with background. Common sources are anthropogenic noise, antenna/preamp noise, charge generated by blowing snow, lightning, and, at low frequencies, radiation from the Milky Way. While narrowband noise impacts triggering and contaminates signal quality, impulsive backgrounds could mimic a signal. One of the major issues for radio-detection experiments is anthropogenic noise. Most anthropogenic noise has distinctive characteristics (such as being narrow-band, and coming from near the horizon) which makes it relatively easy to reject during data analysis, via narrow-band filters and other techniques [72]. However, these factors complicate triggering and reduce data purity. This is even an issue in Antarctica, where communication radios and passing satellites can mimic showers, at least at the trigger level. The need to limit anthropogenic noise has led most experimental groups to select remote locations for their detectors. Still, experiments have used approaches to reduce trigger-level noise, and/or to reject background at the analysis level. For example, for multi-element arrays, the threshold drops as the square root of number of antennas, since the signal adds in-phase while the backgrounds add with random phases [95]. It seems, however, that triboelectric signals recorded in periods with winds exceeding 10 m/s are a problematic trigger-level background, for experiments in polar regions [96] and will require removal during analysis.

Most dedicated air shower experiments have used radio antennas in combination with at least one other detector technology, such as scintillation counters, if the site quality is not sufficient and/or computing power on autonomous stations is limited. One exception is ARIANNA, which is located in an uninhabited part of Antarctica, enabling them to efficiently self-trigger on air showers [97].

Lunar experiments (discussed below) use different techniques to reduce the anthropogenic background. Some experiments use multiple antennas, separated by at least hundreds of meters; by requiring a coincidence within a small time window, anthropogenic noise can be rejected. With good enough timing, beam-forming techniques can be used to further reduce the background. An alternative approach is to use beam forming with multiple feed antennas viewing a single reflector, to ensure that the signal points back to the moon.

Due to the similarity in the radio emission of air showers and neutrino showers, the more abundant cosmic rays can act as background to neutrino searches. In-ice detectors need to suppress in-air emission that is refracted into the ice, emission that is created from developing air showers continuing in the ice, as well as from stochastic energy-losses of atmospheric muons. Lunar experiments may faces challenges in separating neutrino interactions from cosmic ray interactions.

36.3.3.4 *Recent experiments*

Figure 36.8 shows some current limits from neutrino searches, including from prototype arrays. Except for LOFAR, which is fully operational, projected limits from future experiments are not shown in the figure.

i. *Ice*

The most common dense medium transparent to radio waves is ice. Natural ice is an attractive medium for neutrino detection with radio attenuation lengths from over 300 m to 1 km [108]. The attenuation length varies with frequency and ice temperature, with higher attenuation in warmer ice. Although glacial ice is mostly uniform, the top $\approx$ 100 m of ice, the 'firn,' exhibits a gradual transition from packed snow at the surface (typically $\rho = 0.35$ g/cm^3) to solid ice ($\rho = 0.92$ g/cm^3) below [109]. The thickness of the firn varies with location; it is thicker in central Antarctica than in the coastal ice sheets or in Greenland. The varying density has several implications.

The index of refraction depends linearly on the density, so radio waves curve downward in the firn. This bending reduces the effective volume of surface or aerial antennas. A surface antenna cannot see near-surface interactions at large horizontal distances. There are also indications that the increase in firn density is non-monotonic [110, 111]. This leads to non-monotonic changes in index of refraction which may create waveguides that trap a small fraction of the radio energy and propagate it horizontally.

In one type of experiment, antennas mounted on high-altitude balloons observe the ice from above. Radio signals from in-ice neutrino interactions propagate to the surface, traverse the ice-air interface, and then travel to the balloon. The surface roughness of the ice can affect signals as they transition from the ice to the atmosphere. The best known example, ANITA, has made four flights around Antarctica, floating at an altitude around 35 km [112]. Its 32/40/48 (depending on the flight) dual-polarization horn antennas scanned the surrounding ice, out to the horizon (650 km away). Because of the small angle of incidence, ANITA could use polarization information to separate signals from back-

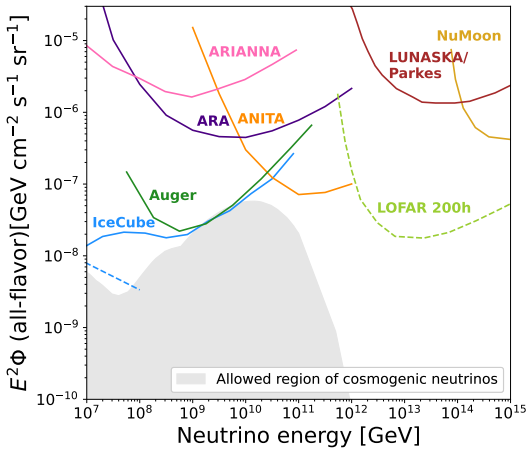

Figure 36.8: Representative 3-flavor (summed, assuming equal fluxes of each flavor) differential (over one decade in energy) limits from different experiments and prototype experiments. Shown are limits from the IceCube ultra-high energy ν search [98], the Auger search for earth-skimming ν_τ [99], the LUNASKA/Parkes [100] and NuMoon lunar searches [101], the ANITA balloon experiment [102], ARA [103] and ARIANNA prototypes [104], along with projections for the LOFAR array [105]. The dashed blue line is the extrapolation of the IceCube through-going ν_μ flux measured at lower energies (few 10s of TeV to 10 PeV), with spectral index $\alpha = -2.37$ [106]. Because of the long extrapolation, this should only be treated as a rough reference. The ARA and ARIANNA limits are from prototype arrays, and indicate the energy range that might be covered, with far higher sensitivity by larger arrays. The shaded area is the allowed region for cosmogenic neutrinos, from a recent global analysis that included the measured cosmic-ray spectrum and composition [107].

ground; ν signals should be vertically polarized, while most background from cosmic-ray air showers should be horizontally polarized.

As with all radio-detection experiments, ANITA had to contend with anthropogenic backgrounds. The ANITA collaboration uses their multiple antennas as a phased array to achieve good pointing accuracy, with a resolution of 0.2-0.4° in elevation, and 0.5-1.1° in azimuth. They rejected all events that pointed toward known or suspected areas of human activity. ANITA has set the most stringent flux limits yet on neutrinos with energies above 10^{20} eV [102]. The ANITA experiment has also reported several anomalous events, matching cosmic ray signals, but with unexpected polarization signature, which the collaboration has indicated might be from Earth-skimming ν_τ [113, 114]. However, this interpretation is controversial.

Because of the significant source-detector separation, ANITA is most sensitive at energies above 10^{19} eV. A lower energy threshold requires a smaller antenna-target separation.

Other ice based experiments use antennas located within the active volume, allowing them to reach thresholds around 10^{17} eV, or lower with phased array antennas. This approach was pioneered by the RICE experiment [115] which buried 18 half-wave dipole antennas in holes drilled for AMANDA at the South Pole, at depths from 100 to 300 m. The hardware was sensitive from 200 MHz to 1 GHz. Each antenna fed an in-situ preamplifier which transmitted the signals to surface digitizing electronics.

More recently, two groups have deployed prototype arrays which have explored different detector concepts. The Askaryan Radio Array (ARA) deployed surface and buried antennas at the South Pole [116], while the Antarctic Ross Iceshelf Antenna Neutrino Array (ARIANNA) installed surface antennas on the Ross Ice Shelf [104], about 110 km north of McMurdo station. ARIANNA offered the possibility of detecting downward-going ν, from the radio waves reflected off the ice-sea water interface on the bottom of the Ross Ice Shelf, while ARA took advantage of the colder, deeper ice at the South Pole, with its longer radio attenuation length. ARA buried antennas up to 200 m deep to be able to observe a larger portion of ice, due to the refraction of the signal in the firn. In contrast, ARIANNA deployed antennas just below the surface, allowing them to use high-gain, but large log periodic dipole antennas. Recently, phased-array trigger techniques have been demonstrated that can reduce the energy threshold by a factor of several [95, 117].

Both experiments use stations which operate independently, spaced far enough to maximize sensitivity, but where only a small fraction of neutrino events will be visible in multiple stations. Each station includes multiple antennas, which will be sensitive to both horizontal and vertical polarization. The expected angular resolution is a few degrees [94].

In 2021, the Radio Neutrino Observatory Greenland (RNO-G) started deploying stations at Summit Station. RNO-G is planned to consist of 35 stations, which employ ARIANNA-style surface antennas, an ARA-style phased array and deep antennas, and draw heavily on ANITA's electronics heritage [118].

ii. *The Moon*

Because of its large size and non-conducting regolith, and the availability of large radio-telescopes, the Moon is an attractive target [119]. Conventional radio-telescopes are quite well suited to lunar neutrino searches, with natural beam widths not too dissimilar from the size of the Moon. Still, there are experimental challenges. The attenuation length is typically estimated to be 9m/f(GHz) [120], so only near-surface interactions can be studied. The composition of the lunar regolith is not well known, and there are significant uncertainties due to this uncertainty. One big limitation of lunar experiments is that the 385,000 km target-antenna separation leads to energy thresholds above 10^{20} eV.

The effective volume probed by experiments depends on the geometry, which itself depends on the frequency range used. At high frequencies f, the electric field strength is high, leading to a lower energy threshold, but the sensitive volume is limited because the Cherenkov cone only points toward the Earth for a narrow range of geometries. Lower frequency radiation is more isotropic, so the effective volume is larger, but, because the electric field is weaker, the energy threshold is higher. The $1/f$ dependence of the attenuation length in the lunar regolith further increases the effective volume at low frequencies. The frequency range affects the energy dependence of the sensitivity. As can be seen in Fig. 36.8, a low-frequency experiment like NuMoon (which covered 115-180 MHz) has good sensitivity, but only above about 10^{14} GeV, while Lunaska/Parkes, which observed in the range 1200-1500 MHz, has a higher flux limit, but is sensitive above about $10^{12.5}$ GeV.

Current limits and projected sensitivities are sensitive to many details. A recent review [121] compared different radio-detection experiments using a common framework, and found some significant shifts in sensitivities due to, e.g. different assumptions about lunar composition and inelasticities.

With modern technology, it is increasingly viable to search over very broad frequency ranges [122]. One technical challenge is due to dispersion (frequency dependent time delays) in the ionosphere. Dispersion can be largely removed with a de-dispersion filter, using either analog circuitry or post-collection digital processing.

iii. *Air*

Radio detection in air is sensitive to all particles inducing air showers. Radio-detection can be used to determine the energy of cosmic rays, as done by e.g. the Auger and Tunka-Rex experiments [123, 124]. Radio signals can also be used to infer the altitude for shower-maximum, where the shower contains the most particles, as done by e.g. the LOFAR and Tunka-Rex collaborations [124, 125]. This altitude is sensitive to the cosmic-ray composition. Reconstructing the particle arrival direction is much easier in air since the Cherenkov angle, and thus the radio wavefront, aligns with the axis to 1°. Radio-detection is also useful for energy cross-calibrations between different experiments and may

be able to provide an independent energy scale calibration for air shower arrays [126].

One variation on the radio-detection approach is to look for radio emission from Earth-skimming ν_τ [127,128]. Although ν_τ are much less commonly produced than ν_μ and ν_e, over astrophysical distances, oscillations lead to a $\nu_e : \nu_\mu : \nu_\tau$ ratio near $1 : 1 : 1$, for almost all non-exotic acceleration and propagation mechanisms.

If the ν_τ traverse the Earth and interact while traveling upward, the resulting $\tau^\pm$ may exit the Earth before decaying. 83% of the time, the decay produces a hadronic or electromagnetic shower in the atmosphere [129]. Experiments have searched for these upgoing showers, and for the resulting optical Cherenkov and coherent RF radiation. The threshold energy dependence for these searches depends on several factors, notably including the average $\tau^\pm$ decay length, which increases linearly with energy. For somewhat lower energy ν_τ, with shorter decay lengths, a mountain may serve as a target, with $\tau^\pm$ expected to emerge from the other side. The Pierre Auger observatory sets stringent limits on this neutrino flux at energies above 10^{17} eV [99].

36.3.3.5 *Future experiments*

Looking ahead, RNO-G [118] will continue deployment until 2026 and reach the largest yearly sensitivity of any radio array thus far. Further out, the proposed IceCube-Gen2 expansion includes a substantial radio array component [68], which will be sensitive to both neutrinos from the ice and air showers from cosmic rays. PUEO, a successor of ANITA has been funded and is scheduled for its first flight in 2025 [130].

In the near future, several large radio detector arrays should reach significantly lower energies for lunar neutrino detection. The LOFAR array is taking data with 36 detector clusters spread over Northern Europe [105]. In the longer term, the Square Kilometer Array (SKA) with its 1 km^2 effective area will push thresholds down to near 10^{20} eV [122]. The SKA will also study air showers.

A number of dedicated prototype ν_τ radio-detection experiments exist. The GRAND Collaboration, e.g., is proposing to deploy a large array of simple autonomous radio stations optimized for near-horizontal signals [131]. The Pierre Auger Collaboration is currently upgrading their surface array to include radio antennas at all water Cherenkov detectors. This array will improve the sensitivity of the instrument to horizontal showers, both for composition sensitivity for cosmic rays and for the detection of Earth skimming neutrinos [132].

36.4 Large time-projection chambers for rare event detection

Written August 2023 by L. Baudis (Zurich U.).

Initially developed for particle physics experiments at accelerators (see *Section 35.6.5*), the concept of a Time Projection Chamber (TPC) [133] evolved and is now tailored to a large range of applications, most notably to experiments in astroparticle physics searching for rare interactions deep underground. Present and proposed experiments designed to observe interactions of dark matter and other exotic particles, second order weak nuclear decays, as well as neutrinos from a variety of sources are based on TPCs operated with pure noble elements, either in gaseous or liquid form. The detectors aim for large target masses, low energy thresholds (keV-scale) and ultra-low levels of backgrounds from radioactivity and cosmic rays. Historical introductions, reviews of the operation principles, instrumentation and technological aspects, as well as applications, are found in Refs. [134–138].

The two most common noble fluids employed as detector media in present TPCs for rare event searches are argon and xenon, either as a high-pressure gas, or in liquid phase, or in liquid and gas phase (dual-phase). An interaction within the active volume of a TPC will create ionisation electrons and scintillation photons. The prompt scintillation signal is detected with one or two arrays of photosensors, while the ionisation electrons, which drift in the pure medium under the influence of an external, uniform electric field, are observed either directly with charge sensors, or via proportional scintillation, or electroluminescence. Since transverse electron diffusion is small, albeit non-negligible, the ionisation signal provides the $x - y$ information of the interaction site, with the $z-$information coming from the drift time measurement. The TPC thus yields a three-dimensional event localisation, enabling fiducial volume selections and differentiation between single- and multiple-scatters in the active volume. These features are crucial for filtering out rare events from the much higher backgrounds due to residual radioactivity of detector components. The specific energy loss (dE/dx) depends on the primary interacting particle, and leads to a distinct ratio of scintillation to ionisation for gammas/electrons, alphas and fast neutrons, allowing for further background discrimination. Two examples for the operation principle of TPCs for rare event detection are shown in Fig. 36.9.

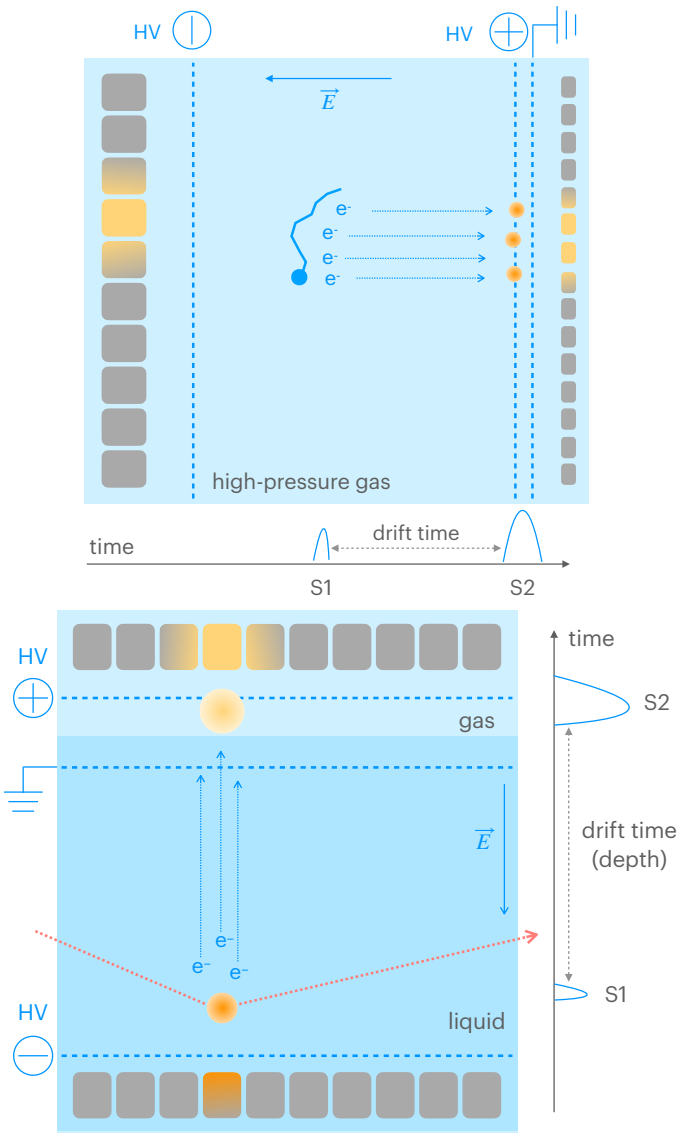

Figure 36.9: Operation principle of TPCs for rare event detection: a high-pressure gas (left) and a dual (liquid/gas) phase (right) TPC. A particle interaction yields a prompt scintillation signal (S1) and a delayed, amplified proportional scintillation signal (S2). The latter is caused by ionisation electrons drifted in a homogeneous electric field (and, for dual phase TPCs, extracted into the gas phase above the liquid). In these examples, both S1 and S2 signals are observed with photosensor arrays placed behind the anode and cathode (left), or at the top and bottom (right) of the TPC. The position information along the drift field is inferred from the time difference between the two light signals, while the position in the transverse plane to the field is derived from the S2 light pattern in the photosensor plane close to the electroluminiscent light production site.

The properties of liquid argon as detection medium in a TPC are reviewed in *Section 35.7*. Here some properties for xenon are given in Tab. 36.4. In the liquid phase, the high xenon density allows for compact, large and homogeneous detector geometries with efficient self-shielding against external radiation, given that the cross sections for the photoelectric effect, Compton scattering and pair production scale as $Z^5/E_\gamma^{7/2}$, Z/E_γ and $Z^2 \ln(2E_\gamma)$, respectively, for incoming X-rays and gammas with energy E_γ. The radioactive isotopes ^{124}Xe, ^{126}Xe, ^{134}Xe and ^{136}Xe have very long half-lives, and their second-order weak decay modes are subject to investigation (see *Section 36.4.2*).

In an argon or xenon detector, the energy loss of an incident particle is shared between ionisation, excitation and sub-excitation electrons liberated in the ionisation process. The average energy loss in ionisation is slightly larger than the ionisation potential, as it includes multiple ionisation processes. In their condensed phases, argon and xenon exhibit a band structure of electronic states, with the band gap energy being around 14.3 eV and 9.3 eV for liquid argon and xenon, respectively. In gaseous xenon, the ionisation potential is about 12.1 eV. Scintillation arises from excited atoms (excitons) and from ions, via recombination, with the emitted vacuum-ultraviolet (VUV) photons in single bands centred at $\lambda = 128$ nm for argon and $\lambda = 175$ nm for xenon. The excited dimers (or excimers), at their lowest excited level, de-excite to the dissociative ground state by the emission of a single VUV photon. This comes from the large energy gap between the lowest excitation and the ground levels, forbidding other decay channels such as non-radiative transitions. The scintillation light has two decay components due to de-excitation of spin singlet and spin triplet states of the excited dimers to the ground state. The singlet and triplet states refer to the total spin quantum number (s=0 or s=1) of the excited Rydberg electron and the angular momentum due to the molecular orbit, with the shorter and longer decay shapes being produced by the de-excitation of s=0 states and s=1 states, respectively. The different pulse decay time for different type of particle interactions, and thus ionisation densities, is employed to discriminate electronic from nuclear recoils in dark matter detectors. While this is very effective in liquid argon, due to the large time separation of (6 ± 1) ns versus (1500 ± 100) ns, it is difficult to put in practice for xenon [139], considering the much smaller separation, (2.2 ± 0.3) ns versus (27 ± 1) ns, of the two components.

The recombination-independent, mean energy required to produce a single detectable quantum (photon or electrons), called the W-value, assumes that each recombining electron-ion pair produces an exciton, which leads to a photon. In liquid argon, the W-value is (19.5 ± 1.0) eV [148]. In liquid xenon, the widely-adopted W-value is (13.7 ± 0.2) eV, measured with 122 keV γ-rays from an external ^{57}Co source [149]. Recently, a lower value of $11.5^{+0.2}_{-0.3}$ (syst.) eV was obtained in a small TPC with internal sources at energies between 2.8 keV and 42 keV [150], consistent with the value measured at the MeV-scale, 11.5 ± 0.5(syst.) $\pm$ 0.1(stat.) eV with theEXO-200 detector [151]. The ionisation and scintillation W-values in gaseous xenon are 24.8 eV and (76 ± 6) eV, respectively [152].

The partition between excitation and ionisation depends on the density of the electron-ion pairs produced along the track of a particle, and the recombination fraction depends on the applied electric field, as well as on the ionisation density in the track. While several phenomenological models exist to describe electron-ion recombination as a function of stopping power and electric drift field (see [134] and discussions therein), a solid theory of energy loss of low-energy ions in noble fluids is still missing. For nuclear recoils as generated by interactions of neutrons, neutrinos or hypothetical WIMPs, an energy-dependent quenching is introduced via the Lindhard factor $\mathcal{L}$ [153], with $\mathcal{L}$ being around $0.2 - 0.25$ and $0.15 - 0.2$ in liquid argon [154] and xenon [155], respectively, at nuclear recoil energies in the range 3-100 keV. A comprehensive framework to simulate scintillation and ionisation yields in argon and xenon as a function of interaction type, energy and electric field in a TPC is the Noble Element Simulation Technique (NEST) [156].

To calibrate the energy scale and determine the energy resolution of low-background TPCs, mono-energetic lines from external (e.g., ^{57}Co, ^{60}Co, ^{137}Cs, ^{228}Th, etc) and internal (^{83m}Kr, ^{37}Ar) calibration sources, as well as from neutron activation lines (e.g., ^{129m}Xe, ^{131m}Xe in xenon) are used. Relative energy resolutions (σ/μ) at the level of 4-6% at energies of a few tens of keV and 2-3% at energies of a few 100 keV were reached in argon and xenon TPCs, respectively. At higher energies, relevant for the neutrinoless double beta decay of ^{136}Xe, relative resolutions of 0.67%, 0.8% and 1.2% around 2.5 MeV were obtained by LZ [157], XENON1T [158] and EXO-200 [159], respectively. Superior energy resolutions are attained in high-pressure gas TPCs with electroluminiscent amplification [160], with a relative resolution of 0.4% obtained in the NEXT-White detector [161]. This is due to the fact that the Fano factor in pure gaseous xenon, $F_{GXe} = 0.15\pm0.02$, is about two orders of magnitude smaller than in the liquid phase.

To achieve a high collection efficiency for both ionisation and scintillation signals, the concentration of impurities is reduced and maintained at a level below one part per 10^9 (ppb) oxygen equivalent. While the light can be strongly reduced by the presence of water vapour, the ionisation signal also requires high purity in terms of molecules with high electronegative affinity. The purity is commonly expressed via the electron drift lifetime, τ_e, which is the time over which the number of drifting electrons, n_e, is reduced by a factor e: $n_e(t) = n_e(t_0) \exp(-t/\tau_e)$. Ideally, τ_e should be a few times larger than the total drift time in a TPC, to prevent charge losses. Lifetimes > 10 ms were achieved both in argon and xenon (corresponding to impurity concentrations $\ll 1$ ppb O_2 equivalent) via continuous recirculation and purification in the liquid or gas phase.

The drift velocity of electrons, which depends on the drift field E_d and the electron mobility μ as $v_d = \mu \cdot E_d$, has been measured for drift fields between $\sim (10 - 10^4)$ V/cm. It also depends on the temperature in the medium and the impurity concentration, often making the comparison between different measurements difficult. In general, the drift velocity raises from about 0.25 mm/μs at low fields to 2 mm/μs at high fields in both argon and xenon. As electrons drift in the electric field, the initial electron cloud spreads both in longitudinal and transversal direction to the field, expressed in terms of longitudinal D_L and transversal D_T diffusion coefficients, with $D_L < D_T$ and $D_L/D_T \approx 1$ for fields approaching zero. In argon, D_L was measured as $\sim$4.2 cm^2/s at 200 V/cm [162], $\sim$3.7 cm^2/s at 274 V/cm [163], $\sim$7.2 cm^2/s at 500 V/cm and D_T as $\sim$12 cm^2/s [164]. In xenon, D_L is around 100 cm^2/s at low fields, reaching $\sim$25 cm^2/s at higher drift fields [142], while D_T has been measured to be $\sim$55 cm^2/s at fields between (20-600) V/cm [165]. As an example, the spatial distribution of an initially point-like electron cloud, after a drift time t, is $\sigma_D = \sqrt{2Dt}$, resulting in a value of $\sim$20 mm for 1 ms drift and a 25 cm^2/s diffusion coefficient.

The scintillation light can be attenuated by absorption on impurities or due to Rayleigh scattering, the latter depending strongly on the wavelengths of the photons and the optical properties of the materials. Since only the combined effect is observed, it is non-trivial to disentangle the two contributions. A combination of measurements and theoretical calculations yield total attenuation and Rayleigh scattering lengths between 55-110 cm and 60-99 cm for argon and 30-50 cm and 30-50 cm for xenon detectors, with refractive indexes between 1.34 and 1.57-1.72, respectively, and absorption lengths >100 cm [134, 166].

Background sources for rare-event searches, their mitigation techniques and radio-purity assays are discussed in *Section 36.6* of this *Review*. The main backgrounds in large TPCs are due to decays of other noble isotopes mixed with the argon and xenon (^{39}Ar, ^{85}Kr, ^{222}Rn), from natural, anthropogenic or cosmogenic radioactivity of detector materials in close proximity to the target (^{238}U, ^{232}Th, ^{40}K, ^{60}Co), and from muons and their secondary particles, including *in situ* production of isotopes which are sufficiently long-lived to render their vetoing difficult (e.g., ^{137}Xe in xenon TPCs). Astrophysical neutrinos cause largely irreducible backgrounds in dark matter detectors, but deliver exciting physics signatures in their own right. To mitigate the ^{39}Ar background, argon is extracted from underground sources (CO_2 wells), ^{85}Kr

Table 36.4: Physical properties, volume fraction in the atmosphere, radioactive isotopes of the noble element xenon.

Property [unit]	Xe
Atomic number, mean atomic mass [g/mol]	54, 131.29
Boiling T_b and melting T_m point at 1 atm [K]	165.0, 161.4
Gas density at 1 atm and 298 K (T_b) [g/l]	5.40 (9.99)
Liquid density at T_b [g/cm^3]	2.94
Volume ratio ($\rho_{\rm liduid}/\rho_{\rm gas}$)	526
Dielectric constant of liquid	1.95
Scintillation light yield (in liquid, at 122 keV) [140]	63 photons/keV
Wavelength (peak centred at)	175 nm
Decay time constants (s=0, s=1)	2.2 ns, 27 ns
Refractive index	1.69
Electron mobility* [142]	0.29 mm^2/(μs V) ($\lesssim$100 V/cm)
	0.01 mm^2/(μs V) ($\gtrsim$100 V/cm)
Volume fraction in Earth's atmosphere [ppm]	0.087
Isotopes with spin, abundance [%]	^{129}Xe, 26.44; ^{131}Xe, 21.18
Radioactive isotopes,	^{136}Xe, 8.87; 2.2×10^{21} [143, 144]
abundance [%] and $T_{1/2}$ [y]	^{124}Xe, 0.095; 1.1×10^{22} [145]
	^{134}Xe, 10.4; $>8.7\times10^{20}$ (90% C.L.) [146]
	^{126}Xe, 0.089; $>1.9\times10^{22}$ (90% C.L.) [147]

*Measured values in two benchmark regimes, so-called "cold" and "hot" electrons [141]. In the first case, the electron energies are due to thermal bath of the xenon fluid and they rapidly gain energy with increasing field; in the second case, the electrons have gained most of their energy through acceleration in the field and experience increased energy loss on their path due to collisions with Xe atoms.

and ^{222}Rn are reduced by cryogenic distillation, exploiting the different vapour pressures of the different noble gases, or with gas chromatography using synthetic charcoal. In xenon detectors, $^{\rm nat}$Kr concentrations of $<$ 50 ppq [167] and ^{222}Rn concentrations of 0.8 μBq/kg were achieved by cryogenic distillation In argon TPCs, ^{39}Ar concentrations of (0.73 $\pm$ 0.11) mBq/kg were demonstrated [168].

An overview of large TPCs for rare event searches is given in Table 36.5.

36.4.1 *Dark matter and other low energy signals*

TPCs built to search for particle dark matter are based on the two-phase principle. Starting with total masses of a few kilogram the detectors evolved and reached active target masses at the tonne- and more recently multi-tonne scale. Concomitantly, the background levels in the most inner regions constantly decreased, with current electronic recoil rates of 15 events/(t y keV) in the energy region below 100 keV for xenon detectors [169]. Typically, the TPCs contain two arrays of photosensors, one immersed in the liquid, and one in the gas phase above the liquid at similar low temperature. The xenon scintillation light can be observed directly by PMTs with synthetic silica (quartz) windows or with VUV-sensitive SiPMs, while for argon detectors, tetraphenyl butadiene (TPB) is used to shift the 128 nm light to 420 nm, given that it is absorbed by quartz windows.

The DarkSide-50 experiment [168] operated a 50 kg TPC with liquid argon depleted in ^{39}Ar until 2019. DarkSide-20k [170], to operate 51.1 t of underground LAr in an octogonal TPC, the walls made of gadolinium-loaded acrylic panels, with two arrays of SiPMs, is under construction in Hall C of the Laboratori Nazionali del Gran Sasso (LNGS) in Italy. A larger, 400 t LAr detector, Argo, has been proposed for SNOLAB in Canada. After the successful operation of TPCs for LUX, PandaX-II and XENON1T, the current generation of xenon detectors, LUX-ZEPLIN (LZ) [171] at the Sanford Underground Facility (SURF) in USA, PandaX-4T [172] at the China Jinping Laboratory (CJPL) and XENONnT [173] at LNGS, employ several tons of LXe as active target mass. Their overall TPC design is rather similar, with cylindrical, polytetrafluoroethylene (PTFE) enclosed target regions viewed by two arrays of low-radioactivity, 3-inch diameter Hamamatsu R11410 PMTs. The PTFE has a high reflectivity for the Xe scintillation light [174]. Next-generation detectors, at the 50 t LXe scale or beyond, have been proposed with DARWIN/XLZD [175, 176] and PandaX-xT [177]. Recent constraints on various dark matter candidates are presented in *Section 27.6*. The search for WIMP dark matter is ongoing, with the sensitivity goal of current experiments to the spin-independent WIMP-nucleon cross section around 1.5×10^{-48} cm^2 at 40-50 GeV/c^2 mass [171, 173].

Owing to low electronic recoil backgrounds and low energy thresholds in noble liquid TPCs, high-sensitivity searches for dark matter electron scattering with particle candidates from a hidden sector, for keV-scale axion-like-particles (ALPs) and dark photons via absorption in LXe, as well as searches for solar axions, became feasible (see *Section 27.6*). Looking at ionisation-only signals allows for a further reduction of the energy threshold, given the much higher efficiency to detect an ionisation electron compared to a primary scintillation photon (typically 90% versus 10%). While this gain comes at the expense of higher backgrounds, it allows nonetheless to set stringent limits on light dark matter electron interactions at masses from a few tens of MeV to a few GeV, as shown by DarkSide-50 [178], PandaX-4T [179], XENONnT [180] and LZ [181]. Further, current-generation dual-phase TPCs have reached target masses which will allow for the first time the detection of solar *pp* neutrinos via elastic neutrino-electron scattering at energies down to 1 keV and of ^{8}B neutrinos via coherent elastic neutrino-nucleus scattering (CEνNS).

Dual-phase TPCs were successful in gradually scaling up their target mass and in reducing the background levels for each iteration, while maintaining a low-energy threshold of $\sim$1 keV for electronic recoils. Notwithstanding, the construction of next-generation detectors at the multi-ten-tons scale poses multiple technological challenges. The background goals are such that electronic and nuclear recoils rates are below the ones from irreducible astrophysical neutrino interactions. This requirement sets the goals for the intrinsic ^{222}Rn and ^{85}Kr concentrations: the background from the decay of these isotopes should be significantly lower than the solar pp-neutrino elastic scattering rate. This translates into 0.1μBq/kg for ^{222}Rn[2] and 0.1 ppt for $^{\rm nat}$Kr, assuming a ^{85}Kr/$^{\rm nat}$Kr ratio of 2×10^{-11}mol/mol. While $^{\rm nat}$Kr concentrations of $<$ 50 ppq were already achieved, for ^{222}Rn a factor of about 10 reduction compared to the current values is needed. This calls for a high liquid throughput (close to 1 t/hour) with efficient cooling power based on cryogenic heat pumps and radon-free heat exchangers. Cryogenic distillation or charcoal chromatography must go hand in hand with selection of low radon

[2] A ^{222}Rn concentration of 0.1μBq/kg corresponds to less than one radon atom per 100 mol of xenon. The main background is due to ^{214}Bi β-decays which are not accompanied by an α-decay and thus cannot be tagged in the TPC.

Table 36.5: Selected experiments using large TPCs for rare event searches. Shown are experiments that operated until recently, as well as current, soon-to-be-operating and proposed experiments. UAr stands for underground argon; HP-GXe stands for high-pressure gaseous xenon. For some of the proposed experiments, the location or the readout scheme is not yet decided (marked as "TBD").

Experiment	Location	TPC type	Total (active) mass	Readout
Dark matter				
DarkSide-50	LNGS	Dual-phase, UAr	51.1 kg (46.4 kg)	3″ PMTs, TPB
DarkSide-20k	LNGS	Dual-phase, UAr	50 t (50 t)	SiPMs, TPB
Argo	SNOLAB	Dual-phase*, UAr	∼400 t (∼400 t)	SiPMs, TPB
LUX-ZEPLIN	SURF	Dual-phase, Xe	10 t (7 t)	3″ PMTs
PandaX-4T	CJPL	Dual-phase, Xe	5.6 t (3.7 t)	3″ PMTs
PandaX-xT	CJPL	Dual-phase, Xe	47 t (43 t)	2″ PMTs
XENONnT	LNGS	Dual-phase, Xe	8.6 (5.9 t)	3″ PMTs
DARWIN/XLZD	TBD	Dual-phase, Xe	50-100 t (40-80 t)	3″ PMTs
$0\nu\beta\beta$ decay				
EXO-200	WIPP	LXe, ^{136}Xe 81%	175 kg (110 kg)	LAAPDs, wires
nEXO	SNOLAB	LXe, ^{136}Xe 90%	4.8 t (3.65 t)	SiPMs, charge pads
NEXT-White	LSC	HP-GXe, ^{136}Xe 91%	5 kg (4.3 kg)	3″ PMTs, SiPMs, TPB
NEXT-100	LSC	HP-GXe, ^{136}Xe 90%	100 kg (80 kg)	3″ PMTs, SiPMs, TPB
NEXT-HD	TBD	HP-GXe, ^{136}Xe 90%	1.2 t (1 t)	Fibres + SiPMs, TPB
PandaX-III†	CJPL	HP-GXe, ^{136}Xe 90%	140 kg (100 kg)	Micromegas

*The option to build Argo as a single-phase detector is also under consideration.
†This is an R&D program for a future larger, enriched PandaX-xT detector.

emanation materials and new coating techniques to prevent radon emanation from surfaces.

Other challenges related to the liquid target are the continuous purification for electronegative impurities and water, to maintain high charge and light yields, while not introducing radon into the TPCs, as well as new solutions for reliable storage and recuperation at large scales. A dedicated single-closed-loop cryogenic system capable of handling 100 t of underground argon was designed and constructed for DarkSide-20k [182]. Liquid phase purification powered by a liquid xenon pump, as demonstrated in [183], was employed to achieve an electron drift lifetime above 15 ms in about 8.6 t of xenon in XENONnT. A system capable of handling 30 t of xenon in liquid phase, including long-term storage and and transfer of the cryogenic liquid between storage module and detectors was constructed for PandaX-xT [177, 184].

Regarding the detector design, electrodes with large (>2.5 m) diameters, with high transparency, minimal sagging and low spurious electron emission, as well as high-voltage feed-throughs that can safely deliver 50 kV or more to the cathode must be employed. DarkSide-20k will use for the first time anode and cathode plates made out of acrylic coated with a commercial conductive polymer and with TPB. LZ successfully built custom-woven wire-mesh grids with 1.5 m diameter, produced with an in-house built loom to weave the wire meshes [185]. Finally the cryostat design must ensure stability, while reducing as much as possible the amount of material, and thus gamma and neutron emitters in proximity to the TPCs.

Besides Ar and Xe TPCs, detectors using superfluid ^{4}He, targeted at low-mass dark matter, are under development within the HeRALD [186] and DELight [187] programs, based on the basic principles demonstrated by the HERON solar neutrino project [188]. The detectors will be instrumented with transition edge sensors or magnetic micro-calorimeters to observe both atomic signals, such as scintillation light, and quasiparticle (phonon and roton) excitations. As in other noble elements, the He_2^* dimers appear in a short-lived (<10 ns) singlet and long-lived (13 s) triplet state. The former decay promptly, emitting photons with energies peaked around 16 eV, while the triplet states can propagate through the fluid and de-excite at surfaces. Liquid helium is transparent to its VUV photons, since the first excited state of atomic helium is at 20 eV. Quasiparticles will propagate ballistically through the liquid without decaying, and can also be detected via the evaporation of ^{4}He atoms from the surface of the liquid, with the helium binding energy being ∼0.7 meV.

Large volume, low-background TPCs are also developed for directional dark matter searches. An example is CYGNO [189] which aims to built a TPC with 50 cm drift, filled with a He:CF_4 gas mixture at room temperature and atmospheric pressure at LNGS. The liberated charge in a particle interaction is drifted towards an amplification stage consisting of a triple GEM structure, where the charge is multiplied and also light is produced. The readout will consist of light detectors, PMTs and scientific CMOS cameras, yielding the energy and z-position of events and the 2D track projections, respectively. The combined information thus allows for a 3D track reconstruction, with the goal being to achieve energy thresholds for electronic recoils around 1 keV.

36.4.2 $0\nu\beta\beta$ *Decay*

Experiments built to search for the $0\nu\beta\beta$-decay of ^{136}Xe, at a Q-values of 2457.8 keV, are based on single-phase TPCs, filled either with liquid or gas xenon at high pressure. The drift region is horizontal (EXO-200, NEXT-100) or vertical (nEXO, NEXT-HD, PandaX-xT-enriched). For EXO-200 and nEXO, the TPCs are enclosed by radio-pure, thin-walled Cu vessels in cryofluid, hydro-fluoro ether, acting thermal bath and radiation shield. In EXO-200, which took data at the Waste Isolation Pilot Plant (WIPP) until 2018, the charge drifted to crossed-wire planes at each anode, while the light was collected by arrays of large area avalanche photodiodes placed behind the wire planes at both ends. In nEXO, the TPC vessel will be a vertical Cu cylinder with 130 cm height and diameter (for 118.3 cm drift), with the charge collected at the anode by 0.6 cm pitch and 9.6 m long electrode strips, and the scintillation light observed by SiPMs arranged in a barrel configuration. Unlike for dark matter TPCs, there are no reflector panels and the field rings and cathode are coated with reflective aluminium deposition. The design drift field is 400 V/cm and the goal for the relative energy resolution is 0.8%. EXO-200 set a lower limit on the half-life of $0\nu\beta\beta$-decay of 3.5×10^{25} y with a total exposure of 231.4 kg y [190]. The future nEXO aims for a sensitivity of 1.35×10^{28} y with 5 t of enriched xenon and ten years of data taking [191].

TPCs using high-pressure xenon gas aim to reconstruct the tracks from the two electrons emitted in double beta decays, and the decay vertex, thus providing also a topological signature. In the NEXT project at the Laboratorio Subterráneo de Canfranc (LSC), the horizontal TPC, to be operated at 10-15 bar, features a single drift region. The primary (S1) and secondary (S2) scintillation light, the latter due to electroluminescence when the ion-

isation electrons cross a high-field region close to the anode, are collected by arrays of PMTs and SiPMs placed behind the cathode and anode, respectively, for energy measurements and tracking. The surfaces facing the active volume are coated with TPB to shift the VUV light to the visible spectrum. An inner Cu shield absorbs radiation from the high-pressure vessel of the cryostat.

The NEXT-White experiment, a prototype for NEXT-100 and for the proposed tonne-scale NEXT-HD, has been operating a TPC with 20.8 cm radius and 53 cm drift, with 4.3 kg of xenon at 10 bar. It has shown excellent energy resolution (< 1% FWHM [161]) and demonstrated background rejection using the capability to reconstruct the trajectories of ionising charges in the gas, thus separating the two-electron signature of $\beta\beta$-decay from single electrons due to background sources [192, 193]. Using data collected with xenon enriched and depleted in ^{136}Xe, it measured the half-life of the $2\nu\beta\beta$-decay and demonstrated clear Bragg peaks for the 2 electrons emitted in the decay [194]. NEXT-HD will operate a vertical-drift TPC, 2.6 m in diameter and height, to accommodate ∼1.1 t of enriched xenon at 15 bar [195]. An intense R&D programe for the *in situ* identification of the barium ions ($^{136}Ba^{2+}$, $^{136}Ba^{+}$) produced in the $0\nu\beta\beta$-decay (called Ba-tagging) is ongoing [196–198]. PandaX-III, an R&D program for a future, enriched PandaX-xT detector, operates a high-pressure Xe gas TPC, where the xenon is mixed with 1% trimethylamine (TMA) to ensure stable operation of the Micromegas employed in the readout planes, and to minimise electron diffusion [199]. Experimental searches for $0\nu\beta\beta$-decay are discussed in more detail in *Section 14.9*.

Apart from enriched xenon detectors, large TPCs using xenon in its natural isotopic abundance are also sensitive to second-order weak decays, such as the double beta decay of ^{134}Xe and ^{136}Xe, and the double electron capture process in ^{124}Xe and ^{126}Xe. In its electronic recoil channel, XENON1T observed for the first time the 2νECEC process in ^{124}Xe by detecting the simultaneously emitted K-shell X-rays/Auger electrons of the daughter atom ^{124}Te with a combined energy of 64.33 keV, which is twice the K-shell binding energy. With a half-life of $(1.1 \pm 0.2_{\rm stat} \pm 0.1_{\rm sys}) \times 10^{22}$ y, this is the slowest process ever measured directly [145, 200]. The double electron capture in ^{124}Xe can also be studied with high-pressure xenon gas TPCs, as demonstrated by NEXT [201]. LZ, PandaX-4T and XENONnT will improve upon existing results and will also search for the $2\nu\beta^{+}$EC decay. This channel has a distinct signature due to the two 511 keV gammas emitted after the positron annihilates with an electron in the medium. With a predicted half-life around 1.6×10^{23} y [202] its first observation is within reach of these running experiments, which will also measure the half-life and in particular also the shape of the $2\nu\beta\beta$-decay of ^{136}Xe with high statistics and at low energies not previously accessed. The current generation of dark matter detectors will also set constraints on the $0\nu\beta\beta$-decays of ^{136}Xe and ^{134}Xe, as predicted or shown in [145, 203–205], delivering proof-of-principle methods towards higher sensitivity searches in DARWIN/XLZD and PandaX-xT. As an example, with 40 t of natural xenon in a TPC, a ^{136}Xe half-life sensitivity of 3×10^{27} y (90% C.L.) after ten years of operation can be reached [206], a number which increases by about a factor of 1.7 for an enlarged xenon mass of 60 t.

36.5 Sub-kelvin detectors

Revised August 2023 by O. Cremonesi (INFN, Milano-Bicocca), L. Hsu (FNAL) and G. Signorelli (Pisa U.; INFN, Pisa).

36.5.1 *Motivation for Sub-kelvin Detectors*

Detectors operating below 1 K are referred to as low-temperature detectors (LTDs). The advantage of using LTDs over conventional detectors resides in their better energy resolutions, lower noise, and improved energy thresholds, which can all be achieved with a versatile choice in materials. In certain applications, these advantages outweigh the potential drawbacks of cooling and reading out a detector payload at sub-kelvin temperatures, and thus enable exploration of new frontiers in fundamental physics, astrophysics and cosmology. Among the endeavors enabled by LTDs are direct searches for dark matter over a wide mass range, precision experiments to measure the electron neutrino mass, searches for neutrinoless double-beta decay, and X-ray observation of the Universe. Large arrays of LTDs are also employed to measure the properties of the cosmic microwave background (CMB) spectrum whose parameters are determined by fundamental physics. These include dark matter and dark energy densities, the sum of neutrino masses and the number of light relativistic species, as well as probing the physics of inflation at energy scales of $\sim 10^{16}$ GeV. This article presents a brief overview of LTDs, their features, and several applications. More detailed treatment of this subject is available in the literature [207–210].

The advantages of LTDs are enabled by the detection of very low energy excitations (e.g. phonons and quasiparticles). In a typical interaction, energy from an incident particle is dissipated through excitation of secondary particles such as electrons, ions, holes, photons, phonons etc. These particles will in turn produce their own secondaries. Thus there is a cascade down in energy until the original energy deposit is converted entirely into heat and the detector reaches thermal equilibrium. Prior to the equilibrium phase, the energy at any given moment is partitioned among multiple excitation modes. Conventional particle detectors work by sensing the higher energy excitation modes, such as ionization and scintillation, which require an average minimum energy of few eV to 10's of eV to produce. For such detectors, a large fraction of the deposited energy remains undetected in the form of heat. Furthermore, the measurements are subject to the fluctuations inherent in the partition of energy across different excitation modes. Secondaries that don't eventually escape the detector, will de-excite or recombine to dissipate their energy in the form of phonons and quasiparticles, which are characterized by energies in the range of meV down to μeV. These can be detected by LTDs at various stages of their final degradation towards thermal equilibrium. Thus LTDs allow for energy resolutions and operational thresholds much lower than detectors that only sense scintillation and ionization. Furthermore, LTDs provide a precise energy measurement owing to the relatively large number of excitation quanta that can be detected. In fact, LTDs designed to measure thermal phonons achieve the highest possible energy resolutions with optimal noise performance.

At thermal equilibrium, energy E deposited in an LTD causes a temperature rise $\Delta T = E/C$ where C is the heat capacity. Thermal equilibrium is characterized by the condition where the average heat flowing to an LTD equals the average heat flowing from the LTD (into a proper heat sink or bath). In this state, the ideal intrinsic energy resolution is determined by the statistical fluctuations in the phonon system. Fluctuations in the total number of phonons in the LTD absorber have variance C/k_B, which yields a minimum resolution of $\Delta E^2 = k_B T^2 C$ to the device energy resolution, where k_B is Boltzmann's constant. Thus, the smaller the heat capacity, the more sensitive the response of the calorimeter and the better the energy resolution. The most relevant feature of this result is that the latter is independent of the energy deposition. The heat capacity itself is the product of the detector volume (V) and the specific heat (c_p). Optimization of LTD response can be achieved by using small detector volumes and materials with low specific heat. Noise contributions from additional sources will increase the variance and are generally parameterized as a multiplicative factor ($\xi \gtrsim 1$) to the variance expression above.

Similarly, the power P from incident particles or radiation can be measured through a temperature rise given by $\Delta T = P/G$, where G is the thermal conductance to a weakly linked bath held at constant temperature. Power fluctuations are limited by G and have a spectral density of $S_P = NEP^2 = 4k_{\rm B}T^2G$, where NEP is the noise equivalent power, defined as the power in a 1 Hz bandwidth that gives a response signal with an equal amplitude to the noise. Hence lower conductance yields better sensitivities. To minimize thermal conductance in precise power measurements, weak thermal links can be realized by using thin membranes or by decoupling the electron and phonon systems. However, a compromise must be made. While lower G yields better noise metrics, conversely, larger G is needed to dissipate all incident power (which can be large in the case of CMB detectors) or to have a

faster detector response (the characteristic response time being $\tau = C/G$).

LTDs that measure power are sometimes referred to as *bolometers* in literature, as opposed to *calorimeters* that measure energy, generating some confusion. In principle, there is no clear distinction between a calorimeter and a bolometer. The operation mode is generally determined by the ratio of the characteristic time constant and the average time between the arrival of incident particles or quanta [211].Yet another convention is to refer to *non-equilibrium* LTDs as those detectors that measure incident energy or power by counting excitations that have energy $\gg k_B T$. In such detectors, energy resolution is determined by the statistical fluctuations of the energy partition, similar to conventional ionization detectors but with a much lower average excitation energy and hence a larger number of excitation quanta.

Table 36.6: Low temperature dependence on temperature (T) for specific heat, based on different material classes. In the table below Θ_D is the Debye temperature and T_C is the transition temperature of the superconductor.

Heat Capacity	Material
$\propto \left(\frac{T}{\Theta_D}\right)^3$	Dielectric and diamagnetic
$\propto T$	Conductor
$\propto \exp\left(-\frac{2T_C}{T}\right)$	Superconductor
$\propto \left(\frac{\mu_B B}{k_B T}\right)^2 \mathrm{sech}^2\left(\frac{\mu_B B}{k_B T}\right)$	Paramagnet (in magnetic field **B**)

A variety of possible detector materials and sensor technologies makes LTDs very versatile and highly customizable. Dielectric, superconducting and paramagnetic materials are often used owing to the fact that at very low temperatures, the specific heat decreases strongly as a function of T (see table 36.6). Superconductors offer additional advantages: the abrupt change in resistance when a material transitions from its normal to superconducting state enables highly sensitive measures of temperature changes. Additionally, the existence of a small (less than a meV) but distinct energy gap that is required to break a Cooper pair, provides a means to measure energy deposits by counting the resulting quasiparticles (QP). QP relaxation processes are typically faster than thermal processes making these detectors suitable for high-rate photo-counting. In summary, both the sensitivity and energy resolution of an LTD benefit greatly from low temperature operation.

36.5.2 *Detector Types*

A generalized LTD calorimeter consists of an absorber in thermal contact with a phonon or quasiparticle sensor, and a thermal link to a heat bath at a constant temperature (see figure 36.10). The absorber provides the mass necessary for the interaction of the particle and a fast and complete thermalization of the deposited energy. The sensor accomplishes the task of translating the particle interaction into measurable parameters. It is generally sensitive to equilibrium phonons (e.g. thermistors and MMCs) and thus provides a precise measurement of the temperature. However, non-equilibrium (e.g. STJ's) and mixed (e.g. TES) phonon sensors have been devised and implemented in many applications as well. The goal of the thermal link is to cool the absorber down to its equilibrium temperature after the absorption of a particle. In monolithic detectors the thermometer and absorber are identical, while in composite detectors the thermometer is attached to a separate absorber. This basic design applies to single-event particle detection as well as for continuous radiation measurement devices. In the case of the latter, a suitable absorber whose mass is irrelevant, *e.g.* an antenna at the end of a waveguide, collects the incident power and dissipates it onto a resistive (*e.g.* Au) film, which is put in contact with a sensor capable of detecting tiny temperature changes (e.g. semiconductor thermistors, transition-edge sensors, and kinetic inductance detectors, to name a few).

Superconducting Tunnel Junctions (STJs) and Kinetic Inductance Detectors (KIDs) are examples of non-equilibrium detectors. STJs exploit Josephson tunnelling of particles and QPs between two superconductors. The superconductors act as radiation absorbers, and are separated by a thin insulating layer. When such a junction is DC biased at a voltage just below the gap voltage, the excess quasiparticles generated by the incoming radiation are detected as a tunneling-current proportional to the incoming energy. Statistical fluctuations in the tunnelling process limit the energy resolution which is given by:

$$\sigma_E = \sqrt{\varepsilon(F+G)E_0}, \tag{36.5}$$

where $\varepsilon \sim \Delta$, the band-gap, while $F \sim 0.2$ and $G > 1$ are the Fano factor and tunnelling fluctuation respectively. STJs have been proven to be excellent single photon and UV-VIS spectroscopic detectors with near theoretical energy resolutions, high detection efficiencies and excellent time resolution. In astrophysics they are used as mixers to detect radiation in the 100 GHz to 1 THz range by exploiting the non-linear behaviour of their current versus voltage characteristic curve. STJs share similar design elements to charge qubits, which are being used for the development of quantum computers. Such qubits have also recently been used in dark matter searches as single photon detectors to evade the standard quantum limit in measurement noise [212]. Despite their extremely good energy resolutions, STJs cannot be scaled-up to produce sensors with large observing volumes due to readout complexity and the difficulty in uniformly suppressing the superconducting Josephson current, which is superimposed on the QP current.

KIDs exploit the variation of the kinetic energy T stored in a superconductor by Cooper pairs whose inertia acts as an effective inductance, given by:

$$T = \frac{1}{2} n m^* v^2 = \frac{1}{2} L I^2 \tag{36.6}$$

where n is the number density of Cooper pairs, $m^* = 2m_e$ is the Cooper pair mass and $I = 2nev$ is the Cooper pair current. $L = m_e/2ne$ is defined as Kinetic Inductance and is inversely proportional to the number of Cooper pairs [213]. When a KID is placed in series with a superconducting capacitor, the resonance frequency of the circuit will be temporarily shifted by incident radiation, which converts Cooper pairs to QPs, thus changing the effective inductance. The presence and amount of radiation is observed as a change in amplitude or phase of a tuned sinusoidal signal that is sent through the circuit. In practice the change in L is small, and very high Q microwave resonance circuits are needed to sense this variation (hence the name MKIDs, for Microwave-KIDs). Furthermore, only areas of the film where large currents are flowing will be sensitive to pair breaking, thus making the response of a distributed KID position dependent. To overcome this issue, QP trapping (by coupling two superconductors with different band-gaps) is used for absorbing optical photons and X-rays. To detect lower frequencies (*e.g.* in the 100-1000 GHz range for CMB) a lumped element resonator (LEKID), with little current variation across the device, is used. The device itself, based on a series LC circuit inductively coupled to a microstrip feed line, can act as the absorber as well as the sensing element in a detector system. Macroscopic devices (few mm^2) can be fabricated by shaping the inductor in the form of a meander coupled to an inter-digitated capacitor [214]. The theoretical noise limit of these devices is governed by generation-recombination noise and takes the form:

$$NEP_{QP} = 2\Delta\sqrt{\frac{n_{QP}}{\tau_{QP}}}, \tag{36.7}$$

where n_{QP} and τ_{QP} are the QP number and lifetime respectively. KIDs are easy to fabricate, very sensitive, broad band and easily multiplexable: they can be coupled with a single microstrip that simultaneously reads 1000s of detectors resonating at different frequencies. They provide therefore a promising solution

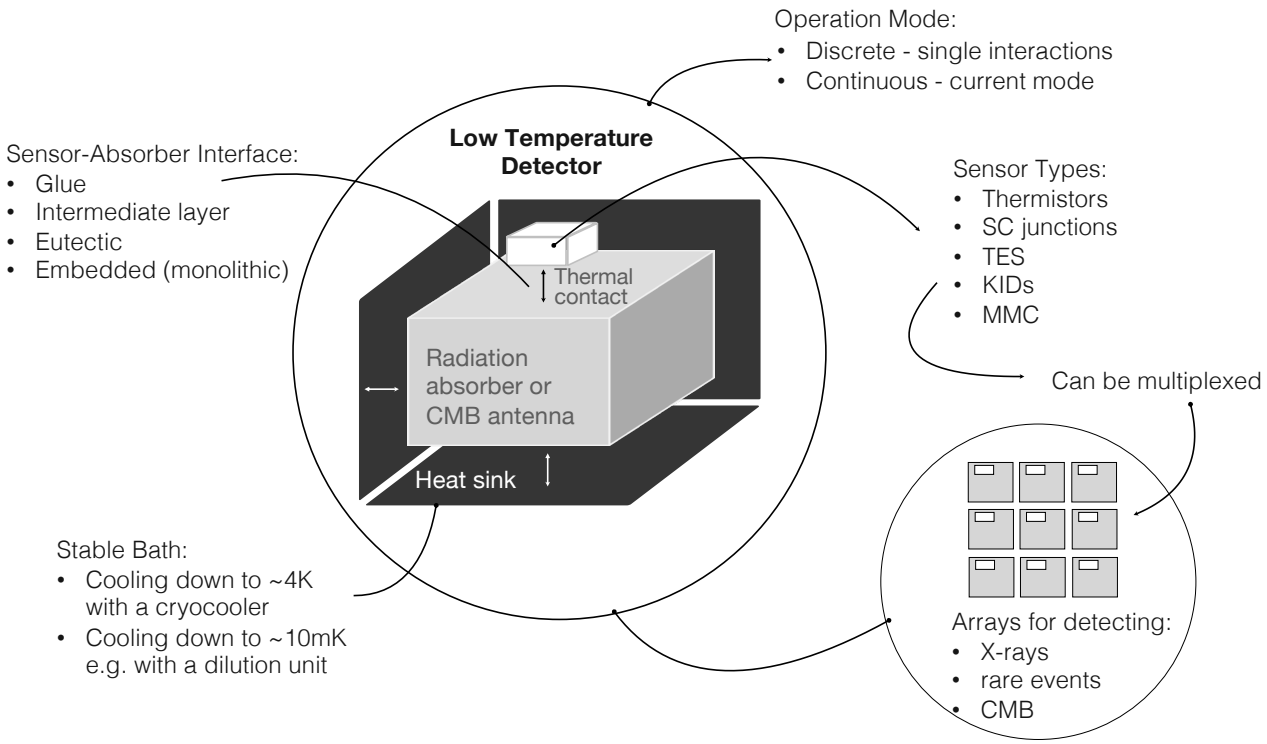

Figure 36.10: A generalized LTD consists of an absorber, a sensor and a thermal link to a stable-temperature bath. Biasing schemes and readout is described in detail in the text for individual sensor types.

for deploying large arrays of detectors with applications to high-energy physics, astronomy or CMB measurements, although there are still some challenges, especially at frequencies below 100 GHz, related to their worse noise performance when compared to other LTDs, and to the choice of materials with a sufficiently small energy-gap.

Semiconductor thermistors are resistive elements characterised by a strong dependence of the resistance on the temperature. Usually, they consist of small crystals of germanium or silicon with a dopant concentration slightly below the metal-to-insulator transition. However, they can also be realized in the form of amorphous films such as NbSi. At low temperatures, their resistivity (ρ) is governed by variable range hopping (VRH) conduction and is described by the expression $\rho(T) = \rho_0 \exp((T_0/T)^\gamma)$, where T_0 and ρ_0 are parameters controlled by the doping level, while γ depends on the compensation level K (ratio of acceptor to donor concentrations). For low values of K, γ is well approximated by 1/4 while it converges to 1/2 as K increases.

Semiconductor thermistors are high impedance devices (1–100 MΩ) whose performance is usually parameterized in terms of the logarithmic sensitivity $\alpha = \mathrm{d}\log R/\mathrm{d}\log T$, typically in the range of 1–10. Silicon thermistors are fabricated using a multiple ion implantation process in high purity silicon wafers to produce a thin and uniformly doped box-like volume. The best germanium thermistors are fabricated starting from bulk, high-purity germanium crystals doped by means of neutron irradiation in the core of a nuclear reactor, referred to as nuclear transmutation doping (NTD). Individual sensors are then produced by dicing the irradiated samples and finishing them by hand. The great advantage of NTDs is the highly uniform doping level over large volumes which results in a better signal to noise ratio with respect to other doping techniques. The doping level depends on the isotopic composition of the starting material and the irradiation time.

The weak coupling to the heat sink can be provided by the electrical leads used for the read-out. However, nowadays microelectronic planar technologies and silicon micromachining are more commonly preferred, and sensors are suspended on thin silicon nitride membranes or thin silicon beams. Thermistors are read-out in an approximately constant current biasing configuration obtained by inserting large load resistors in the bias circuit, which allows for direct conversion of the thermal signal (ΔT) into a voltage signal (ΔV).

Semiconductor thermistors are very practical to use with some drawbacks. One of these is related to their high impedance which requires a JFET front-end placed as close as possible to the device in order to minimize the signal integration on parasitic electrical capacitances. This can represent a technical challenge, because JFETs must be maintained at significantly higher temperatures ($\gtrapprox$100 K). Furthermore, deviations from the exponential behaviour of the conductivity have been observed at low temperatures. They are usually described in terms of a finite thermal coupling between electrons and phonons which results in an intrinsic limit to the signal rise times, which is of the order of hundreds of milliseconds at temperatures below 100 mK. Nevertheless, semiconductor thermistors are an established and robust technology, and arrays of detectors based on these devices have been widely used for neutrinoless double beta decay searches, neutrino mass measurements and X-ray spectroscopy. Energy resolutions lower than 5 eV have been achieved with Sn or HgTe absorbers.

Superconducting Transition Edge Sensors (TESs) exploit the sharp transition between superconducting and normal conducting phases, yielding a high sensitivity to temperature variations. Temperature perturbations, and hence resistance changes, are sensed as modulations in the current through the TES. TESs are operated in a constant voltage biasing configuration where Joule heating, arising from the current flowing in the TES, decreases with a rise in resistance, which then brings the TES back to its nominal operating temperature. This electrothermal feedback (ETF) is achieved by providing a TES with a voltage bias whose power, $P_J = V_{\mathrm{bias}}^2/R(T)$, heats the TES to its nominal operation point, the superconducting transition temperature. Operation in ETF mode improves linearity, speeds up response (to

faster than $\tau = C/G$), and in some cases it provides tolerance for T_C (critical temperature) variation between multiple TESs in a large array. The low impedance in this configuration makes them well-suited for readout by SQUID (Superconducting QUantum Interference Device) based amplifiers. Logarithmic sensitivities $\alpha = \mathrm{d}\log R/\mathrm{d}\log T$ of the order of several hundreds can be achieved. By using different superconductors, or superconductor-metal pairs patterned in suitable shapes, a wide range of resistances, transition temperatures and time constants are obtainable to meet the requirements of the desired application [215].

Nano-TESs are fabricated by lithographic techniques in the form of long (few μm) and narrow (nm) wires that exhibit extremely small NEPs due to their reduced C and G, enabling single-photon sensing. Superconducting Nanonwire Single-Photon Detectors (SNSPDs) are similarly patterned superconductors or superconducting bilayers maintained at a temperature well below their T_C. When a DC current just below the critical current is driven through the nanowire, the absorption of a single photon causes the formation of a hot spot that drives the superconductor to a normal conducting state, resulting in a very fast (tens of picoseconds) current pulse through a shunt resistor. For this reason, nano-TESs and SNSPDs are used as single photon detectors for light dark matter and axion searches in applications where large detecting mass is not critical [216].

Magnetic Metallic Calorimeters (MMC) exploit paramagnetic sensors exposed to a weak magnetic field with a weak thermal link to a heat bath. A temperature rise causes a change in the sensor magnetization, which is sensed by a SQUID magnetometer. A common material is an Au:Er mixture, with the addition of a few hundred ppm of enriched ^{166}Er, which is needed to reduce the unwanted contribution of nuclear magnetic moments of other Er isotopes. The read-out is non-dissipative and avoids the noise sources common to the dissipative devices. The use of a metallic host ensures relatively fast time response, since the typical spin-electron relaxation times are of the order of 0.1 microseconds at ∼50 mK [217]. For an optimized MMC, the energy resolution is given by $\Delta_E = \sqrt{2k_B T^2 C}\,(\tau_0/\tau_1)^{1/4}$, where τ_0 (order of micro second) and τ_1 (order of milli second) denote the signal rising and decay times respectively [207]. In order to obtain a fast and efficient energy thermalization, MMC are typically fabricated from gold. The intrinsically large heat capacity of the paramagnet does not spoil the temperature sensitivity and allows the use of relatively large gold absorbers without degrading the device performance. Furthermore, thermal isolation from the heat sink is not generally an issue. Owing to the simple concept of these devices, MMC can be precisely customized and fabricated by employing standard microtechnology. Planar MMC arrays characterized by an excellent energy resolution, large dynamic range and good linearity have been successfully used for the detection of soft X-rays.

Performance and technological constraints limit the maximum size of LTDs. To improve overall experimental sensitivities, a large number of sensors must be deployed, typically at temperatures of a few tens of mK, where cooling power is limited to a few μW. To reduce the readout complexity and the heat load at the colder stages, multiplexing (MUX) techniques are often employed. Multiplexing consists of reading multiple detectors out through a limited number of lines that traverse room temperature to cryogenic temperatures [218]. In frequency-domain multiplexing (FDM), a tuned superconducting LC circuit is placed in series with each sensor, and a frequency comb of AC biases (usually in the MHz range) is sent to a group of sensors in parallel. A synchronous demodulation of the amplified current signal allows the recovery of the resistance variation of each detector. Microwave-multiplexing (μMUX) represents a variation of this concept, based on the usage of rf-SQUIDs, where the frequency comb is in the GHz range. Alternatively, the signal from a single detector can be recovered by readout of one detector at a time (time-domain multiplexing, TDM). KIDs have been gaining popularity owing to the fact that they naturally form resonant circuits, hence multiplexing in the frequency domain is readily achieved by adjusting their capacitance.

36.5.3 *Experimental Applications*

LTDs are sensitive over a wide range of energy, from centimetre wavelength (∼ meV) through the visible spectrum (∼ eV) up to the X-ray domain (∼ keV) and beyond. Several broad categories of LTD applications towards measurements of fundamental physics are described in more detail in the text below and summarized in tables 36.7 and 36.8.

Bolometric detectors are favored as microwave detectors owing to their nearly constant response over frequency, playing an important role in far-infrared astronomy and in the survey of the cosmic background radiation. The high-frequency instrument of the Planck satellite (HFI) used spiderweb bolometers read by NTD-Ge thermistors, but current experiments use mainly TESs or, more recently, KIDs. Depending on the objective of the experiment, antenna coupling or absorber coupling is used. In the former case, the bolometer detects one polarization and one (or a few) modes of the radiation, while absorber-coupled bolometers do not distinguish between polarizations. In order to avoid the absorption or emission from Earth's atmosphere, many (CMB) instruments are operated by observatories located at high altitude, dry places (such as the Atacama desert or Antarctica), balloon-borne platforms, or from space. In Table 36.7, we list a subset of the ongoing or planned CMB experiments (see Section 29 of this Review for the details on present challenges). In the Atacama desert in Chile, CLASS is taking data, POLARBEAR is being upgraded to Simons Array and ACTPol is being upgraded to AdvancedACT-Pol, the next big step being the deployment of the Simons Observatory. At the South Pole, SPTPol has been upgraded to SPT-3G, while BICEP3 and BICEP array will constitute the South Pole Observatory. The most powerful upgrade in terms of both size and sensitivity will be CMB-S4, a consortium of telescopes both at the Pole and in Chile. In the Canary islands, QUIJOTE and GroundBIRD are operating and LSPE/STRIP is in preparation. QUBIC has recently started operations in Argentina and AliCPT is in preparation in Tibet. Regarding balloon projects, SPIDER and EBEX were already launched while LSPE/SWIPE and PIPER will be in the near future. Finally from space, after the success of Planck, LiteBIRD has been selected by the Japan Aerospace Exploration Agency (JAXA) as the next strategic large mission to be launched in the 2020s.

The incoming radiation couples directly to the antenna probes (as in BICEP/Keck) or through micro-machined horn waveguides (AdvancedACT-Pol, CLASS) or lenslets (Simons Array, SPT-3G), depending on the frequency range. All of these experiments have focal planes with hundreds to hundreds of thousands of sensors. To optimize focal plane occupancy, multi-mode or multi-chroic, dual polarization sensitive detectors are used. In the former case, the sensitivity is enhanced by collecting power from a larger number of modes at the expense of angular resolution. In the latter, one single mode of the radiation is focused on a broad band antenna, and on-chip polarization separation and band-pass filters split the signal in different frequency bands directing the power to different absorbers and sensors.

Experimental design is driven by a trade-off between the sensitivity and the complexity of the production processes and readout. On the one front, single-sensor NEP at the level of 10^{-21} W/$\sqrt{\text{Hz}}$ has been achieved in laboratories and research centers. Meanwhile, efforts are in place for the industrialization of the fabrication processes, which is essential for scaling up production for the large number of detectors needed for future experiments.

Massive cryogenic calorimeters have been proposed since the 1980's as particle detectors for the search of rare processes (e.g. dark matter, neutrinoless double beta decay) [219]. Almost simultaneously, the use of arrays of small mass calorimeters was suggested for X-ray astrophysics [220] and precision measurements of the neutrino mass [221, 222]. Although essential to understanding the nature of neutrinos, neutrinoless double beta decay (NDBD) has eluded discovery (or definitive exclusion) for over 50 years. Calorimeteric techniques provide the best sensitivities to NDBD. However, before the advent of low temperature calorimeters (LTC), only a few isotopes (^{48}Ca, ^{136}Xe and ^{76}Ge) could be utilized for NDBD studies with the calorimetric approach. This limitation was removed by the advancement of LTC's, and in par-

Table 36.7: Some selected experiments using LTDs to measure the CMB. These experiments constrain the physics of inflation and the absolute mass, hierarchy, and number of neutrino species. The experiment location determines the part of the sky that is observed. The size of the aperture determines the angular resolution. The table also indicates the type of sensor used, the number of sensors, the frequency range, and the number of frequency bands. Data for planned upgrades or future experiments are provided in parentheses.

Sub-K CMB Experiment	Location	Aperture	Sensor type	# Sensors (planned)	Frequency (planned)	Bands (planned)

ticular by CUORE, which takes advantage of the naturally high abundance of ^{130}Te in TeO_2 crystals. Additionally, the operation of CUORE at LNGS [223] has demonstrated that the technical challenges of operating ton-sized LTD detectors in a deep, underground location are surmountable. Currently, the most promising future approach is based on the hybrid approach of scintillating LTCs, which unfortunately cannot be used for ^{130}Te. Now, new projects are being proposed based on different scintillating compounds. In particular ^{100}Mo is the choice of CUPID [224] (NTD thermistors glued to $Li_2{}^{100}MoO_4$ crystals), which will use the same infrastracture of CUORE and follows from the successful operation of several demonstrators (CUPID-0 [225] and CUPID-Mo [226]), and AMORE (MMC sensors on $Ca^{100}MoO_4$ or $Li_2{}^{100}MoO_4$ crystals) [227]. With an energy resolution comparable to germanium diodes and a mass of the order of a ton, these experiments aim to probe the inverted hierarchy of neutrino masses. The slow response of these detectors is still a dominant limitation because pile-up may prove to be a serious background. Extremely pure materials, careful assembly procedures, and deep underground laboratories are therefore necessary.

In the 1980's, the calorimetric technique was recognized as a feasible approach to make a direct measurement of the neutrino mass from the end-point of a beta spectrum. Thus, LTCs were proposed as a possible alternative to the standard spectrometric measurements [228]. Calorimetric measurements offer a number of advantages: i) a weak dependence on the final excited states, ii) no source effects (e.g. self-absorption), and iii) lack of backscattering from the detector. Therefore LTCs provide a faithful reconstruction of the beta spectral shape over a broad energy range below the end-point. However, the difficulty in resolving a small fraction of the spectrum near the end-point is a serious limitation that strongly constrains the source strength and the statistics that need to be accumulated. Such an inconvenience can be mitigated by selecting beta emitters with a small Q value, owing to the fact that the fraction of counts in an interval, δ close to Q, scales as $(\delta/Q)^3$. However, this is generally at the cost of choosing decays with more complex nuclear transitions. In addition, LTCs may be affected by specific systematics (e.g. solid state effects). Ultimately it is recognized that spectrometers and calorimeters have complicated but different systematic effects. It is therefore critical to develop complementary experiments exploiting both techniques.

LTCs were initially proposed as perfect calorimeters to measure the energy spectrum of a low Q beta emitter embedded in an absorber. However, the requirements of excellent energy resolution and a low rate (to avoid pileup) requires a very large number, $O(10^4 - 10^6)$, of small mass devices (micro-calorimeters). Early experiments used ^{187}Re, which is a long-lived beta emitter that is naturally abundant in rhenium samples and is characterised by a very low Q value (2.4709 keV [229]). A large number of ^{187}Re based experiments have been developed over the years (MANU [230], MIBETA [231], MARE [232]). Nowadays a different approach is preferred and is based on the measurement of the atomic radiation following electron capture, typically in ^{163}Ho which is also characterized by a very low Q (2.837 keV [233]). Different experiments have been proposed to face the challenge: ECHo in Germany [234] (using MMC sensors), HOLMES in Italy [235] and NUMECS [236] in the US (using TESs). The very large number of microcalorimeters needed to obtain sensitivities comparable to spectrometric measurements is a serious challenge, both for the readout and the thermal heat load. An alternative readout based on the use of KIDs, for their multiplexing capability, has been proposed and is presently under development.

Traditional searches for WIMP-like dark matter aim to measure the scatter of a massive dark matter particle off of a target nucleus. Similar to detectors employed for neutrinoless double beta decay, these searches benefit from large-mass absorbers for the target because the dark matter interaction rate scales directly with the number of nuclei in the target and hence its mass. Among the most successful experiments to date, are those that combine the detection of phonons with another channel such as ionization energy (EDELWEISS and SuperCDMS) or scintilation light (CRESST). This simultaneous, dual measurement takes advantage of the fact that the energy deposited in the absorber is partitioned into these channels differently depending on whether the initial particle interaction produces electron or nuclear recoils (or both). This particle identification allows for the rejection of background from natural sources of radiation, which most commonly

Table 36.8: Selected experiments using low temperature calorimeters. The table shows currently or soon-to-be operating experiments that will search for dark matter or neutrino properties. The dates refer to the start of the program.

manifest themselves as electron recoils in the detector.

In recent years, multi-ton liquid noble detectors have outclassed LTD-based technologies in searches for heavy (>10 GeV/c^2) dark matter owing to their ability to more easily and cheaply scale to large target masses. However, the lower thresholds achieved by LTDs continue to make them the technology of choice for low-mass dark matter searches. New advances have enabled these detectors to reach much lower energy thresholds than previously obtained, albeit sometimes at the cost of being able to detect energy in more than one channel as described above. For example, the use of an electric field to generate Neganov-Trofimov-Luke [238, 239] phonons in proportion to the applied voltage, has enabled the detection of single electron hole pairs in Si detectors with thresholds as low as a few eV (SuperCDMS HVeV). This and similar advances in Ge LTDs (EDELWEISS_SubGeV) have enabled sensitive searches for dark photons and dark matter that scatters off electrons [240, 241]. Next generation experiments such as SPICE/HERALD aim to further optimize the intrinsic energy resolution of TES detectors, coupled with a strategic choice of target materials (superfluid He and polar crystals) to enable sensitivites to dark matter with masses below an MeV/c^2 [242]. Current state-of-the-art axion searches use SQUID based quantum amplifies such as Josephson Parametric Amplifiers along with resonant cavities operating below 100 mK to look for a signal above fluctuations in the thermal noise [243]. Future axion experiments are also working to close the sensitivity gap between particle and wave-like dark matter with the help of LTDs. Broad-band axion searches in the THz range are being proposed, which will make use of TES, SNSPDs or KIDs for single photon detection [244]. Finally, LTD-based dark matter detectors are also actively employed to study coherent neutrino scattering, owing to the fact that the hypothesized signal from dark matter-nucleus scattering is nearly identical to that from neutrino-nucleus scattering, with both inducing nuclear recoils in a similar energy range [245, 246].

36.6 Low-radioactivity background techniques

Revised October 2023 by Al. Ianni (INFN, LNGS) and S. Schönert (Munich Tech. U.).

36.6.1 *Introduction*

The study of rare phenomena in fundamental physics, such as proton decay, neutrinoless double beta decay, dark matter, and MeV-scale neutrino interactions, requires extremely low levels of background radiation. Experiments searching for these rare events record electron recoils or nuclear recoils in the energy scale from a few eV to several MeV. The detector technologies used are multiple from organic and cryogenic liquid scintillators, to bolometers, solide state calorimeters, gaseous detectors, and crystal scintillators. As far as the background contamination is concerned at some extent the application defines the requirements, although the common denominator is that an extreme reduction of all background sources is essential. Leading experiments in rare events search have obtained in the region-of-interest (ROI) a background as low as $\sim 10^{-4}$ cts/kg/y/keV. As a first and crucial step, a dedicated radio-purity assay of the detector set-up components has to be carried out. Over the last fifty years, special screening and cleaning techniques have been developed to measure and mitigate ultra-low levels of background. In order to characterize the background sources we refer to Heusser [247] and identify the following five main categories:

- environmental radioactivity in the location where the detector is installed;
- radioimpurities in the detector and shielding;
- radon and its progenies;
- cosmic rays and induced radioactivity;
- neutrons from natural fission, (α,n) reactions, and from cosmic-ray muons interactions.

The energy range affected by these background sources is mainly <10 MeV. All materials contain traces of long-lived primordial radioimpurities, such as ^{238}U, ^{232}Th, ^{235}U (^{238}U/^{235}U $\sim$ 138), and ^{40}K (^{40}K/K^{nat} $\sim 1.17\times10^{-4}$). We recall that 1 *ppt* of ^{238}U and ^{232}Th corresponds to 12.36 and 4.06 μBq/kg, respectively; 1 *ppb* of K^{nat} corresponds to 30.25 μBq/kg. In the Earth's crust the abundance of uranium and thorium is of the order of $1-10$ ppm which corresponds to about $10-100$ Bq/kg. Taking into account these contamination levels and the low background requirements, a fundamental background reduction and mitigation is essential to carry out rare phenomena research.

Besides primordial radionuclides other radioactive elements are produced through interactions with matter of secondary cosmic ray particles. Among these so-called cosmogenic radionuclides we recall, in particular, ^{3}H, ^{14}C, ^{7}Be, ^{39}Ar, ^{42}Ar , and, in copper, steel and iron often used as shielding materials, ^{57,60}Co.

A third category of background source in our environment consists of anthropogenic radionuclides. These are artificially produced mainly through nuclear reactions in nuclear power plants, nuclear fuel reprocessing plants, and nuclear weapons testing. Anthropogenic background elements of concern for rare phenomena are ^{85}Kr, ^{137}Cs, ^{241}Am, ^{60}Co, and ^{90}Sr. The concentration of ^{85}Kr ($T_{1/2}$=10.76 y, Q_β=687 keV) in air has been slowly increasing since World War Two with a present activity of order 1 Bq/m^3. As a consequence ^{85}Kr is a crucial background in experiments making use of nitrogen, xenon, and argon from air.

Once detector components radioactive backgrounds have been assayed and reduced by a careful selection campaign, which can last several years, a further step to push the background level beyond the screening possibilities is needed to reach the required sensitivity. For this purpose special active vetos, purification methods, and offline analyses have been developed. A meticulous background understanding and mitigation is crucial to explain any possible signal excess which may be detected. Background mitigation techniques are based on:

- use of radio-pure materials that absorb ionizing radiation;
- identify radio-pure material for detector construction;
- perform advanced surface and sub-surface cleaning treatment;
- reduce muon flux with underground detector deployment and using active vetos;
- exploit advanced detection and tagging techniques to discriminate signal from background.

In the following we describe radio-assay and background mitigation techniques developed and exploited in the framework of rare phenomena searches in deep underground laboratories.

36.6.2 *Radio-purity assay*

The radio-purity assay of detector components is a basic prerequisite to be carried out in low counting experiments. Several techniques are exploited for radio-purity assay. They are complementary to characterise the radio-purity of materials for shielding or core detector components. Next generation experiments radioassay campaign requires a considerable effort and organization for several years [248–251].

Gamma spectroscopy (GS) via high purity germanium (HPGe) detectors is a powerful and crucial technique [247]. It is nondestructive and thanks to the energy resolution allows to distinguish various radionuclides elements. Radiation from ^{238}U and ^{232}Th comes with all decay products in the radioactive chains. However, if secular equilibrium is broken, this crucial information can be addressed by separating different gamma-ray lines characterizing elements in the decay chains. In the ^{238}U chain one can have three sub-chains out of equilibrium. The first sub-chain can be assessed through ^{234}Th direct progeny of ^{238}U. The second sub-chain, which originates from ^{226}Ra, can be probed by ^{214}Pb and ^{214}Bi. A third sub-chain, which starts from ^{210}Pb, cannot be efficiently probed by GS, yet is of crucial importance and alternative methods must be used. In the ^{232}Th chain again one can probe two sub-chains which can be out of secular equilibrium: the first one through ^{228}Ac from ^{228}Ra; the second from ^{228}Th can be measured through ^{212}Pb, ^{212}Bi and ^{208}Tl. The technology for HPGe operated in deep underground counting facilities [252,253] or in shallow laboratories with an efficient active veto shielding [254] has been boosted to sensitivities of the order of 10-100 μBq/kg by carefully selecting detector components, electronics and sample handling systems. The HPGe screening method requires order of $\sim$ 0.1-a few kg of material, and weeks of acquisition to produce a reliable measurement.

A second crucial technique is based on inductively coupled plasma mass spectrometry (ICP-MS) [255]. This technique can probe primordial parent activities at the level of 1 μBq/kg. It is a destructive method and often needs special sample preparation on a small quantity of material. The ICP-MS does not measure the radioactive decay of isotopes but determines their concentration. At present, it is the most sensitive and rapid screening technique which allows to select materials at sub-ppt level of impurities. The drawback is that ICP-MS cannot assess whether the uranium and thorium chains are out of equilibrium and to reach ultra-high sensitivities one needs to carefully prepare and handle the samples in a cleanroom environment. ICP-MS screening must be coupled with other methods to properly assess the radio-purity of materials in the context of rare events searches. The Glow Discharge Mass Spectroscopy (GDMS) is a trace element analysis technique somehow alternative to ICP-MS. An advantage of GDMS is the possibility to determine the bulk composition of the sample, assuming homogeneity. Sensitivities of the order of 10 ppt can be achieved.

A third screening technique is based on neutron activation analysis (NAA) [256]. A sample exposed to a neutrons flux can be activated to form radioactive isotopes which can be detected using HPGe detectors or ICP-MS. Considering the difficulties to irradiate samples, this method is less often used. NAA can probe sensitivities at the level of 0.01 μBq/kg.

In case out of secular equilibrium conditions are measured for uranium and thorium from GS screening, a rigorous assessment cannot avoid radon emanation measurements. This matter is discussed in Section 36.6.3.

Complementarity between radio-purity assay techniques is a crucial parameter to design detectors for rare phenomena searches. As it has been pointed out above, requirements can be more stringent than the best sensitivity which can be obtained with the current radioassay techniques. In these cases, a number of prototype detectors have been built and operated to prove the feasibility to reach ultra-low backgrounds.

36.6.3 *Radon and its progeny*

Radon is considered to be rare in nature because most of its isotopes are short-lived. However, ^{222}Rn ($T_{1/2}$=3.82 d) is of particular concern in our context. ^{222}Rn is produced by ^{226}Ra and is a radioactive noble gas which can move within active detector components. ^{222}Rn daughters are heavy metals which can deposit on surfaces. Diffusive ^{222}Rn, supported by ^{226}Ra, can deposit on surfaces the long-lived ^{210}Pb, which is a major concern for low counting experiments. In addition, due to $\sim$100 keV nuclear recoil energies from alpha decays in the ^{226}Ra sub-chain, eventually ^{210}Pb can be implanted into a sub-surface layer of a material exposed to radon. This sub-surface contamination can remain even after surface cleaning. Surface contamination of ^{210}Pb is a serious background for direct dark matter experiments through alpha decay of ^{210}Po, which can generate neutrons by (α,n) reactions. Low energy beta/gamma emissions from ^{210}Pb are also a concern. Therefore, radon-free cleanrooms are essential for the assembly of the detector components. Effective radon abatement systems are available for this purpose.

In assembling and commissioning rare events experiments, special care must be dedicated to the estimate of radon emanation of the materials and continuous radon monitoring. For this purpose different methods for radon assay have been developed and exploited since the beginning of solar neutrino observations. ^{222}Rn atoms are collected inside an exhalation chamber for several half-lives before adsorption and counting. Detection limits of the order of 100 μBq (about 50 ^{222}Rn atoms) can be obtained with $\sim$50 l stainless steel electro-polished chambers [257]. This limit can be pushed down to 30 μBq for 1-liter scale chamber. Emanation of large vessels (cryostats, storage tanks, purification columns) can be determined by collecting exhaled radon into transportable charcoal traps [258]. The same method can be used for liquid samples. In this case instead of evacuating the exhalation chamber into a charcoal trap, He is flushed through a sparger tube for about 10 times the volume of the liquid used. Sensitivities of the order of 10 μBq/kg have been reached.

Nitrogen or synthetic air is often used in rare events experiments for purging, stripping, and assembling the experimental apparatus. These gases might contain radon. In gases ^{222}Rn can also be detected using electrostatic collection of ^{218}Po and ^{214}Po [259,260]. Sensitivities of the order of mBq/m^3 can be obtained. In Borexino three grades of nitrogen purity were used: regular purity, high purity, and low argon and krypton purity. The regular purity is obtained from boil-off gas and has radon, measured with the method reported above, at the level of $< 100\mu$Bq/m^3. For stripping the purified liquid scintillator a higher purity is needed.

To remove radon from regular purity nitrogen a dedicated absorber plant has been built. This system can reduce radon by a factor of 100. Finally, we mention that not only radon is found in nitrogen. For specific applications the long-lived ^{39}Ar and ^{85}Kr in nitrogen are an important source of background.

36.6.4 *Surface backgrounds*

Surface contamination of long-lived ^{222}Rn daughters can be challenging in low-counting experiments. Considering required sensitivities of the next generation experiments, this source of background has to be properly quantified and mitigated. Therefore, exposure to ^{222}Rn should be monitored and limited to reduce build-up of ^{210}Pb on surfaces. In addition, ^{222}Rn exposure could also produce sub-surface contamination as discussed in Section 36.6.3. For one cannot avoid radon contamination in many circumstances during production of detectors components, it is crucial to quantify the effectiveness of cleaning aiming at removing surface contamination of ^{210}Pb, ^{210}Bi, and ^{210}Po. A simple cleaning procedure, which implies degreasing, wiping, and rinsing the material surfaces is not effective in removing these surface contaminants. Studies of cleaning procedures have been carried out exposing stainless steel, copper and other materials to a strong radon source. Etching and electropolishing with subsequential passivation and rinsing have been investigated in great details. Several recipes for etching and electropolishing have been proposed [261]. Electropolishing has been shown to be very effective in reducing ^{210}Pb, ^{210}Bi, and ^{210}Po from both copper and stainless steel by a factor greater than 100. Etching, which is easier to perform than electropolishing, followed by passivation and rinsing with deionized water is effective in reducing ^{210}Pb and ^{210}Bi by a factor between 50 and 100. However, it is less effective for ^{210}Po, which in copper is very poorly reduced. Removing ^{210}Po from surfaces is crucial, therefore, naturally ^{210}Po contaminated copper and stainless steel surfaces have been deeply investigated with a high sensitivity (1 mBq/m^2) alpha spectrometer [262]. After multi-etching steps (≥ 3), followed by a passivation, a reduction of order 100 has been obtained. On the contrary, static etching (single step) is poorly effective. Electropolishing, or multi-etching are recommended in case copper is in direct contact with the active core of the detector and ultra-high radio-purity is essential or when copper electroforming cannot be used. Electroplating of a thin layer of high radio-pure copper onto the surface of less radio-pure copper has also been investigate to mitigate surface background [262]. This technique is shown to be efficient in reducing surface activity of ^{210}Po when electroformed copper is used [262].

Besides copper and steel other materials often used, such as polyethylene and teflon, have been investigated to understand how to reduce radon plate-out contaminations [263].

As far as surface contamination is concerned particulate fallout in cleanroom environments could be of concern. In general, chemical composition of dust reflects local composition of soil and dust. This is not necessarily true in cleanroom spaces, where the composition of dust depends on ongoing activities and handled materials [264]. The rate of fallout is an important information in the framework of rare events experiments, where assembling is performed in cleanrooms. The ^{210}Pb contamination, inferred from stable lead measured by ICP-MS, due to dust fallout has been investigated [264]. This contamination has a different origin with respect to ^{210}Pb from radon progeny implantation. Ultimately, one can conclude that radon exposure is more crucial than dust fallout. Therefore, the best practice for rare events experiments to face surface background contamination is to perform cleaning and assembling in a radon-free cleanroom environment.

36.6.5 *Mitigation of backgrounds and active background discrimination*

In this Section we discuss a selection of different background mitigation techniques used in experiments to search for rare events in deep underground laboratories. This includes both the avoidance or reduction of specific radioactive contamination, as well as active background suppression techniques based on specific event features and topologies.

- *Mitigation of ^{222}Rn daughters deposition.* In dark matter direct search radiogenic (α,n) reactions due to radioactive decays are of great concern. The emitted neutron can mimic a nuclear recoil induced by a dark matter particle interaction. In the DarkSide-50 and LUX-ZEPLIN (LZ) experiments to mitigate this background, cleaning of parts and assembling of the dual-phase Time Projection Chamber have been carried out in a radon-free cleanroom with ^{222}Rn activity of the order of $\lesssim 50\,\mathrm{mBq/m^3}$.
- *Underground argon.* Liquid argon is an excellent scintillator to search for dark matter interactions due to the high electron-recoils rejection power through pulse shape discrimination. Events from $\beta-\gamma$ background can be rejected at the level of 10^7 or better with respect to nuclear-recoils. Liquid argon is very effective as active shield and has been used in experiments for neutrinoless double beta decay. However, a major drawback for dark matter search using argon as a target is due to the fact that atmospheric argon contains about 1 Bq/kg of cosmogenic ^{39}Ar ($T_{1/2}$=269 y, Q_β=565 keV) [265]. For neutrinoless double beta decay search using argon as an active veto, ^{42}Ar ($T_{1/2}$=32.9 y, Q_β=599 keV) with its short lived progeny ^{42}K ($T_{1/2}$=12 h, Q_β=3525 keV) is a major source of background. ^{39}Ar limits significantly the dark matter and ^{42}Ar the neutrinoless double beta decay sensitivity search. Therefore, a source of argon with reduced ^{39}Ar and ^{42}Ar is crucial. Centrifugation or differential thermal diffusion are established methods to separate $^{39/42}$Ar and ^{40}Ar. However, this is an expensive method for a large fiducial mass. Argon from underground natural gas reservoirs is shown to contain low ^{39}Ar [266], and it is expected that ^{42}Ar is similar or even strongly reduced. Therefore, the use of underground argon mitigates the $^{39/42}$Ar backgrounds. DarkSide-50, with a mass of 150 kg of underground argon, has shown that this source of argon contains ^{39}Ar at a level reduced by a factor of $(1.4 \pm 0.3) \times 10^3$ with respect to atmospheric argon [267]. DarkSide-20k and LEGEND-1000 are planning to exploit underground argon from the Urania facility with a production capacity of 330 kg/day [268]. The former to reduce ^{39}Ar and the latter ^{42}Ar.
- *Electro-formed copper.* High radio-purity copper is often used as shielding and as core detectors components. The radioimpurities in the copper can be a dominant source of external background. Copper electro-forming is a technique used to reduce this background component in rare events experiments. Copper electro-forming is a well known process to obtain ultra-high radio-purity copper. This technique has been used in the framework of the Majorana experiment to search for neutrinoless double beta decay and in ANAIS to search for dark matter annual modulation. Sub-ppt levels in uranium and thorium have been achieved with electro-formed copper [269].
- *Background suppression using topological event information.* In addition to rigorous selection of high-purity target and shielding materials from external radiation, additional active suppression techniques must usually be employed in low background experiments to achieve the appropriate experimental sensitivities. While signal and background events may be indistinguishable if only their energy deposition is measured, their event features may differ significantly in time and space. Liquid scintillators use the characteristic photon emission time distributions to distinguish between electron- and alpha-like signals [270] and nuclear recoils [271], respectively. High-purity germanium detectors use the time evolution of the induced charges to separate point-like signal candidates for neutrinoless double-beta decay events from background signals induced, for example, by gamma interactions with multiple interactions within a crystal, or from β or α events on the n+ or p+ electrodes [272]. The operation of bare high-purity germanium detectors in an instrumented liquid argon shield enabled the GERDA and LEGEND experiments to identify backgrounds with signal-like event topology within the HPGe detectors, but with characteristic energy deposition in the surrounding liquid argon. These synergistic back-

ground suppression techniques enabled for a first time ever a quasi background-free search for neutrinoless double beta decays with GERDA [273].

EXO-200 [190] exploited topological event information distinghuishing single-site against multi-site events with a liquid xenon TPC for neutrinoless double beta decay in ^{136}Xe to reject background and threby enhancing signal discovery sensitivity. With a gas xenon TPC the NEXT experiment will fully exploit the differences in the spatial ionization patterns of double beta decay and single electron events [274]. The former is characterized by two Bragg peaks at opposite ends of the tracks, the latter on the contrary displays only one peak. The combination of topology information and good energy resolution offer a powerful tool for background rejection. In general, the 3D reconstruction of detected events in a multivariate fit, which accounts for spacial surface and bulk distributions of signal and background together with other properties, such as pulse shape and topological features, is a powerful tool for background mitigation.

- *Signal selection in direct Dark Matter experiments.* In direct dark matter experiments electron recoil events have to be mitigated with respect to nuclear recoil events. In semiconductor bolometers, operating at a few tens of mK under a bias electric field and used as calorimeters, drifting charges produce a large phonon signal proportional to the ionization, which allows to discriminate electron recoils by the combination of charge and phonon signals [275]. In scintillating bolometers the phonon and light signals are used for the same purpose [276]. Cryogenic scintillators, such as xenon and argon, in time projection chambers offer a strong electron recoils background mitigation through the detection of a primary scintillation signal in liquid and a secondary signal in gas from the drift and extraction of ionization electrons. This background mitigation technique is also being used for neutrinoless double beta decay with ^{136}Xe. The accurate fiducialization and good rejection of multiple-scattering events allow dark matter optimized experiments to attempt a search for this very rare phenomenon.
- *Neutron tagging.* Present and next generation experiments need large neutron tagging detectors. In DarkSide-50 a dedicated active veto has been developed to both suppress and measure *in situ* the rate of neutron-induced background events [277]. The detector consisted of a boron-loaded liquid scintillator, which served both as shielding against γ-rays and as a tag for neutrons. Neutrons are thermalised and captured on ^{10}B. Experimental data has shown a neutron rejection power greater than 99.1% with 5% concentration of TMB in 30 tonnes pseudocumene-based liquid scintillator. The LZ direct dark matter detector with a central TPC of 7 tonnes of liquid xenon makes use of an outer Gd-loaded liquid scintillator neutron tagging veto, which works similarly to the DarkSide-50 veto, replacing boron with gadolinium. The 22 tonnes liquid scintillator is based on linear alkyl benzene (LAB) as solvent. This detector has been designed to operate with a neutron tagging efficiency greater than 95%. The nuclear-recoil background is reduced by a factor of 10. The XENONnT detector is making use of a cylindrical stainless steel tank filled with Gd-loaded water, which surrounds the cryostat with a TPC of 5.9 tonnes of active liquid xenon. The Gd concentration in water is 0.2% in mass. Neutrons leaving the TPC volume will be moderated and captured by the Gd with a probability of 91%. The gamma-rays emitted after the capture are detected from Cherenkov photons, providing a neutron tagging [278].

  Neutron tagging techniques are also crucial for coherent neutrino-nucleus elastic scattering detection from pion-decay-at-rest neutrino source at spallation sources [279, 280]. Neutrons can be produced in the Pb shielding from CC and NC interactions and propagate into the nuclear recoil sensitive volume, generating a beam-related background. Careful shielding design and implementation of neutron tagging is crucial.
- *Mitigation of cosmogenic background.* In recent years the required sensitivity to search for dark matter and neutrinoless double beta decay asks for a strong reduction of cosmogenic background. Muons can produce neutrons that can enter the active volume of the detector from the surrounding rock or from external detector components. The yield of these so-called *cosmogenic neutrons* depend on the muon energies and the material properties of the medium the muon passes through. In addition, muons can produce by spallation radioisotopes inside the detector active volume. Cosmogenic backgrounds are a function of depth and experimental design, and can limit the sensitivity to search for rare events. Most of these radioisotopes are short-lived and their effect can be easily removed by an active veto based on the time correlation with a crossing muon. However, a number of cosmogenic radioisotopes are long-lived and they require an important consideration. Mitigation of these cosmogenic backgrounds produced in-situ deep underground are a major challenge for upcoming and future experiments. Optimizing the detector design and analysis strategies at a given depth equals an effective muon flux reduction. In particular, we mention two discrimination techniques for muon-induced isotopes: 1) ^{11}C tagging by a three-fold coincidence between the crossing muon, the capture of the ejected neutron from ^{12}C, and the ^{11}C decay [281]; 2) similar delayed coincidence tagging can be exploited to mitigate the background due to ^{77}Ge and its metastable state ^{77m}Ge, which have been identified as dominant cosmogenic background in the search for neutrinoless double beta decay of ^{76}Ge [282].
- *Purification.* A number of high efficiency specific purification methods have been developed for different detectors in order to remove long-lived radio-isotopes, ^{39}K, ^{85}Kr, and ^{210}Pb progeny. For organic liquid scintillators, distillation and water extraction have been shown to be very effective to reach radiopurity levels of the order of $10^{-5}\mu$Bq/kg or better in uranium and thorium, and $10^{-3}\mu$Bq/kg in ^{210}Pb [283]. Distillation has been used to reduce ^{85}Kr in xenon by a factor of 10^3 [284]. Cryogenic distillation can be used to reduce the isotopic abundance of ^{39}Ar in argon extracted from underground with a 350 m column in the ARIA project [285]. For semiconductors [286] and scintillating crystals [287] zone-refining followed by single-crystal growth has been exploited to remove impurities at the cost of a small fraction of material kept after the purification.
- *Direct isotope tagging.* In neutrinoless double beta decay in order to explore half-lives greater than 10^{28} y one needs an almost background-free detector. The most robust signature is the identification of the daughter atom in the decay: for example, for ^{136}Xe, the $^{136}Ba^{2+}$. Important step forwards to establish a valid and promising method for this tagging have been recently made [288, 289].

37. Radioactivity and Radiation Protection

Revised July 2023 by S. Roesler (CERN) and M. Silari.

37.1 Definitions [1–3]

It would be desirable if legal protection limits could be expressed in directly measurable *physical quantities*. However, this does not allow quantifying biological effects of the exposure of the human body and its detriment to ionizing radiation.

For this reason, dose limits are expressed in terms of so-called *protection quantities* which, although calculable, are not measurable. Protection quantities are used to quantify the extent of exposure of the human body to ionizing radiation from both whole and partial body external irradiation and from intakes of radionuclides.

In order to demonstrate compliance with dose limits, so-called *operational quantities* are typically used, which aim at providing conservative estimates of protection quantities. Often radiation protection detectors used for individual and area monitoring are calibrated in terms of operational quantities and, thus, these quantities become "measurable".

37.1.1 *Physical quantities*

• **Fluence,** Φ (unit: $1/\mathrm{m}^2$): The fluence is the quotient of the sum of the particle track lengths dl in the volume dV

$$\Phi = dl/dV \ .$$

It can also be expressed in terms of number of particles dN incident upon a small sphere of cross-sectional area da

$$\Phi = dN/da \ .$$

• **Absorbed dose,** D (unit: gray, 1 Gy=1 J/kg=100 rad): The absorbed dose is the energy imparted by ionizing radiation in a volume element of a specified material divided by the mass of this volume element.

• **Kerma,** K (unit: gray): Kerma is the sum of the initial kinetic energies of all charged particles set in motion by indirectly ionizing radiation in a volume element of the specified material divided by the mass of this volume element.

• **Linear energy transfer,** L **or** LET (unit: J/m, often given in keV/μm, 1 keV/μm $\approx 1.602 \times 10^{-10}$ J/m): The linear energy transfer is the mean energy, dE, lost by a charged particle owing to collisions with electrons in traversing a distance dl in matter. *Low-LET radiation:* X rays and gamma rays (accompanied by charged particles due to interactions with the surrounding medium) or light charged particles such as electrons that produce sparse ionizing events far apart at a molecular scale ($L < 10$ keV/μm). *High-LET radiation:* neutrons and heavy charged particles that produce ionizing events densely spaced at a molecular scale ($L > 10$ keV/μm). While the above LET definition refers to electronic stopping power only, at low energy nuclear stopping power could be a significant fraction of the total stopping power.

• **Activity,** A (unit: Becquerel, 1 Bq=1/s=27 pCi): Activity is the expectation value of the number of nuclear decays occurring in a given quantity of material per unit time.

37.1.2 *Protection quantities*

• **Organ absorbed dose,** D_T (unit: gray): The mean absorbed dose in an organ or tissue T of mass m_T is defined as

$$D_T = \frac{1}{m_T} \int_{m_T} D dm \ .$$

• **Equivalent dose,** H_T (unit: sievert, 1 Sv=1 J/kg=100 rem):

The equivalent dose H_T in an organ or tissue T is equal to the sum of the absorbed doses $D_{T,R}$ in the organ or tissue caused by different radiation types R weighted with so-called radiation weighting factors w_R:

$$H_T = \sum_R w_R \times D_{T,R} \ .$$

It expresses long-term risks (primarily cancer and leukemia) from low-level chronic exposure. The values for w_R recommended by ICRP [2] are given in Table 37.1.

Table 37.1: Radiation weighting factors, w_R.

Radiation type	w_R
Photons, electrons and muons	1
Neutrons, $E_n < 1$ MeV	$2.5 + 18.2 \times \exp[-(\ln E_n)^2/6]$
1 MeV $\leq E_n \leq$ 50 MeV	$5.0 + 17.0 \times \exp[-(\ln(2E_n))^2/6]$
$E_n >$ 50 MeV	$2.5 + 3.25 \times \exp[-(\ln(0.04E_n))^2/6]$
Protons and charged pions	2
Alpha particles, fission fragments, heavy ions	20

• **Effective dose,** E (unit: sievert): The sum of the equivalent doses, weighted by the tissue weighting factors w_T ($\sum_T w_T = 1$) of several organs and tissues T of the body that are considered to be most sensitive [2], is called "effective dose":

$$E = \sum_T w_T \times H_T \ . \tag{37.1}$$

37.1.3 *Operational quantities*

• **Dose equivalent,** H (unit: sievert): The dose equivalent at a point in tissue is given by:

$$H = D \times Q \tag{37.2}$$

where D is the absorbed dose and Q is the quality factor at that point. The quality factor at a point in tissue, is given by:

$$Q = \frac{1}{D} \int_{L=0}^{\infty} Q(L) D_L dL$$

where D_L is the distribution of D in unrestricted linear energy transfer L at the point of interest, and $Q(L)$ is the quality factor as a function of L. The integration is to be performed over D_L, due to all charged particles, excluding their secondary electrons.

• **Ambient dose equivalent,** $H^*(10)$ (unit: sievert): The dose equivalent at a point in a radiation field that would be produced by the corresponding expanded and aligned field in a 30 cm diameter sphere of unit density tissue (so-called ICRU sphere/tissue with a mass composition of 76.2% oxygen, 11.1% carbon, 10.1% hydrogen and 2.6% nitrogen) at a depth of 10 mm on the radius vector opposing the direction of the aligned field. Ambient dose equivalent is the operational quantity for *area monitoring*.

• **Personal dose equivalent,** $H_p(d)$ (unit: sievert): The dose equivalent in ICRU tissue at an appropriate depth, d, below a specified point on the human body. The specified point is normally taken to be where the individual dosimeter is worn. For the assessment of effective dose, $H_p(10)$ with a depth $d = 10$ mm is chosen, and for the assessment of the dose to the skin and to the hands and feet the personal dose equivalent, $H_p(0.07)$, with a depth $d = 0.07$ mm, is used. Personal dose equivalent is the operational quantity for *individual monitoring*.

37.1.4 *Dose conversion coefficients*

Dose conversion coefficients allow direct calculation of protection or operational quantities from particle fluence and are functions of particle type, energy and irradiation configuration. The most common coefficients are those for effective dose and ambient dose equivalent. The former are based on simulations in which the dose to organs of anthropomorphic phantoms is calculated for approximate actual conditions of exposure, such as irradiation of the front of the body (antero-posterior irradiation) or isotropic irradiation.

Conversion coefficients from fluence to effective dose are given for anterior-posterior irradiation and various particle types in Fig. 37.1 [4]. For example, the effective dose from an anterior-posterior irradiation in a field of 1-MeV neutrons with a fluence of 1 neutron per cm^2 is about 290 pSv. In Monte Carlo simulations such coefficients allow multiplication with fluence at scoring time such that effective dose to a human body at the considered location is directly obtained.

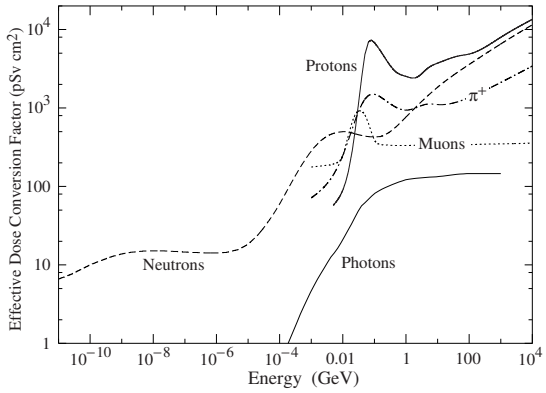

Figure 37.1: Fluence to effective dose conversion coefficients for anterior-posterior irradiation and various particle types [4].

37.2 Radiation levels [5]

• **Natural background radiation**:

On a worldwide average, the annual whole-body dose equivalent due to all sources of natural background radiation ranges from 1.0 to 13 mSv (0.1–1.3 rem) with an annual average of 2.4 mSv [6]. In certain areas values up to 50 mSv (5 rem) have been measured. A large fraction (typically more than 50%) originates from inhaled natural radioactivity, mostly radon and radon daughters [7]. The latter can vary by more than one order of magnitude: it is 0.1–0.2 mSv in open areas, 2 mSv on average in a house and more than 20 mSv in poorly ventilated mines.

• **Cosmic ray background radiation**: At sea level, the whole-body dose equivalent due to cosmic ray background radiation is dominated by muons; at higher altitudes also nucleons contribute. Dose equivalent rates range from less than 0.1 μSv/h at sea level to a few μSv/h at aircraft altitudes. Details on cosmic ray fluence levels are given in the Cosmic Rays section (Sec. 30 of this *Review*).

37.3 Health effects of ionizing radiation

Radiation can cause two types of health effects, deterministic and stochastic:

• **Deterministic effects** are tissue reactions which cause injury to a population of cells if a given threshold of absorbed dose is exceeded. The severity of the reaction increases with dose. The quantity in use for tissue reactions is the absorbed dose, D. When particles other than photons and electrons (low-LET radiation) are involved, a Relative Biological Effectiveness (RBE)-weighted dose may be used. The RBE of a given radiation is the reciprocal of the ratio of the absorbed dose of that radiation to the absorbed dose of a reference radiation (usually X rays) required to produce the same degree of biological effect. It is a complex quantity that depends on many factors such as cell type, dose rate, fractionation, etc.

• **Stochastic effects** are malignant diseases and heritable effects for which the probability of an effect occurring, but not its severity, is a function of dose without threshold.

• **Lethal dose**: The whole-body dose from penetrating ionizing radiation resulting in 50% mortality in 30 days (assuming no medical treatment) is 2.5–4.5 Gy (250–450 rad)[1], as measured internally on the body longitudinal center line. The surface dose varies due to variable body attenuation and may be a strong function of energy.

• **Cancer induction**:

The cancer induction probability is about 5% per Sv on average for the entire population [3].

• **Recommended effective dose limits**: The International Commission on Radiological Protection (ICRP) recommends a limit for radiation workers of 20 mSv effective dose per year averaged over 5 years, with the provision that the dose should not exceed 50 mSv in any single year [3]. The limit in the EU-countries and Switzerland is 20 mSv per year, in the U.S. it is 50 mSv per year (5 rem per year). Many physics laboratories in the U.S. and elsewhere set lower limits. The effective dose limit for the general public is typically 1 mSv per year.

[1] RBE-weighted when necessary

37.4 Prompt neutrons at accelerators

Neutrons dominate the radiation environment outside thick shielding (*e.g.*, > 1 m of concrete) for high energy (> a few hundred MeV) electron and hadron accelerators. In addition, for accelerators with energies above about 10 GeV, muons contribute significantly at small angles with regard to the beam, even behind several meters of shielding. Another special case are synchrotron light sources where particular care has to be taken to shield the very intense low-energy photons extracted from the electron synchrotron into the experimental areas. Due to its importance at high energy accelerators this section focuses on prompt neutrons.

37.4.1 *Electron accelerators*

At electron accelerators, neutrons are generated via photonuclear reactions from bremsstrahlung photons. Neutron production takes place above a threshold value which varies from 10 to 19 MeV for light nuclei (with important exceptions, such as 2.23 MeV for deuterium and 1.67 MeV for beryllium) and from 4 to 6 MeV for heavy nuclei. It is commonly described by different mechanisms depending on the photon energy: the giant dipole resonance interactions (from threshold up to about 30 MeV, often the dominant process), the quasi-deuteron effect (between 30 MeV and a few hundred MeV), the delta resonance mechanism (between 200 MeV and a few GeV) and the vector meson dominance model at higher energies.

The giant dipole resonance reaction consists in a collective excitation of the nucleus, in which neutrons and protons oscillate in the direction of the photon electric field. The oscillation is damped by friction in a few cycles, with the photon energy being transferred to the nucleus in a process similar to evaporation. Nucleons emitted in the dipolar interaction have an anisotropic angular distribution, with a maximum at 90°, while those leaving the nucleus as a result of evaporation are emitted isotropically with a Maxwellian energy distribution described as [8]:

$$\frac{dN}{dE_n} = \frac{E_n}{T^2} e^{-E_n/T} \ , \qquad (37.3)$$

where T is a nuclear 'temperature' (in units of MeV) characteristic of the particular target nucleus and its excitation energy. For heavy nuclei the 'temperature' generally lies in the range of $T =$ 0.5–1.0 MeV. Neutron yields from semi-infinite targets per kW of electron beam power are plotted in Fig. 37.2 as a function of the electron beam energy [8].

While for thick targets neutron production is mainly due to photonuclear interactions, for thin targets (thickness of fractions of the radiation length) electronuclear interactions are the dominating process.

Typical neutron energy spectra outside of concrete (80 cm thick, 2.35 g/cm^3) and iron (40 cm thick) shields are shown in Fig. 37.3. In order to compare these spectra to those caused by proton beams (see below) the spectra are scaled by a factor of 100, which roughly corresponds to the difference in the high energy hadronic cross sections for photons and hadrons (*e.g.*, the fine structure constant). The shape of these spectra are generally characterized by a low-energy peak at around 1 MeV (evaporation neutrons) and a high-energy shoulder at around 70–80 MeV. In case of concrete shielding, the spectrum also shows a pronounced peak at thermal neutron energies.

37.4.2 *Proton accelerators*

At proton accelerators, neutron yields emitted per incident proton by different target materials are roughly independent of proton energy between 20 MeV and 1 GeV, and are given by the ratio C : Al : Cu-Fe : Sn : Ta-Pb = 0.3 : 0.6 : 1.0 : 1.5 : 1.7 [11]. Above about 1 GeV, the neutron yield is proportional to E^m, where $0.80 \leq m \leq 0.85$ [12].

Typical neutron energy spectra outside of concrete and iron shielding are shown in Fig. 37.3. Here, the radiation fields are

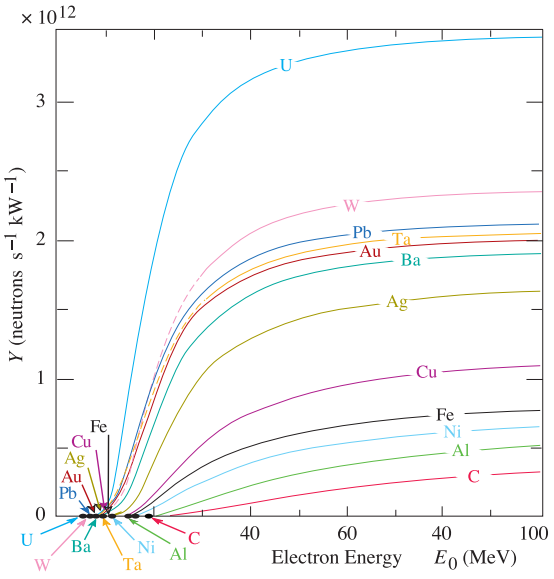

Figure 37.2: Neutron yields from semi-infinite targets per kW of electron beam power, as a function of the electron beam energy, disregarding target self-shielding [8].

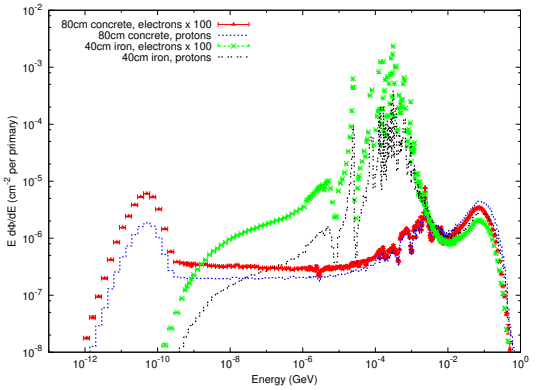

Figure 37.3: Neutron energy spectra calculated with the FLUKA code [9,10] from 25 GeV proton and electron beams on a thick copper target. Spectra are evaluated at 90° to the beam direction behind 80 cm of concrete or 40 cm of iron. All spectra are normalized per beam particle. For better visualization, spectra for electron beam are multiplied by a factor of 100.

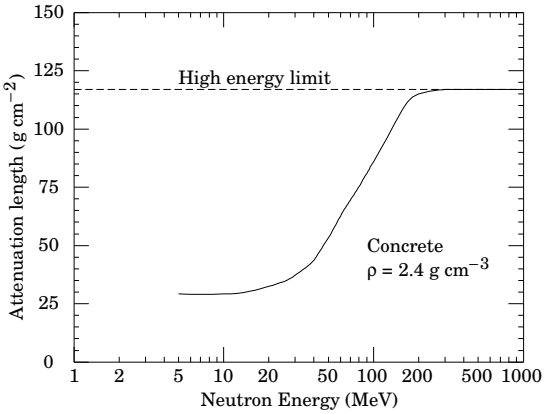

Figure 37.4: The variation of the attenuation length for mono-energetic neutrons in concrete as a function of neutron energy [11].

caused by a 25 GeV proton beam interacting with a thick copper target. The comparison of these spectra with those for an electron beam of the same energy reflects the difference in the hadronic cross sections between photons and hadrons above a few 100 MeV. Differences are increasing towards lower energies because of different interaction mechanisms. Furthermore, the slight shift in energy above about 100 MeV follows from the fact that the energies of the interacting photons are lower than 25 GeV. Apart from this the shapes of the two spectra are similar.

The neutron-attenuation length is shown in Fig. 37.4 for concrete and mono-energetic broad-beam conditions. It reaches an asymptotic value of about 117 g/cm^2 above 200 MeV. As the cascade through thick shielding is carried by particles with energies between about 100 MeV and 300 MeV (in this energy range non-elastic cross sections are at minimum and are dominated by quasi-elastic processes leading to low attenuation) this value is equal to the equilibrium attenuation length for particles emitted at 90° in concrete.

37.5 Photon sources

The dose equivalent rate in tissue (in mSv/h) from a gamma point source emitting one photon of energy E (in MeV) per second at a distance of 1 m is $4.6\times10^{-9}\,\mu_{en}/\rho\,E$, where μ_{en}/ρ is the mass energy absorption coefficient. The latter has a value of 0.029 ± 0.004 cm^2/g for photons in tissue over an energy range between 60 keV and 2 MeV (see Ref. [13] for tabulated values).

Similarly, the dose equivalent rate in tissue (in mSv/h) at the surface of a semi-infinite slab of uniformly activated material containing 1 Bq/g of a gamma emitter of energy E (in MeV) is $2.9 \times 10^{-4}\,R_\mu\,E$, where R_μ is the ratio of the mass energy absorption coefficients of the photons in tissue and in the material.

37.6 Accelerator-induced radioactivity

Typical medium- and long-lived activation products in metallic components of accelerators are ^{22}Na, ^{46}Sc, ^{48}V, ^{51}Cr, ^{54}Mn, ^{55}Fe, ^{59}Fe, ^{56}Co, ^{57}Co, ^{58}Co, ^{60}Co, ^{63}Ni and ^{65}Zn. Gamma-emitting nuclides dominate doses from external irradiation at longer decay times (more than one day) while at short decay times β^+ emitters are also important (through photons produced by β^+ annihilation). Due to their short range, β^- emitters are relevant, for example, only for dose to the skin and eyes or for doses due to inhalation or ingestion. Fig. 37.5 and Fig. 37.6 illustrate the contributions of gamma and β^+ emitters to the total dose rate at 12.4 cm distance to a copper sample [14]. The sample was activated by the stray radiation field created by a 120 GeV mixed hadron beam dumped in a copper target during about 8 hours at intensities between $10^7 - 10^8$ hadrons per second. Here, the contributions by individual nuclides were calculated analytically assuming exponential decay of the nuclide inventory present at 20 minute cooling time. The total dose rate, however, also includes decay chains and as such also contributions from daughter nuclides.

Typically, dose rates at a certain decay time are mainly determined by radionuclides having a half-life of the order of the decay time. Extended irradiation periods might be an exception to this general rule as in this case the activity of long-lived nuclides can build up sufficiently so that it dominates that one of short-lived even at short cooling times.

Activation in concrete is dominated by ^{24}Na (short decay time) and ^{22}Na (long decay time). Both nuclides can be produced either by low-energy neutron reactions on the sodium-component in the concrete or by spallation reactions on silicon, calcium and other constituents such as aluminum. At long decay times nuclides of radiological interest in activated concrete can also be ^{60}Co, ^{152}Eu, ^{154}Eu and ^{134}Cs, all of which produced by (n,γ)-reactions with traces of natural cobalt, europium and cesium, Thus, such trace elements might be important even if their content in concrete is only a few parts per million or less by weight.

The explicit simulation of radionuclide production with general-purpose Monte Carlo codes has become the most commonly applied method to calculate induced radioactivity and its radiological consequences [14] (see also Sec. 37.8). They are complemented by analytical codes based on folding particle fluence spectra with nuclide production cross sections. ActiWiz [15, 16] is an example

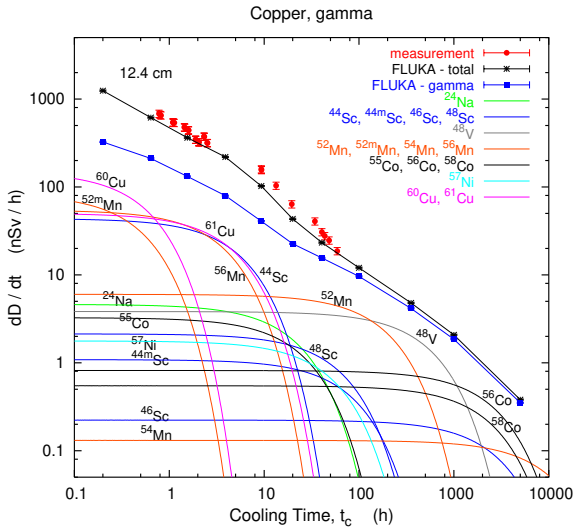

Figure 37.5: Contribution of individual gamma-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [14].

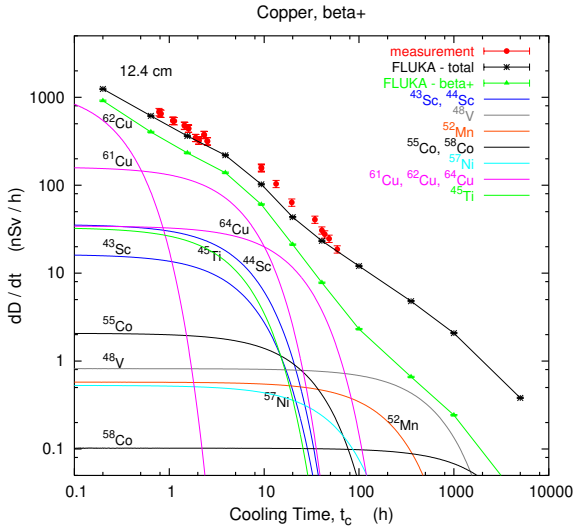

Figure 37.6: Contribution of individual positron-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [14].

of such a code targeting the domain of radiological characterization and material optimization. It allows for calculating nuclide inventories by convolution of fluence spectra with nuclide production data for 85 chemical elements and arbitrary compounds from threshold to an energy of 100 TeV.

37.7 Radiation protection instrumentation

The capacity to distinguish and measure the high-LET (mostly neutrons) and the low-LET components (photons, electrons, muons) of the radiation field at workplaces is of primary importance to evaluate the exposure of personnel. At proton accelerators the prompt dose equivalent outside a shield is mainly due to neutrons, with some contribution from photons and, to a minor extent, charged particles. At high-energy electron accelerators the dominant stray radiation during operation consists also of neutrons, because the shielding is normally thick enough to absorb most of the bremsstrahlung photons. Most of the personnel exposure at accelerator facilities is often received during maintenance interventions, and is due to gamma/beta radiation coming from residual radioactivity in accelerator components.

Radiation detectors used both for radiation surveys and area monitoring are normally calibrated in ambient dose equivalent $H^*(10)$.

37.7.1 *Neutron detectors*

• **Rem counters:** A rem counter [17] is a portable detector consisting of a thermal neutron counter embedded in a polyethylene moderator, with a response function that approximately follows the curve of the conversion coefficients from neutron fluence to $H^*(10)$ over a wide energy range. Conventional rem counters provide a response to neutrons up to approximately 10-15 MeV, extended-range units are heavier as they include a converter consisting of a material with high mass number to correctly measure $H^*(10)$ up to several hundred MeV [18].

• **Bonner Sphere Spectrometer (BSS):** A BSS [19] consists of a thermal neutron detector at the centre of moderating spheres of different diameters made of polyethylene (PE) or a combination of PE and a high-A material to enhance its response to high energy neutrons (similar to rem counters). Each sphere has a different response function versus neutron energy, and the neutron energy, at which the sensitivity peaks, increases with sphere diameter. The energy resolution of the system is rather low but satisfactory for radiation protection purposes. The neutron spectrum is obtained by unfolding the experimental counts of the BSS with its response matrix by a computer code that is often based on an iterative algorithm such as GRAVEL [20] and MAXED [21]. BSS exist in active (using ^{3}He or BF_3 proportional counters or ^{6}LiI scintillators) and passive versions (using CR-39 track detectors or LiF), for use *e.g.* in strongly pulsed fields. With ^{3}He counters the discrimination with respect to gamma rays and noise is excellent.

• **Bubble detectors:** A bubble detector [22] is a dosimeter based on a super-heated emulsion (super-heated droplets suspended in a gel) contained in a vial and acting as a continuously sensitive, miniature bubble chamber. The total number of bubbles evolved from the radiation-induced nucleation of drops gives an integrated measure of the total neutron exposure. Various techniques exist to record and count the bubbles, *e.g.*, visual inspection, automated reading with video cameras or acoustic counting. Bubble detectors are insensitive to low-LET radiation. Super-heated emulsions are used as personal, area and environmental dosimeters, as well as neutron spectrometers.

• **Track etched detectors:** Track etched detectors (TEDs) [23] are based on the preferential dissolution of suitable, mostly insulator, materials along the damage trails of charged particles of sufficiently high-energy deposition density. The detectors are effectively not sensitive to radiation which deposits the energy through the interactions of particles with low LET. These dosimeters are generally able to determine neutron ambient dose equivalent down to around 100 μSv. They are used both as personal dosimeters and for area monitoring, *e.g.*, in BSS.

37.7.2 *Photon detectors* [24]

• **Geiger Müller (GM) counters:** GM counters are low cost devices simple to operate. They work in pulse mode and since they only count radiation-induced events, any spectrometric information is lost. In general they are calibrated in terms of air kerma, for instance in a ^{60}Co field. The response of GM counters to photons is constant within 15% for energies up to 2 MeV and shows considerable energy dependence above.

• **Ionization chambers:** Ionization chambers are gas-filled detectors used both as hand-held instruments (*e.g.*, for radiation surveys) and environmental monitors. They are normally operated in current mode although pulse-mode operation is also possible. They possess a relatively flat response to a wide range of X- and gamma ray energies (typically from 10 keV to several MeV), can measure radiation over a wide intensity range and are capable of discriminating between the beta and gamma components of a radiation field (by use of, *e.g.*, a beta window). Pressurized ion chambers (filled, *e.g.*, with Ar or H gas to several tens of bars) are used for environmental and stray radiation monitoring applications. They have good sensitivity to neutrons and charged hadrons in addition to low LET radiation (gammas and muons), with the response function to the former being strongly non-linear

with energy.

• **Proportional counters:** Proportional counters are another type of gas-filled detector, operated in pulse mode. They are normally of cylindrical geometry, with a thin central wire (the anode) on the axis of a hollow tube (the cathode). The initial electron charge created by the interaction of the radiation with the gas is amplified by the multiplication process (Townsend avalanche) produced by the strong electric field in a narrow volume around the anode. The generated pulses are still proportional to the original number of ion pairs but are much larger than in an ionization chamber, yielding a much improved signal-to-noise ratio. Proportional counters are also used for neutron detection: the rem counter and BSS discussed in the previous sections typically employ ^{3}He or BF_3 filled tubes with a large sensitivity to thermal neutrons.

• **Scintillators:** Scintillation-based detectors are used in radiation protection as hand-held probes and in fixed installations, *e.g.*, portal monitors. A scintillation detector or counter is obtained coupling a scintillator to an electronic light sensor such as a photomultiplier tube (PMT), a photodiode or a silicon photomultiplier (SiPM). There is a wide range of scintillating materials, inorganic (such as CsI and BGO), organic or plastic; they find application in both photon dosimetry and spectrometry.

37.7.3 *Operation in pulsed radiation fields*

There are many practical situations with particle accelerators used for scientific, industrial and medical applications where the time structure of the stray radiation limits the use of active monitors or requires specifically designed electronics. Pulsed neutron and gamma fields may be present because of beam losses at, *e.g.*, targets, collimators and beam dumps. The time duration of a single burst can range from a few ns to about 1 ms with a typical repetition rate in the range 0.1–100 Hz. Conventional detectors generally suffer from dead time effects and have strong limitations in the measurements of pulsed fields. Severe under response has been observed, *e.g.*, in commercial rem counters, with tremendous underestimation of the ambient dose equivalent, $H^*(10)$, up to three orders of magnitude [25]. The common techniques used to correct the response of radiation detectors which include dead-time corrections operate properly in a steady-state radiation field, whereas it is much more difficult to cope with dead time losses in a pulsed radiation field of unknown time structure and burst dose. Generally speaking the monitoring instrumentation must be chosen on the basis of the knowledge of the radiation field. Detectors with specifically designed electronics must be employed in pulsed field conditions in place of conventional rem counters for neutrons, such as the LUPIN detector [26]. If real-time monitoring is not required, passive detectors or dosimeters such as TEDs mentioned in Sec. 37.7.1 or LiF mentioned in Sec. 37.7.5 can be employed, as they are insensitive to the time structure of the radiation.

37.7.4 *Operation in presence of magnetic fields*

There may be circumstances in which a radiation survey needs to be performed in the presence of a magnetic field. This may be the case for example for measurements on activated detector components in the underground experimental areas of CERN LHC experiments without switching off the intense magnetic field ofthe detectors; or measurements of the residual radioactivity of permanent magnets sometimes used in particle accelerators. In hospitals, one of most advanced diagnostic modalities is PET-MRI, in which PET imaging uses radioactive substances (radiopharmaceuticals) in proximity of the strong magnetic field of the MRI scanner. Most of the commercial survey meters do not operate correctly or do not function at all in the presence of even comparatively weak magnetic fields below 0.3 T, and often already at 0.1 T. This is either because of the presence of components in their electronics sensitive to magnetic field (e.g. inductive elements), ferromagnetic materials in general (such as shells, screws and frames), battery drain/heating or LCD screen failure. An instrument called B-RAD has recently been developed [27] that overcomes the above limitations and is now commercially available. It is a hand-held instrument for gamma dose rate and gamma spectrometry measurements, consisting of a central unit (housing a microcontroller, magnetic field insensitive electronic circuitry, the battery and two displays) and a probe connected through a cable, certified to operate up to 3 T fields. The probe uses a $LaBr_3$(Ce) crystal coupled to an array of silicon photomultipliers. The excellent scintillation properties and the high photon resolution of the scintillator (3.3% FWHM at 662 keV) make the device capable of operating in the energy range from 30 keV to 2 MeV photons with a very fast response.

37.7.5 *Personal dosimeters*

Personal dosimeters, calibrated in $H_p(10)$, are worn by persons exposed to ionizing radiation for professional reasons to record the dose received. They are typically passive detectors, either film, track etched detectors, ^{6}Li/^{7}Li-based dosimeters (*e.g.* LiF), optically stimulated luminescence (OSL) or radiophotoluminescence detectors (RPL) but semi-active dosimeters using miniaturized ion-chambers also exist, like the Direct Ion Storage (DIS) dosimeters in use at CERN.

Electronic personal dosimeters are small active units for on-line monitoring of individual exposure, designed to be worn on the body. They can give an alarm on both the integral dose received or dose rate once a pre-set threshold is exceeded.

37.8 Monte Carlo codes for radiation protection studies

The use of general-purpose particle interaction and transport Monte Carlo codes is often the most accurate and efficient choice for assessing radiation protection quantities at accelerators. Due to the vast spread of such codes to all areas of particle physics and the associated extensive benchmarking with experimental data, the modeling has reached an unprecedented accuracy. Furthermore, most codes allow the user to simulate all aspects of a high energy particle cascade in one and the same run: from the first interaction of a TeV nucleus over the transport and re-interactions (hadronic and electromagnetic) of the produced secondaries, to detailed nuclear fragmentation, the calculation of radioactive decays and even of the electromagnetic shower caused by the radiation from such decays. A brief account of the codes most widely used for radiation protection studies at high energy accelerators is given in the following.

• **FLUKA [9, 10, 28, 29]:** FLUKA is a general-purpose particle interaction and transport code. It comprises all features needed for radiation protection, such as detailed hadronic and nuclear interaction models up to 10 PeV, full coupling between hadronic and electromagnetic processes and numerous variance reduction options. The latter include weight windows, region importance biasing, and leading particle, interaction, and decay length biasing (among others). The capabilities of FLUKA are unique for studies of induced radioactivity, especially with regard to nuclide production, decay, and transport of residual radiation. In particular, particle cascades by prompt and residual radiation are simulated in parallel based on the microscopic models for nuclide production and a solution of the Bateman equations for activity build-up and decay.

• **GEANT4 [30–32]:** GEANT4 is an object-oriented toolkit consisting of a kernel that provides the framework for particle transport, including tracking, geometry description, material specifications, management of events and interfaces to external graphics systems. The kernel also provides interfaces to physics processes. It allows the user to freely select the physics models that best serve the particular application needs. Implementations of interaction models exist over an extended range of energies, from optical photons and thermal neutrons to high-energy interactions required for the simulation of accelerator and cosmic ray experiments. To facilitate the use of variance reduction techniques, general-purpose biasing methods such as importance biasing, weight windows, and a weight cut-off method have been introduced directly into the toolkit. Other variance reduction methods, such as leading particle biasing for hadronic processes, come with the respective physics packages.

• **MARS15 [33,34]:** The MARS15 code system is a set of Monte Carlo programs for the simulation of hadronic and electromagnetic cascades. It covers a wide energy range: 1 keV to 100 TeV for muons, charged hadrons, heavy ions and electromagnetic showers; and 0.00215 eV to 100 TeV for neutrons. Hadron-nucleus inter-

actions as well as practically all other strong, weak and electromagnetic interactions in the entire energy range can be simulated either inclusively or exclusively. MARS15 uses ENDFB-VII nuclear data to handle interactions of neutrons with energies below 14 MeV. Several variance reduction techniques, such as weight windows, particle splitting, and Russian roulette, are available. A tagging module allows tagging the origin of a given signal for source term or sensitivity analyses. The geometry module allows either a basic solid body representation option or a ROOT-based powerful engine. Further features of MARS15 include a MAD-MARS merge for a convenient creation of accelerator models and multi-turn tracking and cascade simulation in accelerator and beamline lattices.

• **MCNP6 [35, 36]:** MCNP6 is the latest version of the Monte Carlo N-Particle transport (MCNP) family of neutron interaction and transport codes and, therefore, features one of the most comprehensive and detailed descriptions of the related physical processes. It transports 37 different particle types, including ions and electromagnetic particles. The neutron interaction and transport modules use standard evaluated data libraries mixed with physics models where such libraries are not available. The transport is continuous in energy. MCNP6 contains one of the most powerful implementations of variance reduction techniques. Spherical mesh weight windows can be created by a generator in order to focus the simulation time on certain spatial regions of interest. In addition, a more generalized phase space biasing is also possible through energy- and time-dependent weight windows. Other biasing options include pulse-height tallies with variance reduction and criticality source convergence acceleration.

• **PHITS [37, 38]:** The Particle and Heavy-Ion Transport code System PHITS was among the first general-purpose codes to simulate the transport and interactions of heavy ions in a wide energy range, from 10 MeV/nucleon to 100 GeV/nucleon. It is based on the high-energy hadron transport code NMTC/JAM that was extended to heavy ions. The transport of low-energy neutrons employs cross sections from evaluated nuclear data libraries such as ENDF and JENDL below 20 MeV. Electromagnetic interactions are simulated based on the ITS code in the energy range between 1 keV and 100 MeV for electrons and positrons and between 1 keV and 100 GeV for photons. Several variance reduction techniques, including weight windows and region importance biasing, are available.

$^{241}_{95}$Am/Be	432.6 y	neutrons ($\langle E\rangle = 4$ MeV) and γ's (4.43 MeV from $^{9}_{4}\mathrm{Be}(\alpha, n)$)				
$^{244}_{96}$Cm	18.11 y	α	5.763	24%	Pu L x rays	$\sim 9\%$
			5.805	76%		
$^{252}_{98}$Cf	2.645 y	α	6.076	15%		
		(97%)	6.118	82%		
Fission (3.1%): Average 7.8 γ's/fission; $\langle E_\gamma\rangle = 0.88$ MeV ≈ 4 neutrons/fission; $\langle E_n\rangle = 2.14$ MeV						

"Emission probability" is the probability per decay of a given emission; because of cascades these may total more than 100%. Only principal emissions are listed. EC means electron capture, and e^- means monoenergetic internal conversion (Auger) electron. The intensity of 0.511 MeV e^+e^- annihilation photons depends upon the number of stopped positrons. Endpoint $\beta^\pm$ energies are listed. In some cases when energies are closely spaced, the γ-ray values are approximate weighted averages. Radiation from short-lived daughter isotopes is included where relevant.

Isotopic data may be found at `https://physics.nist.gov/cgi-bin/Compositions/stand_alone.pl`.

Neutron sources: See *e.g.* J. Liu *et al.*, "Neutron Calibration Sources in the Daya Bay Experiment" [1]. $^{51}_{24}$Cr calibration of neutrino detectors is discussed in *e.g.* J.N. Abdurashitov *et al.*, "Measurement of the response of a gallium metal solar neutrino experiment to neutrinos from a ^{51}Cr source" [2]. The use of $^{75}_{34}$Se and other isotopes has also been proposed.

Mathematical Tools or Statistics, Monte Carlo, Group Theory

39. Probability

Revised August 2021 by G. Cowan (RHUL).

39.1 General

Further discussion of probability can be found, *e.g.*, in Refs. [1–8].

An abstract definition of probability can be given by considering a set S, called the sample space, and possible subsets $A, B, \ldots$, the interpretation of which is left open. The probability P is a real-valued function defined by the following axioms due to Kolmogorov [9]:

1. For every subset A in S, $P(A) \geq 0$;
2. For disjoint subsets (*i.e.*, $A \cap B = \emptyset$), $P(A \cup B) = P(A) + P(B)$;
3. $P(S) = 1$.

In addition, one defines the conditional probability $P(A|B)$ (read as P of A given B) as

$$P(A|B) = \frac{P(A \cap B)}{P(B)} \ . \tag{39.1}$$

From this definition and using the fact that $A \cap B$ and $B \cap A$ are the same, one obtains *Bayes' theorem*,

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)} \ . \tag{39.2}$$

From the three axioms of probability and the definition of conditional probability, one obtains the *law of total probability*,

$$P(B) = \sum_i P(B|A_i)P(A_i) \ , \tag{39.3}$$

for any subset B and for disjoint A_i with $\cup_i A_i = S$. This can be combined with Bayes' theorem (Eq. (39.2)) to give

$$P(A|B) = \frac{P(B|A)P(A)}{\sum_i P(B|A_i)P(A_i)} \ , \tag{39.4}$$

where the subset A could, for example, be one of the A_i.

The most commonly used interpretation of the elements of the sample space are outcomes of a repeatable experiment. The probability $P(A)$ is assigned a value equal to the limiting frequency of occurrence of A. This interpretation forms the basis of *frequentist statistics*.

The elements of the sample space might also be interpreted as *hypotheses*, *i.e.*, statements that are either true or false, such as 'The mass of the W boson lies between 80.3 and 80.5 GeV.' Upon repetition of a measurement, however, such statements are either always true or always false, *i.e.*, the corresponding probabilities in the frequentist interpretation are either 0 or 1. Using *subjective probability*, however, $P(A)$ is interpreted as the degree of belief that the hypothesis A is true. Subjective probability is used in *Bayesian* (as opposed to frequentist) statistics. Bayes' theorem can be written

$$P(\text{theory}|\text{data}) \propto P(\text{data}|\text{theory})P(\text{theory}) \ , \tag{39.5}$$

where 'theory' represents some hypothesis and 'data' is the outcome of the experiment. Here $P(\text{theory})$ is the *prior* probability for the theory, which reflects the experimenter's degree of belief before carrying out the measurement, and $P(\text{data}|\text{theory})$ is the probability to have gotten the data actually obtained, given the theory, which is also called the *likelihood*.

Bayesian statistics provides no fundamental rule for obtaining the prior probability, which may depend on previous measurements, theoretical prejudices, *etc.* Once this has been specified, however, Eq. (39.5) tells how the probability for the theory must be modified in the light of the new data to give the *posterior* probability, $P(\text{theory}|\text{data})$. As Eq. (39.5) is stated as a proportionality, the probability must be normalized by summing (or integrating) over all possible hypotheses.

39.2 Random variables

A *random variable* is a numerical characteristic assigned to an element of the sample space. In the frequency interpretation of probability, it corresponds to an outcome of a repeatable experiment. Let x be a possible outcome of an observation. If x can take on any value from a continuous range, we write $f(x;\theta)dx$ as the probability that the measurement's outcome lies between x and $x + dx$. The function $f(x;\theta)$ is called the *probability density function* (p.d.f.), which may depend on one or more parameters θ. If x can take on only discrete values (*e.g.*, the non-negative integers), then we use $f(x;\theta)$ to denote the probability to find the value x. In the following the term p.d.f. is often taken to cover both the continuous and discrete cases, although technically the term density should only be used in the continuous case.

The p.d.f. is always normalized to unity. Both x and θ may have multiple components and are then often written as vectors. If θ is unknown, we may wish to estimate its value from a given set of measurements of x; this is a central topic of *statistics* (see Sec. 40).

The *cumulative distribution function* $F(a)$ is the probability that $x \leq a$:

$$F(a) = \int_{-\infty}^{a} f(x)\,dx \ . \tag{39.6}$$

Here and below, if x is discrete-valued, the integral is replaced by a sum. The endpoint a is expressly included in the integral or sum. Then $0 \leq F(x) \leq 1$, $F(x)$ is nondecreasing, and $P(a < x \leq b) = F(b) - F(a)$. If x is discrete, $F(x)$ is flat except at allowed values of x, where it has discontinuous jumps equal to $f(x)$.

Any function of random variables is itself a random variable, with (in general) a different p.d.f. The *expectation value* of any function $u(x)$ is

$$E[u(x)] = \int_{-\infty}^{\infty} u(x)\,f(x)\,dx \ , \tag{39.7}$$

assuming the integral is finite. The expectation value is linear, *i.e.*, for any two functions u and v of x and constants c_1 and c_2, $E[c_1u + c_2v] = c_1E[u] + c_2E[v]$.

The n^{th} moment of a random variable x is

$$\alpha_n \equiv E[x^n] = \int_{-\infty}^{\infty} x^n f(x)\,dx \ , \tag{39.8a}$$

and the n^{th} central moment of x (or moment about the mean, α_1) is

$$m_n \equiv E[(x - \alpha_1)^n] = \int_{-\infty}^{\infty} (x - \alpha_1)^n f(x)\,dx \ . \tag{39.8b}$$

The most commonly used moments are the mean μ and variance σ^2:

$$\mu \equiv \alpha_1 \ , \tag{39.9a}$$

$$\sigma^2 \equiv V[x] \equiv m_2 = \alpha_2 - \mu^2 \ . \tag{39.9b}$$

The mean is the location of the "center of mass" of the p.d.f., and the variance is a measure of the square of its width. Note that $V[cx + k] = c^2V[x]$. It is often convenient to use the *standard deviation* of x, σ, defined as the square root of the variance.

Any odd moment about the mean is a measure of the skewness of the p.d.f. The simplest of these is the dimensionless coefficient of skewness $\gamma_1 = m_3/\sigma^3$.

The fourth central moment m_4 provides a convenient measure of the tails of a distribution. For the Gaussian distribution (see Sec. 39.4), one has $m_4 = 3\sigma^4$. The *kurtosis* is defined as $\gamma_2 = m_4/\sigma^4 - 3$, *i.e.*, it is zero for a Gaussian, positive for a *leptokurtic* distribution with longer tails, and negative for a *platykurtic* distribution with tails that die off more quickly than those of a Gaussian.

The *quantile* x_α is the value of the random variable x at which the cumulative distribution is equal to α. That is, the quantile

is the inverse of the cumulative distribution function, *i.e.*, $x_\alpha = F^{-1}(\alpha)$. An important special case is the *median*, $x_{\rm med}$, defined by $F(x_{\rm med}) = 1/2$, *i.e.*, half the probability lies above and half lies below $x_{\rm med}$. (More rigorously, $x_{\rm med}$ is a median if $P(x \geq x_{\rm med}) \geq 1/2$ and $P(x \leq x_{\rm med}) \geq 1/2$. If only one value exists, it is called '*the* median.')

Under a monotonic change of variable $x \to y(x)$, the quantiles of a distribution (and hence also the median) obey $y_\alpha = y(x_\alpha)$. In general the expectation value and *mode* (most probable value) of a distribution do not, however, transform in this way.

Let x and y be two random variables with a *joint* p.d.f. $f(x,y)$. The *marginal* p.d.f. of x (the distribution of x with y unobserved) is

$$f_1(x) = \int_{-\infty}^{\infty} f(x,y)\,dy \ , \tag{39.10}$$

and similarly for the marginal p.d.f. $f_2(y)$. The *conditional* p.d.f. of y given fixed x (with $f_1(x) \neq 0$) is defined by $f_3(y|x) = f(x,y)/f_1(x)$, and similarly $f_4(x|y) = f(x,y)/f_2(y)$. From these, we immediately obtain Bayes' theorem (see Eqs. (39.2) and (39.4)),

$$f_4(x|y) = \frac{f_3(y|x)f_1(x)}{f_2(y)} = \frac{f_3(y|x)f_1(x)}{\int f_3(y|x')f_1(x')\,dx'} \ . \tag{39.11}$$

The mean of x is

$$\mu_x = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} x\,f(x,y)\,dx\,dy = \int_{-\infty}^{\infty} x\,f_1(x)\,dx \ , \tag{39.12}$$

and similarly for y. The *covariance* of x and y is

$$\mathrm{cov}[x,y] = E[(x-\mu_x)(y-\mu_y)] = E[xy] - \mu_x\mu_y \ . \tag{39.13}$$

A dimensionless measure of the covariance of x and y is given by the *correlation coefficient*,

$$\rho_{xy} = \mathrm{cov}[x,y]/\sigma_x\sigma_y \ , \tag{39.14}$$

where σ_x and σ_y are the standard deviations of x and y. It can be shown that $-1 \leq \rho_{xy} \leq 1$.

Two random variables x and y are *independent* if and only if

$$f(x,y) = f_1(x)f_2(y) \ . \tag{39.15}$$

If x and y are independent, then $\rho_{xy} = 0$; the converse is not necessarily true. If x and y are independent, $E[u(x)v(y)] = E[u(x)]E[v(y)]$, and $V[x+y] = V[x]+V[y]$; otherwise, $V[x+y] = V[x]+V[y]+2\mathrm{cov}[x,y]$, and $E[uv]$ does not necessarily factorize.

Consider a set of n continuous random variables $\boldsymbol{x} = (x_1,\ldots,x_n)$ with joint p.d.f. $f(\boldsymbol{x})$, and a set of n new variables $\boldsymbol{y} = (y_1,\ldots,y_n)$, related to $\boldsymbol{x}$ by means of a function $\boldsymbol{y}(\boldsymbol{x})$ that is one-to-one, *i.e.*, the inverse $\boldsymbol{x}(\boldsymbol{y})$ exists. The joint p.d.f. for $\boldsymbol{y}$ is given by

$$g(\boldsymbol{y}) = f(\boldsymbol{x}(\boldsymbol{y}))|J| \ \ , \tag{39.16}$$

where $|J|$ is the absolute value of the determinant of the square matrix $J_{ij} = \partial x_i/\partial y_j$ (the Jacobian determinant). If the transformation from $\boldsymbol{x}$ to $\boldsymbol{y}$ is not one-to-one, the $\boldsymbol{x}$-space must be broken into regions where the function $\boldsymbol{y}(\boldsymbol{x})$ can be inverted, and the contributions to $g(\boldsymbol{y})$ from each region summed.

Given a set of functions $\boldsymbol{y} = (y_1,\ldots,y_m)$ with $m < n$, one can construct $n-m$ additional independent functions, apply the procedure above, then integrate the resulting $g(\boldsymbol{y})$ over the unwanted y_i to find the marginal distribution of those of interest.

For a one-to-one transformation of discrete random variables, the probability is obtained by simple substitution; no Jacobian is necessary because in this case f is a probability rather than a probability density. If the transformation is not one-to-one, then one must sum the probabilities for all values of the original variable that contribute to a given value of the transformed variable. If f depends on a set of parameters $\boldsymbol{\theta}$, a change to a different parameter set $\boldsymbol{\eta}(\boldsymbol{\theta})$ is made by simple substitution; no Jacobian is used.

39.2.1 *Propagation of errors*

Consider n random variables $\boldsymbol{x} = (x_1,\ldots,x_n)$ and m functions $\boldsymbol{y}(\boldsymbol{x}) = (y_1(\boldsymbol{x}),\ldots,y_m(\boldsymbol{x}))$. Suppose here that the mean values $\boldsymbol{\mu} = (\mu_1,\ldots,\mu_n) = E[\boldsymbol{x}]$ are known, although in practice they will only be estimated, and suppose we also know or have estimated the covariance matrix $V_{ij} = \mathrm{cov}[x_i,x_j]$. The goal of *error propagation* is to determine the covariance matrix for the functions, $U_{ij} = \mathrm{cov}[y_i,y_j]$. In particular, the diagonal elements $U_{ii} = V[y_i]$ give the variances. The new covariance matrix can be found by expanding the functions $\boldsymbol{y}(\boldsymbol{x})$ about the means $\boldsymbol{\mu}$ to first order in a Taylor series. Using this one finds

$$U_{ij} \approx \sum_{k,l} \frac{\partial y_i}{\partial x_k}\frac{\partial y_j}{\partial x_l}\bigg|_{\boldsymbol{\mu}} V_{kl} \ . \tag{39.17}$$

This can be written in matrix notation as $U \approx AVA^T$ where the matrix of derivatives A is

$$A_{ij} = \left.\frac{\partial y_i}{\partial x_j}\right|_{\boldsymbol{\mu}} \ \ , \tag{39.18}$$

and A^T is its transpose. The approximation is exact if $\boldsymbol{y}(\boldsymbol{x})$ is linear. If this is not the case, the approximation can break down if, for example, $\boldsymbol{y}(\boldsymbol{x})$ is significantly nonlinear close to $\boldsymbol{\mu}$ in a region of a size comparable to the standard deviations of $\boldsymbol{x}$.

39.3 Characteristic functions

The characteristic function $\phi(u)$ associated with the p.d.f. $f(x)$ is essentially its Fourier transform, or the expectation value of e^{iux}:

$$\phi(u) = E\left[e^{iux}\right] = \int_{-\infty}^{\infty} e^{iux} f(x)\,dx \ . \tag{39.19}$$

Once $\phi(u)$ is specified, the p.d.f. $f(x)$ is uniquely determined and vice versa; knowing one is equivalent to the other. Characteristic functions are useful in deriving a number of important results about moments and sums of random variables.

It follows from Eqs. (39.8) and (39.19) that the n^{th} moment of a random variable x that follows $f(x)$ is given by

$$i^{-n}\ \left.\frac{d^n\phi}{du^n}\right|_{u=0} = \int_{-\infty}^{\infty} x^n f(x)\,dx = \alpha_n \ . \tag{39.20}$$

Thus it is often easy to calculate all the moments of a distribution defined by $\phi(u)$, even when $f(x)$ cannot be written down explicitly.

If the p.d.f.s $f_1(x)$ and $f_2(y)$ for independent random variables x and y have characteristic functions $\phi_1(u)$ and $\phi_2(u)$, then the characteristic function of the weighted sum $ax+by$ is $\phi_1(au)\phi_2(bu)$. The rules of addition for several important distributions (*e.g.*, that the sum of two Gaussian distributed variables also follows a Gaussian distribution) easily follow from this observation.

Let the (partial) characteristic function corresponding to the conditional p.d.f. $f_2(x|z)$ be $\phi_2(u|z)$, and the p.d.f. of z be $f_1(z)$. The characteristic function after integration over the conditional value is

$$\phi(u) = \int \phi_2(u|z)f_1(z)\,dz \ . \tag{39.21}$$

Suppose we can write ϕ_2 in the form

$$\phi_2(u|z) = A(u)e^{ig(u)z} \ . \tag{39.22}$$

Then

$$\phi(u) = A(u)\phi_1(g(u)) \ . \tag{39.23}$$

The cumulants (semi-invariants) κ_n of a distribution with characteristic function $\phi(u)$ are defined by the relation

$$\phi(u) = \exp\left[\sum_{n=1}^{\infty}\frac{\kappa_n}{n!}(iu)^n\right] = \exp\left(i\kappa_1 u - \frac{1}{2}\kappa_2 u^2 + \ldots\right) \ . \tag{39.24}$$

The values κ_n are related to the moments α_n and m_n. The first few relations are

$$\begin{aligned}\kappa_1 &= \alpha_1 \ (= \mu, \text{ the mean})\\ \kappa_2 &= m_2 \ = \alpha_2 - \alpha_1^2 \ (= \sigma^2, \text{ the variance})\\ \kappa_3 &= m_3 = \alpha_3 - 3\alpha_1\alpha_2 + 2\alpha_1^3.\end{aligned} \tag{39.25}$$

39.4 Commonly used probability distributions

Table 39.1 gives a number of common probability density functions and corresponding characteristic functions, means, and variances. Further information may be found in Refs. [1–8] [10], and [11], which has particularly detailed tables. Monte Carlo techniques for generating each of them may be found in our Sec. 42.4 and in Ref. [10]. We comment below on all except the trivial uniform distribution.

39.4.1 *Binomial and multinomial distributions*

A random process with exactly two possible outcomes which occur with fixed probabilities is called a *Bernoulli* process. If the probability of obtaining a certain outcome (a "success") in an individual trial is p, then the probability of obtaining exactly r successes ($r = 0, 1, 2, \ldots, N$) in N independent trials, without regard to the order of the successes and failures, is given by the binomial distribution $f(r; N, p)$ in Table 39.1. If r and s are binomially distributed with parameters (N_r, p) and (N_s, p), then $t = r + s$ follows a binomial distribution with parameters $(N_r + N_s, p)$. If there are are m possible outcomes for each trial having probabilities $p_1, p_2, \ldots, p_m$, then the joint probability to find $r_1, r_2, \ldots, r_m$ of each outcome after a total of N independent trials is given by the multinomial distribution as shown in Table 39.1. We can regard outcome i as "success" and all the rest as "failure", so individually, any of the r_i follow a binomial distribution for N trials and a success probability p_i.

39.4.2 *Poisson distribution*

The Poisson distribution $f(n; \nu)$ gives the probability of finding exactly n events in a given interval of x (*e.g.*, space or time) when the events occur independently of one another and of x at an average rate of ν per the given interval. The variance σ^2 equals ν. It is the limiting case $p \to 0$, $N \to \infty$, $Np = \nu$ of the binomial distribution. The Poisson distribution approaches the Gaussian distribution for large ν.

For example, a large number of radioactive nuclei of a given type will result in a certain number of decays in a fixed time interval. If this interval is small compared to the mean lifetime, then the probability for a given nucleus to decay is small, and thus the number of decays in the time interval is well modeled as a Poisson variable.

39.4.3 *Normal or Gaussian distribution*

The normal (or Gaussian) probability density function $f(x; \mu, \sigma^2)$ given in Table 39.1 has mean $E[x] = \mu$ and variance $V[x] = \sigma^2$. Comparison of the characteristic function $\phi(u)$ given in Table 39.1 with Eq. (39.24) shows that all cumulants κ_n beyond κ_2 vanish; this is a unique property of the Gaussian distribution. Some other properties are:

$$\begin{aligned}&P(x \text{ in range } \mu \pm \sigma) = 0.6827,\\ &P(x \text{ in range } \mu \pm 0.6745\sigma) = 0.5,\\ &E[|x - \mu|] = \sqrt{2/\pi}\sigma = 0.7979\sigma,\\ &\text{half-width at half maximum} = \sqrt{2\ln 2}\,\sigma = 1.177\sigma.\end{aligned}$$

For a Gaussian with $\mu = 0$ and $\sigma^2 = 1$ (the *standard normal*) the cumulative distribution, often written $\Phi(x)$, is related to the error function erf by

$$F(x; 0, 1) \equiv \Phi(x) = \frac{1}{2}\left[1 + \mathrm{erf}(x/\sqrt{2})\right] \ . \tag{39.26}$$

The error function and standard Gaussian are tabulated in many references (*e.g.*, Ref. [11, 12]) and are available in software packages such as ROOT [13]. For a mean μ and variance σ^2, replace x by $(x - \mu)/\sigma$. The probability of x in a given range can be calculated with Eq. (40.76).

For x and y independent and normally distributed, $z = ax + by$ follows a normal p.d.f. $f(z; a\mu_x + b\mu_y, a^2\sigma_x^2 + b^2\sigma_y^2)$; that is, the weighted means and variances add.

The Gaussian derives its importance in large part from the *central limit theorem*:

If independent random variables $x_1, \ldots, x_n$ are distributed according to *any* p.d.f. with finite mean and variance, then the sum $y = \sum_{i=1}^{n} x_i$ will have a p.d.f. that approaches a Gaussian for large n. If the p.d.f.s of the x_i are not identical, the theorem still holds under somewhat more restrictive conditions. The mean and variance are given by the sums of corresponding terms from the individual x_i. Therefore, the sum of a large number of fluctuations x_i will be distributed as a Gaussian, even if the x_i themselves are not.

For a set of n Gaussian random variables $\boldsymbol{x}$ with means $\boldsymbol{\mu}$ and covariances $V_{ij} = \mathrm{cov}[x_i, x_j]$, the p.d.f. for the one-dimensional Gaussian is generalized to

$$f(\boldsymbol{x}; \boldsymbol{\mu}, V) = \frac{1}{(2\pi)^{n/2}\sqrt{|V|}} \exp\left[-\frac{1}{2}(\boldsymbol{x} - \boldsymbol{\mu})^T V^{-1} (\boldsymbol{x} - \boldsymbol{\mu})\right] \ , \tag{39.27}$$

where the determinant $|V|$ must be greater than 0. For diagonal V (independent variables), $f(\boldsymbol{x}; \boldsymbol{\mu}, V)$ is the product of the p.d.f.s of n Gaussian distributions.

For $n = 2$, $f(\boldsymbol{x}; \boldsymbol{\mu}, V)$ is

$$\begin{aligned}f(x_1, x_2;\ \mu_1, \mu_2, \sigma_1, \sigma_2, \rho) &= \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}}\\ \times\ \exp&\left\{\frac{-1}{2(1-\rho^2)}\left[\frac{(x_1-\mu_1)^2}{\sigma_1^2} - \frac{2\rho(x_1-\mu_1)(x_2-\mu_2)}{\sigma_1\sigma_2} + \frac{(x_2-\mu_2)^2}{\sigma_2^2}\right]\right\}.\end{aligned} \tag{39.28}$$

The characteristic function for the multivariate Gaussian is

$$\phi(\boldsymbol{u}; \boldsymbol{\mu}, V) = \exp\left[i\boldsymbol{\mu}\cdot\boldsymbol{u} - \frac{1}{2}\boldsymbol{u}^T V \boldsymbol{u}\right] \ . \tag{39.29}$$

If the components of $\boldsymbol{x}$ are independent, then Eq. (39.29) is the product of the characteristic functions of n Gaussians.

For an n-dimensional Gaussian distribution for $\boldsymbol{x}$ with mean $\boldsymbol{\mu}$ and covariance matrix V, the marginal distribution for any single x_i is is a one-dimensional Gaussian with mean μ_i and variance V_{ii}. The equation $(\boldsymbol{x} - \boldsymbol{a})^T V^{-1} (\boldsymbol{x} - \boldsymbol{a}) = C$, where C is any positive number, defines an n-dimensional ellipse centered about $\boldsymbol{a}$. If $\boldsymbol{a}$ is equal to the mean $\boldsymbol{\mu}$, then C is a random variable obeying the χ^2 distribution for n degrees of freedom, which is discussed in the following section. The probability that $\boldsymbol{x}$ lies outside the ellipsoid for a given value of C is given by $1 - F_{\chi^2}(C; n)$, where F_{χ^2} is the cumulative χ^2 distribution. This may be read from Fig. 40.1. For example, the "s-standard-deviation ellipsoid" occurs at $C = s^2$. For the two-variable case ($n = 2$), the point $\boldsymbol{x}$ lies outside the one-standard-deviation ellipsoid with 61% probability. The use of these ellipsoids as indicators of probable error is described in Sec. 40.4.2.2; the validity of those indicators assumes that $\boldsymbol{\mu}$ and V are correct.

39.4.4 *Log-normal distribution*

If a random variable y follows a Gaussian distribution with mean μ and variance σ^2, then $x = e^y$ follows a log-normal distribution, as given in Table 39.1. As a consequence of the central limit theorem described in Sec. 39.4.3, the distribution of the product of a large number of positive random variables approaches a log-normal. It is bounded below by zero and is thus well suited for modeling quantities that are intrinsically non-negative such as an efficiency. One can implement a log-normal model for a random variable x by defining $y = \ln x$ so that y follows a Gaussian distribution.

39.4.5 χ^2 *distribution*

If $x_1, \ldots, x_n$ are independent Gaussian random variables, the sum $z = \sum_{i=1}^{n} (x_i - \mu_i)^2/\sigma_i^2$ follows the χ^2 p.d.f. with n *degrees*

Table 39.1: Some common probability density functions, with corresponding characteristic functions and means and variances. In the Table, $\Gamma(k)$ is the gamma function, equal to $(k-1)!$ when k is an integer; ${}_1F_1$ is the confluent hypergeometric function of the 1st kind [11].

Distribution	Probability density function f (variable; parameters)	Characteristic function $\phi(u)$	Mean	Variance
Uniform	$f(x;a,b) = \begin{cases} 1/(b-a) & a \le x \le b \\ 0 & \text{otherwise} \end{cases}$	$\frac{e^{ibu}-e^{iau}}{(b-a)iu}$	$\frac{a+b}{2}$	$\frac{(b-a)^2}{12}$
Binomial	$f(r;N,p) = \frac{N!}{r!(N-r)!}\, p^r q^{N-r}$ $r = 0,1,2,\ldots,N; \quad 0 \le p \le 1; \quad q = 1-p$	$(q + pe^{iu})^N$	Np	Npq
Multinomial	$f(r_1,\ldots,r_m;N,p_1,\ldots,p_m) = \frac{N!}{r_1!\cdots r_m!} p_1^{r_1}\cdots p_m^{r_m}$	$\left(\sum_{k=1}^m p_k e^{iu_k}\right)^N$	$E[r_i] = Np_i$	$\mathrm{cov}[r_i,r_j] = Np_i(\delta_{ij} - p_j)$
Poisson	$f(n;\nu) = \frac{\nu^n e^{-\nu}}{n!}$; $n = 0,1,2,\ldots$; $\nu > 0$	$\exp[\nu(e^{iu}-1)]$	ν	ν
Normal (Gaussian)	$f(x;\mu,\sigma^2) = \frac{1}{\sigma\sqrt{2\pi}}\, \exp(-(x-\mu)^2/2\sigma^2)$	$\exp(i\mu u - \frac{1}{2}\sigma^2 u^2)$	μ	σ^2
Multivariate Gaussian	$f(\boldsymbol{x};\boldsymbol{\mu},V) = \frac{1}{(2\pi)^{n/2}\sqrt{\lvert V\rvert}}$ $\times \exp\left[-\frac{1}{2}(\boldsymbol{x}-\boldsymbol{\mu})^T V^{-1}(\boldsymbol{x}-\boldsymbol{\mu})\right]$ $-\infty < x_j < \infty; \quad -\infty < \mu_j < \infty; \quad \lvert V\rvert > 0$	$\exp\left[i\boldsymbol{\mu}\cdot\boldsymbol{u} - \frac{1}{2}\boldsymbol{u}^T V \boldsymbol{u}\right]$	$\boldsymbol{u}$	V_{jk}
Log-normal	$f(x;\mu,\sigma^2) = \frac{1}{\sigma\sqrt{2\pi}}\frac{1}{x}\, \exp(-(\ln x-\mu)^2/2\sigma^2)$ $0 < x < \infty; \quad -\infty < \mu < \infty; \quad \sigma > 0$	—	$\exp(\mu+\sigma^2/2)$	$\exp(2\mu+\sigma^2)$ $\times[\exp(\sigma^2)-1]$
χ^2	$f(z;n) = \frac{z^{n/2-1}e^{-z/2}}{2^{n/2}\Gamma(n/2)}$; $z \ge 0$	$(1-2iu)^{-n/2}$	n	$2n$
Student's t	$f(t;n) = \frac{1}{\sqrt{n\pi}}\, \frac{\Gamma[(n+1)/2]}{\Gamma(n/2)} \left(1+\frac{t^2}{n}\right)^{-(n+1)/2}$ $-\infty < t < \infty$; n not required to be integer	—	0 for $n > 1$	$n/(n-2)$ for $n > 2$
Gamma	$f(x;\lambda,k) = \frac{x^{k-1}\lambda^k e^{-\lambda x}}{\Gamma(k)}$; $0 \le x < \infty$; k not required to be integer	$(1-iu/\lambda)^{-k}$	k/λ	k/λ^2
Beta	$f(x;\alpha,\beta) = \frac{\Gamma(\alpha+\beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha-1}(1-x)^{\beta-1}$ $0 \le x \le 1$	${}_1F_1(\alpha;\alpha+\beta;iu)$	$\frac{\alpha}{\alpha+\beta}$	$\frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$

of freedom, which we denote by $\chi^2(n)$. More generally, for n correlated Gaussian variables as components of a vector $\boldsymbol{X}$ with covariance matrix V, $z = \boldsymbol{X}^T V^{-1} \boldsymbol{X}$ follows $\chi^2(n)$ as in the previous section. For a set of z_i, each of which follows $\chi^2(n_i)$, $\sum z_i$ follows $\chi^2(\sum n_i)$. For large n, the χ^2 p.d.f. approaches a Gaussian with a mean and variance given by $\mu = n$ and $\sigma^2 = 2n$, respectively (here the formulae for μ and σ^2 are valid for all n).

The χ^2 p.d.f. is often used in evaluating the level of compatibility between observed data and a hypothesis for the p.d.f. that the data might follow. This is discussed further in Sec. 40.3.2 on significance tests.

39.4.6 *Student's t distribution*

Suppose that y and $x_1,\ldots,x_n$ are independent and Gaussian distributed with mean 0 and variance 1. We then define

$$z = \sum_{i=1}^{n} x_i^2 \quad \text{and} \quad t = \frac{y}{\sqrt{z/n}}\,. \tag{39.30}$$

The variable z thus follows a $\chi^2(n)$ distribution. Then t is distributed according to Student's t distribution with n degrees of freedom, $f(t;n)$, given in Table 39.1.

If defined through gamma functions as in Table 39.1, the parameter n is not required to be an integer. As $n \to \infty$, the distribution approaches a Gaussian, and for $n = 1$ it is a *Cauchy* or *Breit–Wigner* distribution.

As an example, consider the *sample mean* $\overline{x} = \sum x_i/n$ and the *sample variance* $s^2 = \sum(x_i - \overline{x})^2/(n-1)$ for normally distributed x_i with unknown mean μ and variance σ^2. The sample mean has a Gaussian distribution with a variance σ^2/n, so the variable $(\overline{x}-\mu)/\sqrt{\sigma^2/n}$ is normal with mean 0 and variance 1. The quantity $(n-1)s^2/\sigma^2$ is independent of this and follows $\chi^2(n-1)$. The ratio

$$t = \frac{(\overline{x}-\mu)/\sqrt{\sigma^2/n}}{\sqrt{(n-1)s^2/\sigma^2(n-1)}} = \frac{\overline{x}-\mu}{\sqrt{s^2/n}} \tag{39.31}$$

is distributed as $f(t;n-1)$. The unknown variance σ^2 cancels, and t can be used to test the hypothesis that the true mean is some particular value μ.

39.4.7 *Gamma distribution*

For a process that generates events as a function of x (*e.g.*, space or time) according to a Poisson distribution, the distance in x from an arbitrary starting point (which may be some particular event) to the k^{th} event follows a *gamma* distribution, $f(x;\lambda,k)$. The Poisson parameter μ is λ per unit x. The special case $k = 1$ (*i.e.*, $f(x;\lambda,1) = \lambda e^{-\lambda x}$) is called the *exponential* distribution. A sum of k' exponential random variables x_i is distributed as $f(\sum x_i;\lambda,k')$.

The parameter k is not required to be an integer. For $\lambda = 1/2$ and $k = n/2$, the gamma distribution reduces to the $\chi^2(n)$ distribution.

39.4.8 *Beta distribution*

The beta distribution describes a continuous random variable x in the interval $[0,1]$. By scaling and translation one can easily generalize it to have arbitrary endpoints. In Bayesian inference about the parameter p of a binomial process, if the prior p.d.f. is a beta distribution $f(p;\alpha,\beta)$ then the observation of r successes out of N trials gives a posterior beta distribution $f(p;r+\alpha,N-r+\beta)$ (Bayesian methods are discussed further in Sec. 40). The uniform distribution is a beta distribution with $\alpha = \beta = 1$.

40. Statistics

Revised August 2023 by G. Cowan (RHUL).

This chapter gives an overview of statistical methods used in high-energy physics. In statistics, we are interested in using a given sample of data to make inferences about a probabilistic model, *e.g.*, to assess the model's validity or to determine the values of its parameters. There are two main approaches to statistical inference, which we may call frequentist and Bayesian.

In frequentist statistics, probability is interpreted as the limiting frequency of the outcome of a repeatable experiment. The most important tools in this framework are parameter estimation, covered in Section 40.2, statistical tests, discussed in Section 40.3, and confidence intervals, which are constructed so as to cover the true value of a parameter with a specified probability, as described in Section 40.4.2. Note that in frequentist statistics one does not define a probability for a hypothesis or for the value of a parameter.

In Bayesian statistics, the subjective interpretation of probability is used to quantify one's *degree of belief* in a hypothesis. This allows one to define a probability density function (p.d.f.) for a parameter, which reflects one's knowledge about where its true value lies.

Bayesian methods provide a natural means to include additional information, which in general may be subjective; in fact they *require* prior probabilities for the hypotheses (or parameters) in question, *i.e.*, the degree of belief about the parameters' values, before carrying out the measurement. Using Bayes' theorem (Eq. (39.4)), the prior degree of belief is updated by the data from the experiment. Bayesian methods for interval estimation are discussed in Sections 40.4.1 and 40.4.2.4.

For many inference problems, the frequentist and Bayesian approaches give similar numerical values, even though they answer different questions and are based on fundamentally different interpretations of probability. In some important cases, however, the two approaches may yield very different results. For a discussion of Bayesian vs. non-Bayesian methods, see references written by a statistician [1], by a physicist [2], or the detailed comparison in Ref. [3].

40.1 Fundamental concepts

Consider an experiment whose outcome is characterized by one or more data values, which we can write as a vector $\boldsymbol{x}$. A *hypothesis* H is a statement about the probability for the data, often written $P(\boldsymbol{x}|H)$. (We will usually use a capital letter for a probability and lower case for a probability density. Often the term p.d.f. is used loosely to refer to either a probability or a probability density.) This could, for example, define completely the p.d.f. for the data (a *simple* hypothesis), or it could specify only the functional form of the p.d.f., with the values of one or more parameters not determined (a *composite* hypothesis).

If the probability $P(\boldsymbol{x}|H)$ for data $\boldsymbol{x}$ is regarded as a function of the hypothesis H, then it is called the *likelihood* of H, usually written $L(H)$. Often the hypothesis is characterized by one or more parameters $\boldsymbol{\theta}$, in which case $L(\boldsymbol{\theta}) = P(\boldsymbol{x}|\boldsymbol{\theta})$ is called the likelihood function.

In some cases one can obtain at least approximate frequentist results using the likelihood evaluated only with the data obtained, for example, when determining confidence regions with Eq. (40.79). In general, however, the frequentist approach requires a full specification of the probability model $P(\boldsymbol{x}|H)$ both as a function of the data $\boldsymbol{x}$ and hypothesis H.

In the Bayesian approach, inference is based on the posterior probability for H given the data $\boldsymbol{x}$, which represents one's degree of belief that H is true given the data. This is obtained from Bayes' theorem (39.4), which can be written

$$P(H|\boldsymbol{x}) = \frac{P(\boldsymbol{x}|H)\pi(H)}{\int P(\boldsymbol{x}|H')\pi(H')\,dH'} \,. \tag{40.1}$$

Here $P(\boldsymbol{x}|H)$ is the likelihood for H, which depends only on the data actually obtained. The quantity $\pi(H)$ is the prior probability for H, which represents one's degree of belief for H before carrying out the measurement. The integral in the denominator (or sum, for discrete hypotheses) serves as a normalization factor. If H is characterized by a continuous parameter θ then the posterior probability is a p.d.f. $p(\theta|\boldsymbol{x})$. Note that the likelihood function itself is not a p.d.f. for θ.

40.2 Parameter estimation

Here we review *point estimation* of parameters, first with an overview of the frequentist approach and its two most important methods, maximum likelihood and least squares, treated in Sections 40.2.2 and 40.2.3. The Bayesian approach is outlined in Sec. 40.2.6.

An *estimator* $\widehat{\theta}$ (written with a hat) is a function of the data used to estimate the value of the parameter θ. Sometimes the word 'estimate' is used to denote the value of the estimator when evaluated with given data. There is no fundamental rule dictating how an estimator must be constructed. One tries, therefore, to choose that estimator which has the best properties. The most important of these are (a) *consistency*, (b) *bias*, (c) *efficiency*, and (d) *robustness*.

(a) An estimator is said to be *consistent* if the estimate $\widehat{\theta}$ converges in probability (see Ref. [3]) to the true value θ as the amount of data increases. This property is so important that it is possessed by all commonly used estimators.

(b) The *bias*, $b = E[\widehat{\theta}] - \theta$, is the difference between the expectation value of the estimator and the true value of the parameter. The expectation value is taken over a hypothetical set of similar experiments in which $\widehat{\theta}$ is constructed in the same way. When $b = 0$, the estimator is said to be unbiased. The bias depends on the chosen metric, *i.e.*, if $\widehat{\theta}$ is an unbiased estimator of θ, then $\widehat{\theta}^{\,2}$ is not in general an unbiased estimator for θ^2.

(c) *Efficiency* is the ratio of the minimum possible variance for any estimator of θ to the variance $V[\widehat{\theta}]$ of the estimator $\widehat{\theta}$. For the case of a single parameter, under rather general conditions the minimum variance is given by the Rao-Cramér-Fréchet bound,

$$\sigma^2_{\rm min} = \left(1 + \frac{\partial b}{\partial \theta}\right)^2 / I(\theta) \,, \tag{40.2}$$

where

$$I(\theta) = E\left[\left(\frac{\partial \ln L}{\partial \theta}\right)^2\right] = -E\left[\frac{\partial^2 \ln L}{\partial \theta^2}\right] \tag{40.3}$$

is the *Fisher information*, L is the likelihood, and the operator $E[]$ in (40.3) is the expectation value with respect to the data. For the final equality to hold, the range of allowed data values must not depend on θ.

The *mean-squared error*,

$$\text{MSE} = E[(\widehat{\theta} - \theta)^2] = V[\widehat{\theta}] + b^2 \,, \tag{40.4}$$

is a measure of an estimator's quality which combines bias and variance.

(d) *Robustness* is the property of being insensitive to departures from assumptions about the p.d.f., *e.g.*, owing to uncertainties in the distribution's tails.

It is not in general possible to optimize simultaneously for all the measures of estimator quality described above. For some common estimators, the properties above are known exactly. More generally, it is possible to evaluate them by Monte Carlo simulation. Note that they will in general depend on the unknown θ.

40.2.1 *Estimators for mean, variance, and median*

Suppose we have a set of n independent measurements, $x_1, \ldots, x_n$, each assumed to follow a p.d.f. with unknown mean μ and unknown variance σ^2 (the measurements do not necessarily have to follow a Gaussian distribution). Then

$$\widehat{\mu} = \frac{1}{n}\sum_{i=1}^{n} x_i \tag{40.5}$$

$$\widehat{\sigma^2} = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \widehat{\mu})^2 \tag{40.6}$$

are unbiased estimators of μ and σ^2. The variance of $\widehat{\mu}$ is σ^2/n and the variance of $\widehat{\sigma^2}$ is

$$V\left[\widehat{\sigma^2}\right] = \frac{1}{n}\left(m_4 - \frac{n-3}{n-1}\sigma^4\right) , \tag{40.7}$$

where m_4 is the 4^{th} central moment of x (see Eq. (39.8)). For Gaussian distributed x_i, this becomes $2\sigma^4/(n-1)$ for any $n \geq 2$, and for large n the standard deviation of $\widehat{\sigma}$ is $\sigma/\sqrt{2n}$. For any n and Gaussian x_i, $\widehat{\mu}$ is an efficient estimator for μ, and the estimators $\widehat{\mu}$ and $\widehat{\sigma^2}$ are uncorrelated. Otherwise the arithmetic mean (40.5) is not necessarily the most efficient estimator; this is discussed further in Sec. 8.7 of Ref. [4].

If σ^2 is known, it does not improve the estimate $\widehat{\mu}$, as can be seen from Eq. (40.5); however, if μ is known, one can substitute it for $\widehat{\mu}$ in Eq. (40.6) and replace $n-1$ by n to obtain an estimator of σ^2 still with zero bias but smaller variance. If the x_i have different, known variances σ_i^2, then the weighted average

$$\widehat{\mu} = \frac{1}{w}\sum_{i=1}^{n} w_i x_i , \tag{40.8}$$

where $w_i = 1/\sigma_i^2$ and $w = \sum_i w_i$, is an unbiased estimator for μ with a smaller variance than an unweighted average. The standard deviation of $\widehat{\mu}$ is $1/\sqrt{w}$.

As an estimator for the median x_{med}, one can use the value $\widehat{x}_{\text{med}}$ such that half the x_i are below and half above (the sample median). If there are an even number of observations and the sample median lies between two observed values, the estimator is set by convention to their arithmetic average. If the p.d.f. of x has the form $f(x-\mu)$ and μ is both mean and median, then for large n the variance of the sample median approaches $1/[4nf^2(0)]$, provided $f(0) > 0$ [5]. Although estimating the median can often be more difficult computationally than the mean, the resulting estimator is generally more robust, as it is insensitive to the exact shape of the tails of a distribution.

40.2.2 *The method of maximum likelihood*

Suppose we have a set of measured quantities $\boldsymbol{x}$ and the likelihood $L(\boldsymbol{\theta}) = P(\boldsymbol{x}|\boldsymbol{\theta})$ for a set of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$. The *maximum likelihood estimators* (MLEs) for $\boldsymbol{\theta}$ are defined as the values that give the maximum of L. Because of the properties of the logarithm, it is usually easier to work with $\ln L$, and since both are maximized for the same parameter values $\boldsymbol{\theta}$, the MLEs can be found by solving the *likelihood equations*,

$$\frac{\partial \ln L}{\partial \theta_i} = 0 , \qquad i = 1, \ldots, M . \tag{40.9}$$

Often the solution must be found numerically. Maximum likelihood estimators are important because they are asymptotically (*i.e.*, for large data samples) unbiased, efficient and have a Gaussian sampling distribution under quite general conditions, and the method has a wide range of applicability.

In general the likelihood function is obtained from the probability of the data under assumption of the parameters. An important special case is when the data consist of *i.i.d.* (independent and identically distributed) values. Here one has a set of n statistically independent quantities $\boldsymbol{x} = (x_1, \ldots, x_n)$, where each component follows the same p.d.f. $f(x;\boldsymbol{\theta})$. In this case the joint p.d.f. of the data sample factorizes and the likelihood function is

$$L(\boldsymbol{\theta}) = \prod_{i=1}^{n} f(x_i;\boldsymbol{\theta}) . \tag{40.10}$$

Here the number n of observations (usually individual "events" in particle physics) is regarded as fixed. If, however, the probability to observe n events itself depends on the parameters $\boldsymbol{\theta}$, then this dependence should be included in the likelihood. For example, if n follows a Poisson distribution with mean μ and the independent x values all follow $f(x;\boldsymbol{\theta})$, then the likelihood becomes

$$L(\boldsymbol{\theta}) = \frac{\mu^n}{n!}e^{-\mu}\prod_{i=1}^{n} f(x_i;\boldsymbol{\theta}) . \tag{40.11}$$

Equation (40.11) is often called the *extended likelihood* (see, *e.g.*, Refs. [6–8]). If μ is given as a function of $\boldsymbol{\theta}$, then including the probability for n given $\boldsymbol{\theta}$ in the likelihood provides additional information about the parameters. This therefore leads to a reduction in their statistical uncertainties and in general changes their estimated values.

In evaluating the likelihood function, it is important that any normalization factors in the p.d.f. that involve $\boldsymbol{\theta}$ be included. However, we will only be interested in the maximum of L and in ratios of L at different values of the parameters; hence any multiplicative factors that do not involve the parameters that we want to estimate may be dropped, including factors that depend on the data but not on $\boldsymbol{\theta}$.

Under a one-to-one change of parameters from $\boldsymbol{\theta}$ to $\boldsymbol{\eta}$, the MLEs $\widehat{\boldsymbol{\theta}}$ transform to $\boldsymbol{\eta}(\widehat{\boldsymbol{\theta}})$. That is, the maximum-likelihood solution is invariant under change of parameter. However, other properties of MLEs, in particular the bias, are not invariant under change of parameter.

The inverse V^{-1} of the covariance matrix $V_{ij} = \text{cov}[\widehat{\theta}_i, \widehat{\theta}_j]$ for a set of MLEs can be estimated by using

$$(\widehat{V}^{-1})_{ij} = -\left.\frac{\partial^2 \ln L}{\partial\theta_i \partial\theta_j}\right|_{\widehat{\boldsymbol{\theta}}} . \tag{40.12}$$

Equation (40.12) holds for a sufficiently large data sample (or for a small sample only in special cases, e.g., where the means of Gaussian distributed data are linear functions of the parameters); otherwise it can result in a misestimation of the variances. Under the conditions where the equation is valid, L has a Gaussian form and $\ln L$ is (hyper)parabolic. In this case, s times the standard deviations σ_i of the estimators for the parameters can be obtained from the hypersurface defined by the $\boldsymbol{\theta}$ such that

$$\ln L(\boldsymbol{\theta}) = \ln L_{\max} - s^2/2 , \tag{40.13}$$

where $\ln L_{\max}$ is the value of $\ln L$ at the solution point (compare with Eq. (40.79)). The minimum and maximum values of θ_i on the hypersurface then give an approximate s-standard deviation confidence interval for θ_i (see Section 40.4.2.2).

40.2.2.1 *Maximum likelihood with binned data*

If the total number of data values x_i, $(i = 1, \ldots, n_{\text{tot}})$, is small, the unbinned maximum-likelihood method, *i.e.*, use of Equation (40.10) (or (40.11) for extended maximum likelihood), is preferred since binning can only result in a loss of information, and hence larger statistical errors for the parameter estimates. If the sample is large, it can be convenient to bin the values in a histogram with N bins, so that one obtains a vector of data $\boldsymbol{n} = (n_1, \ldots, n_N)$ with expectation values $\boldsymbol{\mu} = E[\boldsymbol{n}]$ and probabilities $f(\boldsymbol{n};\boldsymbol{\mu})$. Suppose the mean values $\boldsymbol{\mu}$ can be determined as a function of a set of parameters $\boldsymbol{\theta}$. Then one may maximize the likelihood function based on the contents of the bins.

As mentioned in Sec. 40.2.2, the total number of events $n_{\text{tot}} = \sum_i n_i$ can be regarded either as fixed or as a random variable. If it is fixed, the histogram follows a multinomial distribution,

$$f_{\text{M}}(\boldsymbol{n};\boldsymbol{\theta}) = \frac{n_{\text{tot}}!}{n_1! \cdots n_N!} p_1^{n_1} \cdots p_N^{n_N} , \tag{40.14}$$

where we assume the probabilities p_i are given functions of the parameters $\boldsymbol{\theta}$. The distribution can be written equivalently in terms of the expected number of events in each bin, $\mu_i = n_{\text{tot}} p_i$. If the n_i are regarded as independent and Poisson distributed, then the data are instead described by a product of Poisson probabilities,

$$f_{\text{P}}(\boldsymbol{n};\boldsymbol{\theta}) = \prod_{i=1}^{N} \frac{\mu_i^{n_i}}{n_i!} e^{-\mu_i} , \tag{40.15}$$

where the mean values μ_i are given functions of $\boldsymbol{\theta}$. The total number of events n_{tot} thus follows a Poisson distribution with mean $\mu_{\text{tot}} = \sum_i \mu_i$.

When using maximum likelihood with binned data, one can find the estimators and at the same time obtain a statistic usable for a test of goodness of fit (see Sec. 40.3.3.1). For independent Poisson distributed data, maximizing the likelihood

$L(\boldsymbol{\theta}) = f_{\rm P}(\boldsymbol{n};\boldsymbol{\theta})$ is equivalent to maximizing the likelihood ratio $\lambda(\boldsymbol{\theta}) = f_{\rm P}(\boldsymbol{n};\boldsymbol{\theta})/f_{\rm sat}(\boldsymbol{n};\hat{\boldsymbol{\mu}})$, where in the denominator $f_{\rm sat}(\boldsymbol{n};\boldsymbol{\mu})$ is the corresponding model with an adjustable parameter for each bin, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_N)$, with estimators $\hat{\boldsymbol{\mu}} = (n_1, \ldots, n_N)$ (called the "saturated model"). Equivalently one often minimizes the quantity $-2\ln\lambda(\boldsymbol{\theta})$. For independent Poisson distributed n_i this is [9]

$$-2\ln\lambda(\boldsymbol{\theta}) = 2\sum_{i=1}^{N}\left[\mu_i(\boldsymbol{\theta}) - n_i + n_i\ln\frac{n_i}{\mu_i(\boldsymbol{\theta})}\right] , \qquad (40.16)$$

where for bins with $n_i = 0$, the last term in (40.16) is zero. The expression (40.16) without the terms $\mu_i - n_i$ also gives $-2\ln\lambda(\boldsymbol{\theta})$ for multinomially distributed n_i, *i.e.*, when the total number of entries is regarded as fixed. In the limit of zero bin width, minimizing (40.16) is equivalent to maximizing the unbinned extended likelihood function (40.11); in the corresponding multinomial case without the $\mu_i - n_i$ terms one obtains Eq. (40.10).

A smaller value of $-2\ln\lambda(\widehat{\boldsymbol{\theta}})$ corresponds to better agreement between the data and the hypothesized form of $\boldsymbol{\mu}(\boldsymbol{\theta})$. The value of $-2\ln\lambda(\widehat{\boldsymbol{\theta}})$ can thus be translated into a p-value as a measure of goodness-of-fit, as described in Sec. 40.3.3.1. Assuming the model is correct, then according to Wilks' theorem [10], for sufficiently large μ_i and provided certain regularity conditions are met, the minimum of $-2\ln\lambda$ as defined by Eq. (40.16) follows a χ^2 distribution (see, *e.g.*, Ref. [9]). If there are N bins and M fitted parameters, then the number of degrees of freedom for the χ^2 distribution is $N - M$ if the data are treated as Poisson-distributed, and $N - M - 1$ if the n_i are multinomially distributed.

Suppose the n_i are Poisson-distributed and the overall normalization $\mu_{\rm tot} = \sum_i \mu_i$ is taken as an adjustable parameter, so that $\mu_i = \mu_{\rm tot} p_i(\boldsymbol{\theta})$, where the probability to be in the ith bin, $p_i(\boldsymbol{\theta})$, does not depend on $\mu_{\rm tot}$. Then by minimizing Eq. (40.16), one obtains that the area under the fitted function is equal to the sum of the histogram contents, *i.e.*, $\sum_i \hat{\mu}_i = \sum_i n_i$. This is a property not possessed by the estimators from the method of least squares (see, *e.g.*, Sec. 40.2.3 and Ref. [8]).

40.2.2.2 *Frequentist treatment of nuisance parameters*

Suppose we want to determine the values of parameters $\boldsymbol{\theta}$ using a set of measurements $\boldsymbol{x}$ described by a probability model $P(\boldsymbol{x}|\boldsymbol{\theta})$. In general the model is not perfect, which is to say it cannot provide an accurate description of the data even at the most optimal point of its parameter space. As a result, the estimated parameters can have a systematic bias.

One can improve the model by including in it additional parameters. That is, $P(\boldsymbol{x}|\boldsymbol{\theta})$ is replaced by a more general model $P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})$, which depends on parameters of interest $\boldsymbol{\theta}$ and *nuisance parameters* $\boldsymbol{\nu}$. The additional parameters are not of intrinsic interest but must be included for the model to be sufficiently accurate for some point in the enlarged parameter space.

Although including additional parameters may eliminate or at least reduce the effect of systematic uncertainties, their presence will result in increased statistical uncertainties for the parameters of interest. This occurs because the estimators for the nuisance parameters and those of interest will in general be correlated, which results in an enlargement of the contour defined by Eq. (40.13).

To reduce the impact of the nuisance parameters one often tries to constrain their values by means of control or calibration measurements, say, having data $\boldsymbol{y}$. For example, some components of $\boldsymbol{y}$ could represent estimates of the nuisance parameters, often from separate experiments. Suppose the measurements $\boldsymbol{y}$ are statistically independent from $\boldsymbol{x}$ and are described by a model $P(\boldsymbol{y}|\boldsymbol{\nu})$. The joint model for both $\boldsymbol{x}$ and $\boldsymbol{y}$ is in this case therefore the product of the probabilities for $\boldsymbol{x}$ and $\boldsymbol{y}$, and thus the likelihood function for the full set of parameters is

$$L(\boldsymbol{\theta},\boldsymbol{\nu}) = P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})P(\boldsymbol{y}|\boldsymbol{\nu}) . \qquad (40.17)$$

Note that in this case if one wants to simulate the experiment by means of Monte Carlo, both the primary and control measurements, $\boldsymbol{x}$ and $\boldsymbol{y}$, must be generated for each repetition under assumption of fixed values for the parameters $\boldsymbol{\theta}$ and $\boldsymbol{\nu}$.

Using all of the parameters $(\boldsymbol{\theta},\boldsymbol{\nu})$ in Eq. (40.13) to find the statistical errors in the parameters of interest $\boldsymbol{\theta}$ is equivalent to using the *profile likelihood*, which depends only on $\boldsymbol{\theta}$. It is defined as

$$L_{\rm p}(\boldsymbol{\theta}) = L(\boldsymbol{\theta},\widehat{\widehat{\boldsymbol{\nu}}}(\boldsymbol{\theta})), \qquad (40.18)$$

where the double-hat notation indicates the profiled values of the parameters $\boldsymbol{\nu}$, defined as the values that maximize L for the specified $\boldsymbol{\theta}$. The profile likelihood is discussed further in Section 40.3.2.1 in connection with hypothesis tests.

40.2.3 *The method of least squares*

The *method of least squares* (LS) coincides with the method of maximum likelihood in the following special case. Consider a set of N independent measurements y_i at known points x_i. The measurement y_i is assumed to be Gaussian distributed with mean $\mu(x_i;\boldsymbol{\theta})$ and known variance σ_i^2. The goal is to construct estimators for the unknown parameters $\boldsymbol{\theta}$. The log-likelihood function contains the sum of squares

$$\chi^2(\boldsymbol{\theta}) = -2\ln L(\boldsymbol{\theta}) + \text{ constant } = \sum_{i=1}^{N}\frac{(y_i - \mu(x_i;\boldsymbol{\theta}))^2}{\sigma_i^2} . \qquad (40.19)$$

The parameter values that maximize L are the same as those which minimize χ^2.

The minimum of the chi-square function in Equation (40.19) defines the least-squares estimators $\widehat{\boldsymbol{\theta}}$ for the more general case where the y_i are not Gaussian distributed as long as they are independent. If they are not independent but rather have a covariance matrix $V_{ij} = \mathrm{cov}[y_i, y_j]$, then the LS estimators are determined by the minimum of

$$\chi^2(\boldsymbol{\theta}) = (\boldsymbol{y} - \boldsymbol{\mu}(\boldsymbol{\theta}))^T V^{-1}(\boldsymbol{y} - \boldsymbol{\mu}(\boldsymbol{\theta})) , \qquad (40.20)$$

where $\boldsymbol{y} = (y_1, \ldots, y_N)$ is the (column) vector of measurements, $\boldsymbol{\mu}(\boldsymbol{\theta})$ is the corresponding vector of predicted values, and the superscript T denotes the transpose. If the y_i are not Gaussian distributed, then the least-squares and maximum-likelihood estimators will not in general coincide.

Often one further restricts the problem to the case where $\mu(x_i;\boldsymbol{\theta})$ is a linear function of the parameters, *i.e.*,

$$\mu(x_i;\boldsymbol{\theta}) = \sum_{j=1}^{m}\theta_j h_j(x_i) . \qquad (40.21)$$

Here the $h_j(x)$ are m linearly independent functions, *e.g.*, $1, x, x^2, \ldots, x^{m-1}$ or Legendre polynomials. We require $m < N$ and at least m of the x_i must be distinct.

Minimizing χ^2 in this case with m parameters reduces to solving a system of m linear equations. Defining $H_{ij} = h_j(x_i)$ and minimizing χ^2 by setting its derivatives with respect to the θ_i equal to zero gives the LS estimators,

$$\widehat{\boldsymbol{\theta}} = (H^T V^{-1} H)^{-1} H^T V^{-1}\boldsymbol{y} \equiv D\boldsymbol{y} . \qquad (40.22)$$

The covariance matrix for the estimators $U_{ij} = \mathrm{cov}[\widehat{\theta}_i, \widehat{\theta}_j]$ is given by

$$U = DVD^T = (H^T V^{-1} H)^{-1} , \qquad (40.23)$$

or equivalently, its inverse U^{-1} can be found from

$$(U^{-1})_{ij} = \frac{1}{2}\frac{\partial^2\chi^2}{\partial\theta_i\partial\theta_j}\bigg|_{\boldsymbol{\theta}=\widehat{\boldsymbol{\theta}}} = \sum_{k,l=1}^{N} h_i(x_k)(V^{-1})_{kl}h_j(x_l) . \qquad (40.24)$$

The LS estimators can also be found from the expression

$$\widehat{\boldsymbol{\theta}} = U\boldsymbol{g} , \qquad (40.25)$$

where the vector $\boldsymbol{g}$ is defined by

$$g_i = \sum_{j,k=1}^{N} y_j h_i(x_k)(V^{-1})_{jk} . \qquad (40.26)$$

For the case of uncorrelated y_i, for example, one can use (40.25) with

$$(U^{-1})_{ij} = \sum_{k=1}^{N} \frac{h_i(x_k)h_j(x_k)}{\sigma_k^2} \ , \tag{40.27}$$

$$g_i = \sum_{k=1}^{N} \frac{y_k h_i(x_k)}{\sigma_k^2} \ . \tag{40.28}$$

Expanding $\chi^2(\boldsymbol{\theta})$ about $\widehat{\boldsymbol{\theta}}$, one finds that the contour in parameter space defined by

$$\chi^2(\boldsymbol{\theta}) = \chi^2(\widehat{\boldsymbol{\theta}}) + 1 = \chi^2_{\rm min} + 1 \tag{40.29}$$

has tangent planes located at plus-or-minus-one standard deviation $\sigma_{\widehat{\boldsymbol{\theta}}}$ from the LS estimates $\widehat{\boldsymbol{\theta}}$ (the relation is approximate if the fit function $\mu(x;\boldsymbol{\theta})$ is nonlinear in the parameters).

In constructing the quantity $\chi^2(\boldsymbol{\theta})$ one requires the variances or, in the case of correlated measurements, the covariance matrix. Often these quantities are not known *a priori* and must be estimated from the data. In this case the least-squares and maximum-likelihood methods are no longer exactly equivalent even for Gaussian distributed measurements. An important example is where the measured value y_i represents the event count in a histogram bin. If, for example, y_i represents a Poisson variable, for which the variance is equal to the mean, then one can either estimate the variance from the predicted value, $\mu(x_i;\boldsymbol{\theta})$, or from the observed number itself, y_i. In the first option, the variances become functions of the parameters, and as a result the estimators may need to be found numerically. The second option can be undefined if y_i is zero, and for small y_i, the variance will be poorly estimated. In either case, one should constrain the normalization of the fitted curve to the correct value, *i.e.*, one should determine the area under the fitted curve directly from the number of entries in the histogram (see Ref. [8], Section 7.4). As noted in Sec. 40.2.2.1, this issue is avoided when using the method of extended maximum likelihood with binned data by minimizing Eq. (40.16). In that case if the expected number of events $\mu_{\rm tot}$ does not depend on the other fitted parameters $\boldsymbol{\theta}$, then its extended MLE is equal to the observed total number of events.

As the minimum value of the χ^2 represents the level of agreement between the measurements and the fitted function, it can be used for assessing the goodness-of-fit; this is discussed further in Section 40.3.3.1.

40.2.4 *Parameter estimation with constraints*

In some applications one is interested in using a set of measured quantities $\boldsymbol{y} = (y_1, \ldots, y_N)$ to estimate parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$ subject to a number of constraints. For example, one may have measured coordinates from two tracks, and the goal is to estimate their momentum vectors subject to the constraint that the tracks have a common vertex. The parameters can also include momenta of undetected particles such as neutrinos, as long as the constraints from conservation of energy and momentum and from known masses of particles involved in the reaction chain provide enough information for these quantities to be inferred.

A set of K constraints can be given in the form of equations

$$c_k(\boldsymbol{\theta}) = 0 \ , \quad k = 1, \ldots, K \ . \tag{40.30}$$

In some problems it may be possible to define a new set of parameters $\boldsymbol{\eta} = (\eta_1, \ldots, \eta_L)$ with $L = M - K$ such that every point in $\boldsymbol{\eta}$-space automatically satisfies the constraints. If this is possible then the problem reduces to one of estimating $\boldsymbol{\eta}$ with, *e.g.*, maximum likelihood or least squares and then transforming the estimators back into $\boldsymbol{\theta}$-space.

In many cases it may be difficult or impossible to find an appropriate transformation $\boldsymbol{\eta}(\boldsymbol{\theta})$. Suppose that the parameters are determined by minimizing an objective function such as $\chi^2(\boldsymbol{\theta})$ in the method of least squares. Here one may enforce the constraints by finding the stationary points of the *Lagrange function*

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{\lambda}, \boldsymbol{y}) = \chi^2(\boldsymbol{\theta}, \boldsymbol{y}) + \sum_{k=1}^{K} \lambda_k c_k(\boldsymbol{\theta}) \tag{40.31}$$

with respect to both the parameters $\boldsymbol{\theta}$ and a set of *Lagrange multipliers* $\boldsymbol{\lambda} = (\lambda_1, \ldots, \lambda_K)$. Combining the parameters and Lagrange multipliers into an $(M + K)$-component vector $\boldsymbol{\gamma} = (\theta_1, \ldots, \theta_M, \lambda_1, \ldots, \lambda_K)$, the solutions for $\boldsymbol{\gamma}$, *i.e.*, the estimators $\hat{\boldsymbol{\gamma}}$, are found (*e.g.*, numerically) from the system of equations

$$F_i(\boldsymbol{\gamma}, \boldsymbol{y}) \equiv \frac{\partial \mathcal{L}}{\partial \gamma_i} = 0 \ , \quad i = 1, \ldots, M + K \ . \tag{40.32}$$

To obtain the covariance matrix of the estimated parameters one can find solutions $\tilde{\boldsymbol{\gamma}}$ corresponding to the expectation values of the data $\langle \boldsymbol{y} \rangle$ and expand $F_i(\hat{\boldsymbol{\gamma}}, \boldsymbol{y})$ to first order about these values. This gives (see, e.g., Sec. 11.6 of Ref. [8]) linearized approximations for the estimators, $\hat{\boldsymbol{\gamma}}(\boldsymbol{y}) \approx \tilde{\boldsymbol{\gamma}} + C(\boldsymbol{y} - \langle \boldsymbol{y} \rangle)$, where the matrix $C = -A^{-1}B$, and A and B are given by

$$A_{ij} = \left[\frac{\partial F_i}{\partial \gamma_j} \right]_{\tilde{\boldsymbol{\gamma}}, \langle \boldsymbol{y} \rangle} \quad \text{and} \quad B_{ij} = \left[\frac{\partial F_i}{\partial y_j} \right]_{\tilde{\boldsymbol{\gamma}}, \langle \boldsymbol{y} \rangle} \ . \tag{40.33}$$

In practice the values $\langle \boldsymbol{y} \rangle$ and corresponding solutions $\tilde{\boldsymbol{\gamma}}$ are estimated using the data from the actual measurement. Using this approximation for $\hat{\boldsymbol{\gamma}}(\boldsymbol{y})$, one can find the covariance matrix $U_{ij} = \mathrm{cov}[\hat{\gamma}_i, \hat{\gamma}_j]$ of the estimators for the γ_i in terms of that of the data $V_{ij} = \mathrm{cov}[y_i, y_j]$ using error propagation (cf. Eqs. (39.17) and (39.18)),

$$U = CVC^T \ . \tag{40.34}$$

The upper-left $M \times M$ block of the matrix U gives the covariance matrix for the estimated parameters $\mathrm{cov}[\hat{\theta}_i, \hat{\theta}_j]$. One can show for linear constraints that $\mathrm{cov}[\hat{\theta}_i, \hat{\theta}_j]$ is also given by the upper-left $M \times M$ block of $2A^{-1}$. If the parameters are estimated using the method of least squares, then the number of degrees of freedom for the distribution of the minimized χ^2 is increased by the number of constraints, *i.e.*, it becomes $N - M + K$. Further details can be found in, *e.g.*, Ch. 8 of Ref. [4] and Ch. 7 of Ref. [11].

40.2.5 *Unfolding*

An important class of parameter estimation problem involves measurement of the differential distribution of a kinematic variable in the form of a histogram with N bins. The data thus consist of the vector of measured data values $\boldsymbol{n} = (n_1, \ldots n_N)$, with expectation values $\nu_i = E[n_i]$. The n_i are usually independent and often modeled as Poisson distributed, from which it follows that the maximum-likelihood estimators are $\hat{\nu}_i = n_i$ for all i.

Because of the limited acceptance and resolution of the experiment, however, the measured values of the kinematic variable in question differ in general from their true values, and as a consequence the form of the data histogram is distorted relative to what would be obtained with perfect resolution. The desired parameters are not, therefore, the ν_i but rather one wants to estimate the expected number of entries in a given bin that would be found with a perfect detector. We call this the "true histogram" and denote it with $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_M)$, where the number of bins M is not required to equal that of the observed histogram. The μ_i are related to the expected numbers of events in the observed histogram by

$$\nu_i = \sum_{j=1}^{M} R_{ij}\mu_j + \beta_i \ , \tag{40.35}$$

where β_i here represents the expected number of events in bin i due to background processes and the $N \times M$ *response matrix* R_{ij} gives the probability for an event to be observed in bin i of $\boldsymbol{\nu}$ given that the true value of the variable was in bin j of $\boldsymbol{\mu}$. For purposes of this discussion let us suppose that the response matrix and expected background values are known. There are two main approaches to this type of problem, which we can call *unfolding* and *folding*.

In unfolding, one treats the true histogram $\boldsymbol{\mu}$ as the parameters of interest. The result is thus given by estimators $\hat{\boldsymbol{\mu}}$ and the corresponding covariance matrix $U_{ij} = \mathrm{cov}[\hat{\mu}_i, \hat{\mu}_j]$. Provided the response matrix can be inverted, the maximum-likelihood solution is easily found as $\hat{\boldsymbol{\mu}} = R^{-1}(\boldsymbol{n} - \boldsymbol{\beta})$. If the response matrix allows for significant migration of events between bins, then the variances of these estimators can be very large, sometimes to the point where the $\hat{\boldsymbol{\mu}}$ bear essentially no resemblance to the true $\boldsymbol{\mu}$. In such cases the estimators can be found by maximizing a linear combination of the log-likelihood and a regularization function that imposes some degree of smoothness on the unfolded distribution. In achieving a reduction in variance one inevitably introduces some bias into the estimators.

In the approach of folding, by contrast, to test a given model prediction for the true histogram $\boldsymbol{\mu}$ it is first "folded" with the response matrix and corrected for expected background to give the corresponding $\boldsymbol{\nu}$ according to Eq. (40.35), and these are compared to the corresponding $\boldsymbol{n}$ using, e.g., a likelihood ratio as shown in Sec. 40.2.2.1. In this way, one avoids any bias due to regularization.

To account for systematic uncertainties, the response matrix and background values may not be expressed as constants but rather as functions of nuisance parameters $\boldsymbol{\theta}$. These may be constrained by auxiliary measurements $\boldsymbol{u}$ with p.d.f. $p(\boldsymbol{u}|\boldsymbol{\theta})$ so that the full likelihood becomes (as in Eq. (40.17) but with different notation)

$$L(\boldsymbol{\mu}, \boldsymbol{\theta}) = P(\boldsymbol{n}|\boldsymbol{\nu}(\boldsymbol{\mu}, \boldsymbol{\theta}))p(\boldsymbol{u}|\boldsymbol{\theta}) \; . \tag{40.36}$$

Here the mean values $\boldsymbol{\nu} = R(\boldsymbol{\theta})\boldsymbol{\mu} + \boldsymbol{\beta}(\boldsymbol{\theta})$ now depend on both the true histogram parameters $\boldsymbol{\mu}$ as well as the nuisance parameters $\boldsymbol{\theta}$. Thus to record enough information for a future analysis using folding one must provide all of the ingredients used above: the primary data $\boldsymbol{n}$, the auxiliary measurements $\boldsymbol{u}$, and also the response matrix $R(\boldsymbol{\theta})$ and expected backgrounds $\boldsymbol{\beta}(\boldsymbol{\theta})$ as functions of the nuisance parameters. If unfolding is used, then future model tests or comparisons with other experiments can be carried out directly using the estimators $\hat{\boldsymbol{\mu}}$ and their covariance matrix.

If several distributions are unfolded, then to combine these in a test of a given model one should know how estimators for bins of different distributions are correlated, as can arise, e.g., through common systematic effects. If only the unfolded distributions and their separate covariance matrices are reported, however, then information on such correlations is not retained. In folding, one can include information on correlated systematic effects if the ingredients (R and $\boldsymbol{\beta}$) are known in terms of nuisance parameters that are common to different distributions.

In unfolding, the estimators for $\boldsymbol{\mu}$ can be constructed either by maximizing the log-likelihood using Eq. (40.36) or in the case where regularization is required one can maximize $\varphi(\boldsymbol{\mu}, \boldsymbol{\theta}) = \ln L(\boldsymbol{\mu}, \boldsymbol{\theta}) + \tau S(\boldsymbol{\mu})$, where the *regularization function* $S(\boldsymbol{\mu})$ reflects the smoothness of the true histogram and serves to reduce the variances of the estimators. Possible functions are based on the mean squared second derivative (a commonly used type of Tikhonov regularization) or the entropy of the true histogram. The parameter τ fixes the relative weighting of the log-likelihood and the regularization function and thus determines the balance between the bias and variance of the resulting estimators. Further discussion of the unfolding problem including methods for choosing the regularization function and parameter, as well as techniques that employ other types of regularization such as the iterative Bayes (Richardson-Lucy) method, can be found in Refs. [8, 11–13] and references therein.

40.2.6 *The Bayesian approach*

In the frequentist methods discussed above, probability is associated only with data, not with the value of a parameter. This is no longer the case in Bayesian statistics, however, which we introduce in this section. For general introductions to Bayesian statistics see, *e.g.*, Refs. [14–17].

Suppose the outcome of an experiment is characterized by a vector of data $\boldsymbol{x}$, whose probability distribution depends on an unknown parameter (or parameters) $\boldsymbol{\theta}$ that we wish to determine. In Bayesian statistics, all knowledge about $\boldsymbol{\theta}$ is summarized by the posterior p.d.f. $p(\boldsymbol{\theta}|\boldsymbol{x})$, whose integral over any given region gives the degree of belief for $\boldsymbol{\theta}$ to take on values in that region, given the data $\boldsymbol{x}$. It is obtained by using Bayes' theorem,

$$p(\boldsymbol{\theta}|\boldsymbol{x}) = \frac{P(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})}{\int P(\boldsymbol{x}|\boldsymbol{\theta}')\pi(\boldsymbol{\theta}')\, d\boldsymbol{\theta}'} \; , \tag{40.37}$$

where $P(\boldsymbol{x}|\boldsymbol{\theta})$ is the likelihood function, *i.e.*, the joint p.d.f. for the data viewed as a function of $\boldsymbol{\theta}$, evaluated with the data actually obtained in the experiment, and $\pi(\boldsymbol{\theta})$ is the prior p.d.f. for $\boldsymbol{\theta}$. Note that the denominator in Eq. (40.37) serves to normalize the posterior p.d.f. to unity.

As it can be difficult to report the full posterior p.d.f. $p(\boldsymbol{\theta}|\boldsymbol{x})$, one would usually summarize it with statistics such as the mean, mode or median value and covariance matrix. In addition one may construct intervals with a given probability content, as is discussed in Sec. 40.4.1 on Bayesian interval estimation.

40.2.6.1 *Priors*

Bayesian statistics supplies no unique rule for determining the prior $\pi(\boldsymbol{\theta})$; this reflects the analyst's subjective degree of belief (or state of knowledge) about $\boldsymbol{\theta}$ before the measurement was carried out. For the result to be of value to the broader community, whose members may not share these beliefs, it is important to carry out a *sensitivity analysis*, that is, to show how the result changes under a reasonable variation of the prior probabilities.

One might like to construct $\pi(\boldsymbol{\theta})$ to represent complete ignorance about the parameters by setting it equal to a constant. A problem here is that if the prior p.d.f. is flat in $\boldsymbol{\theta}$, then it is not flat for a nonlinear function of $\boldsymbol{\theta}$, and so a different parametrization of the problem would lead in general to a non-equivalent posterior p.d.f.

For the special case of a constant prior, one can see from Bayes' theorem (40.37) that the posterior is proportional to the likelihood, and therefore the mode (peak position) of the posterior is equal to the maximum-likelihood estimator. The posterior mode, however, will change in general upon a transformation of parameter. One may use as the Bayesian estimator a summary statistic other than the mode, such as the median, which is invariant under parameter transformation. But this will not in general coincide with the MLE.

The difficult and subjective nature of encoding personal knowledge into priors has led to what is called *objective Bayesian statistics*, where prior probabilities are based not on an actual degree of belief but rather derived from formal rules. These give, for example, priors which are invariant under a transformation of parameters, or ones which result in a maximum gain in information for a given set of measurements. For an extensive review see, *e.g.*, Ref. [18].

Objective priors do not in general reflect degree of belief, but they could in some cases be taken as possible, although perhaps extreme, subjective priors. The posterior probabilities as well therefore do not necessarily reflect a degree of belief. However one may regard investigating a variety of objective priors to be an important part of the sensitivity analysis. Furthermore, use of objective priors with Bayes' theorem can be viewed as a recipe for producing estimators or intervals which have desirable frequentist properties.

An important procedure for deriving objective priors is due to Jeffreys. According to *Jeffreys' rule* one takes the prior as

$$\pi(\boldsymbol{\theta}) \propto \sqrt{\det(I(\boldsymbol{\theta}))} \; , \tag{40.38}$$

where

$$I_{ij}(\boldsymbol{\theta}) = -E\left[\frac{\partial^2 \ln P(\boldsymbol{x}|\boldsymbol{\theta})}{\partial\theta_i \partial\theta_j}\right] \tag{40.39}$$

is the *Fisher information matrix*. One can show that the Jeffreys prior leads to inference that is invariant under a transformation of parameters. One should note that the Jeffreys prior does not in general correspond to one's degree of belief about the value of a parameter. As examples, the Jeffreys prior for the mean μ of a Gaussian distribution is a constant, and for the mean of a Poisson distribution one finds $\pi(\mu) \propto 1/\sqrt{\mu}$.

Neither the constant nor $1/\sqrt{\mu}$ priors can be normalized to unit area and are therefore said to be *improper*. This can be allowed because the prior always appears multiplied by the likelihood function, and if the likelihood falls to zero sufficiently quickly then one may have a normalizable posterior density.

An important type of objective prior is the reference prior due to Bernardo and Berger [19]. To find the reference prior for a given problem one considers the Kullback-Leibler divergence $D_n[\pi, p]$ of the posterior $p(\boldsymbol{\theta}|\boldsymbol{x})$ relative to a prior $\pi(\boldsymbol{\theta})$, obtained from a set of i.i.d. data $\boldsymbol{x} = (x_1, \ldots, x_n)$:

$$D_n[\pi, p] = \int p(\boldsymbol{\theta}|\boldsymbol{x}) \ln \frac{p(\boldsymbol{\theta}|\boldsymbol{x})}{\pi(\boldsymbol{\theta})}\, d\boldsymbol{\theta} \; . \tag{40.40}$$

This is effectively a measure of the gain in information provided by the data. The reference prior is chosen so that the expectation value of this information gain is maximized for the limiting case of $n \to \infty$, where the expectation is computed with respect to the marginal distribution of the data,

$$p(\boldsymbol{x}) = \int p(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})\, d\boldsymbol{\theta} \; . \tag{40.41}$$

For a single, continuous parameter the reference prior is usually identical to the Jeffreys prior. In the multiparameter case an iterative algorithm exists, which requires sorting the parameters by order of inferential importance. Often the result does not depend on this order, but when it does, this can be part of a sensitivity analysis. Further discussion and applications to particle physics problems can be found in Ref. [20].

40.2.6.2 *Bayesian treatment of nuisance parameters*

As discussed in Sec. 40.2.2, a model may depend on parameters of interest $\boldsymbol{\theta}$ as well as on nuisance parameters $\boldsymbol{\nu}$, which must be included for an accurate description of the data. Knowledge about the values of $\boldsymbol{\nu}$ may be supplied by control measurements, theoretical insights, physical constraints, etc. Suppose, for example, one has data $\boldsymbol{y}$ from a control measurement which is characterized by a probability $p(\boldsymbol{y}|\boldsymbol{\nu})$. Suppose further that before carrying out the control measurement one's state of knowledge about $\boldsymbol{\nu}$ is described by an initial prior $\pi_0(\boldsymbol{\nu})$, which in practice is often taken to be a constant or in any case very broad. By using Bayes' theorem (40.1) one obtains the updated prior $\pi(\boldsymbol{\nu})$ (*i.e.*, now $\pi(\boldsymbol{\nu}) = \pi(\boldsymbol{\nu}|\boldsymbol{y})$, the probability for $\boldsymbol{\nu}$ given $\boldsymbol{y}$),

$$\pi(\boldsymbol{\nu}|\boldsymbol{y}) \propto p(\boldsymbol{y}|\boldsymbol{\nu})\pi_0(\boldsymbol{\nu}) \; . \tag{40.42}$$

In the absence of a model for $P(\boldsymbol{y}|\boldsymbol{\nu})$ one may make some reasonable but *ad hoc* choices in order to approximate $\pi(\boldsymbol{\nu})$. For a single nuisance parameter ν, for example, one might characterize the uncertainty by a p.d.f. $\pi(\nu)$ centered about its nominal value with a certain standard deviation σ_ν. Often a Gaussian p.d.f. provides a reasonable model for one's degree of belief about a nuisance parameter; in other cases, more complicated shapes may be appropriate. If, for example, the parameter represents a non-negative quantity then a log-normal or gamma p.d.f. can be a more natural choice than a Gaussian truncated at zero. Note also that truncation of the prior of a nuisance parameter ν at zero will in general make $\pi(\nu)$ nonzero at $\nu = 0$, which can lead to an unnormalizable posterior for a parameter of interest that appears multiplied by ν.

The likelihood function, prior, and posterior p.d.f.s all depend on both $\boldsymbol{\theta}$ and $\boldsymbol{\nu}$, and are related by Bayes' theorem, as usual. Note that the likelihood here only refers to the primary measurement $\boldsymbol{x}$. Once any control measurements $\boldsymbol{y}$ are used to find the updated prior $\pi(\boldsymbol{\nu})$ for the nuisance parameters, this information is fully encapsulated in $\pi(\boldsymbol{\nu})$ and the control measurements do not appear further.

One can obtain the posterior p.d.f. for $\boldsymbol{\theta}$ alone by integrating over the nuisance parameters, *i.e.*,

$$p(\boldsymbol{\theta}|\boldsymbol{x}) = \int p(\boldsymbol{\theta}, \boldsymbol{\nu}|\boldsymbol{x})\, d\boldsymbol{\nu} \; . \tag{40.43}$$

Such integrals can often not be carried out in closed form, and if the number of nuisance parameters is large, then they can be difficult to compute with standard Monte Carlo methods. *Markov Chain Monte Carlo* (MCMC) techniques are often used for computing integrals of this type (see Sec. 42.6).

40.3 Statistical tests

In addition to estimating parameters, one often wants to assess the validity of certain statements concerning the data's underlying distribution. Frequentist *hypothesis tests*, described in Sec. 40.3.1, provide a rule for accepting or rejecting hypotheses depending on the outcome of a measurement. In *significance tests*, covered in Sec. 40.3.2, one gives the probability to obtain a level of incompatibility with a certain hypothesis that is greater than or equal to the level observed with the actual data. Goodness-of-fit tests that quantify the general level of compatibility between data and a hypothesis are described in Sec. 40.3.3. In the Bayesian approach, the corresponding procedure is based fundamentally on the posterior probabilities of the competing hypotheses. In Sec. 40.3.4 we describe a related construct called the Bayes factor, which can be used to quantify the degree to which the data prefer one or another hypothesis.

40.3.1 *Hypothesis tests*

A frequentist *test* of a hypothesis (often called the null hypothesis, H_0) is a rule that states for which data values $\boldsymbol{x}$ the hypothesis is rejected. A region of $\boldsymbol{x}$-space called the critical region, w, is specified such that there is no more than a given probability under H_0, α, called the *size* or *significance level* of the test, to find $\boldsymbol{x} \in w$. If the data are discrete, it may not be possible to find a critical region with exact probability content α, and thus we require $P(\boldsymbol{x} \in w|H_0) \leq \alpha$. If the data are observed in the critical region, H_0 is rejected.

The data $\boldsymbol{x}$ used to construct a test could be, for example, a set of values that characterizes an individual event. In this case the test corresponds to classification as, *e.g.*, signal or background. Alternatively the data could represent a set of values from a collection of events. Often one is interested in knowing whether all of the events are of a certain type (background), or whether the sample contains at least some events of a new type (signal). Here the background-only hypothesis plays the role of H_0, and in the alternative H_1 both signal and background are present. Rejecting H_0 is, from the standpoint of frequentist statistics, the required step to establish discovery of the signal process.

The critical region is not unique. Its choice should take into account the probabilities for the data predicted by some alternative hypothesis (or set of alternatives) H_1. Rejecting H_0 if it is true is called a *type-I error*, and occurs by construction with probability no greater than α. Not rejecting H_0 if an alternative H_1 is true is called a *type-II error*, and for a given test this will have a certain probability $\beta = P(\boldsymbol{x} \notin w|H_1)$. The quantity $1 - \beta$ is called the *power* of the test of H_0 with respect to the alternative H_1. A strategy for defining the critical region can therefore be to maximize the power with respect to some alternative (or alternatives) given a fixed size α.

To maximize the power of a test of H_0 with respect to the alternative H_1, the *Neyman–Pearson lemma* states that the critical region w should be chosen such that for all data values $\boldsymbol{x}$ inside w, the likelihood ratio

$$\lambda(\boldsymbol{x}) = \frac{f(\boldsymbol{x}|H_1)}{f(\boldsymbol{x}|H_0)} \tag{40.44}$$

is greater than or equal to a given constant c_α, and everywhere outside the critical region one has $\lambda(\boldsymbol{x}) < c_\alpha$, where the value of c_α is determined by the size of the test α. The hypotheses H_0 and H_1 must be simple, *i.e.*, they should not contain undetermined parameters.

It is convenient to define the test using a scalar function of the data $\boldsymbol{x}$ called a *test statistic*, $t(\boldsymbol{x})$, such that the boundary of the critical region is given by a surface of constant $t(\boldsymbol{x})$. The Neyman–Pearson lemma is equivalent to the statement that the likelihood ratio (40.44) represents the optimal test statistic. It can be difficult in practice, however, to determine $\lambda(\boldsymbol{x})$, since this requires knowledge of the joint p.d.f.s $f(\boldsymbol{x}|H_0)$ and $f(\boldsymbol{x}|H_1)$.

Often one does not have explicit formulae for these, but rather Monte Carlo models that allow one to generate instances of $\boldsymbol{x}$ that follow the p.d.f.s.

In the case where the likelihood ratio (40.44) cannot be used explicitly, there exist a variety of other multivariate methods for constructing a test statistic that may approach its performance. These are based on machine-learning algorithms that use samples of *training data* corresponding to the hypotheses in question, often generated from Monte Carlo models. Further information on Machine Learning can be found in Sec. 41 of this Review.

The multivariate algorithms designed to classify events into signal and background types also form the basis of tests of the hypothesis that a sample of events consists of background only. Such a test can be constructed using the distributions of the test statistic $t(\boldsymbol{x})$ for event classification obtained from a multivariate algorithm such as a Neural Network output. The distributions $p(t|s)$ and $p(t|b)$ for signal and background events, respectively, are used to construct the likelihood ratio of the signal-plus-background hypothesis relative to that of background only. To the extent that the test statistic $t(\boldsymbol{x})$ approximates the likelihood ratio (or a monotonic function thereof) for individual events given by (40.44), the resulting test of the background-only hypothesis for the event sample will have maximum power with respect to the signal-plus-background alternative (see Ref. [21]).

40.3.2 *Tests of significance, p-values*

A frequentist *significance test* allows one to assign a numerical value, called the p-value, that reflects the level of agreement between a hypothesis H_0 and the observed data $\boldsymbol{x}$. To carry out a significance test one must specify a subset of the data space, whose boundary includes the observed data point $\boldsymbol{x}_{\rm obs}$, that is deemed to have equal or lesser compatibility with H_0 relative to $\boldsymbol{x}_{\rm obs}$. The p-value of H_0 is the probability, assuming data distributed according to H_0, to find $\boldsymbol{x}$ in the region of equal or lesser compatibility.

For continuous data, one can show that the p-value of H_0, here called p_0, follows a uniform distribution for data generated under H_0. Therefore one has $P(p_0 \leq \alpha|H_0) = \alpha$ for any constant α in $[0,1]$. In this way the region of data space where $p_0 \leq \alpha$ gives a critical region w of a test of size α, as it satisfies $P(\boldsymbol{x} \in w|H_0) \leq \alpha$. Thus rejecting H_0 if $p_0 \leq \alpha$ is equivalent to the hypothesis test of Sec. 40.3.1 above. For the critical region w defined by $p_0 \leq \alpha$ one can find the power $P(\boldsymbol{x} \in w|H_1)$ with respect to an alternative hypothesis H_1, as defined in Sec. 40.3.1. In general the region of low compatibility with H_0 is defined so as to have a high probability for data generated under H_1, so that the distribution of p_0, assuming data $\boldsymbol{x}$ that follows H_1, will be concentrated at low values, and the critical region w derived from $p_0 \leq \alpha$ will have a high power with respect to H_1.

Similar to construction of a test's critical region in Sec. 40.3.1, finding the p-value is generally done by defining a statistic $t(\boldsymbol{x})$ whose value corresponds to better or worse levels of agreement with the hypothesis. The hypothesis being tested, H_0, will determine the p.d.f. $f(t|H_0)$ for the statistic. If, for example, t is defined such that large values correspond to poor agreement with the hypothesis, then the p-value is

$$p = \int_{t_{\rm obs}}^{\infty} f(t|H_0)\, dt \ , \tag{40.45}$$

where $t_{\rm obs} = t(\boldsymbol{x}_{\rm obs})$ is the value of the statistic obtained in the actual experiment.

Note that the p-value is not the probability of the hypothesis, which in frequentist statistics is not defined. The p-value should also not be confused with the size (significance level) of a test, or the confidence level of a confidence interval (Section 40.4), both of which are pre-specified constants.

When searching for a new phenomenon, one tries to reject the hypothesis H_0 that the data are consistent with known (*e.g.*, Standard Model) processes. If the p-value of H_0 is sufficiently low, then one is willing to accept that some alternative hypothesis is true. Often one converts the p-value into an effective significance Z, defined as an equivalent number of standard deviations of a Gaussian distributed random variable. In a search for an intrinsically positive signal, *i.e.*, where only upward fluctuations of the estimated rate appear signal like, this is defined as

$$Z = \Phi^{-1}(1-p) \ . \tag{40.46}$$

Here Φ is the cumulative distribution of the standard Gaussian, and Φ^{-1} is its inverse (quantile) function. In this way, a p-value of $1/2$ gives $Z = 0$, *i.e.*, having an estimated signal rate of zero corresponds to zero significance. If either positive or negative data fluctuations would indicate evidence of the signal, then one defines

$$Z = \Phi^{-1}(1-p/2) \ . \tag{40.47}$$

In this case an estimated signal rate of zero gives $p = 1$ and $Z = 0$.

Often in particle physics the level of significance where an effect is said to qualify as a discovery is $Z = 5$, *i.e.*, a 5σ effect, corresponding to a p-value of 2.87×10^{-7}. One's actual degree of belief that a new process is present, however, will depend in general on other factors as well, such as the plausibility of the new signal hypothesis and the degree to which it can describe the data, one's confidence in the model that led to the observed p-value, and possible corrections for multiple observations out of which one focuses on the smallest p-value obtained (the "look-elsewhere effect", discussed in Section 40.3.2.2).

40.3.2.1 *Frequentist treatment of nuisance parameters and asymptotic methods for tests*

Suppose one wants to test hypothetical values of parameters $\boldsymbol{\theta}$, but the model also contains nuisance parameters $\boldsymbol{\nu}$. To find a p-value for $\boldsymbol{\theta}$ we can construct a test statistic $q_{\boldsymbol{\theta}}$ such that larger values constitute increasing incompatibility between the data and the hypothesis. Then for an observed value of the statistic $q_{\boldsymbol{\theta},\rm obs}$, the p-value of $\boldsymbol{\theta}$ is

$$p_{\boldsymbol{\theta}}(\boldsymbol{\nu}) = \int_{q_{\boldsymbol{\theta},\rm obs}}^{\infty} f(q_{\boldsymbol{\theta}}|\boldsymbol{\theta},\boldsymbol{\nu})\, dq_{\boldsymbol{\theta}} \ , \tag{40.48}$$

which depends in general on the nuisance parameters $\boldsymbol{\nu}$. In the strict frequentist approach, $\boldsymbol{\theta}$ is rejected only if the p-value is less than α for all possible values of the nuisance parameters.

The difficulty described above is effectively solved if we can define the test statistic $q_{\boldsymbol{\theta}}$ in such a way that its distribution $f(q_{\boldsymbol{\theta}}|\boldsymbol{\theta})$ is independent of the nuisance parameters. Although exact independence is only found in special cases, it can be achieved approximately by use of the *profile likelihood ratio*. This is given by the profile likelihood from Eq.(40.18) divided by the value of the likelihood at its maximum, *i.e.*, when evaluated with the maximum-likelihood estimators $\widehat{\boldsymbol{\theta}}$ and $\widehat{\boldsymbol{\nu}}$:

$$\lambda_p(\boldsymbol{\theta}) = \frac{L(\boldsymbol{\theta},\widehat{\widehat{\boldsymbol{\nu}}}(\boldsymbol{\theta}))}{L(\widehat{\boldsymbol{\theta}},\widehat{\boldsymbol{\nu}})} \ . \tag{40.49}$$

Wilks' theorem [10] states that, providing certain general conditions are satisfied, the distribution of $-2\ln\lambda_{\rm p}(\boldsymbol{\theta})$, under assumption of $\boldsymbol{\theta}$, approaches a χ^2 distribution in the limit where the data sample is very large, independent of the values of the nuisance parameters $\boldsymbol{\nu}$. Here the number of degrees of freedom is equal to the number of components of $\boldsymbol{\theta}$. More details on use of the profile likelihood are given in Refs. [22, 23] and in contributions to the PHYSTAT conferences [24]; explicit formulae for special cases can be found in Ref. [25]. Further discussion on how to incorporate systematic uncertainties into p-values can be found in Ref. [26].

Even with use of the profile likelihood ratio, for a finite data sample the p-value of hypothesized parameters $\boldsymbol{\theta}$ will retain in general some dependence on the nuisance parameters $\boldsymbol{\nu}$. Ideally one would find the the maximum of $p_\theta(\boldsymbol{\nu})$ from Eq. (40.48) explicitly, but that is often impractical. An approximate and computationally feasible technique is to use $p_\theta(\widehat{\widehat{\boldsymbol{\nu}}}(\theta))$, where $\widehat{\widehat{\boldsymbol{\nu}}}(\theta)$ are the profiled values of the nuisance parameters as defined in Section 40.2.2.2. The resulting p-value is correct if the true values of the nuisance parameters are equal to the profiled values used; otherwise it could be either too high or too low. This is discussed further in Section 40.4.2 on confidence intervals.

The methods above based on the profile likelihood ratio are useful in practice because, provided one has a sufficiently large data sample, the distributions of the test statistics are related through Wilks' theorem to the chi-square p.d.f. If the data sample is not large enough to justify use of the asymptotic formulae, then some adjustments can be made to the test statistics so that their distributions are better approximated by the asymptotic ones; these improvements go under the general name of "higher-order asymptotics". Using these methods one may obtain p-values using the asymptotic formulae even for smaller data samples, avoiding costly Monte Carlo simulation to find distributions of test statistics.

Roughly speaking, the chi-square distribution for the profile likelihood ratio relies on having a Gaussian distribution for estimators of the model's parameters. An important type of corrected statistic relies on an improved distribution for the maximum-likelihood estimator due to Barndorff-Nielsen [27] (the p^* approximation). Another class of improved statistic due to Bartlett [28, 29] starts with a statistic t which, asymptotically, should be chi-square distributed with n_d degrees of freedom. A new statistic is defined as $t' = tn_\mathrm{d}/E[t]$, which by construction has mean $E[t'] = n_\mathrm{d}$, as for the chi-square distribution. Further details and applications of these methods are described in Refs. [30, 31].

One may also treat model uncertainties in a Bayesian manner but then use the resulting model in a frequentist test. Suppose the uncertainty in a set of nuisance parameters $\boldsymbol{\nu}$ is characterized by a Bayesian prior p.d.f. $\pi(\boldsymbol{\nu})$. This can be used to construct the marginal (also called the prior predictive) model for the data $\boldsymbol{x}$ and parameters of interest $\boldsymbol{\theta}$,

$$P_\mathrm{m}(\boldsymbol{x}|\boldsymbol{\theta}) = \int P(\boldsymbol{x}|\boldsymbol{\theta},\boldsymbol{\nu})\pi(\boldsymbol{\nu})\, d\boldsymbol{\nu}\ . \tag{40.50}$$

The marginal model does not represent the probability of data that would be generated if one were really to repeat the experiment, as in that case one would assume that the nuisance parameters do not vary. Rather, the marginal model represents a situation in which every repetition of the experiment is carried out with new values of $\boldsymbol{\nu}$, randomly sampled from $\pi(\boldsymbol{\nu})$. It is in effect an average of models each with a given $\boldsymbol{\nu}$, where the average is carried out with respect to the prior p.d.f. $\pi(\boldsymbol{\nu})$.

The marginal model for the data $\boldsymbol{x}$ can be used to determine the distribution of a test statistic Q, which can be written

$$P_\mathrm{m}(Q|\boldsymbol{\theta}) = \int P(Q|\boldsymbol{\theta},\boldsymbol{\nu})\pi(\boldsymbol{\nu})\, d\boldsymbol{\nu}\ . \tag{40.51}$$

In a search for a new signal process, the test statistic can be based on the ratio of likelihoods corresponding to the experiments where signal and background events are both present, L_{s+b}, to that of background only, L_b. Often the likelihoods are evaluated with the profiled values of the nuisance parameters, which may give improved performance. It is important to note, however, that it is through use of the marginal model for the distribution of Q that the uncertainties related to the nuisance parameters are incorporated into the result of the test. Different choices for the test statistic itself only result in variations of the power of the test with respect to different alternatives. Studies of marginalization versus profiling of nuisance parameters for specific problems, e.g., related to a Poisson counting experiment, can be found in Refs. [32, 33].

40.3.2.2 *The look-elsewhere effect*

The "look-elsewhere effect" relates to multiple measurements used to test a single hypothesis. The classic example is when one searches in a distribution for a peak whose position is not predicted in advance. Here the no-peak hypothesis is tested using data in a given range of the distribution. In the frequentist approach the correct p-value of the no-peak hypothesis is the probability, assuming background only, to find a signal as significant as the one found or more so anywhere in the search region. This can be substantially higher than the probability to find a peak of equal or greater significance in the particular place where it appeared. There is in general some ambiguity as to what constitutes the relevant search region or even the broader set of relevant measurements. Although the desired p-value is well defined once the search region has been fixed, an exact treatment can require extensive computation.

The "brute-force" solution to this problem by Monte Carlo involves generating data under the background-only hypothesis and for each data set, fitting a peak of unknown position and recording a measure of its significance. To establish a discovery one often requires a p-value smaller than 2.87×10^{-7}, corresponding to a 5σ or larger effect. Determining this with Monte Carlo thus requires generating and fitting a very large number of experiments, perhaps several times 10^7. In contrast, if the position of the peak is fixed, then the fit to the distribution is much easier, and furthermore one can in many cases use formulae valid for sufficiently large samples that bypass completely the need for Monte Carlo (see, *e.g.*, Ref. [25]). However, this fixed-position or "local" p-value would not be correct in general, as it assumes the position of the peak was known in advance.

A method that allows one to modify the local p-value computed under assumption of a fixed position to obtain an approximation to the correct "global" value using a relatively simple calculation is described in Ref. [34]. Suppose a model contains a nuisance parameter such as the peak position that is only defined under the signal model (there is no peak in the background-only model). Furthermore, suppose a test statistic q_0 is defined using the profile likelihood ratio, so that by Wilk's theorem it would be asymptotically chi-square distributed if the peak position were to be fixed. The asymptotic distribution no longer holds if the peak position is adjustable, however, as this violates the regularity conditions of Wilks' theorem. If the statistic has an observed value u, then an approximation for the global p-value is found to be

$$p_\mathrm{global} \approx p_\mathrm{local} + \langle N_u \rangle\ , \tag{40.52}$$

where $\langle N_u \rangle$, which is much smaller than one in cases of interest, is the mean number of "upcrossings" (as defined in Ref. [34]) of the statistic q_0 above the level u in the range of the nuisance parameter considered (*e.g.*, the mass range). The value of $\langle N_u \rangle$ can be estimated from the number of upcrossings $\langle N_{u_0} \rangle$ above some much lower value, u_0, by using a relation due to Davis [35],

$$\langle N_u \rangle \approx \langle N_{u_0} \rangle e^{-(u-u_0)/2}\ . \tag{40.53}$$

By choosing u_0 sufficiently low, the value of $\langle N_u \rangle$ can be estimated by simulating only a very small number of experiments, or even from the observed data, rather than of the order 10^7 needed if one is dealing with a 5σ effect.

40.3.3 *Goodness of fit*

At times one wants to quantify the level of agreement between the data $\boldsymbol{x}$ and a hypothesis H_0 without explicit reference to alternative hypotheses. In the frequentist approach this is done using a *goodness-of-fit test*. The result is quantified with a p-value, in general obtained from a statistic $t(\boldsymbol{x})$ as done in Sec. 40.3.2 with a significance test. Here, however, the *goodness-of-fit statistic* is defined using general considerations of what constitutes greater or lesser compatibility between data and hypothesis and not with reference to alternative hypotheses or power. Nevertheless, for a given statistic $t(\boldsymbol{x})$, the power of the resulting test with respect to an alternative can be found, so that types of alternatives to which one is sensitive (*i.e.*, to which the test has high power) can be investigated.

The Neyman-Pearson lemma (see Sec. 40.3.1) states that a test of H_0 that has maximum power with respect to an alternative H_1 should be based on a statistic that is monotonic in the likelihood ratio $P(\boldsymbol{x}|H_1)/P(\boldsymbol{x}|H_0)$. Therefore a goodness-of-fit statistic derived without reference to a specific H_1 will not in general attain this maximum power. And even if a given $t(\boldsymbol{x})$ happens to be optimal or nearly so for some alternative H_1, there may be other relevant alternatives for which its power is lower. In practice, goodness-of-fit statistics are defined so as to provide sensitivity to a broad class of alternatives, e.g., those that differ in the location of the bulk of the distribution's probability or the distribution's width or the nature of the tails. It may therefore be useful to use

several goodness-of-fit tests that are sensitive to different aspects of the data distribution in question.

The most important application of goodness-of-fit tests is no doubt in conjunction with the method of least squares, which we describe in Sec. 40.3.3.1 below. Other types of tests, particularly those based on the *empirical distribution function* are described in Sec. 40.3.3.2. Further discussion of goodness of fit can be found in Refs. [4, 36] and references therein.

40.3.3.1 *Goodness-of-fit with chi-square or likelihood ratio*

An important type of goodness-of-fit test arises when a set of measurements $\boldsymbol{y} = (y_1, \ldots, y_N)$ are used to test the hypothesis that the values are Gaussian distributed with given mean values $E[y_i] = \mu_i$ and variances $V[y_i] = \sigma_i^2$ (or covariance $V_{ij} = \mathrm{cov}[y_i, y_j]$ if the values are correlated). The general procedures also hold when the data are Poisson or multinomially distributed with sufficiently large mean values so that the Gaussian represents an adequate approximation. The Gaussian hypothesis may be simple (all parameters fully specified), or the mean values μ_i may be given as functions of some other parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_M)$, with $M < N$. The (co)variances are treated as fixed.

The test statistic derived from the likelihood ratio has already been introduced in Sec. 40.2.3 in connection with the method of least squares, and is given by the minimum of the function $\chi^2(\boldsymbol{\theta})$ with respect to $\boldsymbol{\theta}$, i.e., $t = \chi^2_{\min} = \chi^2(\hat{\boldsymbol{\theta}})$, *e.g.*, in the case of uncorrelated measurements

$$t = \sum_{i=1}^{N} \frac{(y_i - \mu_i(\hat{\boldsymbol{\theta}}))^2}{\sigma_i^2} \; . \tag{40.54}$$

For Gaussian distributed $\boldsymbol{y}$, the statistic t follows a chi-square distribution for $N - M$ degrees of freedom. From Eq. (40.54) one sees that greater t corresponds to increasing incompatibility between the measured y_i and predicted μ_i. The p-value of the Gaussian hypothesis is therefore taken to be

$$p = \int_{\chi^2_{\min}}^{\infty} f(t; n_\mathrm{d})\, dt \; , \tag{40.55}$$

where $f(t; n_\mathrm{d})$ is the χ^2 p.d.f. and $n_\mathrm{d} = N - M$ is the appropriate number of degrees of freedom. Values are shown in Fig. 40.1 or obtained from standard computer libraries. If the asymptotic conditions for using the χ^2 p.d.f. do not hold, the statistic can still be defined as before, but its p.d.f. must be determined by other means in order to obtain the p-value, *e.g.*, using a Monte Carlo calculation.

Often the data represent numbers of events in N bins of a histogram, *i.e.*, $\boldsymbol{n} = (n_1, \ldots, n_N)$. An important case is when $\boldsymbol{n}$ follows a multinomial distribution with $n_\mathrm{tot} = \sum_{i=1}^{N} n_i$ total entries and mean values μ_i, or equivalently bin probabilities $p_i = \mu_i / n_\mathrm{tot}$. Alternatively one may model the n_i as independent and Poisson distributed with means μ_i. If there are no adjustable parameters in the hypotheses, then the goodness-of-fit can be quantified with *Pearson's* χ^2 *statistic*, defined for multinomial data as

$$t_\mathrm{M} = \sum_{i=1}^{N} \frac{(n_i - n_\mathrm{tot} p_i)^2}{n_\mathrm{tot} p_i} \; , \tag{40.56}$$

or for the independent Poisson data as

$$t_\mathrm{P} = \sum_{i=1}^{N} \frac{(n_i - \mu_i)^2}{\mu_i} \; . \tag{40.57}$$

In the limit where the means μ_i are large, the statistics t_M and t_P are found to follow chi-square distributions for $N - 1$ and N degrees of freedom, respectively. Having one fewer degrees of freedom in the multinomial case is related to the fact that n_tot is fixed and thus the n_i are correlated.

Alternatively one can use the test statistic based on the likelihood ratio $t = -2 \ln \lambda(\hat{\boldsymbol{\theta}})$ given previously in Eq. (40.16). Here the likelihood ratio λ is chosen to correspond to the multinomial or Poisson model as appropriate, as described in Sec. 40.2.2.1. One finds that the distribution of the likelihood-ratio statistic approaches the asymptotic limit faster than does Pearson's chi-square and thus when using the chi-square p.d.f. to compute a p-value one obtains in general a more accurate result from $-2 \ln \lambda$ (see [9]).

Since the mean of the chi-square distribution is equal to n_d, one expects in a "reasonable" experiment to obtain $\chi^2 \approx n_\mathrm{d}$ (here χ^2 refers to the minimized value). Hence the quantity χ^2/n_d is sometimes reported. Since the p.d.f. of χ^2/n_d depends on n_d, however, one must report n_d as well if one wishes to determine the p-value. The p-values obtained for different values of χ^2/n_d are shown in Fig. 40.2.

If the minimized χ^2 value indicates a low level of agreement between data and hypothesis, one may be tempted to expect a high degree of uncertainty for any fitted parameters. Poor goodness-of-fit, however, does not mean that one will have large statistical errors for parameter estimates. If, for example, the error bars (or covariance matrix) used in constructing the χ^2 are underestimated, then this will lead to underestimated statistical errors for the fitted parameters and an increased value of the minimized χ^2. The standard deviations of estimators that one finds from, say, Eq. (40.13) reflect how widely the estimates would be distributed if one were to repeat the measurement many times, assuming that the hypothesis and measurement errors used in the χ^2 are also correct. They do not include the systematic error which may result from an incorrect hypothesis or incorrectly estimated measurement errors in the χ^2.

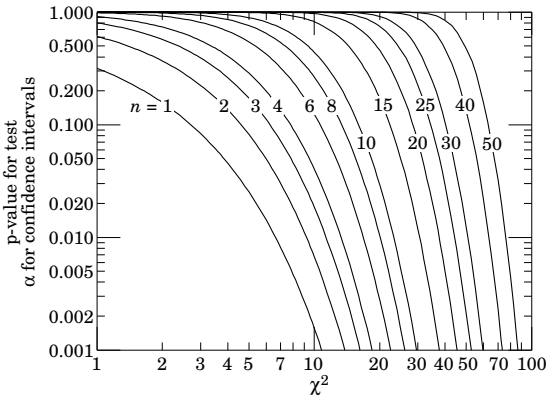

Figure 40.1: One minus the χ^2 cumulative distribution, $1 - F(\chi^2; n)$, for n degrees of freedom. This gives the p-value for the χ^2 goodness-of-fit test as well as one minus the coverage probability for confidence regions (see Sec. 40.4.2.2).

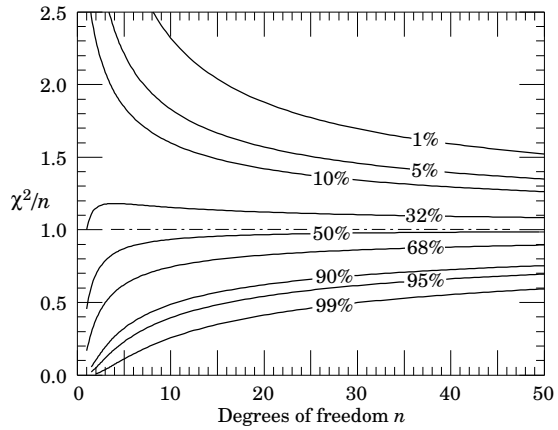

Figure 40.2: The 'reduced' χ^2, equal to χ^2/n, for n degrees of freedom. The curves show as a function of n the χ^2/n that corresponds to a given p-value.

40.3.3.2 *Goodness-of-fit with the empirical distribution function*

Suppose a measurement yields a sample of independent and identically distributed (i.i.d.) values $\boldsymbol{x} = (x_1, \ldots, x_n)$. Often the values may be summarized by creating a histogram, but this inevitably results in a loss of information, since the position of the x values within each bin is not retained. Particularly with small numbers of observations n one therefore may prefer to keep the values of each of the x_i (*i.e.*, "unbinned"). The sample may be displayed graphically using the *empirical distribution function* (e.d.f.)

$$F_n(x) = \frac{\text{number of elements in sample with value } \leq x}{n} \,. \tag{40.58}$$

The e.d.f. $F_n(x)$ begins at zero for x less than the lowest observed value, increases by $1/n$ at each observed x_i, and saturates at unity for x equal to the highest value in the sample.

Given an i.i.d. data sample $\boldsymbol{x} = (x_1, \ldots, x_n)$, suppose one wants to test the hypothesis H_0 that x follows the p.d.f. $f(x)$ using a goodness-of-fit test, *i.e.*, without reference to a specific alternative. The hypothesis of the p.d.f. $f(x)$ is equivalent to saying the cumulative distribution function (c.d.f.) is $F(x) = \int_{-\infty}^{x} f(x')\,dx'$. As the e.d.f. $F_n(x)$ can be viewed as an estimator for the c.d.f. $F(x)$, we can derive a goodness-of-fit statistic by some appropriately defined measure of the "distance" between the two.

A widely used example is the Kolmogorov-Smirnov (K-S) test, based on

$$D_n = \sup_x |F_n(x) - F(x)| \,, \tag{40.59}$$

where sup denotes the supremum. That is, D_n is the greatest vertical distance between $F_n(x)$ and $F(x)$ for any x. In the limit of large sample size n, one can show that the distribution of D_n, assuming the data follows the c.d.f. $F(x)$, approaches the Kolmogorov distribution, which is independent of the specific form of $F(x)$ and is provided in many software packages. A larger value of D_n corresponds to greater incompatibility between data and hypothesis, so the p-value is the probability $P(D_n \geq D_{n,\text{obs}}|H_0)$. The K-S test is sensitive in particular to differences in location (*i.e.*, in the mean of x), as this corresponds to a horizontal shift between $F_n(x)$ and $F(x)$, giving a large maximum vertical distance D_n.

The Cramér-von Mises family of tests is based on the squared difference between $F_n(x)$ and $F(x)$ through an integral of the form

$$W^2 = \int_{-\infty}^{\infty} (F(x) - F_n(x))^2 w(x) f(x)\,dx \,, \tag{40.60}$$

where $f(x) = dF/dx$ is the p.d.f. of x and $w(x)$ is a weight function that must be specified. Two important choices are the classic Cramér-von Mises test with $w(x) = 1$, and the Anderson-Darling test with $w(x) = [F(x)(1 - F(x))]^{-1}$, which gives increased sensitivity to departures in the tails of the distribution. For cases such as these where the weight function depends on x only through the cumulative distribution $F(x)$, one can show (see, *e.g.*, Refs. [4,36]) that the distribution of W^2, assuming data that follows $F(x)$, is independent of the form of $F(x)$. The distributions of the Smirnov-Cramér-von Mises and Anderson-Darling statistics are available in standard computer libraries.

40.3.4 *Bayes factors*

In Bayesian statistics, all of one's knowledge about a model is contained in its posterior probability, which one obtains using Bayes' theorem (Eq. (40.37)). Thus one could reject a hypothesis H if its posterior probability $P(H|\boldsymbol{x})$ is sufficiently small. The difficulty here is that $P(H|\boldsymbol{x})$ is proportional to the prior probability $P(H)$, and there will not be a consensus about the prior probabilities for the existence of new phenomena. Nevertheless one can construct a quantity called the Bayes factor (described below), which can be used to quantify the degree to which the data prefer one hypothesis over another, and is independent of their prior probabilities.

Consider two models (hypotheses), H_i and H_j, described by vectors of parameters $\boldsymbol{\theta}_i$ and $\boldsymbol{\theta}_j$, respectively. Some of the components will be common to both models and others may be distinct. The full prior probability for each model can be written in the form

$$\pi(H_i, \boldsymbol{\theta}_i) = P(H_i)\pi(\boldsymbol{\theta}_i|H_i) \,. \tag{40.61}$$

Here $P(H_i)$ is the overall prior probability for H_i, and $\pi(\boldsymbol{\theta}_i|H_i)$ is the normalized p.d.f. of its parameters. For each model, the posterior probability is found using Bayes' theorem,

$$P(H_i|\boldsymbol{x}) = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i) P(H_i) \pi(\boldsymbol{\theta}_i|H_i)\,d\boldsymbol{\theta}_i}{P(\boldsymbol{x})} \,, \tag{40.62}$$

where the integration is carried out over the internal parameters $\boldsymbol{\theta}_i$ of the model. The ratio of posterior probabilities for the models is therefore

$$\frac{P(H_i|\boldsymbol{x})}{P(H_j|\boldsymbol{x})} = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i)\,d\boldsymbol{\theta}_i}{\int P(\boldsymbol{x}|\boldsymbol{\theta}_j, H_j)\pi(\boldsymbol{\theta}_j|H_j)\,d\boldsymbol{\theta}_j} \frac{P(H_i)}{P(H_j)} \,. \tag{40.63}$$

The *Bayes factor* is defined as

$$B_{ij} = \frac{\int P(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i)\,d\boldsymbol{\theta}_i}{\int P(\boldsymbol{x}|\boldsymbol{\theta}_j, H_j)\pi(\boldsymbol{\theta}_j|H_j)\,d\boldsymbol{\theta}_j} \,. \tag{40.64}$$

This gives what the ratio of posterior probabilities for models i and j would be if the overall prior probabilities for the two models were equal. If the models have no nuisance parameters, *i.e.*, no internal parameters described by priors, then the Bayes factor is simply the likelihood ratio. The Bayes factor therefore shows by how much the probability ratio of model i to model j changes in the light of the data, and thus can be viewed as a numerical measure of evidence supplied by the data in favor of one hypothesis over the other.

Although the Bayes factor is by construction independent of the overall prior probabilities $P(H_i)$ and $P(H_j)$, it does require priors for all internal parameters of a model, *i.e.*, one needs the functions $\pi(\boldsymbol{\theta}_i|H_i)$ and $\pi(\boldsymbol{\theta}_j|H_j)$. In a Bayesian analysis where one is only interested in the posterior p.d.f. of a parameter, it may be acceptable to take an unnormalizable function for the prior (an improper prior) as long as the product of likelihood and prior can be normalized. Improper priors are, however, only defined up to an arbitrary multiplicative constant, and so the Bayes factor would depend on this constant. Furthermore, although the range of a constant normalized prior is unimportant for parameter determination (provided it is wider than the likelihood), this is not so for the Bayes factor when such a prior is used for only one of the hypotheses. So to compute a Bayes factor, all internal parameters must be described by normalized priors that represent meaningful probabilities over the entire range where they are defined.

An exception to this rule may be considered when the identical parameter appears in the models for both numerator and denominator of the Bayes factor. In this case one can argue that the arbitrary constants would cancel. One must exercise some caution, however, as parameters with the same name and physical meaning may still play different roles in the two models.

Both integrals in Equation (40.64) are of the form

$$m = \int P(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})\,d\boldsymbol{\theta} \,, \tag{40.65}$$

which is similar to the marginal likelihood seen previously in Eq. (40.50) (in some fields this quantity is called the *evidence*). Computing marginal likelihoods can be difficult; in many cases it can be done with the nested sampling algorithm [37] as implemented, *e.g.*, in the program `MultiNest` [38]. A review of Bayes factors can be found in Ref. [39].

40.4 Intervals and limits

When the goal of an experiment is to determine a parameter θ, the result is usually expressed by quoting, in addition to the point estimate, some sort of interval which reflects the statistical precision of the measurement. In the simplest case, this can be

given by the parameter's estimated value $\widehat{\theta}$ plus or minus an estimate of the standard deviation of $\widehat{\theta}$, $\widehat{\sigma_{\widehat{\theta}}}$. If, however, the p.d.f. of the estimator is not Gaussian or if there are physical boundaries on the possible values of the parameter, then one usually quotes instead an interval according to one of the procedures described below.

In reporting an interval or limit, the experimenter may wish to

- communicate as objectively as possible the result of the experiment;
- provide an interval that is constructed to cover on average the true value of the parameter with a specified probability;
- provide the information needed by the consumer of the result to draw conclusions about the parameter or to make a particular decision;
- draw conclusions about the parameter that incorporate stated prior beliefs.

With a sufficiently large data sample, the point estimate and standard deviation (or for the multiparameter case, the parameter estimates and covariance matrix) satisfy essentially all of these goals. For small data samples, no single method for quoting an interval will achieve all of them.

In addition to the goals listed above, the choice of method may be influenced by practical considerations such as ease of producing an interval from the results of several measurements. Of course the experimenter is not restricted to quoting a single interval or limit; one may choose, for example, first to communicate the result with a confidence interval having certain frequentist properties, and then in addition to draw conclusions about a parameter using a judiciously chosen subjective Bayesian prior. It is recommended, however, that there be a clear separation between these two aspects of reporting a result. In the remainder of this section, we assess the extent to which various types of intervals achieve the goals stated here.

40.4.1 *Bayesian intervals*

As described in Sec. 40.2.6, a Bayesian posterior probability may be used to determine regions that will have a given probability of containing the true value of a parameter. In the single parameter case, for example, an interval (called a Bayesian or credible interval) $[\theta_{\rm lo}, \theta_{\rm up}]$ can be determined which contains a given fraction $1-\alpha$ of the posterior probability, *i.e.*,

$$1-\alpha = \int_{\theta_{\rm lo}}^{\theta_{\rm up}} p(\theta|\boldsymbol{x})\, d\theta \; . \tag{40.66}$$

Sometimes an upper or lower limit is desired, *i.e.*, $\theta_{\rm lo}$ or $\theta_{\rm up}$ can be set to a physical boundary or to plus or minus infinity. In other cases, one might be interested in the set of θ values for which $p(\theta|\boldsymbol{x})$ is higher than for any θ not belonging to the set, which may constitute a single interval or a set of disjoint regions; these are called highest posterior density (HPD) intervals. Note that HPD intervals are not invariant under a nonlinear transformation of the parameter.

If a parameter is constrained to be non-negative, then the prior p.d.f. can simply be set to zero for negative values. An important example is the case of a Poisson variable n, which counts signal events with unknown mean s, as well as background with mean b, assumed known. For the signal mean s, one often uses the prior

$$\pi(s) = \begin{cases} 0 & s < 0 \\ 1 & s \geq 0 \end{cases} \; . \tag{40.67}$$

This prior may be regarded as providing an interval whose frequentist properties can be studied, rather than as representing a degree of belief. For example, to obtain an upper limit on s, one may proceed as follows. The likelihood for s is given by the Poisson distribution for n with mean $s+b$,

$$P(n|s) = \frac{(s+b)^n}{n!} e^{-(s+b)} \; , \tag{40.68}$$

along with the prior (40.67) in (40.37) gives the posterior density for s. An upper limit $s_{\rm up}$ at confidence level (or here, rather, *credibility* level) $1-\alpha$ can be obtained by requiring

$$1-\alpha = \int_{-\infty}^{s_{\rm up}} p(s|n) ds = \frac{\int_{-\infty}^{s_{\rm up}} P(n|s)\, \pi(s)\, ds}{\int_{-\infty}^{\infty} P(n|s)\, \pi(s)\, ds} \; , \tag{40.69}$$

where the lower limit of integration is effectively zero because of the cut-off in $\pi(s)$. By relating the integrals in Eq. (40.69) to incomplete gamma functions, the solution for the upper limit is found to be

$$s_{\rm up} = \frac{1}{2} F^{-1}_{\chi^2}\left[p, 2(n+1)\right] - b \; , \tag{40.70}$$

where $F^{-1}_{\chi^2}$ is the quantile of the χ^2 distribution (inverse of the cumulative distribution). Here the quantity p is

$$p = 1 - \alpha\left(1 - F_{\chi^2}\left[2b, 2(n+1)\right]\right) \; , \tag{40.71}$$

where F_{χ^2} is the cumulative χ^2 distribution. For both F_{χ^2} and $F^{-1}_{\chi^2}$ above, the argument $2(n+1)$ gives the number of degrees of freedom. For the special case of $b=0$, the limit reduces to

$$s_{\rm up} = \frac{1}{2} F^{-1}_{\chi^2}(1-\alpha; 2(n+1)) \; . \tag{40.72}$$

It happens that for the case of $b=0$, the upper limit from Eq. (40.72) coincides numerically with the frequentist upper limit discussed in Section 40.4.2.3. Values for $1-\alpha = 0.9$ and 0.95 are given by the values $\mu_{\rm up}$ in Table 40.3. The frequentist properties of confidence intervals for the Poisson mean found in this way are discussed in Refs. [2] and [40].

As in any Bayesian analysis, it is important to show how the result changes under assumption of different prior probabilities. For example, one could consider the Jeffreys prior as described in Sec. 40.2.6. For this problem one finds the Jeffreys prior $\pi(s) \propto 1/\sqrt{s+b}$ for $s \geq 0$ and zero otherwise. As with the constant prior, one would not regard this as representing one's prior beliefs about s, both because it is improper and also as it depends on b. Rather it is used with Bayes' theorem to produce an interval whose frequentist properties can be studied.

If the model contains nuisance parameters then these are eliminated by marginalizing, as in Eq. (40.43), to obtain the p.d.f. for the parameters of interest. For example, if the parameter b in the Poisson counting problem above were to be characterized by a prior p.d.f. $\pi(b)$, then one would first use Bayes' theorem to find $p(s,b|n)$. This is then marginalized to find $p(s|n) = \int p(s,b|n)\pi(b)\, db$, from which one may determine an interval for s. One may not be certain whether to extend a model by including more nuisance parameters. In this case, a Bayes factor may be used to determine to what extent the data prefer a model with additional parameters, as described in Section 40.3.4.

40.4.2 *Frequentist confidence intervals*

The unqualified phrase "confidence intervals" refers to frequentist intervals obtained with a procedure due to Neyman [41], described below. The boundary of the interval (or in the multiparameter case, region) is given by a specific function of the data, which would fluctuate if one were to repeat the experiment many times. The *coverage probability* refers to the fraction of intervals in such an ensemble that contain the true parameter value. Confidence intervals are constructed so as to have a coverage probability greater than or equal to a given *confidence level*, regardless of the true parameter's value. It is important to note that in the frequentist approach, such a probability is not meaningful for a fixed interval. In this section we discuss several techniques for producing intervals that have, at least approximately, this property of coverage.

40.4.2.1 *The Neyman construction for confidence intervals*

Consider a p.d.f. $f(x;\theta)$ where x represents the outcome of the experiment and θ is the unknown parameter for which we want to construct a confidence interval. The variable x could (and often does) represent an estimator for θ. Using $f(x;\theta)$, we can find using a pre-defined rule and probability $1-\alpha$ for every value of

θ, a set of values $x_1(\theta,\alpha)$ and $x_2(\theta,\alpha)$ such that

$$P(x_1 < x < x_2;\theta) = \int_{x_1}^{x_2} f(x;\theta)\,dx \geq 1-\alpha\ . \qquad (40.73)$$

If x is discrete, the integral is replaced by the corresponding sum. In that case there may not exist a range of x values whose summed probability is exactly equal to a given value of $1-\alpha$, and one requires by convention $P(x_1 < x < x_2;\theta) \geq 1-\alpha$.

This is illustrated for continuous x in Fig. 40.3: a horizontal line segment $[x_1(\theta,\alpha), x_2(\theta,\alpha)]$ is drawn for representative values of θ. The union of such intervals for all values of θ, designated in the figure as $D(\alpha)$, is known as a *confidence belt*. Typically the curves $x_1(\theta,\alpha)$ and $x_2(\theta,\alpha)$ are monotonic functions of θ, which we assume for this discussion.

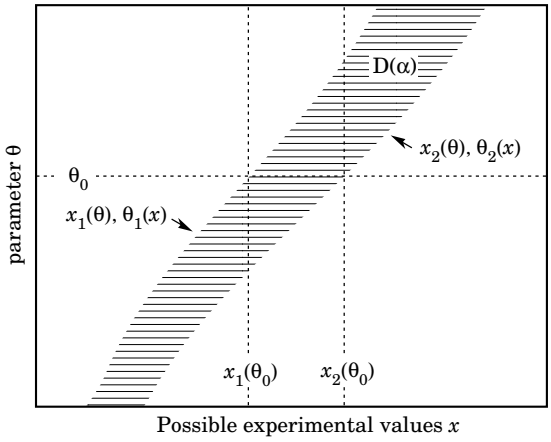

Figure 40.3: Construction of the confidence belt (see text).

Upon performing an experiment to measure x and obtaining a value x_0, one draws a vertical line through x_0. The confidence interval for θ is the set of all values of θ for which the corresponding line segment $[x_1(\theta,\alpha), x_2(\theta,\alpha)]$ is intercepted by this vertical line. Such confidence intervals are said to have a *confidence level* (CL) equal to $1-\alpha$.

Now suppose that the true value of θ is θ_0, indicated in the figure. We see from the figure that θ_0 lies between $\theta_1(x)$ and $\theta_2(x)$ if and only if x lies between $x_1(\theta_0)$ and $x_2(\theta_0)$. The two events thus have the same probability, and since this is true for any value θ_0, we can drop the subscript 0 and obtain

$$1-\alpha = P(x_1(\theta) < x < x_2(\theta)) = P(\theta_2(x) < \theta < \theta_1(x))\ . \quad (40.74)$$

In this probability statement, $\theta_1(x)$ and $\theta_2(x)$, *i.e.*, the endpoints of the interval, are the random variables and θ is an unknown constant. If the experiment were to be repeated a large number of times, the interval $[\theta_1,\theta_2]$ would vary, covering the fixed value θ in a fraction $1-\alpha$ of the experiments.

The condition of coverage in Eq. (40.73) does not determine x_1 and x_2 uniquely, and additional criteria are needed. One possibility is to choose *central intervals* such that the probabilities to find x below x_1 and above x_2 are each $\alpha/2$. In other cases, one may want to report only an upper or lower limit, in which case one of $P(x \leq x_1)$ or $P(x \geq x_2)$ can be set to α and the other to zero. Another principle based on *likelihood ratio ordering* for determining which values of x should be included in the confidence belt is discussed below.

When the observed random variable x is continuous, the coverage probability obtained with the Neyman construction is $1-\alpha$, regardless of the true value of the parameter. Because of the requirement $P(x_1 < x < x_2) \geq 1-\alpha$ when x is discrete, one obtains in that case confidence intervals that include the true parameter with a probability greater than or equal to $1-\alpha$.

An equivalent method of constructing confidence intervals is to consider a test (see Sec. 40.3) of the hypothesis that the parameter's true value is θ (assume one constructs a test for all physical values of θ). One then excludes all values of θ where the hypothesis would be rejected in a test of size α or less. The remaining values constitute the confidence interval at confidence level $1-\alpha$. If the critical region of the test is characterized by having a p-value $p_\theta \leq \alpha$, then the endpoints of the confidence interval are found in practice by solving $p_\theta = \alpha$ for θ.

In the procedure outlined above, one is still free to choose the test to be used; this corresponds to the freedom in the Neyman construction as to which values of the data are included in the confidence belt. One possibility is to use a test statistic based on the *likelihood ratio*,

$$\lambda(\theta) = \frac{f(x;\theta)}{f(x;\widehat{\theta})}\ , \qquad (40.75)$$

where $\widehat{\theta}$ is the value of the parameter which, out of all allowed values, maximizes $f(x;\theta)$. The confidence belt is taken to contain the values of x that give the greatest values of $\lambda(\theta)$. This results in the intervals described in Ref. [42] by Feldman and Cousins.

If the model contains nuisance parameters $\boldsymbol{\nu}$, then these can be incorporated into the test (or the p-values) used to determine the limit by profiling as discussed in Section 40.3.2.1. As mentioned there, the strict frequentist approach is to regard the parameter of interest θ as excluded only if it is rejected for all possible values of $\boldsymbol{\nu}$. The resulting interval for θ will then cover the true value with a probability greater than or equal to the nominal confidence level for all points in $\boldsymbol{\nu}$-space.

If the p-value is based on the profiled values of the nuisance parameters, *i.e.*, with $\boldsymbol{\nu} = \widehat{\widehat{\boldsymbol{\nu}}}(\theta)$ used in Eq. (40.48), then the resulting interval for the parameter of interest will have the correct coverage if the true values of $\boldsymbol{\nu}$ are equal to the profiled values. Otherwise the coverage probability may be too high or too low. This procedure has been called *profile construction* in particle physics [32] (see also Ref. [26]).

40.4.2.2 *Gaussian distributed measurements*

An important example of constructing a confidence interval is when the data consists of a single random variable x that follows a Gaussian distribution; this is often the case when x represents an estimator for a parameter and one has a sufficiently large data sample. If there is more than one parameter being estimated, the multivariate Gaussian is used. For the univariate case with known σ, the probability that the measured value x will fall within $\pm\delta$ of the true value μ is

$$\begin{aligned} 1-\alpha &= \frac{1}{\sqrt{2\pi}\sigma}\int_{\mu-\delta}^{\mu+\delta} e^{-(x-\mu)^2/2\sigma^2}\,dx \\ &= \mathrm{erf}\left(\frac{\delta}{\sqrt{2}\,\sigma}\right) = 2\Phi\left(\frac{\delta}{\sigma}\right) - 1\ , \end{aligned} \qquad (40.76)$$

where erf is the Gaussian error function, which is rewritten in the final equality using Φ, the Gaussian cumulative distribution. Fig. 40.4 shows a $\delta = 1.64\sigma$ confidence interval unshaded. The choice $\delta = \sigma$ gives an interval called the *standard error* which has $1-\alpha = 68.27\%$ if σ is known. Values of α for other frequently used choices of δ are given in Table 40.1.

Table 40.1: Area of the tails α outside $\pm\delta$ from the mean of a Gaussian distribution.

α	δ	α	δ
0.3173	1σ	0.2	1.28σ
4.55×10^{-2}	2σ	0.1	1.64σ
2.7×10^{-3}	3σ	0.05	1.96σ
6.3×10^{-5}	4σ	0.01	2.58σ
5.7×10^{-7}	5σ	0.001	3.29σ
2.0×10^{-9}	6σ	10^{-4}	3.89σ

We can set a one-sided (upper or lower) limit by excluding above $x+\delta$ (or below $x-\delta$). The values of α for such limits are half the values in Table 40.1.

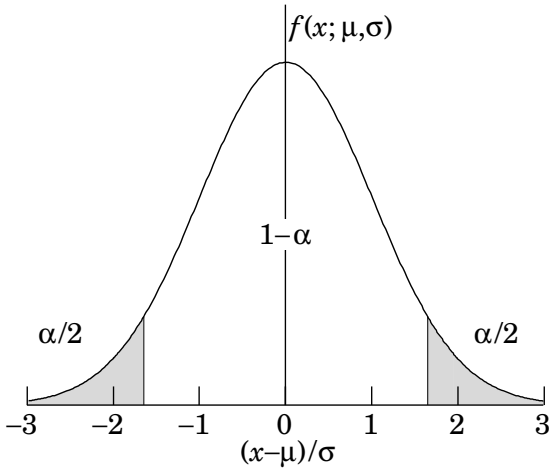

Figure 40.4: Illustration of a symmetric 90% confidence interval (unshaded) for a Gaussian-distributed measurement of a single quantity. Integrated probabilities, defined by $\alpha = 0.1$, are as shown.

The relation (40.76) can be re-expressed using the cumulative distribution function for the χ^2 distribution as

$$\alpha = 1 - F(\chi^2; n) \; , \tag{40.77}$$

for $\chi^2 = (\delta/\sigma)^2$ and $n = 1$ degree of freedom. This can be seen as the $n = 1$ curve in Fig. 40.1 or obtained using standard computer libraries. For multivariate measurements of, say, M parameter estimates $\widehat{\boldsymbol{\theta}} = (\widehat{\theta}_1, \ldots, \widehat{\theta}_M)$, construction of the confidence region requires the full covariance matrix $V_{ij} = \mathrm{cov}[\widehat{\theta}_i, \widehat{\theta}_j]$, which can be estimated as described in Sections 40.2.2 and 40.2.3. Under fairly general conditions with the methods of maximum-likelihood or least-squares in the large sample limit, the estimators will be distributed according to a multivariate Gaussian centered about the true (unknown) values $\boldsymbol{\theta}$, and furthermore, the likelihood function itself will take on a Gaussian shape.

The standard error ellipse for the pair $(\widehat{\theta}_i, \widehat{\theta}_j)$ is shown in Fig. 40.5, corresponding to a contour $\chi^2 = \chi^2_{\min} + 1$ or $\ln L = \ln L_{\max} - 1/2$. The ellipse is centered about the estimated values $\widehat{\boldsymbol{\theta}}$, and the tangents to the ellipse give the standard deviations of the estimators, σ_i and σ_j. The angle of the major axis of the ellipse is given by

$$\tan 2\phi = \frac{2\rho_{ij}\sigma_i\sigma_j}{\sigma_j^2 - \sigma_i^2} \; , \tag{40.78}$$

where $\rho_{ij} = \mathrm{cov}[\widehat{\theta}_i, \widehat{\theta}_j]/\sigma_i\sigma_j$ is the correlation coefficient.

The correlation coefficient can be visualized as the fraction of the distance σ_i from the ellipse's horizontal center-line at which the ellipse becomes tangent to vertical, *i.e.*, at the distance $\rho_{ij}\sigma_i$ below the center-line as shown. As ρ_{ij} goes to $+1$ or -1, the ellipse thins to a diagonal line.

It could happen that one of the parameters, say, θ_j, is known from previous measurements to a precision much better than σ_j, so that the current measurement contributes almost nothing to the knowledge of θ_j. However, the current measurement of θ_i and its dependence on θ_j may still be important. In this case, instead of quoting both parameter estimates and their correlation, one sometimes reports the value of θ_i, which minimizes χ^2 at a fixed value of θ_j, such as the PDG best value. This θ_i value lies along the dotted line between the points where the ellipse becomes tangent to vertical, and has statistical error σ_{inner} as shown on the figure, where $\sigma_{\mathrm{inner}} = (1 - \rho_{ij}^2)^{1/2}\sigma_i$. Instead of the correlation ρ_{ij}, one reports the dependency $d\widehat{\theta}_i/d\theta_j$, which is the slope of the dotted line. This slope is related to the correlation coefficient by $d\widehat{\theta}_i/d\theta_j = \rho_{ij} \times \frac{\sigma_i}{\sigma_j}$.

As in the single-variable case, because of the symmetry of the Gaussian function between $\boldsymbol{\theta}$ and $\widehat{\boldsymbol{\theta}}$, one finds that contours of

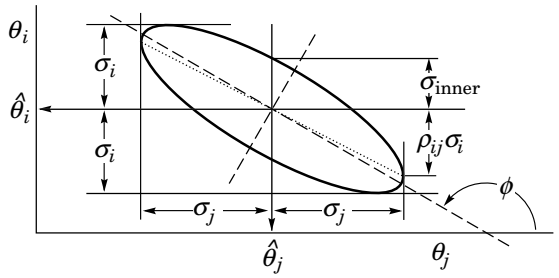

Figure 40.5: Standard error ellipse for the estimators $\widehat{\theta}_i$ and $\widehat{\theta}_j$. In the case shown the correlation is negative.

constant $\ln L$ or χ^2 cover the true values with a certain, fixed probability. That is, the confidence region is determined by

$$\ln L(\boldsymbol{\theta}) \geq \ln L_{\max} - \Delta \ln L \; , \tag{40.79}$$

or where a χ^2 has been defined for use with the method of least-squares,

$$\chi^2(\boldsymbol{\theta}) \leq \chi^2_{\min} + \Delta\chi^2 \; . \tag{40.80}$$

Values of $\Delta\chi^2$ or $2\Delta \ln L$ are given in Table 40.2 for several values of the coverage probability $1 - \alpha$ and number of fitted parameters M. For Gaussian distributed data, these are related by $\Delta\chi^2 = 2\Delta \ln L = F^{-1}_{\chi^2_M}(1 - \alpha)$, where $F^{-1}_{\chi^2_M}$ is the chi-square quantile (inverse of the cumulative distribution) for M degrees of freedom.

Table 40.2: Values of $\Delta\chi^2$ or $2\Delta \ln L$ corresponding to a coverage probability $1 - \alpha$ in the large data sample limit, for joint estimation of M parameters.

$(1-\alpha)$ (%)	$M = 1$	$M = 2$	$M = 3$
68.27	1.00	2.30	3.53
90.	2.71	4.61	6.25
95.	3.84	5.99	7.82
95.45	4.00	6.18	8.03
99.	6.63	9.21	11.34
99.73	9.00	11.83	14.16

For non-Gaussian data samples, the probability for the regions determined by Equations (40.79) or (40.80) to cover the true value of $\boldsymbol{\theta}$ becomes independent of $\boldsymbol{\theta}$ only in the large-sample limit. So for a finite data sample these are not exact confidence regions according to our previous definition. Nevertheless, they can still have a coverage probability only weakly dependent on the true parameter, and approximately as given in Table 40.2. In any case, the coverage probability of the intervals or regions obtained according to this procedure can in principle be determined as a function of the true parameter(s), for example, using a Monte Carlo calculation.

One of the practical advantages of intervals that can be constructed from the log-likelihood function or χ^2 is that it is relatively simple to produce the interval for the combination of several experiments. If N independent measurements result in log-likelihood functions $\ln L_i(\boldsymbol{\theta})$, then the combined log-likelihood function is simply the sum,

$$\ln L(\boldsymbol{\theta}) = \sum_{i=1}^{N} \ln L_i(\boldsymbol{\theta}) \; . \tag{40.81}$$

This can then be used to determine an approximate confidence interval or region with Eq. (40.79), just as with a single experiment.

40.4.2.3 *Poisson or binomial data*

Another important class of measurements consists of counting a certain number of events, n. In this section, we will assume these are all events of the desired type, *i.e.*, there is no background. If n

represents the number of events produced in a reaction with cross section σ and selection efficiency ε in a fixed integrated luminosity $\mathcal{L}$, then it follows a Poisson distribution with mean $\mu = \sigma\varepsilon\mathcal{L}$. If, on the other hand, one has selected a larger sample of N events and found n of them to have a particular property, then n follows a binomial distribution where the parameter p gives the probability for the event to possess the property in question. This is appropriate, *e.g.*, for estimates of branching ratios or selection efficiencies based on a given total number of events.

For the case of Poisson distributed n, limits on the mean value μ can be found from the Neyman procedure as discussed in Section 40.4.2.1 with n used directly as the statistic x . The upper and lower limits are found to be

$$\mu_{\rm lo} = \frac{1}{2} F^{-1}_{\chi^2}(\alpha_{\rm lo}; 2n) \ , \tag{40.82a}$$

$$\mu_{\rm up} = \frac{1}{2} F^{-1}_{\chi^2}(1-\alpha_{\rm up}; 2(n+1)) \ , \tag{40.82b}$$

where confidence levels of $1-\alpha_{\rm lo}$ and $1-\alpha_{\rm up}$ refer separately to the corresponding intervals $\mu \geq \mu_{\rm lo}$ and $\mu \leq \mu_{\rm up}$, and $F^{-1}_{\chi^2}$ is the quantile of the χ^2 distribution (inverse of the cumulative distribution). For central confidence intervals at confidence level $1-\alpha$, set $\alpha_{\rm lo} = \alpha_{\rm up} = \alpha/2$.

Table 40.3: Lower and upper (one-sided) limits for the mean μ of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

	$1-\alpha$ =90%		$1-\alpha$ =95%	
n	$\mu_{\rm lo}$	$\mu_{\rm up}$	$\mu_{\rm lo}$	$\mu_{\rm up}$
0	–	2.30	–	3.00
1	0.105	3.89	0.051	4.74
2	0.532	5.32	0.355	6.30
3	1.10	6.68	0.818	7.75
4	1.74	7.99	1.37	9.15
5	2.43	9.27	1.97	10.51
6	3.15	10.53	2.61	11.84
7	3.89	11.77	3.29	13.15
8	4.66	12.99	3.98	14.43
9	5.43	14.21	4.70	15.71
10	6.22	15.41	5.43	16.96

It happens that the upper limit from Eq. (40.82b) coincides numerically with the Bayesian upper limit for a Poisson parameter, using a uniform prior p.d.f. for μ. Values for confidence levels of 90% and 95% are shown in Table 40.3. For the case of binomially distributed n successes out of N trials with probability of success p, the upper and lower limits on p are found to be

$$p_{\rm lo} = \frac{nF^{-1}_F[\alpha_{\rm lo}; 2n, 2(N-n+1)]}{N-n+1 \ + \ nF^{-1}_F[\alpha_{\rm lo}; 2n, 2(N-n+1)]} \ , \tag{40.83a}$$

$$p_{\rm up} = \frac{(n+1)F^{-1}_F[1-\alpha_{\rm up}; 2(n+1), 2(N-n)]}{(N-n) \ + \ (n+1)F^{-1}_F[1-\alpha_{\rm up}; 2(n+1), 2(N-n)]} \ . \tag{40.83b}$$

Here F^{-1}_F is the quantile of the F distribution (also called the Fisher–Snedecor distribution; see Ref. [4]).

40.4.2.4 *Parameter exclusion in cases of low sensitivity*

An important example of a statistical test arises in the search for a new signal process. Suppose the parameter μ is defined such that it is proportional to the signal cross section. A statistical test may be carried out for hypothesized values of μ, which may be done by computing a p-value, p_μ, for all μ. Those values not rejected in a test of size α, *i.e.*, for which one does not find $p_\mu \leq \alpha$, constitute a confidence interval with confidence level $1-\alpha$.

In general one will find that for some regions in the parameter space of the signal model, the predictions for data are almost indistinguishable from those of the background-only model. This corresponds to the case where μ is very small, as would occur, *e.g.*, in a search for a new particle with a mass so high that its production rate in a given experiment is negligible. That is, one has essentially no experimental sensitivity to such a model.

One would prefer that if the sensitivity to a model (or a point in a model's parameter space) is very low, then it should not be excluded. Even if the outcomes predicted with or without signal are identical, however, the probability to reject the signal model will equal α, the type-I error rate. As one often takes α to be 5%, this would mean that in a large number of searches covering a broad range of a signal model's parameter space, there would inevitably be excluded regions in which the experimental sensitivity is very small, and thus one may question whether it is justified to regard such parameter values as disfavored.

Exclusion of models to which one has little or no sensitivity occurs, for example, if the data fluctuate very low relative to the expectation of the background-only hypothesis. In this case the resulting upper limit on μ may be anomalously low. As a means of controlling this effect one often determines the mean or median limit under assumption of the background-only hypothesis, as discussed in Sec. 40.5.

One way to mitigate the problem of excluding models to which one is not sensitive is the $\rm CL_s$ method, where the measure used to test a parameter is increased for decreasing sensitivity [43, 44]. The procedure is based on a statistic called $\rm CL_s$, which is defined as

$$\rm CL_s = \frac{p_\mu}{1-p_b} \ , \tag{40.84}$$

where $p_{\rm b}$ is the p-value of the background-only hypothesis. In the usual formulation of the method, both p_μ and $p_{\rm b}$ are defined using a single test statistic, and the definition of $\rm CL_s$ above assumes this statistic is continuous; more details can be found in Refs. [43, 44].

A point in a model's parameter space is regarded as excluded if one finds $\rm CL_s \leq \alpha$. As the denominator in Eq. (40.84) is always less than or equal to unity, the exclusion criterion based on $\rm CL_s$ is more stringent than the usual requirement $p_\mu \leq \alpha$. In this sense the $\rm CL_s$ procedure is conservative, and the coverage probability of the corresponding intervals will exceed the nominal confidence level $1-\alpha$. If the experimental sensitivity to a given value of μ is very low, then one finds that as p_μ decreases, so does the denominator $1-p_{\rm b}$, and thus the condition $\rm CL_s \leq \alpha$ is effectively prevented from being satisfied. In this way the exclusion of parameters in the case of low sensitivity is suppressed.

The $\rm CL_s$ procedure has the attractive feature that the resulting intervals coincide with those obtained from the Bayesian method in two important cases: the mean value of a Poisson or Gaussian distributed measurement with a constant prior. The $\rm CL_s$ intervals overcover for all values of the parameter μ, however, by an amount that depends on μ.

The problem of excluding parameter values to which one has little sensitivity is particularly acute when one wants to set a one-sided limit, *e.g.*, an upper limit on a cross section. Here one tests a value of a rate parameter μ against the alternative of a lower rate, and therefore the critical region of the test is taken to correspond to data outcomes with a low event yield. If the number of events found in the search region fluctuates low enough, however, it can happen that all physically meaningful signal parameter values, including those to which one has very little sensitivity, are rejected by the test.

Another solution to this problem, therefore, is to replace the one-sided test by one based on the likelihood ratio, where the critical region is not restricted to low rates. This is the approach followed in the Feldman-Cousins procedure described in Section 40.4.2.1. The critical region for the test of a given value of μ contains data values characteristic of both higher and lower rates. As a result, for a given observed rate one can in general obtain a two-sided interval. If, however, the parameter estimate $\hat{\mu}$ is sufficiently close to the lower limit of zero, then only high values of μ are rejected, and the lower edge of the confidence interval is at zero. Note, however, that the coverage property of $1-\alpha$ pertains to the entire interval, not to the probability for the upper edge $\mu_{\rm up}$ to be greater than the true value μ. For parameter estimates increasingly far away from the boundary, *i.e.*, for increasing signal significance, the point $\mu = 0$ is excluded and the interval has nonzero upper and lower edges.

An additional difficulty arises when a parameter estimate is not significantly far away from the boundary, in which case it is natural to report a one-sided confidence interval (often an upper limit). It is straightforward to force the Neyman prescription to produce only an upper limit by setting $x_2 = \infty$ in Eq. (40.73). Then x_1 is uniquely determined and the upper limit can be obtained. If, however, the data come out such that the parameter estimate is not so close to the boundary, one might wish to report a central confidence interval (*i.e.*, an interval based on a two-sided test with equal upper and lower tail areas). As pointed out by Feldman and Cousins [42], if the decision to report an upper limit or two-sided interval is made by looking at the data ("flip-flopping"), then in general there will be parameter values for which the resulting intervals have a coverage probability less than $1-\alpha$. With the confidence intervals suggested in Ref. [42], the prescription determines whether the interval is one- or two-sided in a way which preserves the coverage probability (and are thus said to be *unified*).

The intervals according to this method for the mean of Poisson variable in the absence of background are given in Table 40.4. (Note that α in Ref. [42] is defined following Neyman [41] as the coverage probability; this is opposite the modern convention used here in which the coverage probability is $1-\alpha$.) The values of $1-\alpha$ given here refer to the coverage of the true parameter by the whole interval $[\mu_1, \mu_2]$. In Table 40.3 for the one-sided upper limit, however, $1-\alpha$ refers to the probability to have $\mu_{\rm up} \geq \mu$ (or $\mu_{\rm lo} \leq \mu$ for lower limits).

Table 40.4: Unified confidence intervals $[\mu_1, \mu_2]$ for a the mean of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

	$1-\alpha$ =90%		$1-\alpha$ =95%	
n	μ_1	μ_2	μ_1	μ_2
0	0.00	2.44	0.00	3.09
1	0.11	4.36	0.05	5.14
2	0.53	5.91	0.36	6.72
3	1.10	7.42	0.82	8.25
4	1.47	8.60	1.37	9.76
5	1.84	9.99	1.84	11.26
6	2.21	11.47	2.21	12.75
7	3.56	12.53	2.58	13.81
8	3.96	13.99	2.94	15.29
9	4.36	15.30	4.36	16.77
10	5.50	16.50	4.75	17.82

A potential difficulty with unified intervals arises if, for example, one constructs such an interval for a Poisson parameter s of some yet to be discovered signal process with, say, $1-\alpha = 0.9$. If the true signal parameter is zero, or in any case much less than the expected background, one will usually obtain a one-sided upper limit on s. In a certain fraction of the experiments, however, a two-sided interval for s will result. Since, however, one typically chooses $1-\alpha$ to be only 0.9 or 0.95 when setting limits, the value $s = 0$ may be found below the lower edge of the interval before the existence of the effect is well established. It must then be communicated carefully that in excluding $s = 0$ at, say, 90% or 95% confidence level from the interval, one is not necessarily claiming to have discovered the effect, for which one would usually require a higher level of significance (*e.g.*, 5 σ).

Another possibility is to construct a Bayesian interval as described in Section 40.4.1. The presence of the boundary can be incorporated simply by setting the prior density to zero in the unphysical region. More specifically, the prior may be chosen using formal rules such as the reference prior or Jeffreys prior mentioned in Sec. 40.2.6.

In particle physics a widely used prior for the mean μ of a Poisson distributed measurement has been the uniform distribution for $\mu \geq 0$. This prior does not follow from any fundamental rule nor can it be regarded as reflecting a reasonable degree of belief, since the prior probability for μ to lie between any two finite values is zero. The procedure above can be more appropriately regarded as a way for obtaining intervals with frequentist properties that can be investigated. The resulting upper limits have a coverage probability that depends on the true value of the Poisson parameter, and is nowhere smaller than the stated probability content. Lower limits and two-sided intervals for the Poisson mean based on uniform priors undercover, however, for some values of the parameter, although to an extent that in practical cases may not be too severe [2, 40].

In any case, it is important to always report sufficient information so that the result can be combined with other measurements. Often this means giving an unbiased estimator and its standard deviation, even if the estimated value is in the unphysical region.

It can also be useful with a frequentist interval to calculate its subjective probability content using the posterior p.d.f. based on one or several reasonable guesses for the prior p.d.f. If it turns out to be significantly less than the stated confidence level, this warns that it would be particularly misleading to draw conclusions about the parameter's value from the interval alone.

40.5 Experimental sensitivity

In this section we describe methods for characterizing the sensitivity of a search for a new physics signal. As discussed in Sec. 40.3, an experimental analysis can often be formulated as a test of hypothetical model parameters. Therefore we may quantify the sensitivity by giving the results that we expect from such a test under specific assumptions about the signal process.

Here to be concrete we will consider a parameter μ proportional to the rate of a signal process, although the concepts described in this section may be easily generalized to other parameters. One may wish to establish discovery of the signal process by testing and rejecting the hypothesis that $\mu = 0$, and in addition one often wants to test nonzero values of μ to construct a confidence interval (*e.g.*, limits) as described in Sec. 40.4. In the frequentist framework, the result of each tested value of μ is the p-value p_μ or equivalently the significance $Z_\mu = \Phi^{-1}(1-p_\mu)$, where as usual Φ is the standard Gaussian cumulative distribution and its inverse Φ^{-1} is the standard Gaussian quantile.

Prior to carrying out the experiment, one generally wants to quantify what significance Z_μ is expected under given assumptions for the presence or absence of the signal process. Specifically, for the significance of a test of $\mu = 0$ (the discovery significance) one usually quotes the Z_0 one would expect if the signal is present at a given nominal rate, which we can define in general to correspond to $\mu = 1$. For limits, one often gives the expected limit under assumption of the background-only ($\mu = 0$) model. These quantities are used to optimize the analysis and to quantify the experimental sensitivity, that is, to characterize how likely it is to make a discovery if the signal is present, and to say what values of μ one may be able to exclude if the signal is in fact absent.

First we clarify the notion of *expected significance*. Because the significance Z_μ is a function of the data, it is itself a random quantity characterized by a certain sampling distribution. This distribution depends on the assumed value of μ, which is not necessarily the same as the hypothesized value of μ being tested. We may therefore consider the distribution $f(Z_\mu|\mu')$, *i.e.*, the distribution of Z_μ that would be obtained by considering data samples generated under assumption of μ'. In a similar way one can talk about the sampling distribution of an upper limit for μ, $f(\mu_{\rm up}|\mu')$.

One can identify the expected significance or limit with either the mean or median of these distributions, but the median may be preferred since it is invariant under monotonic transformations. For example, the monotonic relation between p-value and significance, $p = 1-\Phi(Z)$, then gives $\mathrm{med}[p_\mu|\mu'] = 1-\Phi(\mathrm{med}[Z_\mu|\mu'])$, whereas the corresponding relation does not hold in general for the mean.

In some cases one may be able to write down approximate formulae for the distributions of Z_μ and for limits, but more generally they must be determined from Monte Carlo calculations. In many cases of interest, the significance Z_μ and the limits on μ will have approximate Gaussian distributions.

As an example, consider a Poisson counting experiment, where the result consists of an observed number n of events, modeled as a Poisson distributed variable with a mean of $\mu s + b$. Here s and b,

the expected numbers of events from signal and background processes, are taken to be known. If we are interested in discovering the signal process we test and try to reject the hypothesis $\mu = 0$. To characterize the experimental sensitivity, we want to give the discovery significance expected under the assumption of $\mu = 1$.

In the limit where its mean value is large, the Poisson variable n can be approximated as an almost continuous Gaussian variable with mean $\mu s + b$ and standard deviation $\sigma = \sqrt{\mu s + b}$. In the usual case where a physical signal model corresponds to $\mu > 0$, the p-value of $\mu = 0$ is the probability to find n greater than or equal to the value observed,

$$p_0 = \Phi\left(\frac{n-b}{\sqrt{b}}\right) , \tag{40.85}$$

and the corresponding significance is $Z_0 = \Phi^{-1}(1-p_0) = (n-b)/\sqrt{b}$. The median (here equal to the mean) of n assuming $\mu = 1$ is $s + b$, and therefore the median discovery significance is

$$\mathrm{med}[Z_0|\mu = 1] = \frac{s}{\sqrt{b}} . \tag{40.86}$$

The figure of merit "$s/\sqrt{b}$" has been widely used in particle physics as a measure of expected discovery significance. A better approximation for the Poisson counting experiment, however, may be obtained by testing $\mu = 0$ using the likelihood ratio (40.49) $\lambda(0) = L(0)/L(\hat{\mu})$, where

$$L(\mu) = \frac{(\mu s + b)^n}{n!} e^{-(\mu s + b)} \tag{40.87}$$

is the likelihood function, and $\hat{\mu} = (n-b)/s$ is the estimator of μ. In this example there are no nuisance parameters, as s and b are taken to be known. For the case where the relevant signal models correspond to positive μ, one may test the $\mu = 0$ hypothesis with the statistic $q_0 = -2\ln\lambda(0)$ when $\hat{\mu} > 0$, *i.e.*, an excess is observed, and $q_0 = 0$ otherwise. One can show (see, *e.g.*, Ref. [25]) that in the large-sample limit, the discovery significance is then $Z_0 = \sqrt{q_0}$, for which one finds

$$Z_0 = \sqrt{2\left(n\ln\frac{n}{b} + b - n\right)} \tag{40.88}$$

for $n > b$ and $Z_0 = 0$ otherwise. To approximate the expected discovery significance assuming $\mu = 1$, one may simply replace n with the expected value $E[n|\mu = 1] = s + b$ (the so-called "Asimov data set"), giving

$$\mathrm{med}[Z_0|\mu = 1] = \sqrt{2\left((s+b)\ln\left(1 + \frac{s}{b}\right) - s\right)} . \tag{40.89}$$

This has been shown in Ref. [25] to provide a good approximation to the median discovery significance for values of s of several and for b well below unity. The right-hand side of Eq. (40.89) reduces to $s/\sqrt{b}$ in the limit $s \ll b$.

Beyond the simple Poisson counting experiment, in general one may test values of a parameter μ with more complicated functions of the measured data to obtain a p-value p_μ, and from this one can quote the equivalent significance Z_μ or find, *e.g.*, an upper limit μ_{up}. In this case as well one may quantify the experimental sensitivity by giving the significance Z_μ expected if the data are generated with a different value of the parameter μ'. In some problems, finding the sampling distribution of the significance or limits may be possible using large-sample formulae as described, *e.g.*, in Ref. [25]. In other cases a Monte Carlo study may be needed. Using whatever method of calculation is most appropriate, one usually quotes the expected (mean or, preferably, median) discovery significance or exclusion limit as the primary measure of experimental sensitivity.

Even if the true signal is present at its nominal rate, the actual discovery significance Z_0 obtained from the real data is subject to statistical fluctuations and will not in general be equal to its expected value. In an analogous way, the observed limit will differ from the expected limit even if the signal is absent. Upon observing such a difference one would like to know how large this is compared to expected statistical fluctuations. Therefore, in addition to the observed significance and limits it is useful to communicate not only their expected values but also a measure of the width of their distributions.

As the distributions of significance and limits are often well approximated by a Gaussian, one may indicate the intervals corresponding to plus-or-minus one and/or two standard deviations. If the distributions are significantly non-Gaussian, one may use instead the quantiles that give the same probability content, *i.e.*, $[0.1587, 0.8413]$ for $\pm 1\sigma$, $[0.02275, 0.97725]$ for $\pm 2\sigma$. An upper limit found significantly below the background-only expectation may indicate a strong downward fluctuation of the data, or perhaps as well an incorrect estimate of the background rate.

The procedures described above pertain to frequentist hypothesis tests and limits. Bayesian limits, just like those found from a frequentist procedure, are functions of the data and one may therefore find, usually with approximations or Monte Carlo studies, their sampling distribution and corresponding mean (or, preferably, median) and standard deviation.

When trying to establish discovery of a signal process, the Bayesian approach may employ a Bayes factor as described in Sec. 40.3.4. In the case of the Poisson counting experiment with the likelihood from Eq. (40.87), the log of the Bayes factor that compares $\mu = 1$ to $\mu = 0$ is $\ln B_{10} = \ln(L(1)/L(0)) = n\ln(1 + s/b) - s$. That is, the expectation value, assuming $\mu = 1$, of $\ln B_{10}$ for this problem is

$$E[\ln B_{10}|\mu = 1] = (s+b)\ln\left(1 + \frac{s}{b}\right) - s . \tag{40.90}$$

Comparing this to Eq. (40.89), one finds $\mathrm{med}[Z_0|1] = \sqrt{2E[\ln B_{10}|1]}$. Thus for this particular problem the frequentist median discovery significance can be related to the corresponding Bayes factor in a simple way.

In some analyses, the goal may not be to establish discovery of a signal process but rather to measure, as accurately as possible, the signal rate. If we consider again the Poisson counting experiment described by the likelihood function of Eq. (40.87), the maximum-likelihood estimator $\hat{\mu} = (n-b)/s$ has a variance, assuming $\mu = 1$, of

$$V[\hat{\mu}] = V\left[\frac{n-b}{s}\right] = \frac{1}{s^2}V[n] = \frac{s+b}{s^2} , \tag{40.91}$$

so that the standard deviation of $\hat{\mu}$ is $\sigma_{\hat{\mu}} = \sqrt{s+b}/s$. One may therefore use $s/\sqrt{s+b}$ as a figure of merit to be maximized in order to obtain the best measurement accuracy of a rate parameter. The quantity $s/\sqrt{s+b}$ is also the expected significance with which one rejects s assuming the signal is absent, and thus can be used to optimize the expected upper limit on s.

41. Machine Learning

Written November 2021 by K. Cranmer (Wisconsin U.), U. Seljak (UC Berkeley; LBNL) and K. Terao (SLAC; Stanford U.).

41.1 Introduction

This chapter gives an overview of the core concepts of machine learning that are relevant to particle physics with some examples of applications to the energy, intensity, cosmic, and accelerator frontiers. Machine learning (ML) is an enormous field that has grown substantially in the last decade, propelled largely by the emergence of so-called deep learning (DL) [1, 2]. ML has a long history in particle physics going back to the late 1980s and early 1990s, see Refs. [3–5] for recent reviews.

Physicists are exploring and contributing to machine learning at an unprecedented rate, which poses a challenge for those that wish to have an up-to-date view of the field. This motivated an effort to create *A Living Review of Machine Learning for Particle and Nuclear Physics* [6], which can be downloaded here: `https://github.com/iml-wg/HEPML-LivingReview`. As of the time of this writing, the Living Review includes over 500 references organized hierarchically by topic. While we make references to some of these papers, this chapter focuses on the methodology and does not attempt to give a comprehensive review of the applications.

Despite the connotations of machine learning and artificial intelligence as a mysterious and radical departure from traditional approaches, we stress that machine learning has a mathematical formulation that is closely tied to statistics, the calculus of variations, approximation theory, and optimal control theory.

The topic can be organized along a few axes, which we use to organize this section. First, there are different learning paradigms, for example supervised learning, unsupervised learning, and reinforcement learning. We focus on the first two in this review, since reinforcement learning is less commonly used in particle physics. Within these paradigms there are various tasks; for example, classification and regression – which have been the primary use of ML in particle physics – are examples of supervised learning. In addition to the learning paradigm and tasks, there are various types of machine learning models that generically process some input and produce some output. The types of models vary based on what it is they are modelling (*e.g.* so-called discriminative vs. generative

models), as well as the way that they are implemented (*e.g.* neural networks, decision trees, and kernel machines). Next, there are the issues around training or learning within the context of a given task and model class, which connects to optimization and regularization. We will briefly discuss the various considerations that emerge in the application of machine learning methods to physics, such as the treatment of systematic uncertainty, the interpretability of the models, the incorporation of symmetry, *etc.*.

41.1.1 *A gentle introduction with a representative example*

We will use a specific, familiar example to introduce the various ingredients in context before factorizing and abstracting them. Consider the task of *classifying* energy deposits in a particle detector as electrons or protons. For this example, let the detector data consist of energy deposits in d sensors so that the data can be represented as *feature vector* $x \in \mathbb{R}^d$. Different components of x may have different units (e.g. units of energy, momentum, position etc.). Due to the complex interactions of particles in the detector, we do not have an explicit probability model for the high-dimensional data for the electron and proton scenarios, but we do have a simulator that allows us to generate Monte Carlo samples for each. This allows us to assemble a *training dataset* $\{x_i, y_i\}_{i=1,\ldots,n}$, where y is used as a *label* to identify how the example was generated (*e.g.* $y = 0$ for electrons and $y = 1$ for protons). We would like to find a function $f : x \to y$ that is able to accurately *predict* the label on new data. Because we have feature-label pairs, this is considered a *supervised learning* problem. We can use a *neural network* to provide a flexible family of functions $f_\phi : \mathbb{R}^d \to \mathbb{R}$, where ϕ denotes the internal parameters of the neural network (*i.e.* the weights and biases that we will discuss in Sec.41.5.3). The goal of the *training procedure* is to find the value of the parameters ϕ that provide the 'best' predictions, but since no model is perfect, we must be explicit about the tradeoffs. This is made concrete through a *loss function* $\mathcal{L}(f_\phi(x), y)$. For this example, instead of the obvious zero-one loss (which is 0 if $f_\phi(x)$ equals y and 1 if they are not), we choose to use the squared-loss $\mathcal{L}_{\text{sq}}(f_\phi(x), y) = (y - f_\phi(x))^2$ (which may seem *ad hoc* now, but will be motivated in Sec. 41.3.1.3). We can evaluate the average of the loss on the training set of size n, which is referred to as the *emprical risk* $\mathcal{R}_{\text{emp}}(f_\phi) = \sum_{i=1}^n \mathcal{L}(f_\phi(x), y)/n$. *Training* refers to numerically minimizing the empirical risk (often referred to as the *training loss* through some abuse of terminology). We can numerically optimize the model through *gradient descent*, which iteratively adjusts the parameters of the network according to $\phi^{t+1} = \phi^t - \lambda \nabla_\phi \mathcal{R}_{\text{emp}}(f_\phi)$, where λ is referred to as the *learning rate*. Once the optimization is complete and we obtain the solution $\hat{\phi}$, it is natural to assess the quality of the trained model $f_{\hat{\phi}}$ on an independent *testing dataset*. The empirical risk evaluated on the testing set is often larger than on the training set, and large differences indicate *overfitting*, which indicates that the model does not generalize well to the unseen data. The ability to accurately predict on unseen data is referred to as *generalization* and the empirical risk on the test data provides a measure of the *generalization error*. In order to reduce the *generalization error* one might explore different model choices (*e.g.* neural network architectures), additional regularization terms in the loss function, different learning rates, optimization algorithms, or early stopping criterion in the optimization. Once trained, the model can be applied to data. In order to produce a binary electron vs. proton decision from the continuous ouptut of the neural network, we must threshold (*i.e.* classify as proton if $f_{\hat{\phi}}(x) > k$). The choice of the threshold k is often referred to as a working point and it sets the tradeoff between electron and proton efficiency, fake-rates, purity, etc. These familiar concepts in particle physics are usually referred to in different terms in machine learning and a *receiver operating characteristic curve*, or ROC curve, is used to summarize the tradeoff between true positive rate (TPR) and false positive rate (FPR). Importantly, the characterization of the efficiency / rejection (or equivalently the ROC curve) requires labeled data. In a particle physics context, it is recognized that the simulation is not perfect and the mismodelling is associated to the presence of systematic uncertainty. In machine learning, the discrepancy between the distribution of the training dataset and the distribution of the data that the model will be applied to in practice is referred to as *domain shift* or *distribution shift*. While mismodelling in the training dataset might lead to a less-than-optimal classifier in practice, the real source of systematic uncertainty comes from mismatch between the data used to characterize the performance of the classifier and the unlabeled data that the classifier is applied to. This motivates the use of data-driven methods to calibrate the resulting model.

This example provides a vertical slice through the various aspects of supervised machine learning in particle physics. Now we factorize and abstract the various ingredients in order to provide a more general treatment with a broader scope.

41.2 Fundamental concepts

41.2.1 *Loss, risk, empirical risk*

The term *learning* in machine learning generally refers to optimization of some objective, which can be thought of as maximizing utility or minimizing *risk*. The risk brings together three main ingredients. The first is the *model family* $\mathcal{F}$ (where $f \in \mathcal{F}$ is the quantity that we vary during optimization), the second is the *loss function* $\mathcal{L}$, and the third is a data distribution $p(u)$. The *risk* for a model $f \in \mathcal{F}$ is defined as its expected loss

$$\mathcal{R}[f] \coloneqq \mathbb{E}_{p(u)}[\mathcal{L}(u, f(u))] \equiv \int \mathcal{L}(u, f(u))\, p(u)\, \mathrm{d}u \,, \tag{41.1}$$

where $\mathbb{E}_p[\cdot]$ refers to the expectation with respect to the distribution p. In the context of supervised learning, the distribution $p(u)$ describes a joint distribution over the features x and the labels y (*i.e.* $p(u) = p(x, y)$), the model only depends on the features $f(u) = f(x)$, and the loss function takes on the special form $\mathcal{L}(u, f(u)) = \mathcal{L}(y, f(x))$. In the context of unsupervised learning there are no labels, and $u = x$. Written this way, the risk is a functional, and the idealized goal for machine learning is to solve the optimization problem

$$f^* = \arg\min_{f \in \mathcal{F}} \mathcal{R}[f] \,, \tag{41.2}$$

where $\mathcal{F}$ would include all possible functions.

One of the defining characteristics of machine learning in practice is that one does not know the data distribution $p(u)$, but does have access to samples from that distribution, *i.e.* $\{u_i\}_{i=1,\ldots,n}$ with $u_i \overset{i.i.d.}{\sim} p(u)$. This leads to the corresponding *empirical risk*

$$\mathcal{R}_{\text{emp}}[f] \coloneqq \mathbb{E}_{\hat{p}(u)}[\mathcal{L}(u, f(u))] \equiv \frac{1}{n} \sum_{i=1}^{n} \mathcal{L}(u_i, f(u_i)) \,, \tag{41.3}$$

where $\hat{p}(u) = \frac{1}{n} \sum_{i=1}^n \delta(u - u_i)$ is referred to as the empirical distribution of the dataset $\{u_i\}_{i=1,\ldots,n}$. The *empirical risk minimization* principle is a core idea in statistical learning theory [7], which approximates f^* with its empirical analogue

$$\hat{f} = \arg\min_{f \in \hat{\mathcal{F}}} \mathcal{R}_{\text{emp}}[f] \,, \tag{41.4}$$

where $\hat{\mathcal{F}}$ are all possible functions parametrized by the model parameters ϕ. In an idealized infinite parameter limit machine learning functions, such as neural networks, are universal approximators, such that they cover all functions and $\mathcal{F} = \hat{\mathcal{F}}$. For finite size networks this may or may not be a valid assumption. Expressivity of the network characterizes this universality property and is a function of the network architecture and its parameters such as width and depth of neural network layers. If the expressivity is too small it leads to underfitting. However, an equally important consideration is the risk of overfitting if we optimize equation 41.4 for too long.

While the loss function may quantify some well-motivated notion of (negative) utility, it is also common to design loss functions so that f^* has some desired property. While in practice one does not know the data distribution $p(u)$, it is constructive to imagine that one does and analyze Eq. 41.2 with the calculus of variations. In Secs. 41.3 we will consider several such loss functions where one can show that the corresponding f^* has the desired property even

if the form of the loss is not obvious from the point of view of utility. Furthermore, there are often multiple loss functions that can lead to the same f^*. Then one can think of machine learning as applied calculus of variations where one solves Eq. 41.4 with a sufficiently flexible model, powerful optimization algorithms, and practical considerations to break the degeneracy between different loss functions that lead to the same f^*.

41.2.2 *Generalization*

With a sufficiently flexible model, it is possible to fit the training dataset very well, though the model might not *generalize* well to unseen data due to overfitting. More concretely, for a non-negative loss function one might have $\mathcal{R}_{\text{emp}}[\hat{f}] \to 0$, while the true risk might be large ($\mathcal{R}[\hat{f}] \gg 0$). The gap between the $\mathcal{R}[\hat{f}] - \mathcal{R}_{\text{emp}}[\hat{f}]$ is typically referred to as the *excess risk*[1]. While it is generally not possible to evaluate $\mathcal{R}[\hat{f}]$ exactly because we do not know $p(u)$, we can use an independent testing dataset (also called validation dataset) to obtain an unbiased estimate of it. This *cross-validation* method motivates the test – train split of the data.

Intuitively, a model with many parameters has more flexibility and is more prone to overfitting. A common and intuitive heuristic is that one should not fit a model with more parameters than there are data points. However, a more careful treatment reveals that this heuristic can be both pessimistic and optimistic. For example, the single-parameter model $f_\phi(x) = \text{sign}(\sin(\phi x))$ can perfectly classify any assignment of labels on data (x_i, y_i) with $x \in \mathbb{R}$ and $y \in \{-1, 1\}$ and generalize poorly. Conversely, sometimes highly over-parameterized models (that have large subspaces of their parameters where $\mathcal{R}_{\text{emp}}[\hat{f}_\phi] \to 0$) might generalize well [8,9]. Often this is achieved through *regularization*, both explicit and implicit (section 41.3.1.2).

Structural risk minimization is a modification to the empirical risk minimization principle that was introduced by Vapnik and Chervonenkis to account for the potential for overfitting [7]. However, the bounds are based on a worst-case type analysis and are often very weak. Recall that while one cannot calculate the true risk, one can obtain an unbiased estimate of it with a held-out, independent testing sample. Thus one can empirically compare the generalization error of two models and find that one generalizes better than the other even if the bounds might suggest the opposite. One of the major conceptual shifts that happened with the rise of deep learning was to more fully appreciate that these bounds and structural risk minimization were not a good learning principle in practice and that more theoretical work is needed to close the gap between formal bounds and empirical estimates of generalization error.

41.3 Common tasks and their associated loss functions

We now move to common tasks encountered in machine learning and their associated loss functions.

41.3.1 *Supervised learning*

Supervised learning generally refers to the class of problems where the training dataset are presented as input-output pairs $\{x_i, y_i\}_{i=1,\ldots,n}$, where $x_i \in \mathcal{X}$ are the input features and $y_i \in \mathcal{Y}$ are the corresponding target labels. Furthermore, it is typically assumed that $(x_i, y_i) \overset{i.i.d.}{\sim} p(x, y)$, though $p(x, y)$ is usually not known explicitly. Finally, the loss function in supervised learning takes on the special form $\mathcal{L}(y, f(x))$. The resulting trained model is then used to predict the labels for dataset where labels are not available.

In what follows we will make use of the equalities $p(x, y) = p(x|y)p(y) = p(y|x)p(x)$ and Bayes theorem, which is discussed in Sec. 39.1. We will also use the notation $x \sim p(x)$ to indicate that the random variable x is being drawn, sampled, or generated from the distribution $p(x)$.

[1] Similarly, the gap between the true risk of the learned model and the true risk of the optimal model (*i.e.* $\mathcal{R}[\hat{f}] - \mathcal{R}[f^*]$) is referred to as the *regret*. This quantity is mainly of interest for theoretical analysis of machine learning algorithms, and not of practical concern since usually neither term is tractable.

41.3.1.1 *Regression*

The goal of regression is to predict a label $y \in \mathcal{Y}$ given an input feature vector $x \in \mathcal{X}$. Typically, the label is a real-valued scalar, but $\mathcal{X}$ can be $\mathbb{R}^d$ or some more structured target (*e.g.* an image, sequence, graph, quantile, or distribution). When $\mathcal{Y}$ is discrete, the task is usually referred to as classification; however, the two are closely related and *logistic regression* is an example where the model predicts a continuous probability associated to the possible label values. In elementary statistical language, the target label y is often called a dependent variable, while the feature x is called the independent variable. In classical statistics, one often assumes a model for the data such as

$$y_i = f_\phi(x_i) + e_i \,, \tag{41.5}$$

where e_i is an additive error term that is often assumed to be independent of x and often assumed to be normally distributed. This leads to classic approaches like least-squares (see Sec. 40.2.3), and when the model f_ϕ is linear in ϕ (not in x!) one has linear regression that has a closed-form solution. However, we can relax these assumptions and consider the general case of an arbitrary joint distribution $p(x, y)$, which can be written as $p(y|x)p(x)$ without loss of generality. Consider the *squared error* as a loss function, which leads to the mean-squared error (MSE) for the empirical risk:

$$\mathcal{L}_{\text{MSE}}(y, f(x)) = (y - f(x))^2 \,. \tag{41.6}$$

One might expect that the squared error would only be appropriate in the case that the conditional distribution $p(y|x)$ is normally distributed, but one can use the calculus of variations to show that in general

$$f^*_{\text{MSE}}(x) = \mathbb{E}_{p(y|x)}[y] \,, \tag{41.7}$$

that is the optimal regressor for the MSE is the conditional expectation of y given x.

One issue with the squared-error as a loss function is that it is sensitive to outliers. Alternatively, one can use the absolute error $|y - f(x)|$ as a loss function[2]. However, the discontinuous derivative of the absolute (L1) error leads to challenges in optimization. As a result there are various other loss functions, such as the Huber loss, that aim to be both robust and more amenable to optimization that we do not discuss here.

Note that these this framing of regression yields a function $f(x)$ that only provides a point estimate for y. An alternative approach to regression is to model the full conditional distribution $p(y|x)$. One such example is Gaussian Process regression, which is discussed in Sec. 41.5.1. In that probabilistic approach, one can still obtain a point estimator, such as the conditional expectation or the maximum a posteriori (MAP) estimator

$$f^*(x) = \arg\max_y p(y|x) \,, \tag{41.8}$$

and one can also derive uncertainty estimates on the predicted value y. In this setting, the prior distribution on the model family is closely related to the concept of regularization, which we touch on in Sec. in Sec. 41.3.1.2 and in Sec. 41.5.1.

When one directly models $p(y|x)$, or goes further to model the joint distribution $p(x, y) = p(y|x)p(x)$, then one can use maximum likelihood for the loss function. In that approach, the problem is really one of density estimation, which is a type of unsupervised learning that we discuss in Sec. 41.3.2.1. These two approaches are a classic examples of two different approaches to modelling. Regression with $f^*_{\text{MSE}}(x)$ is the prototypical example of *descriminative* modelling, while modelling the joint distribution is a prototypical example of *generative* modelling. Generally, discriminative approaches with supervised learning out perform generative approaches when there is sufficient data, but generative approaches can be beneficial in data-starved settings [10].

[2] The absolute error and squared error are often denoted as L1 and L2 errors, respectively, in reference to the corresponding norms.

41.3.1.2 *A note on regularization*

The trained model $\hat{f}$, or equivalently, the parameters of the trained model $\hat{\phi}$ can be thought of as point estimates of f^*, and there is a correspondence to the issues of bias and variance discussed in Sec. 40.2 on parameter estimation. Generically, there is a bias–variance tradeoff, and when the number of parameters is large and the number of data points is not much larger, introducing a small bias can often lead to a significant reduction in variance. This motivates the explicit addition of a *regularization* term to the loss function, which will introduce some bias $f^*_{\text{reg}} \neq f^*$. A common form for of regularization is to penalize by the L2 norm of the parameters (*i.e.* $\|\phi\|^2$), which is referred to as *Tikhonov regularization*. This appears in the form of penalized maximum likelihood, and it is also commonly used in unfolding [11]. One can also interpret the regularization term as an explicit prior on the parameters, and the resulting model as the Bayesian maximum a posteriori (MAP) estimator. When paired with linear regression this is known as *ridge regression*, and when paired with kernel machines (see Sec. 41.5.1) this gives rise to kernel ridge regression or Gaussian process regression.

Another form of regularization is to restrict the model class $\hat{\mathcal{F}}$. For example, a neural network and a sequence of narrow step functions (delta functions) can both be shown to be universal approximators in infinite parameter size limit, but on real world examples the former generalizes much better than the latter. Within the class of neural network models, convolutional neural networks are a subset of generic feedforward neural networks that enforce translational symmetry (see Sec. 41.5.3.5 for more discussion). Similarly, one might restrict to Lipschitz continuous functions. These types of choices are often encoded in the architecture of a neural network and are broadly referred to as *inductive bias* in the model.

In addition to explicit regularization terms in the loss function or through restrictions to the model class, it is also possible to regularize implicitly. One implicit regularization is through early stopping [11, 12], where we monitor the loss on training dataset and the loss on test dataset. While the training dataset loss continues to decrease with more gradient descent cycles, the test loss may not, and early stopping stops the training when test loss flattens out or begins to increase. Another powerful form of regularization used in deep learning models is known as *dropout* [13], which randomly removes some some parts of the model during training and can be thought of as implementing a type of model averaging [14]. What is more surprising is that in the case of highly over-parameterized models where there is a large degenerate parameter space that achieves zero loss, $\Phi_0 = \{\phi | \mathcal{R}_{\text{emp}}[f_\phi]\} = 0$, that the dynamics of the optimization algorithm that is used will break the degeneracy and favor some particular $\hat{\phi} \in \Phi_0$ as if an additional regularization term was secretly included. Despite zero loss and over-parametrization, the corresponding generalization error may be small, a phenomenon called *benign overfitting* [15]. Importantly, the dynamics of different optimization algorithms will have different implicit regularization effects, and thus favor different parameter points in Φ_0 that will have different generalization error [16]. Understanding this interaction is a topic of contemporary research in machine learning [17].

41.3.1.3 *Classification*

The goal of classification is to predict one of a finite number of class labels $y \in \mathcal{Y}$ given an input feature vector $x \in \mathbb{X}$. It is similar to regression in this way, but the focus is on discrete target space $\mathcal{Y}$. An important special case is when the label can only take on one of two values (*e.g.* "signal" or "background"), which is referred to as binary classification and is equivalent to simple hypothesis testing in statistics. It is common for a classifier to be the composition of a model $g : \mathcal{X} \to \mathbb{R}^{|\mathcal{Y}|}$ that predicts continuous probabilities for each class (*i.e.* $g(x) \approx p(y|x)$) followed by an operation that then chooses the discrete label $y \in \mathcal{Y}$, such as a fixed threshold or $f(x) = \arg\max g(x) \approx \arg\max_y p(y|x)$. This is the case for both classical methods like logistic regression and modern, deep learning approaches to classification; therefore, we will use the term probabilistic classifier for $g(x)$ or just classifier when it is clear in context.

An intuitive loss function for classification is the zero-one loss, which simply counts the number of mis-classifications:

$$\mathcal{L}_{0/1}(y, f(x)) = \begin{cases} 0, & \text{if } f(x) = y \\ 1, & \text{otherwise} . \end{cases} \tag{41.9}$$

The zero-one loss can also be written as $\mathcal{L}_{0/1}(y, f(x)) = \mathbf{1}(y \neq f(x))$, where $\mathbf{1}(\cdot)$ is the indicator function. The zero-one loss is non-differentiable, so it does not pair well with gradient-based optimization.

For binary classification, one can use $y = \{0, 1\}$ as numerical values for the class labels and the mean-squared error $\mathcal{L}_{\text{MSE}}(y, f(x))$ in Eq. 41.6 for the loss function. The resulting model will approximate f^*_{MSE}, the conditional expectation of Eq. 41.7 takes on the form

$$\begin{aligned} f^*_{\text{MSE}}(x) &= \mathbb{E}_{p(y|x)}[y] \to p(y = 1|x) \\ &= \frac{p(x|y = 1)p(y = 1)}{p(x|y = 0)p(y = 0) + p(x|y = 1)p(y = 1)} . \end{aligned} \tag{41.10}$$

That is the MSE loss for binary classification leads to the Bayesian posterior probability that the label $y = 1$ given the feature vector x.

Equation 41.10 highlights an important general feature of supervised learning relevant for particle physics, which is that the joint distribution $p(x, y)$ of the training dataset implies a prior distribution $p(y)$ on the labels or classes. This prior distribution need not reflect a degree of belief or the frequency in real data, it represents the frequency in the training dataset. However, it is important to keep in mind that when applying the resulting model to a different dataset with the same conditional distribution (data likelihood) $p(x|y)$ for the features and a different prior $p'(y)$ for the labels that the probabilistic interpretation of the result will not be properly calibrated. A common choice for binary classification is to use a balanced training dataset with $p(y = 0) = p(y = 1) = \frac{1}{2}$, while in many cases the true $p'(y = 1)$ in the experimental data might be very small (*i.e.* low signal-to-background), unknown, or zero (*i.e.* a hypothetical particle that does not exist).

If $p'(y)$ and $p(y)$ are known then the Bayes theorem can be used to re-calibrate the posterior $p(y|x)$ from one prior to another. One example of such re-calibration is the correspondence of binary classification to simple hypothesis tests in frequentist statistics discussed in Sec. 40.3.1 of the Statistics chapter. In that setting, the Neyman-Pearson lemma states that the optimal classifier is given by the likelihood-ratio. Adapting to the notation of this chapter, we have

$$f^*_{\text{N.P.}}(x) = \frac{p(x|y = 1)}{p(x|y = 0)} , \tag{41.11}$$

which does not depend on the prior probabilities $p'(y = 0)$ or $p'(y = 1)$ as in Eq. 41.10, or, equivalently, assumes equal priors $p'(y = 0) = p'(y = 1)$. From Bayes theorem, we have the identity $p(y = 1|x)/p(y = 0|x) = [p(x|y = 1)p(y = 1)]/[p(x|y = 0)p(y = 0)]$, which can be used to show that the two functions are related by a one-to-one, monotonic transformation

$$f^*_{\text{N.P.}}(x) = \frac{p(y = 0)}{p(y = 1)} \frac{f^*_{\text{MSE}}(x)}{1 - f^*_{\text{MSE}}(x)} , \tag{41.12}$$

which is referred to as the *likelihood-ratio trick*, which plays an important role in simulation-based inference (see Sec. 41.3.5). Importantly, the monotonic transformation does not impact the tradeoff of type-I and type-II error (or, equivalently, the FPR and TPR), therefore the ROC curve for $f_{\text{N.P.}}(x)$ and $f_{\text{MSE}}(x)$ are identical and do not depend on the prior probabilities $p(y)$. This property has been leveraged in the context of *weakly supervised* approaches [18] and enables one to train a classifier on data without access to labels as long as one has two datasets with different ratios $p(y = 1)/p(y = 0)$ and the same conditional distribution $p(x|y)$ of the features given the labels.

A generalization of the binary loss function for classification of Eq. 41.10, which applies to multiple classes, is the *cross-entropy* loss

$$\mathcal{L}_{\text{xe}}(y, f(x)) = -\sum_{c\in|\mathcal{Y}|} \mathbf{1}(y=c)\log(f_c(x)) \,, \tag{41.13}$$

where $f : \mathcal{X} \to \mathbb{R}^{|\mathcal{Y}|}$ and the indicator function picks out the term in the sum for the corresponding class label y. This loss can be derived from maximizing the posterior of Eq. 41.57 using a discrete set of class labels y, which identifies $f_c(x) = \tilde{f}(y=c|x) = p(y=c|x)$ and thus enforces the constraint $\sum_c f_c(x) = 1$ and $f_c(x) \geq 0$ (for all $x \in \mathcal{X}$, *e.g.* by using the *softmax* function). The notation is aligned with the interpretation of $\tilde{f}(y|x)$ as a conditional distribution, i.e. an approximation to the true posterior $p(y|x)$. The risk associated to the cross entropy loss function is

$$\begin{aligned}\mathcal{R}_{\text{xe}}[f] &= \mathbb{E}_{p(x,y)}\left[-\sum_{c\in|\mathcal{Y}|}\mathbf{1}(y=c)\log f_c(x)\right] \\ &= -\sum_{c\in|\mathcal{Y}|} p(y=c)\mathbb{E}_{p(x|y)}[\log\tilde{f}(y=c|x)] \,.\end{aligned} \tag{41.14}$$

This is equivalent to $\mathcal{R}_{\text{xe}}[f] = \mathbb{E}_{p(x)}[H[p(y|x), \tilde{f}(y|x)]]$, where $H[p,f] = \mathbb{E}_p[-\log f]$ is the cross-entropy between the two distributions. One can use a Lagrange multiplier λ to enforce the normalization constraint (e.g. equation 41.10) and the calculus of variations to show that

$$f^*_{\text{x.e.},c}(x) = \lambda p(x, y=c) = \lambda p(y=c|x)p(x) = p(y=c|x) \,. \tag{41.15}$$

This approach is closely related to the loss functions that are used for density estimation, the forward Kullback–Leibler (KL) divergence, and the maximum likelihood estimation. Minimizing cross entropy $H[p, f_\phi]$ with respect to ϕ is equivalent to minimizing the forward KL divergence

$$KL(p||f_\phi) \coloneqq \mathbb{E}_p[\log p(x)) - \log f_\phi] = H[p, f_\phi] - H[p] \,, \tag{41.16}$$

where $H[p] \coloneqq \int p(x)\log p(x)dx$ is the entropy and independent of f_ϕ. The KL divergence $KL[p||f] \geq 0$, and equal if and only if $p = f$.

One can also consider the reverse KL divergence $KL[f_\phi||p]$, which is also minimized by $f_\phi = p$; however, this requires one to be able to generate samples $x_i \sim f_\phi(x)$ and be able to evaluate the probability density $p(x_i)$. Often this is not the case for real world data, but this approach is useful in the context of variational inference, where $f_\phi(x)$ is an approximation to the posterior of x, and $p(x)$ is the likelihood times the prior, which can be evaluated on samples x_i drawn from f_ϕ. Because likelihood times prior is not normalized this KL divergence optimizes the lower bound to the normalization (Evidence Lower Bound Objective or ELBO).

The forward KL is also closely related to the variational free energy principle in statistical mechanics where $H[f_\phi]$ represents the entropy of the variational distribution, $p(x) \propto \exp(-E(x)/kT)$ is the Boltzman factor for the state x with energy $E(x)$, and $H[f_\phi, p] = \mathbb{E}_{f_\phi}[E(x)]$ represents the expected energy for the variational distribution. As is well known to physicists, minimizing the free energy involves a balance between minimizing the energy and maximizing the entropy.

In some cases it is possible to augment the training dataset with an unbiased, stochastic estimate of $p(y=c|x)$ that we denote $s_c(x,z)$. For example, when the simulation involves latent variables z (*i.e.* Monte Carlo truth quantities), then the simulation encodes $p(x,z|y)$, the joint distribution over the observed features x and the latent variables z conditioned on the class y. In many cases the simulation evolves through a Markov process (*e.g.* the detector response only depends on the momenta of the incoming particles z, not the details of the hard scattering y). In that case, it is often possible to calculate $s_c(x,z) = p(y=c|x,z)$ for each training sample [19]. Using the identity, $\mathbb{E}_{p(z|x)}[p(y|x,z)] = p(y|x)$, we see that $s_c(x,z)$ is an unbiased estimator of $p(y=c|x)$. In this case, one can use $s_c(x,z)$ in place of the indicator function in Eq. 41.13 to construct an improved (lower-variance) loss function that reproduces the same cross-entropy risk function[3,4]

$$\begin{aligned}\mathcal{R}'_{\text{xe}}[f] &= \mathbb{E}_{p(x,y,z)}\left[-\sum_{c\in|\mathcal{Y}|} s_c(x,z)\log f_c(x)\right] \\ &= -\sum_{c\in|\mathcal{Y}|}\mathbb{E}_{p(x)}[p(y=c|x)\log f_c(x)] \,,\end{aligned} \tag{41.17}$$

which yields the same optimal classifier $f^*_{\text{x.e.},c}(x) = p(y=c|x)$ [20, 21].

We note that unlike in the binary classification case, the multiclass classifier is sensitive to the priors $p(y)$ used in training. This leads to complications as often the class proportions are unknown. For example, one might be interested in classifying a signal when multiple backgrounds are present and the relative proportion of those different background components is uncertain. Ideally one would like the class proportions for the background components used in training to match those in the data, which presents an additional training challenge if those proportions are heavily unbalanced.

41.3.2 *Unsupervised learning*

Unsupervised learning generally refers to the class of problems that use unlabeled training dataset $\{x_i\}_{i=1,\ldots,n}$, where $x_i \in \mathcal{X}$ are the input features. Furthermore, it is typically assumed that $(x_i) \overset{i.i.d.}{\sim} p(x)$, though $p(x)$ is usually not known explicitly. Finally, the loss function in supervised learning takes on the special form $\mathcal{L}(x, f(x))$.

A related concept is that of self-supervised learning, which also aims to distill useful features in the data without requiring supervision labels for every sample in the input data. Self-supervised methods can make use of large unsupervised datasets and build meaningful representations by performing data augmentation, and learning the latent space mapping that is insensitive to it. For example, in the case of galaxy images one may augment the data by performing image rotations, adding noise, size scaling, adding point spread function smoothing etc., all of which are realistic transformations expected in a real galaxy image survey [22]. Self-supervised learning then learns the latent space representation where all of these augmentations of the same training sample result in the same latent space position. This training is augmented with contrastive learning, which ensures that different training samples do not all collapse to the same latent space position. When this latent space representation is used for downstream tasks such as classification it outperforms other forms of supervised learning [23].

41.3.2.1 *Density estimation*

The goal of density estimation is to estimate a distribution $p(x)$ based on samples $\{x_i\}_{i=1,\ldots,n}$ with $x_i \overset{i.i.d.}{\sim} p(x)$. Conceptually, this is the same goal as when fitting a parameterized distribution $f(x;\theta)$ to data using the method of maximum likelihood as described in Sec. 40.2.2 of the chapter on statistics. In practice, the difference in the machine learning context has to do with the flexibility of the model and the dimensionality of the data. A highly-flexible model, which can effectively approximate any distribution, is referred to as a non-parametric model (though, ironically, usually this means the model has many parameters). In contrast, typical maximum likelihood fits in particle physics are based on restricted families of distributions with relatively few parameters and the data is typically one- or two-dimensional, though occasionally five- or six-dimensional.

Maximizing the likelihood function in Eq. 40.10 $\mathcal{L}(\theta) =$

[3] A similar approach can also be used for the squared-error, see Ref. [20].

[4] The right hand side of Eqs. 41.14 and 41.17 are written in a different form, but are equivalent.

$\prod_{i=1}^{n} f(x_i;\theta)$ is equivalent to minimizing the empirical risk:

$$\mathcal{R}_{\text{emp,xe}}[f_\phi] = -\frac{1}{n}\sum_{i=1}^{n} \log f_\phi(x) \,, \tag{41.18}$$

where we adopt the notion used in this chapter. The loss is simply $\mathcal{L}(x, f_\phi(x)) = -\log f_\phi(x)$, and the corresponding risk is

$$\mathcal{R}_{\text{xe}}[f_\phi] = \mathbb{E}_{p(x)}[-\log f_\phi(x)] \,, \tag{41.19}$$

which is the cross entropy $H[p, f_\phi]$. For density estimation, the model is usually constructed to enforce $\int f_\phi(x)dx = 1$ and $f_\phi(x) \geq 0$ so that it can be interpreted as a distribution. With this constraint, one can show that $f^*_{\text{xe}}(x) = p(x)$.

The concepts of generalization and overfitting are particularly acute in unsupervised learning, where the likelihood maximization of equation 41.18, combined with universal approximator assumption, must converge onto $\hat{p}(x) = \frac{1}{n}\sum_{i=1}^{n} \delta(x - x_i)$, the empirical distribution of the dataset $\{x_i\}_{i=1,\ldots,n}$. This distribution has the highest likelihood on the training dataset and the lowest likelihood on the test data where it gives $\hat{p}(x) = 0$. as long as the test dataset are not identical to the training dataset. So the empirical distribution of the training dataset has the worst possible generalization property, yet it is the solution we converge to for sufficiently expressive architectures in the absence of any regularization. In contrast, in supervised learning we often observe the phenomenon of benign overfitting, where even zero loss can generalize well.

In addition to approaches to density estimation that involve learning in the sense of minimizing a loss or risk function, we note that there are also classical density estimation techniques such as histogramming and kernel density estimation [24–26].

41.3.2.2 *Representation learning, compression, and auto-encoders*

A recurring topic in machine learning and statistics is how to represent the data. Much of classical statistics involves constructing a low-dimensional summary statistic that extracts the relevant information from the data for a particular task (a sufficient statistic in language of classical statistics). There is a spectrum of representations with trade-offs. At one end of this spectrum is lossless compression that allows you to encode the data into a smaller, intermediate representation that carries all the information since it can be decoded back into the original data. At the other end of the spectrum is something like the likelihood-ratio, which is a single scalar that carries the relevant information needed for hypothesis testing for a single hypothesis, but it discards all the other information that might be needed for other tasks (such as testing other hypotheses). An intermediate point in this spectrum is the process of feature engineering, which refers to the creation of new features $\mathcal{X}'$ from the original features $\mathcal{X}$ in hopes that the down-stream task will be easier with the new features. For example, instead of working directly with the energy and momentum of particles, one might compute invariant masses, angles between particles, etc. This type of feature engineering generally improved performance for shallow neural networks, decision trees, *etc.*; however, with the rise of deep learning this is often no longer necessary and often limits performance compared to working with the original features. One can think of the intermediate layers of a neural network between the input and the output a representation of the data that is good for the task at hand, and by training all the layers of the network simultaneously (or "end-to-end") one can see the intermediate layers as a learned representations. For a review see Ref. [27].

An example of a linear dimensionality reduction representation and data compression is principal component analysis (PCA) of data $x \in \mathbb{R}^d$ at fixed latent space dimensionality k (k<d), which finds the orthogonal linear transformation, O,

$$O : \mathbb{R}^k \to \mathbb{R}^d, z \mapsto Oz,\ OO^T{=}I_d \tag{41.20}$$

that maximizes the data variance in the latent space. Maximizing the variance of the transformed data is equivalent to minimizing the average reconstruction error (the residual variance in data space),

$$\mathcal{L}_{a.e.}(x, f(x)) = \|x - f(x)\|^2 \,. \tag{41.21}$$

A PCA can thus be interpreted as a linear, orthogonal model that is trained to minimize the L_2-distance between the input data and the reconstructed data given the fixed dimensionality k. In practice, the PCA problem can be solved analytically without the use of optimization algorithms or the loss function: the principal components are given by the eigenvectors of the data covariance matrix.

A suitable latent space dimensionality, k, is chosen by ordering the eigenvalues, λ_i, of the data covariance in descending order, and keeping only the first few eigenvectors that correspond to the largest eigenvalues. The cut is often made at dimensionalities that capture around 90% of the data variance. For many data sets this results in $k \ll d$. The average reconstruction error that originates from the discarded eigenvalues is $\sigma^2_{\text{recon}} = \sum_{i=k+1}^{d} \lambda_i$.

Another common type of representation learning and nonlinear dimensionality reduction is based on the *auto-encoder* $f = g \circ e : \mathcal{X} \to \mathcal{X}$, where $e : \mathcal{X} \to \mathcal{Z}$ is referred to as the *encoder* and $g : \mathcal{Z} \to \mathcal{X}$ is referred to as the *generator* or *decoder*. Typically the dimensionality of $\mathcal{Z}$ is much less than $\mathcal{X}$, and $z = e(x)$ can be thought of as a compressed representation of the input. The intermediate space $\mathcal{Z}$ is sometimes referred to as the bottleneck or the latent space of the auto-encoder. If the bottleneck is sufficiently large and the encoder and decoder are sufficiently flexible, then the function f could just be the identity (*i.e.* lossless compression). However, if the encoder and decoder are not sufficiently flexible or the dimensionality of the latent space is not large enough there will be some reconstruction error. Therefore the reconstruction error of Eq. 41.21 serves as a natural loss function of an auto-encoder.

Once trained, the encoder $e(x)$ can be used independently of the decoder to provide a generic low-dimensional representation of the data. The flexibility of this approach is attractive; however, there are no guarantees that this representation will be optimal for the other task. Indeed, the transition from pre-trained auto-encoders to end-to-end learning is one of the important trends that characterized the onset of the deep learning era.

While achieving zero reconstruction error may seem good as it would imply lossless compression, it often performs poorly in practice. First, the encoder may be overfit to the training dataset and not generalize well to held out data. Secondly, it may not be robust to domain shift (see Sec. 41.7.2). One approach to address these issues is the *denoising auto-encoder*, which uses a form of regularization that corrupts the input with noise $x' \sim q(x'|x)$ while still targeting reconstruction of the uncorrupted input x.

$$\mathcal{L}_{d.a.e.}(x, f(x)) = \|x - f(x')\|^2 \qquad \text{with} \qquad x' \sim q(x'|x) \,, \tag{41.22}$$

where $q(x'|x)$ is some probability distribution such as a multivariate normal.

41.3.2.3 *Clustering*

The goal of clustering is to group the data $\{x_i\}_{i=1,\ldots,n}$ into k groups, or *clusters*, usually with $k \ll n$. Intuitively, if two data points belong to the same cluster, then they should be similar in some sense. Conversely, if two data points are very different, then they should be assigned to different clusters. The notion of similarity usually is based on some heuristic, and there are a variety of algorithmic and probabilistic clustering algorithms. In some cases k is specified, while in others it is determined by the clustering algorithm. There is also a distinction between flat clustering that directly partitions the data into k clusters and hierarchical clustering where clusters are nested hierarchically as the name suggests. In many cases clustering uses some notion of distance $d(x_i, x_j)$, which may be the L_p norm $\|x_i - x_j\|_p$.

One of the most common clustering algorithms is known as k-means, where k is specified by the user and results in sets $S = \{S_1, \ldots, S_k\}$ that minimize the variance of each cluster. Thus,

the objective is

$$\begin{aligned}\arg\min_{\mathbf{S}} \sum_{i=1}^{k} \sum_{\mathbf{x}\in S_i} \|\mathbf{x}-\boldsymbol{\mu}_i\|^2 &= \arg\min_{\mathbf{S}} \sum_{i=1}^{k} |S_i| \operatorname{Var} S_i \\ &= \arg\min_{\mathbf{S}} \sum_{i=1}^{k} \frac{1}{2|S_i|} \sum_{\mathbf{x},\mathbf{y}\in S_i} \|\mathbf{x}-\mathbf{y}\|^2\end{aligned} \tag{41.23}$$

where μ_i is the mean of points in S_i.

While k-means and many other clustering algorithms are defined in terms of an optimization problem, the optimization objective is often not representative of the actual notions of performance in a given context. As a result, there are a number of quantities used for the evaluation and assessment of the resulting clustering. These include Davies–Bouldin index, Dunn index, Rand index, Jaccard index, purity, F-measure, Hopkins statistic, *etc.* [28].

41.3.3 *Optimal control, reinforcement learning, and active learning*

Many problems in science and engineering can be cast as a control problem, which comprises a cost functional that is a function of state and some control variables that specify some underlying dynamical system. This is relevant for the control of accelerators where the dynamical system is physical. This formalism can also be used to describe the design of experiments, planning of an observational survey, and other decision making processes relevant to the scientific method. There is a tremendous amount of literature on the subject, and it is closely connected to planning, dynamic programming, and reinforcement learning. Optimal control can be seen as an extension of the calculus of variations, and thus generalizes the framing of learning presented in Sec. 41.2.

Optimal control theory deals with finding a control for a dynamical system over a period of time such that the objective function is optimized. The underlying system can be discrete or continuous and may be deterministic or stochastic. The commonalities and differences between optimal control and reinforcement learning can be best understood through the formalism of a Markov decision process (MDP), which is a discrete-time stochastic control process. We follow common notation, such as that found in Wikipedia.

A Markov decision process comprises four components often organized as a 4-tuple (S, A, P_a, R_a), where: S is a set of states called the state space, A is a set of actions called the action space, $P_a(s, s') = \Pr(s_{t+1} = s' \mid s_t = s, a_t = a)$ is the probability that action a in state s at time t will lead to state s' at time $t + 1$, $R_a(s, s')$ is the immediate reward (or expected immediate reward) received after transitioning from state s to state s', due to action a.

The policy function π is a mapping from state space to action space that can be either deterministic or probabilistic. For examples, the policy that drives a computer chess playing system, decides which move to make given the current state of the board. Similarly, policies dictate which experiment should be built next, which field of the sky should be observed, or how to adjust the operational parameters of an accelerator. The dynamics of the resulting system are then fixed by combining the policy with the underlying MDP. The evolution of the resulting dynamical system behaves like a Markov chain since the action chosen in state s is completely determined by $\pi(s)$ and $\Pr(s_{t+1} = s' \mid s_t = s, a_t = a)$ implies the Markov transition matrix $\Pr(s_{t+1} = s' \mid s_t = s)$.

The objective optimal control is to choose a policy π that will maximize a cumulative function of the instantaneous rewards R_a. A common choice is the expected discounted sum:

$$\mathbb{E}\left[\sum_{t=0}^{\infty} \gamma^t R_{a_t}(s_t, s_{t+1})\right], \tag{41.24}$$

where $a_t \sim \pi(s_t)$ are the actions given by the policy, the expectation computed with respect to the distribution $s_{t+1} \sim P_{a_t}(s_t, s_{t+1})$, and γ is the discount factor satisfying $0 \leq \gamma \leq 1$. The discount factor is usually close to 1 and sometimes reparameterized as $\gamma = 1/(1 + r)$, where r is called the discount rate. A lower discount factor motivates the decision maker to favor taking actions early, rather than postpone them indefinitely.

A policy that maximizes the objective function is called an optimal policy and denoted π^*, though the optimal policy need not be unique. Importantly, the Markov property implies that the optimal policy is only a function of the current state. Dynamic programming can be used to find the optimal policy for MDPs with finite state and action spaces. For instance, in value iteration (a.k.a. backward induction) can be used to solve the "Bellman equation" [29]. For continuous-time systems, the optimal policy is defined by the Hamilton–Jacobi–Bellman equation [30].

In many settings, it is assumed that the state s is fully known when action is to be taken and there are no latent variables. When this assumption is not true, the problem is called a partially observable MDP. These problems are generally more difficult and the dynamic programming algorithms do not directly apply [31].

Reinforcement learning The main difference between the classical dynamic programming methods and reinforcement learning (RL) algorithms is that the latter do not assume knowledge of an exact mathematical model of the MDP and they target large MDPs where exact methods become infeasible. For example, RL was used in the context of jet physics to search for the most likely jet clustering when the number of constituents was too large for the exact dynamic programming algorithm to be used [32]. In addition, RL can be used when the probabilities or rewards are unknown. Instead, the transition probabilities are often accessed indirectly through interaction with a real or simulated environment. For example, in Q-learning one uses experience to estimate the array $Q(s, a)$ defined as

$$Q(s, a) = \sum_{s'} P_a(s, s')(R_a(s, s') + \gamma V(s')). \tag{41.25}$$

While this function is also unknown, it can be estimated during learning based on (s, a) pairs together with the outcome s'.

Numerous variations to RL exist, which include so-called model-based and model-free approaches (referring to models of the instantaneous rewards and the state transitions) and on-policy and off-policy (which describes how the actions taken during learning are related to the current policy). See Ref. [33] for an introduction and Ref. [34] for a recent review.

Multi-arm bandits Multi-arm bandit problems are a classic reinforcement learning problem where one tries to maximize the expected gain by allocating a limited set of resources to various alternatives. The name is a reference to a gambler with a fixed amount of money that must choose between multiple slot machines (or "one-armed" bandits) when the payoff for the individual machines is unknown. A hallmark of multi-arm bandit problems is that they involve a trade-off between exploration (playing machines to estimate their payoff) and exploitation (playing machines with the highest estimated payoff). Multi-armed bandits are used to manage large projects, organizations, and scheduling problems. The theory has a long history going back to Robbins in 1952 that used it to study the sequential design of experiments [35] and Gittins who derived an optimal policy under some conditions [36].

Bayesian optimization A closely related set of techniques involve optimizing some expensive black box function $f(x)$. For instance, the function may be computationally expensive to evaluate or low-latency, *e.g.* it may involve manually re-configuring a system. This is particularly relevant for analysis optimization in particle physics where evaluating $f(x)$ involves processing large numbers of simulated collisions. Another common use case involves optimizing the hyperparameters of a learning algorithm.

Without any assumptions about the function $f(x)$ this is hopeless; however, if one assumes something about the functions (*e.g.*

some notion of smoothness) then one can leverage function evaluations evaluations $\{f(x_t)\}_{t=1,\ldots,T}$ to say something about what value the function might take on at other values of x. This is usually cast in Bayesian terms, and Gaussian processes (Section 41.5.1) are often used to model the distribution over $f(x)$. The optimization techniques that use this framing are generically referred to as Bayesian Optimization [37].

Optimization in this context is usually characterized by an *exploration-exploitation* trade-off, similar to what is found in multi-arm bandits. Here, exploration refers to function evaluations that characterize the function in regions that haven't been evaluated, while exploitation refers to evaluations near what is predicted to be its maximum. This setting is similar to reinforcement learning in that it involves sequential decisions (*i.e.* where to evaluate the function next), but usually the target function $f(x)$ is assumed to be static. In that sense, the state referred to in the language of an MDP is the state of knowledge about the function after sequential evaluations $\{f(x_t)\}_{t=1,\ldots,T}$. The reward at time t is not the value of the function $f(x_t)$, but some quantity that characterizes what was learned about the function's maximum. In this literature, one often refers to the *acquisition function*, which plays a similar role as the expected value of the reward in RL. Common acquisition functions include the probability of improvement, the expected improvement, and an upper-confidence bound [38].

Connection to experimental design In the context of physics experiments we often want to build the next generation experiment which can reach certain target precision on parameters of interest that the experiment can measure. To achieve this precision we may deploy the concept of *experimental design*, where we the objective is to optimize some objective that quantifies the expected performance of an experiment. Moreover, we would like to achieve this within some constraints such as a minimal cost. Such problems are often solved using the Fisher matrix optimization, where Fisher matrix can be viewed as the expectation of the inverse covariance matrix. We can define

$$t(x|\theta_0) \coloneqq \nabla_\theta \log p(x|\theta)|_{\theta_0} \ , \tag{41.26}$$

where $t(x|\theta_0)$ is referred to by statisticians as the score [20]. The score plays an important role in the classical statistics as it is a sufficient statistic when $p(x|\theta)$ is in the exponential family, and through the Rao-Cramér-Fréchet bound on the variance of an estimator for θ, and is used to define the Fisher information matrix $I_{ij}(\theta) \coloneqq \mathbb{E}_{p(x|\theta)}[t_i(x|\theta)t_j(x|\theta)]$. The Fisher information, in turn is an important object in experimental design. In particle physics, the score is closely related to the concept of optimal observables. The corresponding diagonal element of the inverse of the Fisher matrix thus provides expected uncertainty estimation of a given parameter, and is a lower bound to the error of an unbiased estimator (Cramér-Rao bound). In experimental design we vary the experiment parameters within the constraints such as the total cost to minimize this uncertainty. This framework has been widely used in cosmology, where Fisher analysis is the foundation of any experiment proposal.

Active learning Active learning is closely related to Bayesian optimization, described above. In Bayesian optimization one estimates the function $f(x)$ from some set of evaluations $\{y_t = f(x_t)\}_{t=1,\ldots,T}$; however, the goal is to find the maximum $x^* = \arg\max_x f(x)$. In active learning, the goal is not to find the maximum of $f(x)$, but to approximate the function as one does in supervised learning. The main difference compared to vanilla supervised learning is that the labeled training dataset isn't provided a priori in a passive way, but the learning algorithm actively decides where to generate $(x_t, y_t = f(x_t))$ pairs. The function $f(x)$ is sometimes referred to as an *oracle*. Active learning is particularly attractive when obtaining labelled data is a costly process.

More broadly, a challenge of many machine learning applications is obtaining labeled data, which can be a costly process. If a system could learn from small amounts of data, and choose by itself what data it would like the user to label via an external process called oracle, it would make machine learning more powerful. Such frameworks are also called Experiment Design or Active Learning. In Active Learning, a model is trained on a small amount of data (the initial training dataset), and an acquisition function (often based on the model's uncertainty) decides on which data points to ask for a label. The acquisition function selects one or more points from a pool of unlabelled data points, with the pool points lying outside of the training dataset. Once we label the selected data points, these are added to the training dataset, and a new model is trained on the updated training dataset. This process is then repeated, with the training dataset increasing in size over time. The advantage of such systems is that they often result in dramatic reductions in the amount of labelling required to train an ML system (and therefore cost and time).

41.3.4 *Anomaly detection and out-of-distribution detection*

Unsupervised anomaly detection techniques detect anomalies in an unlabeled test data set under the assumption that the majority of the in-distribution data are normal under some measure, while out-of-distribution (OOD) data are not. In the context of auto-encoders a popular technique is to use the reconstruction error of Eq. 41.21 to identify an outlier as one with a large reconstruction error [39, 40]. One issue with this method is that for higher dimensional latent space and flexible neural network architectures the encoder-decoder map become identity for any input data, $f(x) = x$, regardless of whether input x is from the in-distribution training dataset or from the out-of-distribution data. The choice of auto-encoder latent space dimensionality is thus an important hyperparameter that must be tuned.

Another set of anomaly detection techniques construct a model representing normal behavior from a given In Distribution training dataset, and then test the likelihood of a test instance to be generated by the utilized model. For instance, one can use density estimation methods such as normalizing flows (section 41.5.4.3) to learn the density (likelihood) of the In Distribution training dataset $p(x)$, and apply it to the test data. The expectation is that out-of-distribution data will have a lower density (likelihood) under the in-distribution density model. This expectation is however not always met in high dimensions and the method suffers because likelihood based training is sensitive to the smallest variance directions [41]: for example, a zero variance pixels leads to an infinite $p(x)$, and noise must be added to regularize it. But low variance directions may contain little or no information on the global structure of the image, so there is a mismatch between the training objective and outlier detection objective. A related issue is that of typicality: an in-distribution likelihood will typically be lower than the maximum value. For a Gaussian likelihood the typical set is on average be $n/2$ in log likelihood below the peak value, where n is the dimensionality of the data. So an out-of-distribution dataset that is closer to the peak would be preferred in terms of likelihood even though its distribution does not match the in-distribution data. If this happens by chance on low variance directions which dominate the likelihood, normalizing flows can assign higher likelihoods to out-of-distribution data than to in-distribution training dataset [42]. A number of techniques have been proposed to circumvent these limitations, such as likelihood regret [43], likelihood-ratio [41], likelihood in auto-encoder latent space [44], and Wasserstein distance training of the likelihood $p(x)$ [45]. These methods can achieve better anomaly detection performance than the auto-encoder reconstruction error [44, 46].

Supervised anomaly detection techniques require a data set that has been labeled as in-distribution and out-of-distribution and involves training a classifier (the key difference to many other statistical classification problems is the inherent unbalanced nature of outlier detection). These methods assume some form for what out-of-distribution data may look like, and their success relies on whether the assumed form is a realistic representation of actual out-of-distribution data. When this assumption is valid these methods can be more powerful than unsupervised methods, but the reverse is also true. A hybrid between the two approaches is to train a classifier without labels [47]. All these approaches are largely complementary to each other [48]. An example of different anomaly detection methods applied to HEP is LHC Olympics

2020 and Dark Machines challenges [49, 50].

41.3.5 *Simulation-based inference*

The goal of simulation-based inference (related to, but distinct from, likelihood-free inference) is to extend the statistical procedures described in the Chapter on Statistics (*e.g.* parameter estimation, hypothesis tests, confidence intervals, and Bayesian posterior distributions) to the situation where one does not know the explicit likelihood $p(x|\theta)$, the probability of the data given the parameters θ, but has access to a simulator that defines the likelihood $p(x|\theta)$ implicitly [51, 52]. In a typical setup we would like to solve the so called inverse problem of getting the posterior of the parameters given the data, $p(\theta|x)$, but we cannot use Bayes theorem directly because we do not have explicit $p(x|\theta)$.

In particle physics, the simulators usually use Monte Carlo event generators (see Sec. 43) to sample unobserved latent variables z, such as the z_p phase space of the hard scattering (see Sec. 49.4), z_s associated to showering and hadronization, and z_d associated to the interaction of particles with the detector (see Sec. 34). As such, the full simulation chain can be expressed symbolically as

$$\begin{aligned} p(x|\theta) &= \int dz p(x,z|\theta) \\ &= \int \mathrm{d}z_d \int \mathrm{d}z_s \int \mathrm{d}z_p \, p(x|z_d)p(z_d|z_s)p(z_s|z_p)p(z_p|\theta) \ , \end{aligned} \tag{41.27}$$

where θ are the Lagrangian parameters that dictate the hard scattering. Evaluating the likelihood is intractable as it would require evaluating the integral above for each event.

While the likelihood is intractable, simulators provide the ability to generate synthetic data $x_i \overset{i.i.d.}{\sim} p(x|\theta)$ for any value of the parameters θ. One can use a suitable proposal distribution $\tilde{p}(\theta)$, sample $\theta_i \overset{i.i.d.}{\sim} \tilde{p}(\theta)$, generate synthetic data $x_i \sim p(x|\theta_i)$, and then assemble a training dataset $\{x_i, \theta_i\}_{i=1,\ldots,n}$ that can be used to train various machine learning models.

There is thus a close analogy between Simulation-based Inference and data driven machine learning tasks discussed so far, replacing θ with y. One difference is that in simulation-based inference we can always generate new samples by running additional simulations, while we typically view training dataset in machine learning as fixed. This property of Simulation-based Inference enables Active Learning, where the additional simulations are chosen such as to minimize the error on the desired statistical inference task. Another difference is that we often have access to the joint likelihood $p(x, z|\theta)$, where z are unobserved latent variables[5].

Typically in particle physics, one uses histograms or kernel density estimation to model the distribution of observables (low-dimensional summary statistics such as the invariant mass) of simulated data [53]. Alternatively, one can use an explicit parametric family (such as a falling exponential, a Gaussian distribution, *etc.*) to model $\hat{f}(x|\theta) \approx p(x|\theta)$. That model is then used as as a surrogate for the unknown density implicitly defined by the simulator. A related approach is known as Approximate Bayesian Computation (ABC), which approximates the likelihood through an acceptance probability that synthetic data is sufficiently close to the observed data [54, 55]. In practice, these techniques are limited to low-dimensional representations of the data. Thus the potential of recent machine learning approaches to simulation-based inference is to extend this approach to higher-dimensional data, while maintaining the already well-established statistical procedures.

For instance, one can use normalizing flows (see Sec. 41.5.4.3) and the loss functions for density estimation (see Sec. 41.3.2.1) to learn a surrogate model for the likelihood $\hat{f}(x|\theta) \approx p(x|\theta)$ [56]. Similarly, one can use conditional density estimation to learn a surrogate model for the posterior $\hat{f}(\theta|x) \approx p(\theta|x)$, which may involve including the prior-to-proposal ratio $\tilde{p}(\theta)/p(\theta)$ [57]. In addition to the unsupervised learning techniques, one can also use supervised learning to learn the likelihood-ratio $r(x|\theta_0, \theta_1) = p(x|\theta_0)/p(x|\theta_1)$ by leveraging the *likelihood-ratio trick* of Eq. 41.12 [20, 58].

In some cases one can also augment the training dataset to include the joint likelihood-ratio

$$r(x_i, z_i|\theta_0, \theta_1) \coloneqq p(x_i, z_i|\theta_0)/p(x_i, z_i|\theta_1) \ , \tag{41.28}$$

which can be used to reduce the variance for the squared-error loss or the improved cross-entropy estimator of Eq. 41.17 [20, 21]. While the marginal likelihood $p(x|\theta)$ is intractable due to the high-dimensional integral over the latent space, the joint likelihood is often tractable since no integration is necessary. In addition, one can often augment the training dataset with the joint score

$$t(x_i, z_i|\theta_0) \coloneqq \nabla_\theta \log p(x_i, z_i|\theta)|_{\theta_0} \ . \tag{41.29}$$

Regressing on the joint score with the squared loss function $\mathcal{L}(t(x, z|\theta_0), f(x)) = (t(x, z|\theta_0) - f(x))^2$ corresponds to risk functional

$$\mathcal{R}_{\text{score}}[f] \coloneqq \mathbb{E}_{p(x,z|\theta_0)}[(\nabla_\theta \log p(x_i, z_i|\theta)|_{\theta_0} - f(x))^2] \ . \tag{41.30}$$

One can show with the calculus of variations that the risk is minimized by the score of equation 41.26.

41.3.5.1 *Differentiable simulations*

One of the approaches to make inference feasible in high dimensional latent space is to make simulations differentiable with respect to all of its parameters, global variables θ and latent variables z. Latent variable models are known in Machine Learning as generative models and are discussed below, but latent variable models are also common in scientific applications. As an example, in cosmology one can view the initial conditions of the large scale structure or cosmic microwave background as Gaussian distributed latent variables.

While differentiable simulations have traditionally not been developed for scientific applications, the success of Machine Learning, where backpropagation algorithm combined with gradient descent optimization (see Sec. 41.6.1) is the basis of its recent advances, has inspired a new look at this. One recent example is FlowPM cosmological N-body simulation, which takes advantage of Mesh-Tensorflow to achieve a GPU-accelerated, distributed, and differentiable simulation [59].

One broad class of inference problems where gradients make the problem simpler are the so called inverse problems. As a simple example let's assume the data x are observed with some Gaussian noise with known variance σ^2, equal for all data points. The likelihood of the data can be written as

$$\log p(x|z,\theta) = -\frac{N}{2}\log[2\pi\sigma^2] - \frac{||x - g(z,\theta)||^2}{2\sigma^2}. \tag{41.31}$$

Here $g(z, \theta)$ is the forward model (generator or decoder), i.e. the simulation output in the absence of noise. The joint distribution is $p(x, z|\theta) = p(x|z, \theta)p(z|\theta)$, where $p(z|\theta)$ is the prior of latent space variables, assumed to be known, with a known gradient with respect to θ and z. In this case the gradients $\nabla_\theta \log p(x, z|\theta)$ and $\nabla_z \log p(x, z|\theta)$ are available when the simulation forward model gradients $\nabla_\theta g(z, \theta)$ and $\nabla_z g(z, \theta)$ are available.

Availability of simulation gradients in turn enables gradient based optimization or sampling. In sampling approach one can use Monte Carlo Markov Chains to obtain the posterior samples of latent space z and parameter space θ [60]. In optimization approach one can find the best-fit point $\hat{z}$, which is the MAP estimate of the latent space variables z given x and fixed θ [61]. Another optimization approach is Variational Inference, which attempts to model the posterior probability distribution using optimization. This is discussed further in Section 41.5.4.

41.3.5.2 *Unfolding as an inverse problem*

While much of the work on simulation-based inference described above is aimed at inferring the parameters θ of the simulator, there is also work that aims to to infer the latent variables z. Here it is useful to think of the parameters θ as parameters of a theory, such as masses, coupling constants, or Lagrangian parameters, while z

[5] For this reason we prefer to use simulation-based inference instead of likelihood-free inference: joint likelihood $p(x, z|\theta)$ is often available, it is the marginal integral over latent space z that is assumed to be intractable.

might describe the kinematics of a collision before the detector response.

Inferring the distribution $p(z|\{x_1, \ldots, x_n\})$ from a dataset of multiple observations is commonly referred to as unfolding in particle physics, and deconvolution in other contexts. Unfolding is a classic inverse problem, and the collection of ideas being used for machine-learning based simulation-based inference are also being applied in this setting. Examples of recent work exploring these approaches are Refs. [62–73]. In addition, there has been work to infer the posterior distribution for an individual event $p(z|x_i)$ using probabilistic programming techniques [74–76].

41.4 Data representations, inductive bias, and example applications

In Sec. 41.3 we describe the input data as living in an abstract space $x_i \in \mathcal{X}$. In this section, we briefly describe some of the common types of structured data that are encountered in physics and refer to the corresponding models classes that have been developed to work with them. We will describe the model classes in more detail in the following section.

The most basic and common type of data structure is when $\mathcal{X} = \mathbb{R}^d$. This is often referred to as *tabular data* since the entire data set $\{x_i\}_{i=1,\ldots,n}$ can be thought of as a table with n rows and d columns. It is common to think of an individual entry x_i as a vector in d-dimensional Euclidean space, where the coordinates correspond to the columns of this table. In some cases individual components of x_i might be integers or take on only discrete values, in which case describing the space of the data as real-valued is a slight abuse of notation and representation. For many years this was the dominant type of data in high energy physics as it is a natural input type for shallow neural networks, multi-layer perceptrons, support vector machines, and tree-based methods found in popular tools such as `TMVA` [77].

For categorical data, one typically uses a numerical representation such as *integer encoding* where different categories are mapped to integers with a corresponding dictionary. Another common representation of categorical data is based on the so-called *one-hot encoding* (aka 'one-of-K' or 'dummy'), in which case the category is mapped to a k-dimensional binary vector where k is the number of categories and each component of this vector corresponds to a particular category. In the one-hot encoding, only one of the components is non-zero. Finally, there are approaches in one learns an *embedding* that maps discrete categories into $\mathbb{R}^d$; an example of this is `Word2Vec` [78]. Interestingly, such embeddings can preserve various types of semantics; for instance, the vector `walking-walk` is similar to the vector`swimming-swam` as are the vectors connecting countries and their capital cities. This allows for a loose sense of algebra on the word embedings such as `walking-swimming+swam = walk`. Similar types of embeddings have also been used in a number of scientific use-cases including biological sequences (e.g. DNA, RNA, and Proteins) for bioinformatics applications [79].

Particle physics data often is represented with an extension of the simple tabular data structure where the number of columns is not fixed. For instance, if the rows correspond to data for individual collisions, the number of electrons (and positrons) reconstructed in the event is variable. Thus the number of columns needed to represent the energy, momentum, and charge of these particles is also variable. A common solution to this problem is to fix a maximum number of particles and then *truncate* and *zero-pad* to fit the data into a fixed tabular representation, though this is not the natural representation of the data and it leads to a loss of information.

Sequential data is also commonly encountered in physics (*e.g.* in time series). Here an individual entry $x_i = (x_i^1, \ldots, x_i^t, \ldots x_i^{T_i})$ where t is index for the ordered sequence, T_i is the length of the sequence (which might be variable), and the data associated to each "time" $x_i^t \in \mathbb{R}^d$. This is similar to the previous example where the energy, momentum, and charge of the t-th electron in the i-the event would be x_i^t and the electrons might be sorted according to their energy or transverse momentum. Sequential data is also encountered in natural language processing, where x_i^t correspond to individual words in a sentence. Recurrent neural networks (see Sec. 41.5.3.9) are particularly well suited to sequential data. Examples applications from the Living Review include [80–85].

Image-like data is one of the most dominant forms of data in industrial applications of deep learning, is very relevant for astronomy and cosmology, and also appears in particle physics in various forms. Image-like data typically involves d-dimensional features associated to a regular grid or lattice that does not vary across the individual instances x_i. The canonical example is a standard image from a camera with $W \times H$ pixels where the p-th pixel has data $x_i^p \in \mathbb{R}^3$ corresponding to the three *channels* in the RGB color model. It is important to recognize that the data corresponding to the 2-dimensional image is not 2-dimensional; instead, it is $(W \times H \times c)$-dimensional, where c is the number of channels. In astronomy, an image may be grey scale ($c = 1$) or there may be more *channels* ($c > 3$) corresponding to different color filters. In other applications, the grid or lattice might be 3- or 4-dimensional. For example, the data associated to a regularly segmented calorimeter can be thought of as a 3-dimensional image and the data associated to a lattice simulation of a classical or quantum system can be thought of as a 4-dimensional image. Convolutional neural networks, described in Sec. 41.5.3.5, are particularly well suited to image-like data. Example applications from the Living Review include [81, 86–108].

It is also possible that the the data (or features) associated to one "pixel" or lattice site may itself be structured. For example, the single read-out plane of a Liquid Argon time projection chamber (LArTPC) may involve a 1-dimensional or 2-dimensional grid, but the data associated to each "pixel" is itself a sequence or waveform. Example applications in Neutrino Physics from the Living Review include [109–139]. Similarly, in lattice quantum chromodynamics, the data associate to a particular site (or link) would be group valued (*e.g.* $x_i^p \in SU(3)$ as in Refs. [140, 141]).

Both sequential and image-like data have a notion of temporal or spatial structure. While it is possible to unroll an image into a $(W \times H \times c)$-dimensional vector, that would erase the spatial structure and obfuscate the fact that nearby pixels are highly correlated. Similarly, one could permute the time index for sequential data, but that would destroy the temporal structure of the data. The complementary point of view is that the model class should also be aware of the structure of the data. Recurrent neural networks and convolutional neural networks are good examples of what is called *inductive bias* as the models do incorporate something about the structure of the data that they are expected to be used with. In some cases this can be formalized in terms of symmetry. For example, if we train model to classify images of cats and dogs, we would like it's prediction to be invariant to where in the image the cat is. This type of translational invariance can be enforced in the design of the model class.

While permuting the elements of a sequence destroys the temporal structure of a time series, attaching a temporal index t to a set of objects with features x_i^t can also be problematic. If the data corresponding to x_i really are a set $\{x_i^1, \ldots, x_i^{T_i}\}$ (*e.g.* a point cloud), then we would like the output of the model to be *permutation invariance*. A standard sequential or convolutional model will not generally be permutation invariant, but recently models such as Deep Sets, various types of graph neural networks, and transformers can be made to enforce permutation symmetry. Example applications from the Living Review include [100, 142–152]

The temporal and spatial structure of sequences and image like data can also be generalized. For instance, a 1-dimensional sequence can be generalized to a tree structured data like one finds in the hierarchical clustering of jets or as in a directed-acyclic graph (DAG). Generalizations of recurrent neural networks have been constructed that can operate over these more complex data structures [153, 154]. More generally, one can considered graph-structured data composed of nodes and edges or multi-graphs that group together three nodes into faces or k nodes into k-edges. Graph neural networks are a class of models that work with this type of data. The emerging subfield of geometric deep learning aims to unify the notation, terminology, and theory that connect these considerations of the structure of the data and the corresponding model architecture. Example applications in the Living Review include [121, 128, 131, 132, 134, 155–181].

If the data are expected to have a symmetry associated to them but one is working with a model class that does not enforce this symmetry, then *data augmentation* is a common procedure used to improve generalization performance. Here one starts with an initial dataset $\{x_i\}_{i=1,\dots,n}$ and produces an augmented dataset $\{x'_i\}_{i'=1,\dots,n'}$ through some data augmentation strategy. For example, one might apply a random rotation $R_{i'}$ to an image to produce $x'_i = R_{i'}(x_i)$ if one assumes rotational invariance in the underlying problem.

In some cases some of the individual features (components) of x are functions of other features. For instance, one may include components of a four-vector (E, p_x, p_y, p_z) as well as redundant information such as transverse momentum, azimuthal angles, rapidity, etc. In this case, the data is restricted to a lower-dimensional surface embeded in $\mathcal{X}$. Even if the features aren't redundant, statistically the data are often effectively restricted to a small subspace of statistically likely samples and those that are exceedingly unlikely. For instance, the space of natural images is a small and highly structured subspace of all possible images, which are dominated by what we would perceive visually as noise. The term *data manifold* is used to describe this restricted subspace where the data are to be found, even though it does not necessarily satisfy the formal requirements of a manifold in the mathematical sense.

These considerations on the structure of the data not only apply not to the input data $x_i \in \mathcal{X}$, but also to the output data $y_i \in \mathcal{Y}$. For instance, one might want a sequence-to-sequence model as in machine translation of written text [182] or to learn a function that takes sets as input and produces graphs as output as in the Set2Graph mode [183]. One might also want the input and output of the model to be different in representations of an underlying symmetry group and for the model to enforce group-equivariance [140, 141]. The development of the necessary modelling components to enable practitioners to compose and train these types of models is a significant development for the field of physics.

41.5 Flavors of ML models

41.5.1 *Support vector machines and kernel machines*

Support Vector Machines (SVM) are a class of supervised learning models used for classification and regression. The learning algorithm involves a convex optimization problem that has a unique solution and can be solved with quadratic programming techniques. In this sense, they are robust and easier to characterize than neural networks that involve non-convex optimization. While their history goes back to Vapnik and Chervonenkis in the 1960s, they gained popularity after Bernhard Boser, Isabelle Guyon and Vladimir Vapnik suggested a way to create nonlinear classifiers by applying the kernel trick in 1992 [184]. Originally they were developed for binary classification and only supported therestricted case where the training dataset can be separated without errors, but in 1995 Cortes and Vapnik extended the technique to non-separable training dataset [185]. A variant targeting regression, known as support vector regression (SVR), was developed in 1997 [186]. The theory around support vector machines was well developed, and they dominated machine learning research for roughly a decade before the rise of deep learning (see Sec. 41.5.3.4).

Maximum-margin classifiers Linear support vector machines are used for binary classification, where $\mathcal{X} = \mathbb{R}^d$ and the target labels are conventionally defined as $\mathcal{Y} = \{-1, 1\}$. The classification is simply based on which side of a hyperplane the data lie. Any hyperplane can be written as the set of points x satisfying $w^T x - b = 0$, where $w, b \in \mathbb{R}^d$ are the parameters of the model. The vector w is normal to the hyperplane, but not necessarily normalized. The quantity $\frac{b}{\|w\|}$ quantifies the offset of the hyperplane from the origin along the normal vector w.

If the training dataset is linearly separable, then there is a region bounded by two parallel hyperplanes, called the *margin*, that separate the two classes of data. The maximum margin classifier is uniquely defined by making the distance between these two hyperplanes as large as possible. The boundaries of the margin can be defined by $w^T x_i - b = \pm 1$, and the width of the margin is given by $\frac{2}{\|w\|}$. Figure 41.1 illustrates this for $x \in \mathbb{R}^2$.

Since the width of the margin is maximized when $\|w\|$ is minimized, we can state the goal of the (hard) maximum-margin classifier in the linear separable case as the following constrained optimization problem: Minimize $\|w\|^2$ subject to the constraint $y_i(w^T x_i - b) \geq 1$ for $i = 1, \dots, n$. The w and b that solve this problem uniquely determine the resulting classifier, $\hat{y}(x) = \mathrm{sgn}(w^T x - b)$.

This geometric description makes it clear that the maximum-margin hyperplane is completely determined by those x_i that lie nearest to it: the eponymous *support vectors*.

Soft margins and slack variables Often the data will not be linearly separable and thus the hard-margin optimization problem described above has no solution. Such a non-separable case can be accommodated with the use of so-called *slack variables*. One slack variable $\xi_i > 0$ is introduced for each data point. As shown in Figure 41.1 (right), if a data point x_i is outside the margin and correctly classified as in the separable case, then $\xi_i = 0$. If it within the margin but still correctly classified, then $0 < \xi_i < 1$. If it is misclassified, then $\xi_i > 1$. The new constrained optimization problem is to minimize

$$\sum_i \xi_i + \lambda \|w\|^2 \tag{41.32}$$

subject to the constraints $y_i(w^T x_i - b) \geq 1 - \xi_i$ and $\xi_i > 0$ for $i = 1, \dots, n$. Effectively, this corresponds to minimizing $\sum_i \max(0, 1 - y_i(w^T x_i - b)) + \lambda \|w\|^2$, where the first term is called the *hinge loss*.

The dual problem In the language of convex optimization, linear programming, and quadratic programming the optimization problems stated above for the hard and soft maximum-margin classifiers define the *primal* objective to be minimized. There is a *Lagrange dual* problem where the solution corresponds to maximization with $\min_\phi L(\phi) = \sup_{\alpha > 0} \bar{L}(\phi, \alpha)$, where α are Lagrange multipliers. While it is not apparent in the primal formulation of the constrained optimization problems, the solution to the dual problem takes on the form

$$\hat{y}(x) = \mathrm{sgn}\Big(\sum_i y_i \alpha_i x_i^T x - b\Big) \,, \tag{41.33}$$

where the $\alpha_i > 0$ for the support vectors and otherwise zero. This reformulation is plausible since the orientation of the maximum-margin hyperplanes defined by w is completely specified by the support vectors. The crucial observation for the kernel trick described below is that the final model is defined in terms of coefficients and the inner product $\langle x_i, x \rangle_{\mathcal{X}} = x_i^T x$.

The kernel trick One approach to obtain non-linear decision boundaries is introduce a non-linear mapping $\varphi \colon \mathcal{X} \to \mathcal{V}$ that embeds the data in some higher-dimensional space $\mathcal{V}$. One can then use the linear SVM described above in the space $\mathcal{V}$. This is not unlike the many neural network models where the first layers use a non-linear activation function while the last layer is linear.

The *kernel trick* avoids the explicit mapping φ that is needed to get linear learning algorithms to learn a nonlinear function or decision boundary. This is possible because the solution to the dual problem in Eq. 41.33 is represented in terms of inner products $\langle \varphi(x_i), \varphi(x) \rangle_{\mathcal{V}} = \varphi(x_i)^T \varphi(x)$ corresponding to the candidate point x and the support vectors x_i. Thus all that is needed is a way to evaluate the inner products. A *kernel* or a kernel function $k \colon \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is a function that can be expressed as an inner product in another space $\mathcal{V}$ via $k(x, x') = \langle \varphi(x), \varphi(x') \rangle_{\mathcal{V}}$. Critically, one does not need to ever evaluate the map $\varphi(x')$, which is implicitly defined by the kernel. In some cases the kernel is straight forward to evaluate, even though the target space $\mathcal{V}$ implicitly defined by the kernel would be infinite dimensional.

The choice of the kernel is roughly the analog of the architecture of a neural network. It dictates the types of non-linearities the

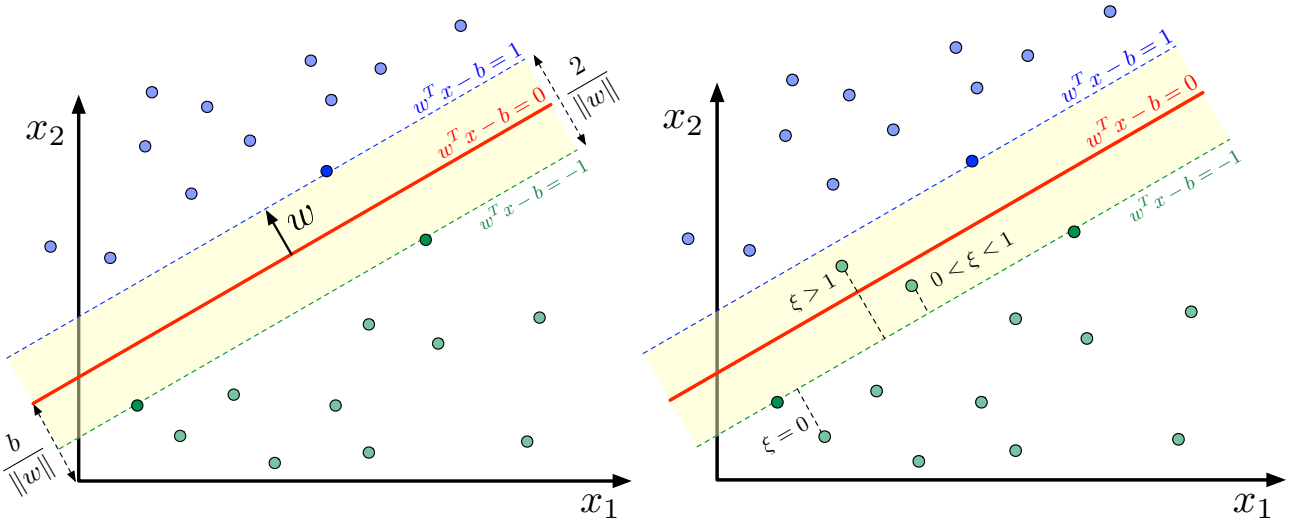

Figure 41.1: Illustration of a maximum margin classifier for a linear support vector machine in the separable case (left) and with the soft-margin and slack variables ξ (right).

SVM can implement in the input space. It also provides an opportunity to encode prior knowledge from physics such as symmetries, length scales, *etc.* There are also connections between very wide neural networks with random weights and biases and the kernel of a Gaussian process [187–189], which, when applied to deep networks, lead to the concept of neural tangent kernel [190]. While it is beyond the scope of this chapter, the interested reader may also be curious to understand the connections as formalized in the language of Reproducing kernel Hilbert spaces (RKHS) [191].

Support vector regression There are a few flavors of SVR. In Vapnik's ϵ-SVR formulation is similar to the picture for classification, but the boundary hyperplane serves as the prediction and the width of the margin for which there is no penalty is ϵ. Again, one can introduce a non-linear map $\phi(x)$ explicitly or implicitly via the corresponding kernel $k(x, x')$. One can view the predictive model as $\hat{y}(x) = w^T \phi(x) - b$ and the goal of the optimization problem is to minimize

$$\|w\|^2 + C \sum_i (\xi_i + \xi_i^*) \tag{41.34}$$

where ξ_i and ξ_i^* are slack variables associated to the model over or under-estimating $y_i \in \mathbb{R}$. The constrained optimization is subject to $w^T x_i - b - y_i \leq \epsilon + \xi_i$, $y_i - w^T x_i + b \leq \epsilon + \xi_i^*$, $\xi_i, \xi_i^* \geq 0$ for $i = 1 \ldots, n$. The solution to the dual problem leads to a kernelized representation of the solution

$$\hat{y}(x) = \sum_i (\alpha^* - \alpha) K(x, x_i) - b \,, \tag{41.35}$$

where the α_i, α_i^* are the parameters of the dual problem. In libraries like `LibSVM` the output of the algorithm is just $\alpha_i^* - \alpha_i$ for $i = 1 \ldots, n$.

Kernel ridge regression Kernel Ridge Regression (KRR) uses the same model as in SVR; however, it uses a different loss function. KRR uses the squared error loss while support vector regression uses the ϵ-insensitive loss function (*i.e.* no penalty is encured if the prediction is within ϵ). Both are combined with l2 regularization (the $\|w\|^2$ term). While SVR leads to a sparse solution that only depends on the support vectors, it can be slow to solve the constrained convex optimization problem. In contrast, KRR can be done in closed-form and is typically faster to train for medium-sized datasets. The consequence is that the learned model is non-sparse and thus slower than SVR to evaluate at prediction-time.

Gaussian Process Regression (krigging) Another variation on kernel-based regression is Gaussian process regression (GPR), also referred to as *krigging*. Again the model is based on the kernel trick. While KRR aims to minimize the mean-squared error loss $(y_i - \hat{y}(x_i))^2$ along with an l2 regularization term proportional to $\|w\|^2$, GPR elevates these terms to a probabilistic interpretation where the first is proportional to a log-likelihood for Gaussian $N(y_i|\hat{y}(x_i)), \sigma)$ likelihood and the second corresponds to the log of a Gaussian prior on w_i. This is related to the discussion on Tikhonov regularization found in Sec. 41.3.1.2. GPR goes further and uses a mean function $m(x)$ and kernel $k(x, x')$ to define a probabilistic model for $y(x)$ and $y(x')$ that includes correlations. For any finite number of points $\{x_j\}_{j=1,\ldots,m}$, the Gaussian process defines the joint distribution for the values that $f(x_i)$ might take. Typically, one specifies the prior mean $m(x)$ and prior covariance function $k(x, x')$ and then conditions on the training dataset $\{x_i, y_i\}_{i=1,\ldots,n}$. The posterior can then be evaluated for an independent set of points $\{x_j\}_{j=1,\ldots,m}$. The posterior mean is typically used as the prediction equivalent to SVR and KRR, but GPR also gives a meaningful notion of uncertainty in the predictions, and can be viewed as a realization of kernel Bayesian regression [192].

One advantage of GPR is that one can work with a family of kernel functions parameterized by some hyperparameters η. One can then optimize the hyperparameters via gradient-ascent on the marginal likelihood function. In contrast, hyperparameter tuning in SVR and KRR typically requires a grid search or some other black-box optimization procedure evaluated on held out data or some form of cross-validation.

Rasmussen and Williams provides an excellent review of Gaussian processes [193]. Numerically, Gaussian Process libraries are confronted with computing the log determinant of the covariance kernel, which naively scales like $\mathcal{O}(n^3)$ in computational complexity. However, recently there have been a number of numerical advances that make these methods fast and scalable to large datasets [194, 195]. While Gaussian Processes are used more widely in cosmology, they are not widely used in particle physics or astro-particle physics. Recent works explore the design of physics-inspired kernels and use Gaussian Processes to model the intensity for a Poisson point process like those found in experimental particle physics and γ-ray and X-ray astronomy [196–198]. Gaussian Processes are also extensively used in Bayesian Optimization (Section 41.3.3).

41.5.2 *Decision trees*

Tree-based models Classification and Regression Trees (CART) typically partition the input space into J disjoint regions $\mathcal{X} = \mathcal{X}^1 \cup \cdots \cup \mathcal{X}^J$ through a sequence of $J-1$ binary splits based

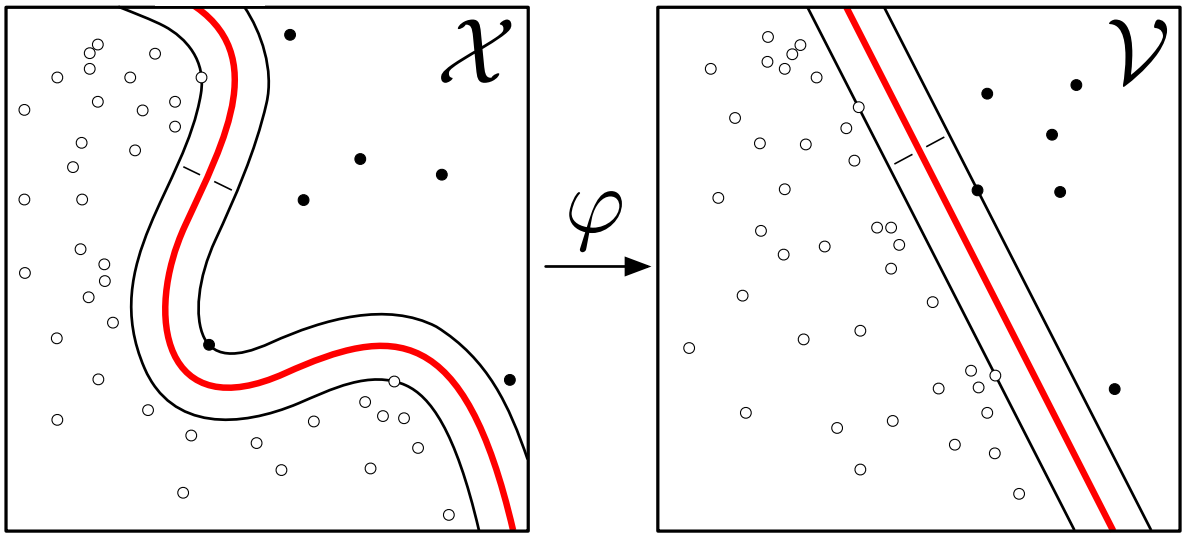

Figure 41.2: Figure depicting the nonlinear SVM decision boundary in $\mathcal{X}$ (left) and the corresponding linear maximum margin classifier in $\mathcal{V}$ (right). Figure adapted from Kernel_Macine.svg Wikimedia Commons (CC BY-SA 4.0) by Cranmer.

on an individual components of $x \in \mathcal{X}$ (*e.g.* $x_4 < 0.7$) [199]. The model is piecewise constant and assigns the value $b_j \in \mathcal{Y}$ to the j-th terminal region $\mathcal{X}^j$. The model can be written

$$\hat{y}(x) = f_\phi(x) = \sum_j b_j \mathbf{1}(x \in \mathcal{X}^j) \,. \tag{41.36}$$

The parameters ϕ of the model comprise the components index and thresholds for the successive splittings and the coefficients b_j.

Tree learning refers to the algorithm used to choosing the tree structure and determining the predictions at leaf nodes. Optimization of the tree structure involves a difficult discrete optimization since the change in the loss with respect to the tree structure is non-differentiable and it is intractable to explore the combinatorially large space of possible trees with brute force. Therefore, the discrete optimization component of tree learning typically involves some approximate algorithm based on heuristics. In contrast, optimization of the b_j for a given tree structure can exploit gradient-based optimization algorithms.

Common approaches to building the decision tree start with a root node and grow with splits based on individual attributes (components of x). These are referred to as top-down induction strategies. There are various impurity heuristics used for choosing the best attribute to split on such as the Gini index, cross-entropy and mis-classification error. Generally they aim to find a split that will refine the the terminal nodes such that they have higher purity than the parent node.

Because most tree learning algorithms consider splits aligned with individual feature components, there are some failure modes for tree-based models. However, tree-based models work well with tabular data that is composed of a mix of continuous and discrete features. Tools such as `XGBoost` [200] are widely used in data science competitions such as Kaggle and the boosted decision trees (BDTs) implemented in `StatPatternRecognition` [201] and `TMVA` [77] have been one of the most used techniques in particle physics [3].

Individual trees are often referred to as weak-learners and they can be combined in various ways described below. Regularization is also an important consideration with tree-based models as one can always learn a tree that assigns exactly one training dataset point per terminal node and memorize the training dataset exactly. One approach to this is called *pre-pruning*, which simply terminates the growing of the trees if the number of training samples reaching the terminal node drops below some threshold, the purity of a terminal nodes is below some threshold, or if the improvement in purity due to a proposed split is not above a threshold. Another regularization approach is called *post-pruning*, which uses a validation data set that is disjoint from the training dataset to probe generalization performance. In this approach, after initially growing a tree with the training dataset, one considers a sequences of pruned trees where splits are removed based on some heuristic. One finds the tree in this sequence of pruned trees that minimizes the generalization error on the validation set. Alternatively, in tools such as *XGBoost* there is an explicit regularization term included in the loss function (see Eq. 41.43).

Ensemble methods The idea of ensemble methods is to combine multiple models into a more performant one by exploiting the bias-variance tradeoff [202]. This is most commonly achieved through averaging (*e.g.* bagging and random forests), which primarily reduces variance, or boosting (*e.g.* AdaBoost and gradient boosting), which primarily reduces bias. Here bias refers to the difference between the Bayes optimal model and the average model produced by the learning procedure with different training sets and variance quantifies how much the learned model varies from one training set to another.

The motivation of boosting is to combine the outputs of many "weak" models to produce a more expressive model. Compared to averagaing techniques like bagging and random forests, the model is built sequentially on modified versions of the data and the final predictions are combined through a weighted sum

$$\hat{y}(x) = \sum_{t=1}^{T} \beta_t \hat{y}_t(x) \,, \tag{41.37}$$

where β_t expand the parameters of the model ϕ.

Bagging The idea behind bagging (bootstrap aggregating) is to create T bootstrap training datasets $B_1, \ldots, B_T$ drawn from the training dataset $\{x_i, y_i\}_{i=1,\ldots,n}$, then learn a model $\hat{y}_t$ for each, and finally construct an average model $\hat{y}(x) = (1/T)\sum_t \hat{y}_t(x)$. If one had T independent training datasets each of size n, then the bias of the average model would be the same as the original model, but the variance would be reduced by a factor of T. By using bootstrap resampling, the bias may increase but the reduction in variance often dominates, which leads to improved performance.

Random forests Random forests refers to a type of "perturb and combine algorithm" that combines bagging and random attribute subset selection. Again one builds trees $\hat{y}_t(x)$ from bootstrap training datasets B_t, but instead of choosing the best split

among all attributes, one select the best split among a random subset of k attributes. If k includes all attributes, then it is equivalent to bagging.

AdaBoost In AdaBoost (adaptive boost) the sequence of trees $\hat{y}_1, \ldots, \hat{y}_T$ are trained with reweighted versions of the original training dataset such that the weight of individual training sample is based on the prediction error in the previous iteration [203]. This requires working with a loss function that and learning procedure for the individual iterations that is amenable to weighted training dataset $\{x_i, y_i, w_i\}_{i=1,\ldots,n}$. Incorporating the weights w_i is straight forward when the risk is expressed as an expectation, since the emperical risk of Eq. 41.3 is just replaced with the weighted average. Similarly, the heuristic for many of the tree-based learning algorithms (*e.g.* the Gini index) also have natural generalizations with weighted events.

In the context of classification, the weighted error of the model $\hat{y}_t(x)$ is

$$\mathrm{err}_t = \frac{\sum_i w_i^{(t)} \mathbf{1}[y_i \neq \hat{y}_t(x_i)]}{\sum_i w_i^{(t)}} \,. \tag{41.38}$$

Based on this weighted error, the coefficient β_t of the component $\hat{y}_t(x)$ in Eq. 41.37 is given by

$$\beta_t = \log\left(\frac{1-\mathrm{err}_t}{\mathrm{err}_t}\right) \,. \tag{41.39}$$

Then for the next iteration the weights of the misclassified events are updated as $w^{(t+1)} = w^{(t)} \exp(\beta_t)$ and then renormalized so that the sum of all weights is 1. This reweighted dataset is then used to train the next model $\hat{y}_{t+1}(x)$ and the entire procedure is initialized with uniform weights $w_i^{t=0} = 1/n$.

There is an analogous procedure for regression with the squared loss function based on the residuals $r_i = y_i - \hat{y}_t(x_i)$ (see for example Ref. [77] for details).

Gradient boosting One of the most powerful forms of tree based models, which is implemented in the tool `XGBoost` is referred to as *gradient boosting* [204]. In this setup, the model is purely additive as in the case of random forests, so the model is Eq. 41.37 with all $\beta_t = 1$. Note this is without loss of generality since the β_t can be absorbed into the b_j of Eq. 41.36. As with AdaBoost, the model is built sequentially through the sequence $\hat{y}_1, \ldots, \hat{y}_T$.

At each iteration, a new term f_t will be added to the sum in Eq. 41.37. For a given decision tree defined by splits on attributes, one can approximate the objective function (the loss function $\mathcal{L}$ plus a regularization term Ω) as a function of b_j in a second order Taylor series:

$$\mathrm{obj}^{(t)} = \sum_{i=1}^{n} [\mathcal{L}(y_i, \hat{y}_i^{(t-1)}) + g_i f_t(x_i) + \frac{1}{2} h_i f_t^2(x_i)] + \Omega(f_t) + \\ + \text{constant} \,, \tag{41.40}$$

where

$$g_i = \partial_{\hat{y}_i^{(t-1)}} \mathcal{L}(y_i, \hat{y}_i^{(t-1)}) \tag{41.41}$$

and

$$h_i = \partial^2_{\hat{y}_i^{(t-1)}} \mathcal{L}(y_i, \hat{y}_i^{(t-1)}) \tag{41.42}$$

In `XGBoost`, the regularization term is taken to be

$$\Omega(f) = \gamma J + \frac{1}{2}\lambda \sum_{j=1}^{J} b_j^2 \,, \tag{41.43}$$

where J is the number of terminal nodes in the tree. With the second-order approximation of the objective, one can directly solve for the optimal b_j for the next tree and the corresponding value of the optimized objective function. The improvement in the objective function can then be used as a heuristic for choosing the best split. Specifically, define $G_j = \sum_{i \in I_j} g_i$ and $H_j = \sum_{i \in I_j} h_i$, where I_j is the set of indices of data points assigned to the j-th leaf. The heuristic used in `XGBoost` for splitting a node is

$$\mathrm{Gain} = \frac{1}{2}\left[\frac{G_L^2}{H_L+\lambda} + \frac{G_R^2}{H_R+\lambda} - \frac{(G_L+G_R)^2}{H_L+H_R+\lambda}\right] - \gamma \,. \tag{41.44}$$

This formula can be interpreted as the score on the new left leaf plus the score on the new right leaf minus the score on the original leaf minus a regularization penalty on the additional leaf. If the gain from splitting a leaf is smaller than γ, then the total Gain is negative and the split will not be added, which can be seen as implementing a form of pruning.

41.5.3 *Neural networks*

In this section we focus on the different types of components used in modern neural network architectures. Gradient-based optimization techniques are most commonly used for training neural networks, and they are described in Sec. 41.6.1. Similarly, other important aspects to effectively training neural network models such as parameter initialization, early stopping, *etc.* are discussed in Sec. 41.6.

The vanishing and exploding gradient problem is a common challenge for gradient-based optimization of neural networks and is described in Sec. 41.6.5. That problem is referred to repeatedly in this section because it has motivated the development of numerous architectural components described below.

41.5.3.1 *Feed-forward multi-layer perceptron*

One of the core components in neural networks is the fully-connected, feedforward network or*multi-layer perceptron* (MLP), which is composed of L *layers*: $f = f^{(L)} \circ \cdots \circ f^{(1)}$. The l^{th} layer defines a function that maps a d_{l-1}-dimensional input vector, called *features*, to an d_l-dimensional output $f^{(l)} : \mathbb{R}^{d_{l-1}} \to \mathbb{R}^{d_l}$. A unit responsible for producing an individual output in d_l-dimesional output is called a *neuron* or a *filter* interchangeably. For $l < L$, the functions f_l are called hidden layers, and the number of neurons (d_l) is referred to as the width of the hidden layers. The layers in an MLP take on the form:

$$f^{(l)}(u) = \sigma^{(l)}(W^{(l)}u + b^{(l)}) \,, \tag{41.45}$$

where $W^{(l)} \in \mathbb{R}^{d_l \times d_{l-1}}$ is called the *weight matrix*, the components of the vector $b^{(l)} \in \mathbb{R}^{d_l}$ are referred to as the *biases*, $u \in \mathbb{R}^{d_{l-1}}$ is the input from the previous layer, $W^{(l)}u$ denotes a matrix-vector product, and $\sigma^{(l)}$ is a non-linear *activation function* that is usually applied element-wise. The parameters of the network comprise the full collection of weights and biases, $\phi = (W^{(1)}, \ldots, W^{(L)}, b^{(1)}, \ldots, b^{(L)})$.

41.5.3.2 *Activation functions*

The activation functions σ in neural networks are nonlinear functions and key to the expressiveness of the resulting family of functions. Two traditionally used functions are *logistic* and *hyperbolic tangent* functions. These functions are bounded to be $(0, 1)$ and $(-1, 1)$ respectively, and are symmetric about the input value of zero. On the other hand, away from the zero input value, a gradient of both functions quickly vanishes and this poses a challenge in using gradient-based optimization method (see Sec. 41.6.1). This can be avoided, to some extent, by normalizing the input values and carefully initializing the values of $W^{(l)}$ and $b^{(l)}$. These are discussed in Sec. 41.6.7, 41.6.8 and 41.6.9. Yet, it becomes difficult to maintain a null input value for a *deep* neural network, a model with many layers. Instead, a popular choice for a deep neural network is *Rectified Linear Unit* (ReLU):

$$\sigma(x) = \begin{cases} x & \text{if } x > 0 \\ 0 & \text{otherwise} \end{cases} \tag{41.46}$$

which computational cost is small and provides the gradient does not vanish for $x \in (0, +\inf)$ [205,206]. An alternative to preserve a non-zero gradient in negative input values are called *Leaky ReLU* and modifies the output to $0.01x$ for $x \in (-inf, 0)$ [207]. Another variant, called *Parametric ReLU* (PReLU), turns the coefficient

0.01 into a variable that is optimized as a part of the model during optimization [208].

The choice of activation functions depends on the model architecture and applications. As described, while the use of ReLU types are a typical choice for a deep neural network, a logistic function is a popular choice at the final layer for classification tasks. Recently, in the area of neural scene representation, sinusoidal activation functions have been found to be surprisingly effective [209].

41.5.3.3 *Softmax*

A softmax function is often used to normalize elements of a discrete vector u, or to interpret the output as a probability over a set of n discrete categories. Given a real-valued input vector $u \in \mathbb{R}^n$, the softmax function computes the output vector $v \in \mathbb{R}^n$ the i-th component is given by:

$$v_i = \frac{\exp(u_i)}{\sum_{j=1}^{n} \exp(u_j)} \ . \tag{41.47}$$

The result has the property that $v_i \in (0, 1)$ and $\sum v_i = 1$. The components of the input vector u are often referred to as *logits* in reference to their connection to the logistic function used in logistic regression. The softmax function is commonly used as the last layer in multi-class classifier. The softmax is also used in the context of attention (see Sec. 41.5.3.11).

41.5.3.4 *The rise of deep learning*

There are a number of universal approximation theorems in the theory of neural networks. One of the first was that even with one hidden layer ($L = 2$), an MLP can approximate any continuous function if the non-linear activation function σ not a polynomial and the width d_1 is large enough [210]. However, it is often more efficient (in terms of the number of parameters) to increase the *depth* of the network L [211].

Training a deep network (*i.e.* $L > 2$) that generalizes well can be more difficult, requiring large training datasets, many gradient updates, and suitable regularization. The introduction of large labeled training sets, advances in computing (*e.g.* graphic processing units or GPUs which enabled orders of magnitude acceleration in parallel computation including matrix multiplies [212]), development of ReLU, research progress in initialization and optimization algorithms for model parameters, and regularization techniques like *dropout* [13] all played an important role in the rise of *deep learning* [2, 213]. Though the name deep learning was originally a reference to the depth L of such networks, modern deep learning is characterized more by the composition of various types of modules that are trained through gradient-based optimization. Below we introduce some other common network architectures.

41.5.3.5 *Convolutional neural networks*

Convolutional Neural Networks (CNNs) are widely used for image-like data. They implement the convolution of the input image u and a *filter* W (also referred to as a kernel). The parameters of the filter are learnable and the convolution involves traversing over input and calculating the inner product of the filter W with the part of the input in the *receptive field*, which has the same spatial shape as the filter and is centered at the target pixel. At each location – indexed by i and j below – there is a pixel that may have a vector of features associated with it. In the context of CNNs, these components of these features – indexed by c and c' below – are often referred to as *channels* in reference to the red, green, and blue color channels in a traditional image. The convolution operation is often denoted with a $*$, and the result can be expressed as

$$v_c(j) = (W * u_c)(j) = \sum_{c'} \sum_{i} W_{c,c'}(i) u_{c'}(\text{“}j - i\text{”}) \ , \tag{41.48}$$

where “$j - i$” is shorthand for the pixel index corresponding to the translation from pixel j to i. By repeating the operation over all pixels, the result of a kernel convolution is also an image as illustrated in Figure 41.3. Note that the the number of channels in the output v does not need to be the same as in the input, and the collection of filters $W_{c,c'}$ is often referred to as a filter bank. The entire image for a fixed channel index is often referred to as a *feature map*.

A key feature of the CNN architecture is that it is *equivariant* to translations, meaning that if the input image is shifted (*e.g.* $u(i) \to u'(i) = u(i - k)$), then the output is also shifted by the same amount (*e.g.* $v(j) \to v'(j) = v(j - k)$). This equivariance property is a natural consequence of using convolutions. A fully connected MLP would not generally have this symmetry; however, it is enlightening to imagine transferring the computation performed by a CNN to the weights and biases of a fully connected MLP, which would result in duplicating the weights of the filters multiple times. In this view, the CNN can be interpreted as a fully connected MLP with *shared weights*, which would maintain the equivariance property. This view is helpful for gaining intuition about the inductive bias of models and makes clear that a CNN is a subset of the fully connected MLPs that satisfy the translation equivariance property.

The discussion above makes it clear that CNNs will have fewer parameters than the corresponding fully connected MLP, which can alleviate the optimization challenge. In addition, the convolutional structure allows for data to be reused effectively as patterns in one part of an image in the training dataset effectively contribute to learning that pattern anywhere in the image. Larger kernel sizes allow for the filters to learn more complicated patterns, but at the expense of having more parameters and needing more data to train (the extreme case being a kernel size that is the the size of the entire image, which would be equivalent to a fully connected MLP). In practice, kernel sizes of 3 are popular, 5 is sometimes used, and larger kernels are rarely used.

A kernel convolution involves three hyperparameters, the size of kernel (typically an odd number so that the filter has an unambiguous center), *stride*, and *padding*. The stride is the number of pixels between each target pixel (*i.e.* the center of the filter). The stride size of 1 implies the target pixels are adjacent, and a stride of 2 implies skipping 1 pixel in between (along each spatial axis). Padding is an operation to expand the input image by a specified number of pixels (i.e. “padding size") for when the target pixel is near the edge and the filter would extend beyond the input image. In Figure 41.3, the input image is 4×4 pixels, the kernel is of size 3, and no (zero) padding is applied. The result is a smaller image. Alternatively, With the padding of size 1, the output would retain the 4×4 shape of the input image.

A kernel size of 1 is also frequently used and is referred to as a *1×1 convolution*. While it cannot capture a geometrical features, it can perform linear operations on the input features, including increasing or decreasing the number of features. When combined with a non-linearity and stacked repeatedly this can be seen as a small MLP attached to an individual pixel, and for this reason the 1×1 convolution is sometimes referred to as a *network-in-network* [214]. This is often used to extract more powerful features to be used by the latter layers, and also to compress features when the next layers may be computationally demanding such as a block of many convolution layers with a large kernel size [215, 216].

One may wonder how CNNs identify features with a spatial size larger than a typical kernel size. One mechanism for this is by stacking multiple convolutional layers – *e.g.* the composition of two 3×3 kernels will lead to an effective 4×4 kernel. In addition, a typical CNN architecture uses pooling (described below), which effectively down-samples the image so that it can be processed at different resolutions. The effective receptive field in the input image may be much larger than the kernel size in this case. An alternative approach is to use an *inception module* which is designed to extract features simultaneously using kernels of different size [215].

41.5.3.6 *Pooling*

Pooling plays an important role in convolutional neural networks both practically and in terms of their mathematical properties. A pooling operation is a type of aggregation or down-sampling that takes many pixels as input and produce one pixel for output. Typically, the pooling operation is applied indepen-

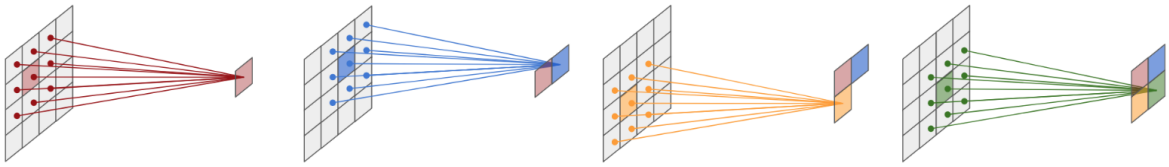

Figure 41.3: A pictorial description of a kernel convolution over four input pixels. It takes a product of the weight matrix (kernel) and the local input matrix centered at a target pixel. The operation is repeated over the input image using the same kernel. The size of the output image depends on the size of the kernel, stride, and padding. In this figure, the kernel size of 3, stride of 1, and padding of 0 is used.

dently for each channel or feature component. The most popular pooling operations are *max* and *average* pooling. Max-pooling picks the highest activation pixel value within the specified receptive field, while the average pooling computes the average pixel value in the receptive field. The idea of pooling generalizes to other architectures, including graph neural networks where the receptive field includes the neighbors of a particular node in the graph (see Sec. 41.5.3.14). The pooling operation gives rise to robustness of the model to small, local deformations in the input, a property called *geometric stability* [217–219]. This type of local deformation is important and distinct from the equivariance to rigid translations provided by the convolutional structure. Repeated pooling operations that eventually lead to a single feature vector with no spatial index is what gives rise to the invariance of common CNN architectures to translations (*i.e.* an image with a dog will be labeled 'dog' even independent of where the dog is in the image).

On the practical side, it is also beneficial to reduce the dimensionality of the input to a smaller hidden state representation. This can be done either a convolution operation with the stride size larger than 1, or employing a *pooling*.

A typical CNN for extracting a 1-dimensional array of features is designed with repeating blocks of convolution layers and pooling operations [220]. Figure 41.4 shows an example evolution of a data tensor through the succession of a convolution and pooling operations in order to extract a 1-dimensional array of features, which then can be fed into a block of MLP for an image classification (or a regression) task. This type of an architecture is referred to as an *encoder* or *feature extractor*.

The reduction in the spatial size of an image is performed *slowly*, typically by a factor of 2, which is the minimum possible reduction factor. After the reduction of the spatial extent, the number of channels is typically increased (also by a factor of 2 in most cases), converging one set of feature maps into a larger number of down-sampled feature maps. There may be more than one convolution layer within each spatial resolution (*i.e.* in between pooling operations). Following these design principles, CNN encoders typically become *deep*, consisting of dozens or sometimes hundreds of convolution layers, and face challenges of vanishing gradients problem (see Sec. 41.6.5). A standard practice to mitigate this issue is explicitly *normalize* the input tensor input at each convolution layer using algorithms like *Batch Normalization*. This will be discussed in Sec. 41.6.9.

41.5.3.7 *CNN architectures for image analysis*

There are three major categories of computer vision tasks where CNNs are often used:

- *Image classification or regression* requires a prediction of single value for the whole image (*i.e.* a category or target value)
- *Object detection* produces a list location information for arbitrary number of objects in the input image
- *Semantic segmentation* outputs an image of the same spatial dimension as the input, in which every pixel is segmented by a predicted value for a target task (classification or regression).

As discussed previously, a CNN feature extractor followed by MLP is often used for image classification and regression tasks in wide range of applications including particle physics. Many successful CNN architectures for object detection and semantic segmentation applications share key designs which we briefly discuss below.

Region Convolutional Neural Network (R-CNN) is one of the most successful design for object detection [221]. R-CNN is explored in HEP experiments where the number and location of signal (e.g. neutrino interactions) are not known apriori in large image data such as neutrino detectors [3, 116, 222].

R-CNN consists of multiple CNNs. The first is a feature extractor which produces a spatially compressed feature tensor. The second CNN applies 1×1 convolution to predict two information: an *object score* which indicates whether there is an object in this (spatially compressed) pixel or not, and prediction of the location and size of a rectangular, axis-aligned bounding box that contains the object (if exists). This second CNN is called *Region Proposal Network* (RPN), and the bounding box is called *Region of Interest* (ROI). The the size of a bounding box is not directly solved by a regression. Instead, the model requires a set of pre-defined *anchor* boxes, which sizes and aspect ratios are hyperparameters, and predict the object score, location, and size (as a multiplicative factor to the defined anchor box) for each anchor box. This allows RPN to detect multiple objects with different aspect ratios even if they are within the same receptive field in the original input image. For each ROI with an object score above threshold (hyperparameter), the third CNN operates in the corresponding sub-field of an already-compressed tensor (*i.e.* by the first CNN) to perform a classification for an object inside the ROI.

This approach can produce multiple ROIs for the same object with a high overlap. Those predictions are reduced using Non-Maximum Suppression (NMS) algorithm. Given a list of bounding boxes with confidence scores, NMS takes the box with the highest score, and computes the Intersection-over-Union (IoU) of this box and all the rest of boxes. Boxes with the IoU higher than a threshold (hyperparameter) are eliminated as they are likely to represent the same object. Then NMS repeats the same operation for the box with the second highest score among the remaining boxes. This is repeated till the list is exhausted.

U-Net is one of the of most successful models used for semantic segmentation [223]. As the output of U-Net is also an image, it gives some interpretability compared to models for an image-level classification or regression tasks. The model is used widely in HEP experiments in both 2D and 3D image data [112,113,118,125,127].

The architecture of U-Net consists of a CNN encoder and *decoder*. A decoder consists of convolution and *convolution-transpose* layer (also called strided transpose-convolution, or rarely deconvolution). The operation of a convolution transpose can be seen an opposite of a convolution: for every pixel in an input image, its value is multiplied to the kernel and copied to the output. $3x3$ kernel in transpose-convolution layer fills $3x3$ pixels in the output tensor. The concept of padding and the stride are also applied to the output tensor. For instance, the stride 2 transpose-convolution fills $3x3$ fields centered at every other pixel (*i.e.* stride 2) for every input pixel. The spatial size of an output tensor is therefore determined by the spatial size of an input tensor, stride, and padding. In the decoder of U-Net, convolution-transpose layers are used to up-sample spatially compressed feature tensors back to the original image resolution. The

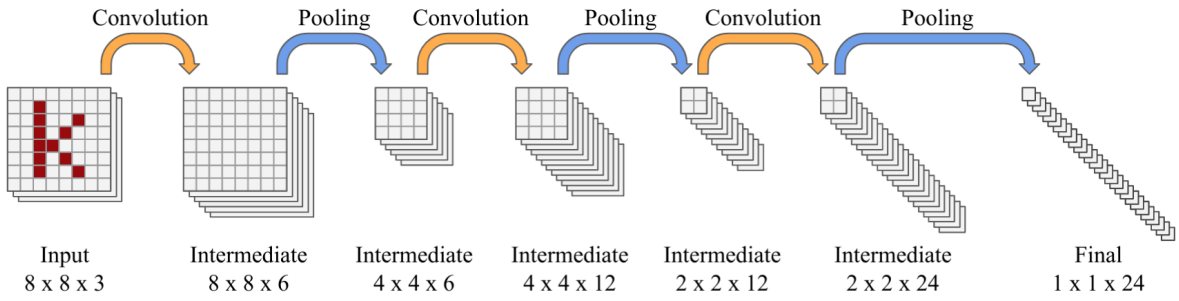

Figure 41.4: An example CNN architecture to extract a 1-dimensional array of features from an image via succession of convolution layers and pooling operations. The (square) kernel, stride, and padding size of a convolution operation are 3, 1, and 1 in respective order. The pooling operation uses a square kernel size of 2. The number of filters at the first convolution layer is 6, and is increased by a factor of 2 at subsequent convolution layers.

stride size of a convolution-transpose layer is almost always 2 in order to *slowly* transform the spatial size, and standard convolution layers (with stride 1) are placed in-between up-sampling operations. Because the output of the decoder has the same size as the input image, features for every pixel can be used for either a classification or a regression task at the pixel-level.

The idea behind encoder-decoder architecture is to extract features in the encoder, and the decoder interpolates those features back to the original spatial resolution. The down-sampling operation (*e.g.* max-pooling) in the encoder is, however, a lossy process where spatial information is permanently lost. This prevents a simple encoder-decoder architecture to perform a semantic segmentation task at the level of precision required for science research and industrial use. Interesting observation made by the U-Net authors is a symmetry in the encoder-decoder architecture in which there are tensors of corresponding (*i.e.* the same) spatial size between two parts of the model. This observation inspired them to concatenate the intermediate tensors in the encoder block to the intermediate tensors of the corresponding size in the decoder block before convolution layers are applied in the decoder, which dramatically improved the performance of semantic segmentation. This is a type of a *skip connection* discussed below.

41.5.3.8 *Residual networks and skip connections*

The representation power of a neural network increases as more hidden layers are added, but gradient-based optimization of deep models can be notoriously difficult due to vanishing gradients (see Sec. 41.6.5). One of powerful techniques to address this challenge is a *residual network* (ResNet), which is a modular architecture design that can be applied to neural network models [216]. Suppose a $f^*(x)$ as the target transformation to be learned by a few stacked layers where x is the input to the first layer. The authors of ResNet hypothesized that it may be easier for a model to learn a residual transformation $\tilde{f}x) \coloneqq f^*(x) - x$, thus the objective to learn is $\tilde{f}(x) + x$ where $\tilde{f}(x)$ denotes the output of stacked layers. This form assumes $\tilde{f}(x)$ and x share the same tensor dimension and size. If they differ in the feature dimension, equivalently the count of channels in an image tensor, one could use 1×1 convolutions to transform and match the dimension. The design is modular as it can be applied per a stack of convolution layers (e.g. U-ResNet introduced for LArTPC detectors uses ResNet modules within a U-Net architecture [112, 113]) widely in the present applications.

The authors of ResNet successfully demonstrated an improved performance of some models at the depth exceeding 1000 layers where the non-residual counter part could not improve the accuracy beyond a few dozens of layers. This remarkable success was due to the *skip connections* in ResNet, namely the element-wise addition of the input to the output at each block of convolution layers as shown in Figure 41.5. Without the presence of the skip connections, the gradients from the loss function is forced to go through all convolution layers (i.e. the reverse direction of orange allows in Figure 41.5), which results in the gradient being altered at every convolution layer. The layers closer to the input receive altered gradients by the continuously updated weights of deeper layers, making conversion difficult and slow. The skip connections provides the path for the gradient to flow directly to the preceding layers. As a result, the gradient can flow more directly to preceding layers and allows simultaneous optimization across layers. It is possible, however, that some convolution layers in ResNet may learn an identity mapping, thus contributing no effect to solving a given task despite consuming computing power.

Another type of skip connections is a concatenation of feature maps, in which case the input and the output of a block of convolution layers do not necessarily have to have the same number of features. This is shown to be very powerful in number of popular model architectures including U-Net [223] and DenseNet [224]. In this case, the input features are re-used: the next block of hidden layers can learn an optimal way to combine the input and the output of the preceding block (i.e. it could learn a simple addition operation, which makes it identical to ResNet). In DenseNet, input to a convolution layer is concatenated with the output of all preceding convolution layers of the same spatial dimension, thus $x_l = f_l([x_1, x_2, \cdots, x_{l-1}])$ where x_l is the output of l-th layer f_l and $[x_1, \cdots, x_{l-1}]$ denotes a concatenation of the inputs. In U-Net, tensors from the encoder block are concatenated with the tensors in the decoder block where they have the same size in spatial dimensions. This was critical for achieving a high spatial resolution for *semantic segmentation*, a class of tasks in Computer Vision to classify every pixel in an image among the predefined set of types (semantics), because the geometrical features at each spatial resolution is otherwise lost via pooling operation in the encoder block [223].

41.5.3.9 *Recurrent neural networks*

Recurrent Neural Networks (RNNs) [225] are a family of neural networks designed for sequential data (*e.g.* time series). Consider sequential data where x_t represents each step in a sequence with $t \in [1, n]$. A typical RNN takes the following form:

$$h_t = g_h(h_{t-1}, x_t, \theta) \tag{41.49}$$

where h_t and θ denote the *hidden state* of the system and parameters of g_h, the RNN model. The term *recurrent* refers the nature of the model operating on the previous state of the system (and hence the whole history). RNNs operate on three types of tasks:

- *One-to-many* takes a single input and generates a sequence (e.g. generates a sequence data, such as a sentence or waveform, given a category).
- *Many-to-one* takes a sequence and generates an output (e.g. sequence-labeling).
- *Many-to-many* takes a sequence and generates a sequence where the length of input and output sequence may be same (e.g. classification of individual element in a sequence) or different (e.g. sequence to sequence mapping).

Figure 41.6 shows an example for a many-to-many task, where $\{x_t\}_{t=1:n}$, $\{y_t\}_{t=1:n}$, and $\{h_t\}_{t=0:n}$ denote the inputs, outputs,

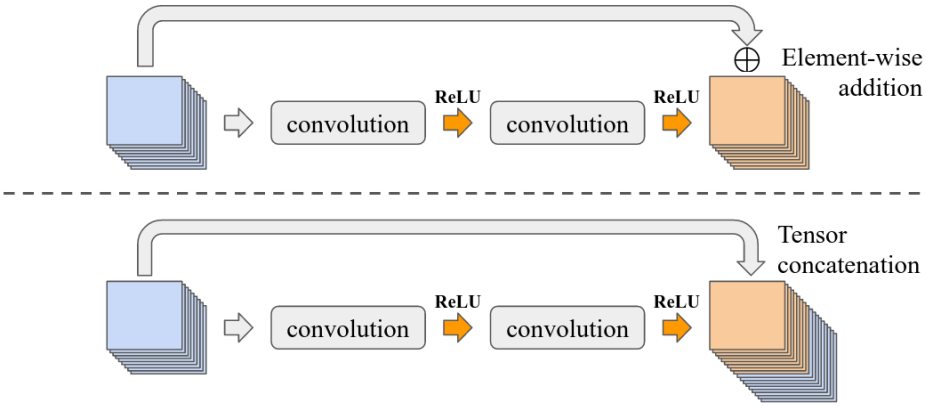

Figure 41.5: Two types of skip connections: the top is from ResNet where the input is element-wise added to the output tensor of a block of convolution layers while the bottom shows a concatenation of the input to the output tensor as employed in other models including U-Net and DenseNet.

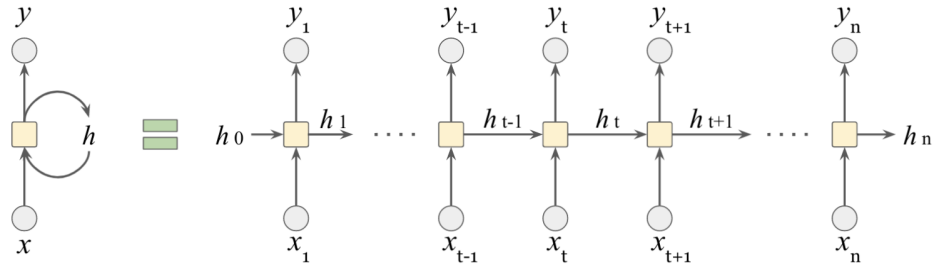

Figure 41.6: Pictorial description of a RNN (on the left) which takes an input and produces an output at every step with a hidden-to-hidden connection. The right diagram is unrolled over discrete steps. The yellow box represents a cell: a set of operations unique to each architecture.

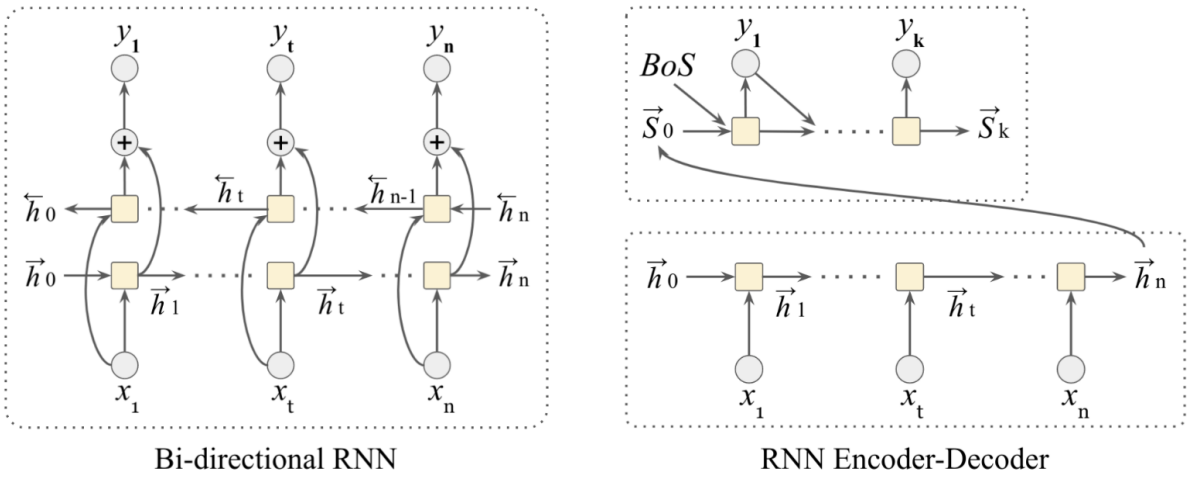

Figure 41.7: Bi-directional RNN (left) provides contexts in the preceding and subsequent parts of the input sequence. RNN encoder-decoder (right) can generate an output with a different sequence length from an input. Each cell in the decoder may take a previously generated element, starting from a special marker that signals the beginning of the sequence (BoS) and ending when the end of sequence is generated.

and hidden states respectively. A set of operations at each time step is called a *cell*. A simple RNN cell may look like:

$$\begin{aligned} h_t &= g_h(Wx_t + Vh_{t-1} + b) \\ y_t &= g_o(Uh_t) \end{aligned} \tag{41.50}$$

where $W \in \mathbb{R}^{d_h \times d_i}$, $V \in \mathbb{R}^{d_h \times d_h}$, $U \in \mathbb{R}^{d_o \times d_h}$ are matrices g_h and g_o represent functions. d_i, d_h, and d_o are the dimension of input, hidden state, and output. $b \in \mathbb{R}^{d_h}$ is a bias term. An example application is sequence-labeling where the goal is for y_t to classify each input x_t in the sequence. In that case, one might use $g_h = \tanh$ and $g_o = \text{softmax}$ and use a loss function that averages clasification accuracy over the sequence.

Variations in RNN architectures result from the design of cells (described below) and flow of information across the cells. For instance, a bi-directional RNN (Figure 41.7 left) employs two set of RNNs, one processing the sequence in the forward direction and the other in the backward direction, and the hidden states from both directions are then combined to capture the context from both parts of the sequence. An RNN encoder-decoder (Figure 41.7 right) use one RNN to generate a context vector that encodes the whole input sequence, and use a separate RNN to generate another sequence from the encoded context. This can be used for machine translation.

41.5.3.10 *LSTM and GRU*

An RNN applies the same functions g_h and g_o in Eq. 41.50 repeatedly for each element of the sequence. This repeated component is similar to the shared weights for a convolutional filter in a CNN.

A hyperbolic tangent (tanh) is traditionally a popular choice for g_h as it regulates the magnitude of the hidden states and prevents it from diverging. Yet, this simple model is challenging to train for a long sequence of data [226, 227]. This is partially due to the fact that tanh contributes to the vanishing gradient problem and because repeated multiplication of the same weight matrices (i.e. V and W in Eq. 41.50) can lead to gradients that can either explode or vanish (see Sec. 41.6.5). Additionally, the way the signal accumulates means that changes early in the sequence have different impact from changes late in the sequence.

Long Short-Term Memory (LSTM) [228] is a model designed to address the issue of vanishing gradient for RNNs. In this model, a *context* is introduced as a way to enable the model to hold long-term memory while the hidden states remain to hold short-term memory. The context c_t and hidden state h_t at step t are computed as follows:

$$\begin{aligned} c_t &= f_t \bigodot c_{t-1} + i_t \bigodot \tilde{c}_t \\ h_t &= o_t \bigodot c_t \end{aligned} \quad \text{where} \quad \begin{aligned} f_t &= \sigma\left(W^f x_t + V^f h_{t-1} + b^f\right) \\ i_t &= \sigma\left(W^i x_t + V^i h_{t-1} + b^i\right) \\ o_t &= \sigma\left(W^o x_t + V^o h_{t-1} + b^o\right) \\ \tilde{c}_t &= \tanh\left(W^c x_t + V^c h_{t-1} + b^c\right) \end{aligned} \tag{41.51}$$

where σ and $\bigodot$ denote logistic function and an element-wise (i.e. Hadamard) product and f_t, i_t, and o_t are referred to as *gates*. Each gate outputs a value between 0 and 1, and is associated with unique weights, W and V, and a bias b. One can see c_t is a combination of the previous context vector c_{t-1} and a new context vector $\tilde{c}_t$. The *forget* gate f_t controls which and how much of the past context should be kept or forgotten. The *input* gate i_t controls how much of the present context $\tilde{c}_t$ should propagate to the current state c_t. The output gate o_t controls which and how much of the context vector should represent the present hidden state h_t. From Figure 41.8, one can see that the context vector c_t evolves with a gated addition operation. As such, it can be seen as an uninterrupted path for gradients to flow. This is similar to a residual connection (see ResNet in Sec. 41.5.3.8), which enabled training of CNNs with thousands of layers.

Another gated model to solve a vanishing gradient problem is the *Gated Recurrent Unit* (GRU) [182]. The GRU is similar to the LSTM with a few simplifications: the GRU merges the context vector and the hidden states and combines three gates into two. As a result, it requires less computational resources while retaining a similar level of performance for long sequences. The GRU operations are defined as follows:

$$h_t = z_t \bigodot h_{t-1} + (1 - z_t)\tilde{h}_t \quad \text{where} \quad \begin{aligned} r_t &= \sigma\left(W^r x_t + V^r h_{t-1} + b^r\right) \\ z_t &= \sigma\left(W^z x_t + V^z h_{t-1} + b^z\right) \\ \tilde{h}_t &= \tanh\left(W^h x_t + V^h \left(r_t \bigodot h_{t-1}\right) + b^h\right) \end{aligned} \tag{41.52}$$

where r_t and z_t are referred to as *reset* and *update* gate. As one can see in Figure 41.6, the reset gate in GRU performs the same task as the forget gate in LSTM by removing or reducing the elements of its memory (*i.e.* the hidden state). The update gate z_t determines the relative proportion of the previous hidden state h_{t-1} and the new context $\tilde{h}_t$ to be mixed in producing the new hidden state.

In addition to sequential data, the LSTM and GRU units can be used for data that has a tree-like structure. In this setting, the networks are often referred to as recursive neural networks or TreeRNN and they have found applications in natural language processing and jet physics [153, 154, 229–231].

41.5.3.11 *Attention*

Many tasks encountered in machine learning can be divided into subtasks. For example, classifying each pixel of an image or element of a sequence, predicting a target for each node in a graph, *etc.*. For each subtask the model may need to draw upon information from the entire input, but some parts of the input will be more relevant than others. At some point, the model will need to form a representation for the input as context for the subtask at hand. A fixed length vector c as a global context for this subtask is possible, but this approach scales poorly as the size of the input and number of subtasks grow. Either the size of the global context must grow or it will not have the capacity to represent all the relevant information, which would lead to a degredation in performance.

The idea behind *attention* is intuitive: one still forms a representation for the entire input, but different parts of the input are weighted differently according to the task at hand. By making the weights a learnable component, the network can learn to attend to the relevant parts of the input. A softmax function is a natural way to represent attention as it assigns a positive value to each component of the input and sums to one. Then for the i-th task, one can simply form a task-specific context c_i by computing the weighted average of the hidden state representations h_j for each component of the input. Let α_{ij} be the weights assigned to the j-th input for the i-th task, such that $\sum_j \alpha_{ij} = 1$. We can satisfy this naturally if for each i the α_{ij} are computed from the logits β_{ij} using a softmax function that normalizes by summing over j.

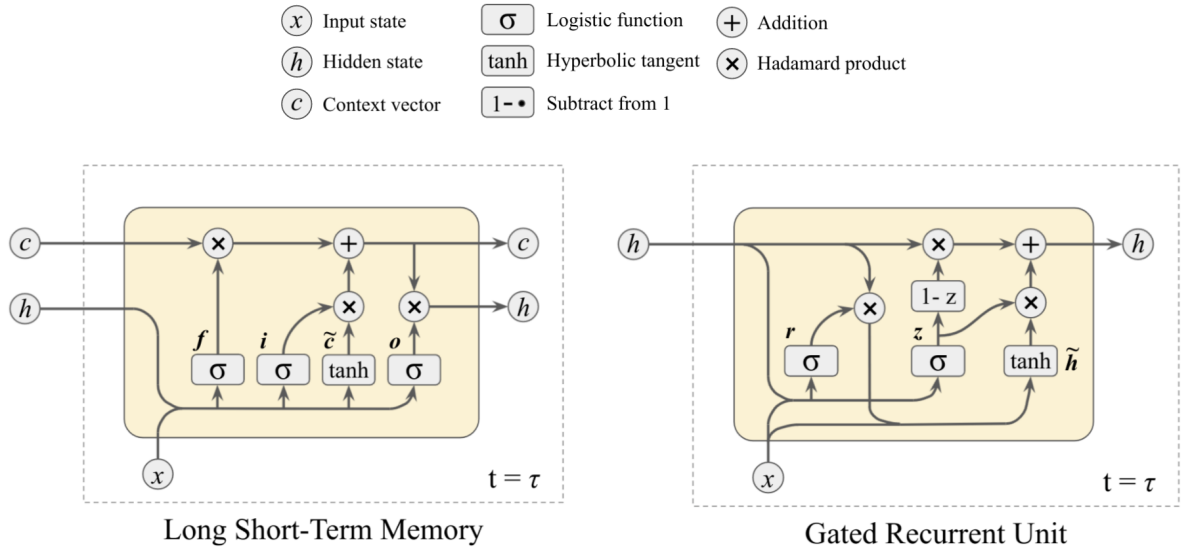

Figure 41.8: LSTM (left) and GRU (right) are both gated neural network designed to address a vanishing gradient problem for RNNs.

Putting these ingredients together, we have the *additive attention mechanism*

$$c_i = \sum_{j=1}^{n} \alpha_{ij} h_j \qquad \text{where} \qquad \alpha_{ij} = \text{softmax}\left(\beta_{ij}\right)_{\text{over } j} . \tag{41.53}$$

As in the case of a multi-class classifier, the logits β_{ij} can be computed from a network component with learnable parameters. For instance, in the case of a cell of an RNN encoder-decoder network (see Fig. 41.7) that is decoding element i with an incoming input state s_{i-1}, the logits for the attention mechanism could be computed as follows

$$\beta_{ij} = U \tanh\left(W s_{i-1} + \tilde{W} h_j + b_i\right) , \tag{41.54}$$

where U, W, $\tilde{W}$ are the weights and b is the bias term of the model. Fig. 41.9 from Ref. [232] illustrates the full attention mechanism. The idea was implemented by a model called *RNNSearch* which made a breakthrough in machine translation by combining a bi-directional RNN with an additive attention mechanism [233].

We end this section by noting that the softmax α_{ij} can be used to visualize the influence of the j-th input element on the i-th output eleement, which improves interpretability of the model. An example of this from Ref. [232] is shown in Fig. 41.10.

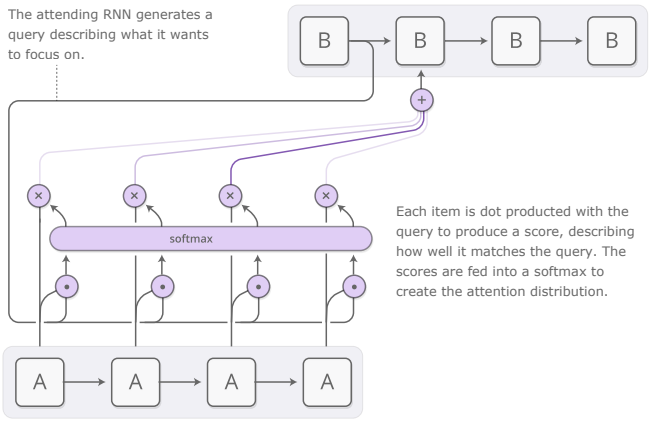

Figure 41.9: An illustration of the attention mechanism From Olah and Carter, "Attention and Augmented Recurrent Neural Networks". Lower boxes labeled `A` represent input elements in the sequence and upper boxes labeled `B` indicate output elements. The left-most line originating from the first `B` corresponds to the state s_{i-1} in the text.

41.5.3.12 *Scaled dot-product attention*

Shortly after the introduction of RNNSearch, the attention mechanism has been recognized as a powerful tool. One such variant is *scaled dot-product attention*, which is most widely recognized as the foundation of the *Transformer* architecture [234], which is described in more detail below.

In additive attention (Eq. 41.53) the hidden representations h_j were combined through a weighted average based on the coefficients α_{ij}, resulting in a task-specific context vector c_i. In the literature around scaled dot-product attention, multi-head attention, and transformers, the hidden states that will be combined are referred to as *values*, and they are often arranged in a matrix labeled $V \in \mathbb{R}^{m \times d_v}$, where the m rows of the matrix correspond to individual hidden state vectors of length d_v. The α_{ij} can also be represented as a $n \times m$ matrix α resulting from applying the softmax function to the $n \times m$ matrix β, normalized independently for each row. With this notation, Eq. 41.53 could be rewritten as $c = \text{softmax}(\beta)V$, where the softmax is normalized per row.

In scaled dot-product attention, the basic structure will be different, but instead of using an non-linear network component to compute the logits β as in Eq. 41.54, the logits will be computed by forming a dot product between a in incoming *query* and a *key*. The set of n query vectors can be arranged into the matrix $Q \in \mathbb{R}^{n \times d}$ and the set of d key vectors can be arranged into the matrix (transpose) $K^T \in \mathbb{R}^{d \times m}$. When the dot product between a particular query vector $q_i \in \mathbb{R}^d$ and key vector $k_j \in \mathbb{R}^d$ is large, then the resulting logit β_{ij} and attention weight α_{ij} will be large. One can interpret the keys as trying to detect certain types of queries and routing the attention to the relevant value. Typically, the dot-product is scalled by a factor of $1/\sqrt{d}$. The resulting task-dependent context is $c_i = \text{softmax}_j(q_i \cdot k_j/\sqrt{d})v_j$, where softmax_j indicates that normalizing sum runs over the index j. A common, though sometimes confusing, notation is simply

$$c = \text{Attention}\left(Q, K, V\right) = \text{softmax}\left(\frac{QK^T}{\sqrt{d}}\right) V , \tag{41.55}$$

where c is a $n \times d_v$ matrix organizing the n context vectors of length d_v that are taylored summaries of the input vector for each of the n tasks.

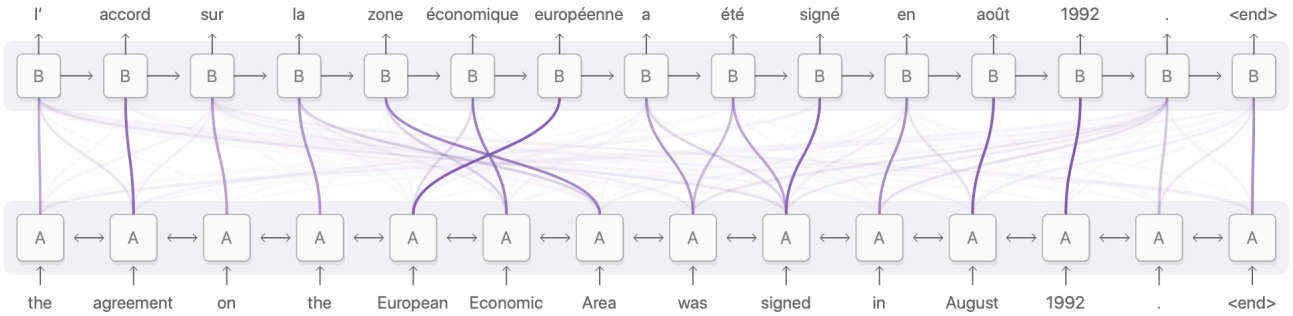

Figure 41.10: Visualization of the attention weights in a sequence-to-sequence problem taken from Olah & Carter, "Attention and Augmented Recurrent Neural Networks" The thickness of the lines is proportional to the attention weights α_{ij}..

41.5.3.13 *Transformer and multi-head attention*

The Transformer architecture is a powerful encoder-decoder model based on the scaled-dot product attention mechanism. It was originally designed for sequential data like RNNSearch, and subsequently used in other areas of research including computer vision. One advantage of scaled-dot product attention compared to the approach used in *RNNSearch* (Eq. 41.54) is that computing the logits β_{ij} (and thus the attention weights) does not involve any sequential processing. This allows the models to better leverage parallelism of the hardware to train much more expressive models than before. In place of the gated unites of an RNN that are key to avoiding the vanishing gradient problem, the Transformer architecture employs a residual connections at every attention module (*i.e.* the input tensor is added to the output as in Fig 41.5).

The second major ingredient in the Transformer architecture is the *multi-head attention* mechanism. A multi-head attention module executes multiple scaled dot-product attention in parallel. The query Q, key K, and value V matrices in each scaled dot-product attention module is obtained by applying a linear transformation (with learnable weights) to the common Q, K, and V input matrices. Each of them can be considered as a different (albeit rotated) *perspective* to derive attention.

For a sequence-to-sequence mapping task, the output of encoder is used to derive key K and value V matrices for the multi-head attention module in the decoder. The decoder is then responsible for mapping between the key-value features derived from the input (the encoder) and the queries from the decoder (which is still executed sequentially) in order to produce the final decoded output.

Finally, we note that the Transformer architecture does not just employ an attention mechanism in the decoder. By employing attention in the encoder as well the model has more capacity to "interpret" the input – a concept referred to as *self-attention*.

Models such as these have made breakthroughs in many areas of scientific and industrial research [235].

41.5.3.14 *Graph networks and geometric deep learning*

Graphs are a powerful data structure for representing structure data. A graph consists of *nodes* as elements and *edges* between between them. Graphs are sufficiently flexible to describe many types of structured data including images and sequences. Graph-based neural networks can also be seen as a generalization of many common types of machine learning models such as recurrent networks, convolutional neural networks, *etc.* [219]. The term *geometric deep learning* refers to this recent formulation that focuses largely on the symmetries of the data.

An earlier attempt to organize the variations on different flavors of graph-based neural networks can be found in Ref. [236]. In their formalism a Graph Network may be represented as $G(\mathbf{u}, V, E)$ where $\mathbf{u}$ represents an array of global features, $V = \{\mathbf{v}_i\}_{i=1:N^v}$ represents a set of N^v nodes with $\mathbf{v}_i$ as features for the i-th node (e.g. such as RGB channels if a node represents a pixel in image data), and $E = \{(\mathbf{e}_k, r_k, s_k)\}_{k=1:N^e}$ represents a set of N^e edges with $\mathbf{e}_k$ as features for the k-th edge. An edge may be (bi-)directional where r_k and s_k denotes the destination and origin nodes respectively. The features of a graph may evolve with three *update* functions ϕ and and three *aggregate* functions ρ:

$$\begin{aligned}
\mathbf{e}'_k &= \phi^e(\mathbf{e}_k, \mathbf{v}_{r_k}, \mathbf{v}_{s_k}, \mathbf{u}) & \mathbf{e}'_i &= \rho^{e\to v}(E'_i) & \text{where} \quad E'_i &= \{(\mathbf{e}'_k, r_k, s_k)\}_{r_k=i, k=1:N^e} \\
\mathbf{v}'_i &= \phi^v(\bar{\mathbf{e}}_i, \mathbf{v}_i, \mathbf{u}) & \bar{\mathbf{e}}' &= \rho^{e\to u}(E') & \text{where} \quad E' &= \cup_i E'_i = \{(\mathbf{e}'_k, r_k, s_k)\}_{k=1:N^e} \\
\mathbf{u}' &= \phi^u(\bar{\mathbf{e}}', \bar{\mathbf{v}}', \mathbf{u}) & \bar{\mathbf{v}}' &= \rho^{v\to u}(V') & \text{where} \quad V' &= \{\mathbf{v}'_i\}_{i=1:N^v}
\end{aligned} \tag{41.56}$$

where $\mathbf{e}'$, $\mathbf{v}'$, and $\mathbf{u}'$ denote the updated node, edge, and graph features. In Graph Networks, three types of information are updated in the following order. The first step is ϕ^e to update every edge. The second step updates every node: for i-th node, compute $\rho^{e\to v}$ to aggregate updated attributes from the edges with $r_k = i$ then compute ϕ^v to update the node attributes. The third step updates the graph attributes through ϕ^u which takes the original state $\mathbf{u}$, aggregated node and edge attributes by $\rho^{v\to u}$ and $\rho^{e\to u}$ respectively.

Graph Neural Networks [237] (GNNs) are the class of neural networks that work on graph-structured data. A direct analog in Computer Vision and physics is the *point cloud* data type, which is an unordered set of points. Operations on point cloud need to be permutation invariant (e.g. *min, max*, $+$, $\cdot$), and analysis of 3-dimensional physical object represented by point cloud need to be rotation and translation invariant as in the case for an image. PointNet [238, 239], a GNN that performs an object classification on point cloud of 3-dimensional positions, treats each point as a node, applies MLPs as ϕ^v to update node features, and global max-pooling operation as $\rho^{v\to u}$. There is no explicit edge definition in PointNet (though the model applies affine transformation to all points using Spatial Transformer Network [240], which could be considered as a separate graph operation, to introduce rotation and translation invariance and to capture topological features). Deep Sets [241] follows the same manner except ϕ^v takes the global entities $\mathbf{u}$. This is same for PointNet when performing point cloud segmentation: ϕ^v takes a step of simply concatenating $\mathbf{u}$ to node entities to combine a local and global features. Dynamic Graph CNN [242] is a variant that (re)define edges dynamically using attention mechanism: $\rho^{e\to v}$ aggregates k neighbor nodes where the inter-node distance is defined as a Cartesian distance in the feature space. ϕ^v remains a MLP and, while edges are defined, there is no associated entity. A similar technique is used in Non-Local Neural Network [243] to efficiently propagate local

feature information to points that may be far in the 3D cartesian coordinate. Message Passing Neural Network [244] (MPNN) explicitly defines a feature vector as edge entities. In MPNN, $\rho^{e\to v}$ performs element-wise sum of features and feed into ϕ^e, explicitly passing features across nodes as the name suggests. While these are representative models that are frequently used in particle physics applications [117, 121, 132, 142, 156, 183, 245, 246], it is only a tiny fraction of GNN models developed over the past decade.

Graph-based models are particularly interesting for science applications because they often offer a natural way to organize the entities in the data and encode how those components should interact each other. This particular type of inductive bias is referred to as *relational inductive bias* in Ref. [237]. The structure of the graph is both an opportunity and a responsibility as one needs to define the graph structure including the edges to define the mode. A naive approach may be defining a fully-connected graph. However, for applications on hundreds of thousands of nodes (e.g. high resolution 3D point cloud), this may require a prohibitive amount of memory and computation. On the other hand, if the graph is too sparse, it may negatively impact the performance. One may need to compare the model performance among differently constructed graphs and balance against computational burden. Ideally the graph would be based on some knowledge of the interactions, but in the absence of such knowledge, popular graph construction methods include fully-connected, $k-$Nearest Neighbors, a Delaunay graph, and Minimum Spanning Tree.

Classification and regression tasks for graphs can be formulated such that the prediction is made for the entire graph or its individual nodes or edges. Graph-level prediction is like classifying an entire image, while node-level prediction is like semantic segmentation where individual pixels are classified. For clustering of points, GNNs can approximate a transformation function for nodes into the latent space where an optimal clustering of points can be performed. Alternatively, one can formulate clustering as an edge classification task. A comprehensive review on particle physics applications have been made available recently [247].

41.5.4 *Deep generative models*

Deep generative models are powerful machine learning models that can learn complex, high-dimensional distributions and generate samples from them. Because of their inherently probabilistic formulation, generative models are rapidly becoming an indispensable tool for scientific data analysis in a range of domains. Generative models can be contrasted against discriminative models that are primarily used for supervised learning tasks. Roughly, discriminative models are used for prediction and $f(x)$ provides a point estimate of the target y, and they are more closely connected to function approximation. In contrast, generative models describe the data distribution $p(x)$ (or the joint data distribuiton $p(x, y)$ in a supervised setting). An enlightening discussion of these two approaches can be found in Ref. [10].

There are a number of different types of deep generative models that have various pros and cons as they do not all have the same capabilities. We will focus on Variational Auto-Encoders (VAEs) [248,249] , Generative Adversarial Networks (GANs) [250, 251], and Normalizing Flows (NFs) [252–256], though there other approaches have been explored in this quickly developing area of research. Consider these three distinct types of functionality:

- **generation:** ability to sample or "generate" a data point $x_i \sim p(x)$.
- **likelihood for generated data:** ability to evaluate the probability density (likelihood) $p(x_i)$ for a data point x_i sampled from the model $x_i \sim p(x)$.
- **likelihood for arbitrary data:** ability to evaluate the probability density $p(x_i)$ for an arbitrary data point $x_i \in \mathcal{X}$.

Each of the models above can be used for generation; however, only normalizing flows provide all three capabilities. For reasons that we will describe below, GANs and VAEs do not provide a tractable likelihood function, and they are sometimes referred to as *implicit models*. This establishes a connection to simulation-based inference where most scientific simulators are also implicit models with an intractable likelihood. Because normalizing flows have a tractable likelihood, they can be trained via maximum likelihood (Eq. 41.18) as described in Sec. 41.3.2.1. GANs and VAEs, on the other hand, need to employ some other loss function to be trained. In the case of VAEs, training is based on the ELBO used in variational inference (see Sec. 41.3.1.3 and the discussion around the reverse KL divergence below Eq. 41.16). While GANs are also implicit models they data they can generate is typically restricted to a lower-dimensional manifold $\mathcal{M} \subset \mathcal{X}$, meaning that almost all real training dataset doesn't "live on" the subspace of possibilities that the model can produce. In this case, the liklelihood is for almost all data is zero, and so even ELBO-based training will not work. The breakthrough idea introduced in Ref. [250] was to use adversarial training where a classifier would be used to quantify how different the data generated from the model is from the data from the target distribution.

VAEs, GANs, and normalizing flows introduce a mapping $g(z, \theta)$ from a base random variable z to the space of the data $\mathcal{X}$. The map $g(z, \theta)$ is typically implemented with a neural network. The random variable z is sampled from some known base distribution $p(z)$ that is both easy to sample and has a density that is easy to evaluate. Typically, the base distribution is a multivariate normal.

In the literature on GANs and normalizing flows, this base random variable is often referred to as a latent variable and $p(z)$ is often referred to as a prior distribution, but this may cause confusion as the relationship between z and the observed x is deterministic. Typically, one would reserve the term latent variable for situations where one must marginalize (integrate) over z to obtain the marginal likelihood as in $p(x) = \int p(x, z)dz$. In this integral would involve a delta function imposing the deterministic relationship $x = g(z, \theta)$. A more natural interpretation of the relationship between x and z is through the change of variables formula, which is the essence of normalizing flows.

In the case of VAEs, the one additionally adds some normally-distributed (Gaussian) random noise ϵ to the output so that $x = g(z, \theta) + \epsilon$. In this case, x and z are not deterministically related and z is a legitimate latent variable in the model and $p(z)$ can be interpreted as the prior on that latent variable. In this case, the model can populate the full space of the data. Unfortunately, the marginal likelihood $p(x) = \int p(x, z)dz$ involves an intractable integral, thus maximum likelihood training is infeasible. However, the likelihood term $p(x|z)$ is tractable (*i.e.* the Gaussian noise), so training with the ELBO is possible.

Note that the dimensionality of of z need not be the same as that of x. If $z \in \mathbb{R}^q$ and $\mathcal{X} = \mathbb{R}^d$ with $q < d$, then all points $g(z, \theta)$ will lie on a d-dimensional surface in $\mathbb{R}^d$. In the case of a VAE, the Gaussian noise ϵ means that the genertd data x will be distributed in a thin region around the surface defined by $g(z, \theta)$. The presence of a bottleneck (*i.e.* $q < d$) leads to advantages and disadvantages. The disadvantages for GANs is that the likelihood assigned to almost all real world data (*i.e.* data not generated by the model) will be zero, so training is more difficult and many tasks in probabilistic inference won't be applicable. However, often real world data is also effectively described by a low-dimensional subspace in the full space of the data – random images look like noise, while natural images are in some sense special. For this reason, images produced by GANs for instance often have better visual quality than those produced by other techniques. This points to the ambiguity encountered in quantifying how close two distributions are, and also motivates the use of distance measures such as the Earth Movers distance or Wasserstein distance [257, 258]. Conversely, the lack of a bottleneck (*i.e.* $q = d$) leads to very large models and scalability issues when the data is high dimensional.

Recent work has also focused on combining ideas from VAEs, GANs, and normalizing flows so that the generative model does involve a bottleneck but can still provide tractable likelihoods for density estimation restricted to that manifold [44,46,252,259,260]. Some of these models can also be used in the context of anomaly detection and out of distribution detection by identifying data that is off the manifold.

The parametrization of the mapping (the architecture of the neural network) should match the structure of the data and be

expressive enough. For problems with explicit symmetries it is beneficial to include them into the architecture of the network explicitly, which restricts the allowed space of the models and matches their inductive bias (implicit regularization inherently built into the choice of architecture of the network) to the data. Different architectures have been proposed [255, 261–263], and to achieve the best performance on a new dataset one needs extensive hyperparameter explorations [264].

41.5.4.1 *Variational auto-encoders*

The auto-encoder was described in Sec. 41.3.2.2 as model for compression and representation learning. The model is $f = g \circ e : \mathcal{X} \to \mathcal{X}$, where $e : \mathcal{X} \to \mathcal{Z}$ is referred to as the *encoder* and $g : \mathcal{Z} \to \mathcal{X}$ is referred to as the *generator* or *decoder*. The standard auto-encoder is not a probabilistic model, but additional probabilitic structure can be added.

One approach is VAE mentioned above [248, 249]. By equipping the latent space with a prior distribution $p(z)$, the decoder of the auto-encoder $g(z, \theta)$ implies a distribution on a manifold in the output space $\mathcal{X}$. VAEs additionally add some normally-distributed (Gaussian) random noise ϵ to the output so that $x = g(z, \theta) + \epsilon$. This implies that $p_\theta(x|z)$ is a tractable quantity, and it is interpreted as the likelihood in this context.

In a VAE one also elevates the encoder to have a probabilistic form. Instead of encoding $z = e(x)$ in a deterministic way, one seeks a distribution over z given x. A natural target for the probabilistic encoder would be to probabilistically invert the decoder. This inverse problem is solved by the posterior distribution $p(z|x)$ via Bayes theorem

$$p(z|x) = \frac{p(x|z)p(z)}{p(x)} \ . \tag{41.57}$$

While the likleihood and the prior may both be tractable, the normalizing constant $p(x) = \int p(x, z)dz$ involves an intractable integral (the same intractable integral that makes maximum likelihood training of the VAE infeasible).

One approach to Bayesian inference in these settings is variational inference (VI). In VI one approximates the posterior with some parametric family $q_\phi(z|x)$ in a parametric form, and then uses optimization to optimize the ELBO with respect to its parameters ϕ.

$$\begin{aligned} \text{ELBO} &= \mathbb{E}_{q(z)} \log p(x|z) - D_{KL}[q(z)||p(z)] \\ &\leq \log \mathbb{E}_{q(z)} \left[\frac{p(x, z)}{q(z)} \right] = \log p(x) \ , \end{aligned} \tag{41.58}$$

where we used Jensen's inequality for concave functions (log) and the reverse Kullback-Leibler (KL) divergence term is

$$D_{KL}[q(z)||p(z)] = \mathbb{E}_{q(z)}[\log q(z) - \log p(z)] \geq 0. \tag{41.59}$$

In a VAE, the variational model for the posterior $q_\phi(z|x)$ is often assumed to be an uncorrelated Gaussian (this is often called mean field approximation) defined by the mean μ and variance Σ. Instead of optimizing the mean and variance independently for each x, VAEs use neural networks to predict the mean $\mu_\phi(x)$ and the variance $\Sigma_\phi(x)$. This is called *amortized inference*, since after an up-front training cost the approximate posterior $q_\phi(z|x)$ can be evaluated effeciently with a single forward pass of the neural network. Note the standard auto-enocder is recovered if one only used the mean $\mu_\phi(x)$ for the encoder and did not add noise ϵ to the decoder.

Both the probabilistic encoder $q_\phi(z|x)$ and the probabilistic decoder $p_\theta(x|z)$ are trained jointly by optimizing the ELBO. Unlike the standard auto-encoder, which only minimizes the reconstruction error, ELBO optimization of Eq. 41.58 has a trade-off between minimizing the reconstruction error in the first term (averaged over the approximate posterior $q(z)$), which encourages high quality reconstructions, and minimizing the KL divergence term, which forces the posterior $q(z)$ to be as close to the chosen prior $p(z)$, and thus controls the sample quality by matching the aggregate posterior with a chosen prior distribution [265]. This term regularizes the VAE latent space, such that every sample drawn from the prior $p(z)$ correspond to a valid sample. Successful VAE training requires to find a delicate balance between the two contributing terms to the ELBO. Whether the VAE training process succeeds in striking this balance depends on a number of factors, including the network architectures, the chosen prior and the class of allowed posterior distributions. Once trained, the VAE can be used as a generative model by sampling from the prior $z_i \sim p(z)$ and then decoding according to $p_\theta(x|z) = g(z, \theta) + \epsilon$.

VAEs allow for expressive architectures, enjoy the benefits of regularization through data compression and have a firm theoretical foundation. Compared to GANs [250], VAEs are of particular interest to the scientific community as they provide a lower bound to the marginal likelihood (albeit potentially with a large gap) and a posterior distribution for the latent variables.

It is also interesting to consider a special case of the auto-encoder and VAE where the encoder and decoder are restricted to be linear transformations, which is effectively PCA. In PCA the (linear) decoder can be written $g(z) = Oz$, where O is a matrix. As in the case of the auto-encoder, PCA is not a probabilitic model, but probabilistic structure can be added. Probabilistic PCA [266] assumes that the latent variables follow a Gaussian distribution with mean zero and covariance Λ, where Λ is a diagonal matrix with the rank-ordered eigenvalues λ_i along its diagonal. The true distribution of the PCA components may be non-Gaussian, but a Gaussian is the maximum entropy approximation given their first two moments. Note that in Probabilistic PCA these moments are measured on training dataset (when finding the principal components).

One can generalize Probabilistic PCA to use non-linear encoder and decoder as in an auto-encoder. A Gaussian prior is a poor ansatz for the latent space distribution of data proceed by an auto-encoder. Instead one can learn the density of the training samples in latent space using a normalizing flow. This model was introduced in $\mathcal{M}$-flows [46] and in Probabilistic Auto-Encoder (PAE) [44], which achieves similar performance to a VAE in terms of sample quality without explicit ELBO optimization. In all these cases the dimensionality of the latent space is a hyperparameter to be chosen or optimized by the user. Unlike a standard VAE, these models do not add noise to the decoded output, thus the data is strictly restricted to the manifold defined by the decoder $g(z, \theta)$. However, unlike a GAN there is a well defined way to take an arbitrary data point x, project it onto the manifold, and calculate the density of the data point projected onto the manifold. Thus these models can also be used in the context of anomaly detection and out of distribution detection by identifying data that is off the manifold.

41.5.4.2 *Generative adversarial networks*

GANs [250] also typically choose a low dimensional latent space z with a known prior distribution $p(z)$, typically a normal (Gaussian) distribution with zero mean and unit variance. GANs do not add noise to the output $g(z, \theta)$, so the likelihood $p(x|z)$ (and marginal likleihood $p(x)$) for almost all of the data space is 0, which precludes training by maximum likelihood and the ELBO. Instead of training on ELBO, GANs train on a dissimilarity measure defined implicitly by a discriminator $D(x)$ (also referred to as the critic). Calculating the dissimilarity often involves it's own learning problem (*i.e.* adversarial training of the discriminator).

The training is usually framed as a mini-max game

$$\begin{aligned} &\min_g \max_D \mathcal{L}_{\text{GAN}} = \\ &\min_g \max_D \{\mathbb{E}_{x\sim p(x)} \log D(x) + \mathbb{E}_{z\sim p(z)} \log[1 - D[g(z)]]\}. \end{aligned} \tag{41.60}$$

The goal of the discriminator is to distinguish between true and generated data, hence we want to maximize this loss with respect to D, assigning 1 to true data and 0 to generated data. The goal of generator is to fool the discriminator such that it cannot distinguish between true and generated data, hence we want to minimize this loss with respect to g at fixed D. This can be viewed as a game theoretical setup in a zero sum game between generator and distriminator.

Instead of this game theory interpretation we can view the internal objective $\max_D \mathcal{L}_{\text{GAN}}$ as an implicit loss function that mea-

sures the dissimilarity between the target and generated distributions. The loss of Eq. 41.60 corresponds to the Jensen-Shannon (JS) divergence, which is a symmetrized form of KL divergence. However, JS divergence is hard to directly work with, and the adversarial training could bring many problems such as vanishing gradient, mode collapse (tendency of generator to cluster the samples around the training samples, with holes between them) and non-convergence [257, 258]. One of the core issues is that the distribution generated by the GAN is restricted to a manifold and the KL divergence isn't well defined in this case (because p is not absolutely continuous with respect to q). To address these issues Wasserstein GANs train on

$$\min_g \max_D \mathcal{L}_{WGAN} = \min_g \max_D \{\mathbb{E}_{x\sim p(x)} D(x) - \mathbb{E}_{z\sim p(z)} D[g(z)]\}. \tag{41.61}$$

Here again the goal of discriminator is to make the loss as large as possible between the true data and the generated data, while the goal of generator is to make it as small as possible, so that the discriminator cannot distinguish between the two. There is no requirement for $D(x)$ to be between 0 and 1, which helps with the above mentioned problems of JS divergence. Instead, this is replaced with a requirement that $D(x)$ is 1-Lipshitz, i.e. the absolute value of the norm of the gradient of the discriminator output with respect to the input has to be less or equal to 1.

Eq. 41.61 can be interpreted as the dual form of the 1-Wasserstein distance between the true and generated distribution [267]. Wasserstein distances are a measure of dissimilarity between two distributions used in the context of Optimal Transport, mathematical theory of how to optimally transport one distribution to another. Since the transport distance increases with the separation between the two distributions when they are non-overlapping, there is no gradient collapse that plagues other measures. In its primal form p-Wasserstein distance, $p \in [1, \infty)$, between two probability distributions p_1 and p_2, is defined as $W_p(p_1, p_2) = \inf_{\gamma\in\Pi(p_1,p_2)} \left(\mathbb{E}_{(x,y)\sim\gamma} \left[|x-y|^p\right]\right)^{\frac{1}{p}}$, where $\Pi(p_1, p_2)$ is the set of all possible joint distributions $\gamma(x, y)$ with marginalized distributions p_1 and p_2. In 1D the Wasserstein distance has a closed form solution via Cumulative Distribution Functions (CDFs), but this evaluation is intractable in high dimensions.

In the dual form of 1-Wasserstein distance, one instead maximizes Eq. 41.61 over all possible functions $D(x)$ that are 1-Lipschitz. One way to implement this is through weight clipping of the parameters of discriminator network, but a simpler solution is to add a gradient norm penalty term explicitly to the loss function [268].

Because of the discriminative nature of the dissimilarity measure defined in data space, GANs often generate more realistic samples than VAE or normalizing flows in high dimensions such as natural images. However, GANs do not provide an encoder from data to latent space, do not provide a tractable likelihood $p(x)$.

41.5.4.3 *Normalizing flows, autoregressive models, and score based models*

Normalizing Flows (NF) provide a powerful framework for density estimation and sampling [252–256, 269]. These models map the data x to latent variables z through a sequence of invertible transformations $f = f_1 \circ f_2 \circ \cdots \circ f_n$, such that $z = f(x)$ or $x = g(z) = f^{-1}(x)$. As in the VAE and GAN, z is modelled as a random number with a simple base distribution $p_Z(z)$, which is typically chosen to be a standard normal (Gaussian) distribution. The probability density of the model be evaluated using the change of variables formula:

$$p_X(x) = p_Z(f(x)) \left|\det\left(\frac{\partial f(x)}{\partial x}\right)\right| = p_Z(f(x)) \prod_{l=1}^{n} \left|\det\left(\frac{\partial f_l(x)}{\partial x}\right)\right|, \tag{41.62}$$

where we have added subscripts to $p_X(x)$ and $p_Z(z)$ for clarity. The Jacobian determinant $\det(\frac{\partial f_l(x)}{\partial x})$ must be efficient to compute for density estimation to be practical, and the transformation f_l should be easy to invert for sampling. In contrast to VAE and GANs, standard normalizing flows preserve the dimensionality of the data space as they are invertible (though there are normalizing flows that are defined on lower dimensional manifolds embeded in the data space [44,46,252,259,260]). As such, they do not have the problems of GANs and VAEs they can be trained via maximum likelihood (Eq. 41.18) as described in Sec. 41.3.2.1.

There are several popular architectures of NFs. A method used by NICE, RealNVP and Glow [253–255] is to split the space into two disjoint sets z_1 and z_2, and then use an identity forward map $z \to x$ for x_1, $x_1 = z_1$, and an affine transformation for x_2 of the form

$$x_2 = \exp(s(z_1)) \odot z_2 + m(z_1), \tag{41.63}$$

where $\odot$ is elementwise product and $m(z_1)$, $s(z_1)$ are neural networks. The Jacobian of this map is lower triangular, and its determinant is simply the product of elements along the diagonal, which is tractable, as is the inverse of the transformation. At the next layer one then performs a different split of dimensions into z_1 and z_2. The affine transformation can be further generalized to a nonlinear form using rational splines [270].

One can interpret the sequence of invertible transformations $f_1 \circ f_2 \circ \cdots \circ f_n$ as n discrete time steps in a continuous flow. In particular, one can think of a continuous-time flow described by an ordinary differential equation (ODE) and then interpret the discrete time steps as the result of a numerical integration of that ODE. This is the approach taken by the Ffjord algorithm [271] and other variants.

A different approach creating a deep generative model with a tractable likelihood is to model $p(x)$ autoregressively as

$$p(x) = \prod_{i=1}^{n} p(x_i|x_1, x_2, \ldots, x_{i-1}) \ . \tag{41.64}$$

This form describes each new dimension conditionally on all previous dimensions. It can model a general likelihood $p(x)$ as a sequence of conditional 1d distributions, whose conditional dependence on the parameters $x_1, x_2, \ldots, x_{i-1}$ can be modeled with neural networks. If x is a time series this form imposes a causal structure where x_i depends on all previous times x_j, $j < i$. WaveNet [272] and PixelCNN [273]) are two well known examples. Sampling from an autoregressive model is sequential, and can be slow in high dimensions. Inverse autoregressive flow reverses this process and makes sampling fast, but the likelihood evaluation is slow. Some normalizing flows have autoregressive coupling layers, such as Masked Autoregressive Flow (MAF) [269].

All of the methods above use maximum likelihood training of likelihood $p(x)$ against network parameters, so the training is to minimize KL divergence between the data distribution and a Gaussian in latent space. This can be overly sensitive to small variance directions that dominate the likelihood, without being sensitive to the global structure of the data. An alternative is to use Optimal Transport Wasserstein distance between the density of the generated samples and the data, which can be evaluated either in data space or in latent space. As Wasserstein distance is difficult to evaluate in high dimensions, one can instead use slices, 1d projections of the data along different directions in high dimensional space, to build the flow [45]. Along each slice direction one obtains the 1d marginal distribution that can be mapped to a Normal distribution using a cumulative distribution function method. In 1d the Jacobian and the inverse transformation are tractable. The projection directions are chosen to maximize the sliced 1d Wasserstein distance between the data and the distribution generated by the samples, or between the inverse flow from the data to the latent space and the target distribution (typically chosen as the Normal distribution). Because this training is less sensitive to small variance directions than maximum likelihood training it achieves better results on anomaly detection tasks [45].

One can reduce the architectural restrictions imposed by normalizing flows or autoregressive models by modeling the "score" $\nabla_x \log p(x)$ instead of $p(x)$. Note this usage of the term "score" is non-standard and goes back to Ref. [274]; the standard use of the term score is theta of Eq. 41.26. Score-based training avoids the normalization requirement. Score based models learn gradients of log probability density functions on a large number of

noise-perturbed data distributions, and then generate samples by Langevin-type sampling. The resulting generative models, called score-based generative models [275] or diffusion probabilistic models [276], have several advantages over existing model families. They achieve GAN-level sample quality without adversarial training, and enable exact log-likelihood computation through their connection to continuous-time flows, which can be represented as a probability flow ordinary differential equation [276]. The main advantage is that the distribution $p(x)$ can be specified solely by its gradient, which can subsequently be sampled from using Langevin dynamics. This is similar to the gradient based Monte Carlo Markov Chain methods (such as Langevin or Hamiltonian Monte Carlo) that sample from Bayesian posteriors without directly estimating the normalizing constant. This in turn enables more flexible model architectures than what can be used in normalizing flows or autoregressive models.

We end by noting that normalizing flows, autoregressive models, and other deep generative models that provide a tractable likelihood are incredibly powerful tools for simulation-based inference. They can provide surrogate models trained from large simulated datasets when the simulators have intractable likelihood functions, which is usually the case. As described in Sec. 41.3.5, one would like to work with models that can provide conditional density estimation in order to model either the likelihood $p(x|\theta)$ or the posterior $p(\theta|x)$ [56, 57]. These techniques are being actively explored and applied to a number of scientific problems.

41.6 Learning algorithms

41.6.1 *Gradient-based optimization*

Given a parameterized model $f(x, \theta)$ and a loss function $\mathcal{L}(x, \theta)$, where x and θ denotes data and model parameters, one way to optimize θ is to first apply an appropriate initialization, $\theta_{t=0}$ (e.g. Sec. 41.6.7 for neural networks), and perform an iterative update:

$$\theta_t = \theta_{t-1} - \lambda \nabla_\theta \mathcal{L}(x, \theta), \tag{41.65}$$

where λ is a small, real valued hyperparameter called *learning rate*. To see how this works, define $\delta\theta \equiv \theta_t - \theta_{t-1}$ and consider $\delta(\nabla_\theta \mathcal{L}(x, \theta))$:

$$\delta\left(\nabla_\theta \mathcal{L}(x, \theta)\right) \approx \delta\theta \cdot \nabla_\theta \mathcal{L}(x, \theta) = -\lambda |\nabla_\theta \mathcal{L}(x, \theta)|^2 \tag{41.66}$$

which would monotonically decrease the loss function, and locally move the parameter values in the desired direction of loss function minimization. This algorithm is called *Gradient Descent* . We note that λ needs to be sufficiently small for the approximation to hold. When λ is too large, this can be a cause of a gradient explosion discussed in Sec. 41.6.7.

41.6.2 *Stochastic gradient descent*

Stochastic Gradient Descent (SGD) follows GD but replaces the exact gradient term $\nabla_\theta \mathcal{L}(x, \theta)$ with a stochastic approximation, where we subsample the data in the loss function using N samples, where $N < n$,

$$\nabla_\theta \mathbb{E}_{\hat{p}(x)} \mathcal{L} \approx \frac{1}{N} \sum_i^N \nabla_\theta \mathcal{L}_i, \tag{41.67}$$

where $\mathcal{L}_i$ is the loss function for data sample i. It should be noted that N needs to be randomly and independently sampled for the approximation to hold. Implementation of SGD follows three steps: take new samples of size N, approximate the gradient, then update the parameters θ.

In the case of optimizing the loss using a static database (*i.e.* one cannot take new N samples for every update), *mini-batch learning* is often employed. This replaces the first step with a randomly sampled *batch* of data, which is a subset of all the samples in the database. In this case, however, since a batch of data used for each parameter update is not entirely independent, a model may overfit. In practice, a part of the whole dataset is reserved as a *validation* sample, and the model performance is carefully monitored during the optimization process to avoid overfitting via an early stopping criterion (see Sec. 41.6.6 and Fig. 41.11).

SGD with slowly decreasing learning rate can be shown to converge to a local minimum almost surely under mild conditions, and to a global minimum for unimodal loss functions. SGD may also prevent getting stuck in shallow local minima of the loss function, thereby reaching a better local minimum for multi-modal loss functions. The noise in SGD with a constant learning rate can be viewed as a form of Langevin dynamics, which under proper conditions on the learning rate and mini-batch size converges to the stationary posterior distribution of the weights [277]. Thus SGD at a constant learning rate can be viewed as a sampler bouncing around and exploring the posterior surface for better solutions, descending onto the best found solution as the learning rate is decreased, a process related to temperature annealing in global optimization.

Another advantage of SGD is simply the computational cost: rather than evaluating the loss over all the data samples at each update, we use a small subset of data instead at each update. Furthermore, mini-batching can take advantage of vectorization libraries and GPU architectures. Large batch training requires specialized methods of training, such as Layer-wise Adaptivee Rate Scaling (LARS).

41.6.3 *Optimization algorithms*

GD and SGD are the basic building blocks for more advanced optimization algorithms. One can improve the convergence rate of gradient based optimization by considering the learning rate λ to depend on individual θ_i. Second order algorithms such as Newton's method take into account second order derivatives (Hessian) to find the minimum, and give an exact solution in a single update when the loss is quadratic around the peak. However, this requires a matrix inversion of the Hessian, which is exceedingly expensive in ML applications, where the number of network parameters is very large. As a consequence, second order optimization is rarely used in ML.

There are several improvements to the basic SGD even in the absence of Hessian information. Momentum based optimization takes a physics perspective of a viscous fluid in an external potential, where one updates current velocity with the potential gradient (force), followed by an update in position based on velocity. This approach therefore uses previous gradients in addition to the current one to compute a running average of the gradient, with a forgetting factor that controls how far back the averaging goes. This helps move faster towards the minimum in ravines, where gradient descent is usually inefficient due to the high condition number of the Hessian.

One way to make the learning rate dependent on θ_i is to consider the gradient norm squared $(\nabla_{\theta_i} \mathcal{L})^2$. RMSprop learns its running average and then reduces the learning rate in directions with a large average gradient norm squared, thereby reducing the oscillations along that direction. ADAM (Adaptive Moment Estimation) combines the momentum and gradient norm ideas, computing running averages of both the gradient and the gradient norm squared, each with its own forgetting factor [278].

41.6.4 *Automatic differentiation and back propagation*

In practice, $f(x, \theta)$ might take a complex form and may include a large set of parameters. The term $\nabla_\theta \mathcal{L} = \nabla_\theta \mathcal{L}(f(x, \theta))$ requires computing partial derivatives with respect to individual parameter θ_i. If f is a composite model (i.e. $f = f_n(f_{n-1}(\cdots, \theta_{n-1}), \theta_n)$), and if all of $f_{i:1,n}$ are differentiable, a chain rule can be applied:

$$\nabla_{\theta_i} \mathcal{L} = \frac{\partial \mathcal{L}(f(x, \theta))}{\partial \theta_i} = \frac{\partial \mathcal{L}}{\partial x_n} \cdot \frac{\partial x_n}{\partial x_{n-1}} \cdots \frac{\partial x_i}{\partial \theta_i} \tag{41.68}$$

where x_n denotes the output of n-th composite function f_n. In order to compute $\nabla_{\theta_i} \mathcal{L}$ for f_i, it needs computation of a gradient at all preceeding (or subsequent if seen in the forward context) functions. As the gradients accumulate across differentiable functions in the reverse order of the model composition, this technique is called *back propagation* [225]. An example of f that satisfies conditions to apply back propagation is a neural network, which consists of repeating blocks of a (differentiable) activation function and an affine transformation.

When the model $f(x, \theta)$ is implemented as a computer program in practice, *automatic differentiation* (AD), also called *algorithmic differentiation*, is used to compute the derivatives. AD ex-

ploits the fact that any computer program consists of a sequence of elementary arithmetic operations (i.e. addition, subtraction, multiplication, division) and functions (e.g. log, exp, sin, cos) and apply chain rules to compute the target derivative. AD has advantages over traditional approaches including symbolic and numerical differentiation. The symbolic differentiation faces a serious difficulty of converting a program into a single expression, and the numerical differentiation suffers from round-off errors. Finally, both methods scale poorly in speed of computation for calculating partial derivatives with a large number of inputs. AD delivers much faster speed and does not suffer from increasing errors for calculating higher derivatives.

There are two modes of AD: the *forward* and *backward* mode. Consider a composite function $f(x, \theta) = f_n(f_{n-1}(\cdots f_1(x, \theta_1)\cdots), \theta_{n-1}), \theta_n)$. The forward mode applies the chain rule in the same order of the forward evaluation of f by computing $\partial f_1/\partial x$ first, then $\partial f_2/\partial f_1$, and continue to $\partial f_n/\partial f_{n-1}$. The backward mode traverses the reverse direction: starting from the last (outer-most) function $\partial f_n/\partial f_{n-1}$, next $\partial f_{n-1}/\partial f_{n-2}$, and continue to $\partial f_1/\partial x$. Therefore, the back propagation of gradients can be implemented using the backward AD, in which the target variable to be differentiated is fixed and the derivative is computed with respect to each sub-expression recursively as shown in Eq. 41.68. The forward mode is simpler to implement as the order of gradient calculation follows the order of composite functions to be executed. The reverse mode typically requires less amount of computation than the forward mode, but more memory is required to store intermediate function output values to calculate derivatives efficiently. Another consideration is the mapping of dimensionality $f : \mathbb{R}^k \to \mathbb{R}^\ell$ as it concerns the number of variables to sweep from each end. The forward mode is efficient when $k << \ell$ while the reverse mode takes an advantage if $\ell << k$. For instance, in the case of an image classification where $(k, \ell) = (\text{pixel count}, 1)$, the reverse AD is more efficient.

41.6.5 *The vanishing and exploding gradient problems*

Gradient based optimization crucially depends on the size of gradient with respect to each model parameter. If the magnitude of gradient is too large with respect to the distance to an optimal parameter value, it may repeatedly overshoot the target and cause an oscillation preventing convergence. If the gradient is too small, it may take an impractically long time to converge. As shown in Eq. 41.68, the gradient of i-th function f_i is a product of gradients from the subsequent functions. If those gradients are too large or too small, the magnitude can can either increase or decrease exponentially in the number of layers. These are called *exploding* and *vanishing* gradient problem respectively.

Modern deep neural networks consist with many composite functions (i.e. layers) and are particularly prone to this effect. Let us consider a simple RNN. From Eq. 41.50, we can write the back-propagating gradient:

$$\frac{\partial h_t}{\partial h_{t-1}} = \text{diagonal}\left(f'\left(Wx_t + Vh_{t-1} + b1\right)\right) W \tag{41.69}$$

where f' denotes the derivative of an activation function. The gradient of the contribution to the loss $\mathcal{L}_i$ from the i-th element in the sequence with respect to the j-th hidden state h_j is therefore:

$$\frac{\partial \mathcal{L}_i}{\partial h_j} = \frac{\partial \mathcal{L}_i}{\partial h_i} V^{i-j} \prod_{j<t\leq i} \text{diagonal}\left(f'\left(Wx_t + Vh_{t-1} + b1\right)\right) \tag{41.70}$$

where we can see that V contributes multiplicatively with $i - j$ powers when $i - j > 1$. This example is explored in depth for recurrent models [226, 227] but is common for all types of deep neural networks.

In practice, one may explicitly inspect the magnitude of gradients propagating across layers to ensure an effective optimization. One way to mitigate an exploding gradient is to set the maximum gradient value $\delta_{\max}$ as a model hyperparameter and *clip* any larger gradients δ where it appears in the back propagation:

$$\delta = \frac{\delta_{\max}}{\|\delta\|}\delta \text{if} \|\delta\| > \delta_{\max}. \tag{41.71}$$

This is called *gradient clipping* [227].

Alternatively, there are many architecture designs that are motivated by the vanishing and exploding gradient problem or which aim to help propagate gradients across many layers. These considerations drove the design of gated models like the LSTM and GRU for sequential data and also motivated the ReLU non-linearity. Other example architectural designs or components motivated by these considerations include identity mapping and skip connections used in ResNet, U-Net, and DenseNet, which allow gradients to flow across many layers.

Other factors contributing to vanishing and exploding gradient include initialization of model parameters and normalization of input data. These factors contribute in keeping the magnitude of activation, which also concerns the magnitude of gradient, within a reasonable range. A recommended practice for a gradient-based optimization of a neural network is to maintain the input values centered around zero and a similar level of covariance across the inputs (and the outputs that are the inputs to the next layer) [279]. These factors are discussed in the following.

41.6.6 *Early stopping*

Early stopping is a form of regularization used to avoid overfitting when an iterative method, such as gradient descent, is used as a learning algorithm. Imagine a plot of the training loss and test loss as a function of iterations (*i.e.* parameter updates). As learning proceeds, the training loss will generally decrease. However, the test loss will often decrease initially and then start to increase, which is the classic sign of overfitting as shown in Fig. 41.11. The basic idea of early stopping is simply to stop training before overfitting takes place. In some approaches to early stopping theoretical analysis of the learning problem provides a prescription for when to stop the training [280]; however, the most straight forward approaches use a held-out validation dataset to monitor the generalization performance [281].

41.6.7 *Initialization of model parameters*

An improper initialization can slow down the optimization process or even result in a loss of convergence. While $b^{(l)}$ is typically initialized to zero, $W^{(l)}$ values need to be stochastic to avoid identical updates during optimization. One way is to sample $W^{(l)}$ from a zero-centered Gaussian distribution with a small variance (e.g. 0.01) [282]. However, this method does not guarantee the same variance in the input to each layer, which depends on the size of the input layer, and makes it difficult to train a deep neural network [220]. The *Xavier* initialization takes this into account and sets the variance of a Gaussian distribution to be $\sigma^2 = 1/d^{(l-1)}$ assuming a symmetric activation function around zero, such as a logistic function or hyperbolic tangent [283]. The *He* initialization uses the variance $\sigma^2 = 0.5/d^{(l-1)}$, and is a simple extension of Xavier initialization for leaky, parametric, and standard ReLU activation [208].

41.6.8 *Input normalization*

Input data to a neural network is often pre-processed for the same goals discussed previously: values are shift to have the mean of zero and scaled to keep a similar covariance across features. Furthermore, a data may be transformed using techniques including PCA and whitening (sphering) to keep input features independent and uncorrelated from each other [279].

41.6.9 *Batch normalization*

Even with careful normalization of the input data and initialization of model parameters, the mean and covariance of the data representations in hidden layers will evolve during training and may pose challenges for learning for downstream layers. This is called an *internal covariate shift* [284] and may cause negative effects to an optimization process. Accordingly, techniques to explicitly normalize features in between hidden layers are often employed for a deep neural network. One of them is *Batch Normalization*, which shifts and scales the input to a hidden layer:

$$\tilde{u}^{(l)} = \gamma \frac{u^{(l)} - \mu_B}{\sqrt{\sigma_B^2 + \epsilon}} + \beta \tag{41.72}$$

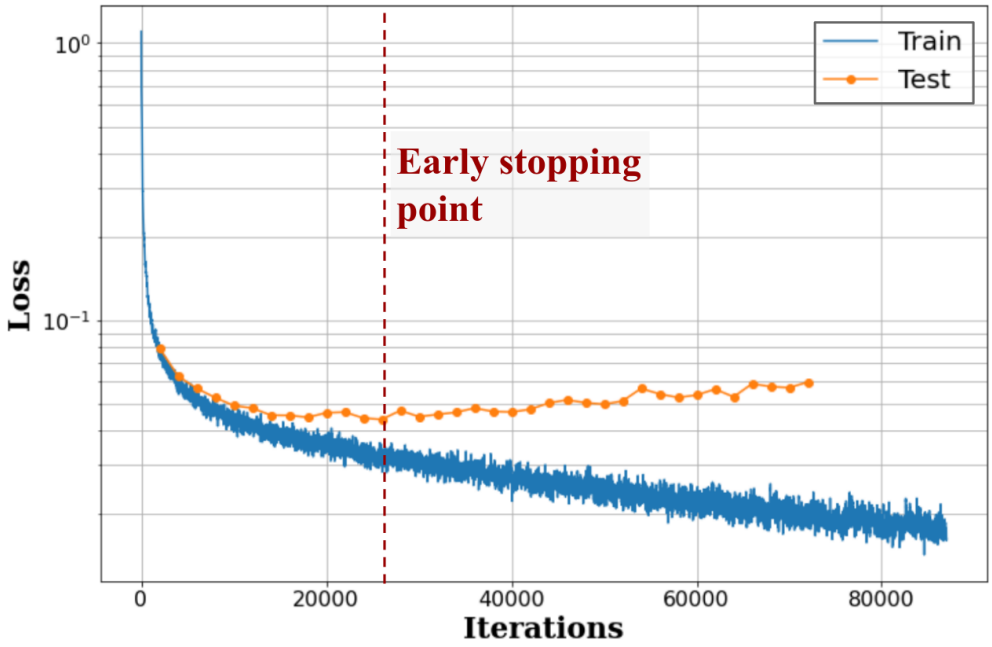

Figure 41.11: An example instance of overfitting. The training loss (vertical axis) shown in blue decreasing over iterations (horizontal axis) while the loss values evaluated on test samples shown in orange start to increase at around 26,000 iterations as indicated by the vertical line.

where $u^{(l)}$ and $\tilde{u}^{(l)}$ refer to the raw and normalized input to the l-th layer, μ_B and σ_B represent the mean and mean-squared-error of $u^{(l)}$ calculated using a *batch* of input data used to update the network parameters. γ and β are part of model parameters that are updated during the optimization. After optimization is complete, these parameters are fixed for model evaluation during production. ϵ is a small, fixed constant value to ensure numerical stability. While it is popular (especially in Computer Vision), a downside of BN is its dependency on the batch size. In situations where the batch size is limited to be a small number (e.g. memory limitation for a large data or a model), the performance using BN could degrade since β and γ values may not be generalized for the dataset during training.

There are several variants to batch normalization with considerations on how to group a subset of values in u^l. For instance, an image naturally has three groupings: a set of pixels across spatial axis, features within one pixel (i.e. image *channels*), alongside with a grouping across multiple images (i.e. batch). Different groupings have been studied and found and some are found effective to particular type of applications: Layer Normalization groups values along the channel and spatial dimensions [285], Instance Normalization groups along the spatial dimension but not along the batch nor channel [286], and Group Normalization is similar to Layer Normalization but forms multiple sub-groups of channels [287]. These variants does not apply normalization across samples within a batch, and thus agnostic to the batch size.

41.6.10 *Transfer learning: pre-training and fine-tuning*

Transfer learning is a technique to improve performance and accelerate optimization process by reusing a pre-trained machine learning model for a new task. Two tasks and data sets for each task may be different: the idea is that fundamental features may be reusable across different data and tasks. Transfer learning typically takes two steps: the first is to alter the model or data if necessary, then train (*fine-tuning*) the model. The first step is required, for example, when solving a different task that requires a different architecture (e.g. regression v.s. classification), or when input data format requires a change (e.g. original model trained on three channel image, such as RGB images, while new data has a single channel). Transfer learning has been widely practiced in the field of Computer Vision where large, labeled data sets are available [288–291]: a CNN trained for classifying images of an animal can be largely reused for object detection, or even for analyzing image data in science (e.g. particle trajectories recorded by an imaging detector). It is a critical aspect for the development of generic AI as well as interdisciplinary sharing of models across research fields.

For sequential models, transfer learning had been challenging before the appearance of Transformer. While Transformer was initially introduced for machine translation, Generative Pre-trained Transformer (GPT-1) showed that the model can be generalized to multiple NLP tasks by achieving the state-of-the-art in several seemingly different tasks including a sentence classification, semantic similarity, question answering and commonsense reasoning [292].

41.6.11 *Zero, one, and a few shot learning*

Fine-tuning (and thus transfer learning) may not be necessary if model is well generalized: humans can picture an imaginary animal in mind just from descriptions, or perform a task that he or she has never done before. One-shot learning is an extreme case of transfer learning where only one example is presented at the fine-tuning stage [293]. A similar variant is called a few-shot learning (fine-tuning using a few examples). This is possible only if the model has already learned the solution during the pre-training and the example is used to map the solution to the task. Zero-shot [294–296] learning is even more extreme where the model is given a new task without any example. This is only possible if the task is already learned during the pre-training in an implicit or unsupervised manner since zero-shot training implies that the model was never trained for the task.

41.7 Incorporating uncertainty

A fundamental aspect of data analysis is the quantification of uncertainty. This broad topic includes the traditional distinction between statistical and systematic uncertainty, procedures for propagation of errors, and the incorporation of uncertainty in to the statistical models (*e.g.* with nuisance parameters) that are used in Bayesian or frequentist statistical procedures (see Sec. 40). Accounting for systematic uncertainty can be seen as a requirement, but ideally systematic uncertainties are also taken into account in the design of the analysis so as to mitigate their effect. The introduction of machine learning into the analysis pipeline

requires revisiting the techniques used for uncertainty quantification and exposes many fundamental issues that have nothing to do with the use of machine learning per se. See Ref. [297] for a recent review on this topic.

In machine learning research and industrial settings, the mismatch between the data distribution $p_{\text{train}}(x, y)$ used for training and the data distribution $p_{\text{prod}}(x, y)$ that the model will be applied to in production is referred to as *covariate shift* or *domain shift*. For example, one might train a classifier to identify cats and dogs with images from a well lit studio and then apply the classifier on images taken in doors with poor lighting conditions and a scratched lens. Not surprisingly, the mis-classification rate of the classifier will be different between the two settings.

Physicists are keenly aware that the simulations that we use to describe the data are not perfect, and this mismodelling corresponds to a large fraction of the of systematic uncertainties accounted for in published works. Since simulated data is often used to train machine learning models (*i.e.* $p_{\text{train}}(x, y)$), it is important to understand and account for how this mismodelling will influence results when applied to real data (*i.e.* $p_{\text{prod}}(x, y)$).

One of the primary approaches to incorporating this type uncertainty is to introduce nuisance parameters ν corresponding to the uncertain inputs to the simulation and to parameterize various types of perturbations (*e.g.* corrections to efficiencies, energy scales, *etc.*) in hopes that the resulting family of distributions $p(x|y, \nu)$ is flexible enough to encompass the true data distribution for class y. In this approach one does not have just two "domains" for the data (*i.e.* p_{train} and p_{prod}), but a continuous family of domains parameterized by the nuisance parameters ν.

With this framing in mind, there are several approaches to incorporating uncertainty into an analysis that includes ML-based components:

- **propagation of errors:** one works with a model $f(x)$ and simply characterizes how uncertainty in the data distribution propagate through the function to the down-stream task irrespective of how it was trained.
- **domain adaptation:** one incorporates knowledge of the distribution for domains (or the parameterized family of distributions $p(x|y, \nu)$) into the training procedure so that the performance of $f(x)$ for the down-stream task is robust or insensitive to the uncertainty in ν.
- **parameterized models:** instead of learning a single function of the data $f(x)$, one learns a family of functions $f(x; \nu)$ that is explicitly parameterized in terms of nuisance parameters and then accounts for the dependence on the nuisance parameters in the down-stream task.
- **data augmentation:** one trains a model $f(x)$ in the usual way using training dataset from multiple domains by sampling from some distribution over ν.

In this setting it is best to consider the trained model $f(x)$ or $f(x; \nu)$ to be a fixed function and decouple the variability associated to training or the choice of architecture. The fact that one could have chosen a different architecture or learning algorithm should be treated in the same way as other choices that are made in the data analysis pipeline. While it is reasonable to want down-stream inference and decisions to be robust to these choices, they are of a different nature than the uncertainty in the modelling of the data distribution. We return to this point in Sections 41.7.5 and 41.7.6.

41.7.1 *Propagation of errors*

In this Section we consider the common scenario in which one has used some machine learning technique to train a model $f(x)$ for classification or regression and wants to assess the sensitivity of the output of $f(x)$ to uncertainty in the input x. We regard the function $f(x)$ as fixed and we are not concerned with how the model was trained.

Propagating uncertainty through a ML-based model $f(x)$ is not fundamentally different than for any other function, and one can use the standard propagation of errors formula of Sec. 39.2.1. As always, it is important to recognize the limitations of the propagation of errors formula, which is accurate when the uncertainty on x is Gaussian and the function $f(x)$ is approximately linear within the region set by the uncertainty on x.

Similarly, classifiers are often used for particle identification or event selection. In that case, one is primarily interested in the efficiency ϵ to satisfy a cut on the classifier output. The efficiency depends on the distribution $p(x|y)$ through the equation $\epsilon_y = P(f(x) > f_{\text{cut}}|y) = \int H(f(x) - f_{\text{cut}})p(x|y)dx$, where H is the Heaviside step function and y is an index or label for the category of data that is being considered (*e.g.* signal or background, electron or jet, *etc.*). Thus, the question in this context is what is the uncertainty on the efficiency ϵ_y due to uncertainty in the distribution $p(x|y)$. In practice, the quantification of the uncertainty in the efficiency ϵ_y is usually based on either a calibration measurement on real data or estimated with simulated data. These procedures typically treat the classifier as a black-box, and thus nothing precludes using those procedures on a ML-based classifier. An early example of this approach for b-tagging can be found in Ref. [298].

In the case where simulation is used to estimate the efficiency ϵ_y and its uncertainty, one usually varies nuisance parameters ν associated to the simulation. One then uses simulated samples to approximate $\epsilon_y(\nu) = P(f(x) > f_{\text{cut}}|y, \nu) = \int H(f(x) - f_{\text{cut}})p(x|y, \nu)dx$. Again, the procedure for incorporating uncertainty isn't fundamentally different if the classifier $f(x)$ is based on machine learning or a hand-crafted observable.

41.7.2 *Domain adaptation*

While estimating the uncertainty for a ML-based model is not fundamentally different than any other hand-crafted observable used for regression or classification, the worry of many physicists is that by working with a high-dimensional set of features x that one is more susceptible to mismodelling of subtle correlations. This is a valid concern, and it should be appreciated that a great deal of prior knowledge and physical insight goes into the construction of hand-crafted observables so that they will be robust to the most uncertain aspects of data. However, much of this craft is based on heuristics that are difficult to systematize. Furthermore, one can only validate that such an observable is robust if one can explicitly evaluate the performance for a perturbed distribution. Thus in the settings where one can validate the robustness to a perturbed scenario ν_0, one must have access to $p(x|y, \nu_0)$.

One approach to formalize this type of robustness is to consider the dependence on the distribution of the output of the model $f(x)$ to the nuisance parameters. In statistics, if the distribution of f is independent of the nuisance parameters, then f is referred to as a *pivotal quantity*. This is a property that we can incorporate directly into the training procedure to target a particular notion of robustness. The authors of Ref. [299] introduced an adversarial approach (similar to what is used in the generative adversarial network of Sec. 41.5.4.2) to penalize a model during training if the distribution of the output varies with the nuisance parameters. To construct the training dataset $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$, one must sample y and ν according to some proposal distribution (similar to a prior, but only used for the creation of training dataset, not necessarily for statistical inference), corresponding to a joint distribution $p(x, y, \nu)$. Instead of minimizing the target loss $\mathcal{L}_f$ (*e.g.* cross-entropy, squared-error, *etc.*) with respect to the parameters ϕ_f that parameterize the model f, one trains with a minimax strategy that also includes an adversary q with parameters ϕ_r. The trained model is characterized by the saddle point

$$\hat{\phi}_f, \hat{\phi}_r = \arg\min_{\phi_f} \arg\max_{\phi_r} E_\lambda(\phi_f, \phi_r) \,, \tag{41.73}$$

where the value function E_λ includes the target loss as well as a regularization term associated to the adversary

$$E_\lambda(\phi_f, \phi_r) = \mathcal{L}_f(\phi_f) - \lambda \mathcal{L}_r(\phi_f, \phi_r) \,. \tag{41.74}$$

The constant λ is a hyperparameter, since generially there is a tradeoff between the two terms and only in special cases can the model that minimizes $\mathcal{L}_f$ also be a pivotal quantity. The regularization term

$$\mathcal{L}_r(\phi_f, \phi_r) = \mathbb{E}_{p(x,y,\nu)}[-\log q_{\phi_r}(\nu|f_{\phi_f}(x))] \tag{41.75}$$

is an example of conditional density estimation (see Sec. 41.3.2.1), where the model $q_{\phi_r}(\nu|f)$ is trying to predict the distribution of the nuisance parameter ν given the output of the model $f(x)$. This term is maximized when f is independent of ν. Earlier work had also used an adversarial technique for domain adaptation, but was limited to just two domains [300–302], while here ν parameterizes a continuous family of distributions and can have multiple components corresponding to different sources of uncertainty. Furthermore, the previous work aimed to make the distribution for a high-dimensional, intermediate representation of the data be invariant to the domain shift as opposed to just the final output $f(x)$.

One way of interpreting Eq. 41.73 is that the goal is to minimize a regularized loss function $\tilde{\mathcal{L}}(\phi_f) = \arg\max_{\phi_r} E_\lambda(\phi_f, \phi_r)$, where the optimization with respect to ϕ_r is not exposed. This motivates another approach in which the regularization is not achieved through a learned adversary, but by a measure of discrepancy between distributions that can be computed directly from samples. In particular, the authors of Ref. [303] proposed the use of *distance correlation* to avoid what can be a challenging min-max optimization problem.

In either case, the optimization of the hyperparameter λ is based on the downstream task. For example, in Ref. [299] considered the case where f was a signal vs. background binary classifier where the nuisance parameter ν was associated to uncertainty in the background model. The hyperparameter λ was then optimized to maximize the approximate median significance (AMS). Similarly, the authors of Refs. [304] and [303] considered new physics searches in the context of boosted jet tagging, where the hyperparameter controls the sculpting of the side-bands used for background estimation.

While these strategies modify the training procedure so that the sensitivity to the nuisance parameters is reduced, it does not typically eliminate it. As a result, one still needs to propagate the uncertainty in the data distribution through the learned model as described in the preceding section.

Note, this adversarial technique has also been employed in other settings where one would like to decorrelate the output of the classifier with an observed quantity so that it can be used for background estimation [304]. Widely used alternative approaches to decorrelation include uboost [305] and DDT [306]. Other examples of the domain adaptation and decorrelation use cases from the Living Review include [299, 303–318].

41.7.3 *Parameterized models*

An alternative to learning a model $f(x)$ that is pivotal — *i.e.* whose distribution is independent of the nuisance parameter ν — is to learn a family of models $f(x;\nu)$ that is parameterized in terms of the nuisance parameters. In general, there is a tradeoff between the two terms of Eq. 41.74 for a single model $f(x)$. In a parameterized model, $f(x;\nu)$ optimizes the performance of the model for every value of ν. Parameterized classifiers were first advocated in Ref. [58] in the context of simulation-based inference (see Sec. 41.7.7) and in Ref. [319] for new physics searches. It has also been applied to simulation-based inference for effective field theory parameters in Ref. [19] and Ref. [320] provides additional pedagogical examples.

The training of a parameterized model is similar to the standard procedure. For example, if one originally wanted to minimize the squared loss function $\mathcal{L}(y, f(x)) = (y - f(x))^2$ with training dataset $\{x_i, y_i\}_{i=1,\ldots,n}$, then the corresponding training procedure for the parameterized model would be as follows. One would need to construct a training set $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$ as described in the preceeding section, construct a parameterized model $f(x;\nu)$ that takes as input the original feature vector x as well as the nuisance parameters ν, and then train using the same loss $\mathcal{L}(y, f(x;\nu)) = (y - f(x;\nu))^2$.

One complication of the parameterized approach is that it is no longer possible to evaluate the model on a dataset $\{x_i\}$ and pass on only $\{f_i\}$ for downstream analysis tasks since $f(x_i;\nu)$ still depends on ν. Instead, one delay evaluating the model to some down-stream stage when the dependence on ν would accounted for. For example, in the context of a likelihood based analysis where one is testing a hypothesis where the nuisance parameters take on a particular value ν_{test}, then one will consider the data distribution $p(x|\nu_{\text{test}})$, and at that point one would evaluate the model at the corresponding nuisance parameter value, *i.e.* $f(x;\nu_{\text{test}})$. Explicit examples are given in Refs. [19, 58, 297, 320]. While this may seem complicated, it actually corresponds to what is done in a typical likelihood-based fit when the statistical model has nuisance parameters; *i.e.* the likelihood-ratio corresponds to the model $f(x;\nu)$ as in Eq. 41.12.

41.7.4 *Data augmentation*

An intuitive approach to building in robustness to systematic effects that can lead to domain shift, is simply to augment the training dataset so that it includes examples corresponding to several values of the nuisance parameter or systematic variations. As before one can construct a dataset $\{x_i, y_i, \nu_i\}_{i=1,\ldots,n}$, but instead of leveraging the information about ν_i, one simply discards this information. This corresponds to sampling from the marginal distribution $x_i, y_i \sim p(x,y) = \int d\nu p(x,y|\nu)p(\nu)$, and is often referred to as *smearing*. One can then use this smeared dataset for supervised learning in the traditional way. While it is possible that this approach will lead to improved robustness to systematic variations (*i.e.* generalization for ν other than the nominal value) than if systematic uncertainty weren't considered at all), this intuitive approach has several shortcomings. The approach does not yield a pivotal quantity as in the adversarial approach, so propagation of uncertainty through the network is still required. Moreover, there is no direct way to control the trade-off between independence from the nuisance parameter and the original target loss as in the adversarial approach. Finally, it can lead to significant performance loss compared to what is possible with the parameterized approach. These trade-offs were studied in Refs. [319, 320] with both pedagogical and physically-motivated examples.

41.7.5 *Aleatoric and epistemic uncertainty*

In the machine learning and risk assessment literature, uncertainty is often characterized in terms of *aleatoric* and *epistemic* uncertainty [321–324]. Familiarity with these terms is useful, but the distinction between the two can be ambiguous, the terms are not always consistently used, and they do not clearly map onto the concepts used physics.

For example, Ref. [323], states that "roughly speaking, aleatoric (aka statistical) uncertainty refers to the notion of randomness, that is, the variability in the outcome of an experiment which is due to inherently random effects", while "epistemic (aka systematic) uncertainty refers to uncertainty caused by a lack of knowledge (about the best model)". This seems clear enough, but in that same reference (and in Ref. [325]) the aleatoric uncertainty is considered irreducible, while the epistemic uncertainty could be reduced with additional information. This may seem backwards for many physicists since often in particle physics, we think of how uncertainties scale as we collect more data but keep the experimental design fixed. In that case, the statistical uncertainty will be reduced with time while the systematic uncertainty will remain constant[6]. There is no paradox here, it is simply a different point of view. The emphasis of the risk assessment community is not on collecting more data with the same experimental design, but collecting different types of data that will inform the models themselves. Clearly even for physicists, data from new experiments or calibration measurements could also reduce our systematic uncertainties. While there are exceptions in the literature, the bulk of it associates aleatoric uncertainty with the randomness of classical probability (*i.e.* the statistical uncertainty associated to repeating the same experiment many times) and epistemic uncertainty with our state of knowledge.

Perhaps a more important distinction between the perspective of physicists and machine learning researchers has to do with the use of the term "model" and what exactly is uncertain. In physics, the systematic and epistemic uncertainty is typically associated to our understanding of the underlying physics and "the model" usually refers to the physics model, detector model encapsulated

[6] Further complicating the relationship between the terms is that many experimental uncertainties that are characterized as systematic are actually statistical in nature as auxiliary measurements and control regions are used to constrain the corresponding nuisance parameters.

in a simulation. In contrast, for machine learning research, "the model" usually refers to the trained model $\hat{f} \in \mathcal{F}$ used as described in Section 41.2.1 (or the class of functions $\mathcal{F}$ itself). This makes sense if we recall that in the bulk of machine learning research, one has little insight into the process that generated the data (*e.g.* images of cats and dogs, natural language, *etc.*). In that sense, the epistemic uncertainty in machine learning is usually associated to uncertainty in the model parameters ϕ after training, which would be reduced if one could collect more training dataset (see Ref. [324] for this point of view).

In the literature on Uncertainty Quantification (UQ), which is more closely connected to physics given the role of computer simulations, the terminology is more fine grained and less ambiguous. That community uses the terms parameter uncertainty (*i.e.* nuisance parameters), structural uncertainty (*i.e.* mismodelling), algorithmic uncertainty (*i.e.* numerical uncertainty), experimental uncertainty (*i.e.* uncertainty from experimental resolution and statistical fluctuations), and interpolation uncertainty (*i.e.* uncertainty due to interpolating between different parameter values due to lack of computational resources).

41.7.6 *Model averaging and Bayesian machine learning*

The core of Bayesian machine learning is the model averaging view. Here one often takes a more ambitious view of learning than described in Sec. 41.2.1, which is framed mainly as function approximation. While in Sec. 41.2.1, the goal is to find a function that minimizes the risk, in Bayesian machine learning one explicitly builds a probability model $q_\phi(x, y)$ for the training dataset $\mathcal{D} = \{x_i, y_i\}_{i=1,\ldots,n}$. It is the same change in perspective that one has when one views the squared error loss function $\mathcal{L}_{MSE} = (y - f_\phi(x))^2$ as the log-likelihood for a probability model $y \sim N(f(x), \sigma)$. In addition, one assumes some prior on the model parameters $p(\phi)$, which is often a Gaussian distribution, and is analogous to Tikhonov regularization (see Sec. 41.3.1.2). With this view in mind, a single trained model $\hat{f} = f_{\hat{\phi}}$ is the MAP point estimate and the more complete Bayesian solution is the entire posterior distribution over the model parameters $p(\phi|\mathcal{D})$. With this view, it is clear how increasing the number of training examples n will lead to a reduction in uncertainty on ϕ. However, this notion of epistemic uncertainty has little to do with the notion of systematic uncertainty as the term is used by particle physicists.

Bayesian methods can be applied to non-probabilistic regression problems, in which case they can provide uncertainty quantification. Consider the case of regression in traditional (non-Bayesian) machine learning. The trained model $f_{\hat{\phi}}(x)$ is used to predict the target label y. For a fixed x, the model does not provide any notion of uncertainty on the prediction. One could propagate uncertainty on x through $f(x)$, but that is also not the desired quantity to characterize the intrinsic spread $p(y|x)$ in the data, which may exist even if x has negligible uncertainty. In contrast, Gaussian process regression (a Bayesian method) does provide a natural way to communicate the uncertainty on the prediction, which is possible because one first had to specify a prior on the mean and covariance of the Gaussian process.

In the context of Bayesian deep learning and Bayesian Neural Networks, one would place a prior on the weights and biases of the neural network $p(\phi)$ and then use one of the many emerging techniques to calculate the approximate posterior $p(\phi|\mathcal{D})$. However, we should recognize that we have little-to-no insight into the parameters of a deep neural network, so the prior on ϕ is hardly well-justified. Furthermore, just as in all Bayesian approaches, the prior is not invariant to reparametrizing the model: $\phi \to \eta(\phi)$. While it is difficult to justify the choice of the prior on the parameters (and, thus, the resulting posterior), the resulting model may perform well empirically. In such high-dimensional parameter spaces, the bias-variance tradeoff can be dramatic.

Bayesian model averaging (BMA) performs Bayesian average over the posterior $p(\phi|\mathcal{D})$. This can be applied to any quantity f_ϕ, such as a regression or classification prediction y. Suppose we can draw from the posterior $\phi \sim p(\phi|\mathcal{D})$. For each draw we can evaluate the predicted regression variable $y = f_\phi(x) + \epsilon$, where ϵ is some noise to account for uncertainty in the predictions. We can denote this process as a draw from $p(y|x, \phi)$, $y \sim p(y|x, \phi) = N(f_\phi(x), \sigma_\epsilon^2)$, where σ_ϵ^2 is the noise variance. The BMA then performs

$$p(y|x, \mathcal{D}) = \int d\phi p(\phi|\mathcal{D}) p(y|x, \phi). \tag{41.76}$$

In practice $p(y|x, \phi)$ is evaluated by drawing samples of y and ϕ, so the posterior is defined implicitly by the samples. For example, the mean prediction is obtained by averaging $f_\phi(x)$ over the samples of ϕ, and the covariance matrix is similarly evaluated by averaging the second moments over the samples of ϕ.

Ref. [326] provides a different perspective on BMA analyzed in what are referred to as the $\mathcal{M}$-open and $\mathcal{M}$-closed settings [326]. The $\mathcal{M}$-closed setting refers to the situation where the true data generating process is in the space of models, even if it is unknown to us. In contrast, the $\mathcal{M}$-open setting refers to when the true data generating process is not in model space (*i.e.* the model is mis-specified). Interestingly, in the $\mathcal{M}$-open case one can potentially do better than any one model in the model class by considering an average over the models, since averaging can create a new model that is not in the model class. BMA provides one such averaging, but other averages, which are not weighted by $p(\phi|\mathcal{D})$, can be a better choice. When the weights of each model are optimized against appropriate loss the resulting procedure is called stacking, which has been shown to be superior to BMA in the $\mathcal{M}$-open setting [326]. Ref. [327] performed experiments indicating that in some cases model averaging can also improve predictive uncertainty estimates under domain shifts.

Neural network model averaging beyond BMA comes in several different flavors. Two successful model averaging procedures are Monte Carlo dropout [328], which uses dropout ensembling, and deep ensembles [329], which use random initialization ensembling. These methods may not only be superior to BMA, they are also often significantly faster than BMA. Whether these model averages are an approximation to BMA, or an alternative to it, remains a debated topic, and both views have been advocated. BMA itself can be accelerated using approximate methods, such as stochastic Variational Inference with reparametrization trick [330].

41.7.7 *Connection to probabilistic machine learning*

We end this Section by reinforcing the connection between uncertainty quantification in traditional machine learning and the more probabilistic approaches to machine learning exemplified by simulation-based inference (see Sec 41.3.5) and deep generative models (see Sec. 41.5.4). In the standard approach to supervised learning (*e.g.* classification and regression) the model $f(x)$ provides a point estimate for y. Estimating an uncertainty on y goes a step further, but the complete picture would be to model the posterior distribution $p(y|x)$. Gaussian processes (see Sec. 41.5.1) are an example, but the form of the models is limited to Gaussian posteriors. In Sec 41.3.5 we discussed approaches to model $p(y|x)$ using conditional density estimation [51, 56, 57]. If we extend this task to include a family of distributions parameterized by some nuisance parameters ν, then the task is to model $p(y|x, \nu)$, which is structurally similar.

In the context of classification, the output is already probabilistic, and the interpretation of the resulting classifier is $\hat{f}_{MSE}(x) \approx p(y = 1|x)$ (see Eq. 41.10). Incorporating the dependence on the nuisance parameter, then connects to the likelihood-ratio trick (see Eq. 41.12), approaches to simulation-based inference that involve learning the likelihood-ratio, and the parameterized approaches described in Sec. 41.7.3.

If one pairs the training procedure for classification, regression, or density estimation used in the approaches above with model averaging techniques such as BMA, then it would be possible to incorporate both uncertainty associated to finite training dataset and the uncertainty associated to systematic uncertainties. However, as described in Sec. 41.7.5 and Sec. 41.7.1, it is not clear that in physics applications it is desirable to account for the variability associated to training when the more common practice is to regard the trained model $\hat{f}(x)$ as fixed.

While these probabilistic approaches to machine learning are attractive conceptually, it is known in the machine learning community that classifiers often are poorly calibrated and often overly

confident in their predictions. This is a problem even if one regards the trained model $\hat{f}(x)$ as fixed. Various approaches, including model averaging, are being pursued to improve the calibration of trained models, but the problem is unlikely to be eliminated entirely. Miscalibration can be verified by evaluating the true positive and false positive rates on held out data. This is common practice in experimental particle physics, where the output of a binary classifier is rarely taken at face value. Instead, the true and false positive rates are estimated with simulated data or control samples as described in Sec. 41.7.1. Furthermore, the true and false positives can be characterized as a function of the nuisance parameters. These procedures can be used to help calibrate parameterized models based on the likelihood-ratio trick (see Refs. [58, 320]). Unfortunately, calibration in the context of density estimation is more challenging. This connects to topics and challenges in anomaly detection (see Sec. 41.3.4).

41.8 Infrastructure for deployment in experiments

The software and computing needs of training a machine learning model are different than those encountered when it deployed for use. In machine learning jargon, the two stages are often referred to as *training* and *inference*, where inference might refer to making a prediction for y given x in a classification or regression problem. Sometimes this transition also involves using different programming languages for implementing the trained model from the ones used for training them. Modern machine learning frameworks support various serialization formats to exchange trained models. For instance, `ONNX` provides an open source format for many types of models and is is widely supported and can be found in many frameworks, tools, and hardware. This is important when integrating a trained model into the large software frameworks used by the large experiments.

While hardware acceleration with GPUs is important for efficiently training modern machine learning techniques, there are also advantages of hardware acceleration at inference time. This may include GPUs or Field Programmable Gate Arrays (FPGAs), and the Living Review includes many example works focusing on efficient inference for a given hardware architecture [81, 108, 331–340]. For applications where latency is a key concern (eg triggering at collider experiments), various accelerators have been investigated [167, 171, 341–355]. In addition, some solutions for deployment of ML models involve deployment in the cloud [356, 357].

42. Monte Carlo Techniques

Revised September 2021 by G. Cowan (RHUL).

Monte Carlo techniques are often the only practical way to evaluate difficult integrals or to sample random variables governed by complicated probability density functions. Here we describe an assortment of methods for sampling some commonly occurring probability density functions.

42.1 Sampling the uniform distribution

Most Monte Carlo sampling or integration techniques assume a "random number generator," which generates uniform statistically independent values on the half open interval $[0, 1)$; for reviews see, *e.g.*, Refs. [1, 2].

Uniform random number generators are available in software libraries such as CLHEP [3], and ROOT [4]. For example, in addition to a basic congruential generator `TRandom` (see below), ROOT provides three more sophisticated routines: `TRandom1` implements the RANLUX generator [5] based on the method by Lüscher, and allows the user to select different quality levels, trading off quality with speed; `TRandom2` is based on the maximally equidistributed combined Tausworthe generator by L'Ecuyer [6]; the `TRandom3` generator implements the Mersenne twister algorithm of Matsumoto and Nishimura [7]. All of the algorithms produce a periodic sequence of numbers, and to obtain effectively random values, one must not use more than a small subset of a single period. The Mersenne twister algorithm has an extremely long period of $2^{19937} - 1$. A recent review of high-quality random number generators can be found in Ref. [8].

The performance of the generators can be investigated with tests such as DIEHARD [9] or TestU01 [10]. Many commonly available congruential generators fail these tests and often have sequences (typically with periods less than 2^{32}), which can be easily exhausted on modern computers. A short period is a problem for the `TRandom` generator in ROOT, which, however, has the advantage that its state is stored in a single 32-bit word. The generators `TRandom1`, `TRandom2`, or `TRandom3` have much longer periods, with `TRandom3` being recommended by the ROOT authors as providing the best combination of speed and good random properties. For further information see, *e.g.*, Ref. [11].

42.2 Inverse transform method

If the desired probability density function is $f(x)$ on the range $-\infty < x < \infty$, its cumulative distribution function (expressing the probability that $x \leq a$) is given by Eq. (39.6). If a is chosen with probability density $f(a)$, then the integrated probability up to point a, $F(a)$, is itself a random variable which will occur with uniform probability density on $[0, 1]$. Suppose u is generated according to a uniformly distributed in $(0, 1)$. If x can take on any value, and ignoring the endpoints, we can then find a unique x chosen from the p.d.f. $f(x)$ for a given u if we set

$$u = F(x) \ , \tag{42.1}$$

provided we can find an inverse of F, defined by

$$x = F^{-1}(u) \ . \tag{42.2}$$

This method is shown in Fig. 42.1a. It is most convenient when one can calculate by hand the inverse function of the indefinite integral of f. This is the case for some common functions $f(x)$ such as $\exp(x)$, $(1 - x)^n$, and $1/(1 + x^2)$ (Cauchy or Breit-Wigner), although it does not necessarily produce the fastest generator. Standard libraries contain software to implement this method numerically, working from functions or histograms in one or more dimensions, *e.g.*, the UNU.RAN package [12], available in ROOT. For a discrete distribution, $F(x)$ will have a discontinuous jump of size $f(x_k)$ at each allowed $x_k, k = 1, 2, \cdots$. Choose u from a uniform distribution on (0,1) as before. Find x_k such that

$$F(x_{k-1}) < u \leq F(x_k) \equiv \text{Prob}\,(x \leq x_k) = \sum_{i=1}^{k} f(x_i) \ ; \tag{42.3}$$

then x_k is the value we seek (note: $F(x_0) \equiv 0$). This algorithm is illustrated in Fig. 42.1b.

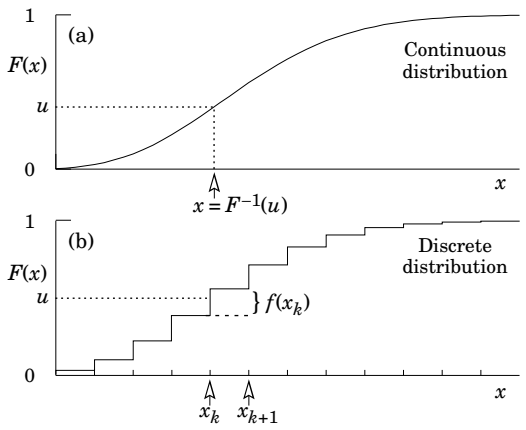

Figure 42.1: Use of a random number u chosen from a uniform distribution (0,1) to find a random number x from a distribution with cumulative distribution function $F(x)$.

42.3 Acceptance-rejection method (Von Neumann)

Very commonly an analytic form for $F(x)$ is unknown or too complex to work with, so that obtaining an inverse as in Eq. (42.2) is impractical. We suppose that for any given value of x, the probability density function $f(x)$ can be computed, and further that enough is known about $f(x)$ that we can enclose it entirely inside a shape which is C times an easily generated distribution $h(x)$, as illustrated in Fig. 42.2. That is, $Ch(x) \geq f(x)$ must hold for all x. Frequently $h(x)$ is uniform or is a normalized sum of uniform distributions. Note that both $f(x)$ and $h(x)$ must be normalized to unit area, and therefore, the proportionality constant $C > 1$. To generate $f(x)$, first generate a candidate x according to $h(x)$. Calculate $f(x)$ and the height of the envelope $C\,h(x)$; generate u and test if $uC\,h(x) \leq f(x)$. If so, accept x; if not reject x and try again. If we regard x and $uC\,h(x)$ as the abscissa and ordinate of a point in a two-dimensional plot, these points will populate the entire area $C\,h(x)$ in a smooth manner; then we accept those which fall under $f(x)$. The efficiency is the ratio of areas, which must equal $1/C$; therefore we must keep C as close as possible to 1.0. Therefore, we try to choose $C\,h(x)$ to be as close to $f(x)$ as convenience dictates, as in the lower part of Fig. 42.2.

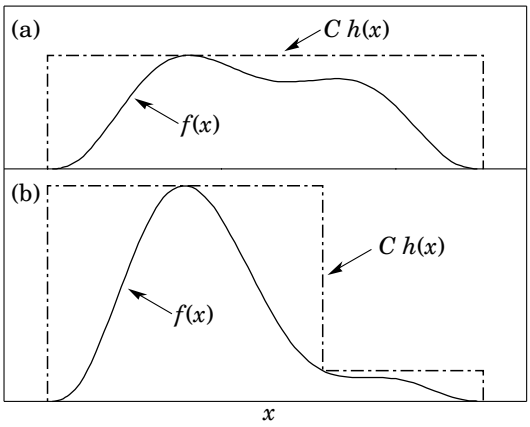

Figure 42.2: Illustration of the acceptance-rejection method. Random points are chosen inside the upper bounding figure, and rejected if the ordinate exceeds $f(x)$. The lower figure illustrates a method to increase the efficiency (see text).

42.4 Algorithms

Algorithms for generating random numbers belonging to many different distributions are given for example by Press [13], Ahrens and Dieter [14], Rubinstein [15], Devroye [16], Walck [17] and Gentle [18]. For many distributions, alternative algorithms exist, varying in complexity, speed, and accuracy. For time-critical applications, these algorithms may be coded in-line to remove the significant overhead often encountered in making function calls.

In the examples given below, we use the notation for the variables and parameters given in Table 39.1. Variables named "u" are assumed to be independent and uniform on [0,1). Denominators must be verified to be non-zero where relevant.

42.4.1 *Exponential decay*

This is a common application of the inverse transform method, and uses the fact that if u is uniformly distributed in $[0,1]$, then $(1-u)$ is as well. Consider an exponential p.d.f. $f(t) = (1/\tau)\exp(-t/\tau)$ that is truncated so as to lie between two values, a and b, and renormalized to unit area. To generate decay times t according to this p.d.f., first let $\alpha = \exp(-a/\tau)$ and $\beta = \exp(-b/\tau)$; then generate u and let

$$t = -\tau \ln(\beta + u(\alpha - \beta)). \tag{42.4}$$

For $(a,b) = (0,\infty)$, we have simply $t = -\tau \ln u$. (See also Sec. 42.4.6.)

42.4.2 *Isotropic direction in 3D*

Isotropy means the density is proportional to solid angle, the differential element of which is $d\Omega = d(\cos\theta)d\phi$. Hence $\cos\theta$ is uniform $(2u_1 - 1)$ and ϕ is uniform $(2\pi u_2)$. For alternative generation of $\sin\phi$ and $\cos\phi$, see the next subsection.

42.4.3 *Sine and cosine of random angle in 2D*

Generate u_1 and u_2. Then $v_1 = 2u_1 - 1$ is uniform on (−1,1), and $v_2 = u_2$ is uniform on (0,1). Calculate $r^2 = v_1^2 + v_2^2$. If $r^2 > 1$, start over. Otherwise, the sine (S) and cosine (C) of a random angle (*i.e.*, uniformly distributed between zero and 2π) are given by

$$S = 2v_1v_2/r^2 \quad \text{and} \quad C = (v_1^2 - v_2^2)/r^2 \ . \tag{42.5}$$

42.4.4 *Gaussian distribution*

If u_1 and u_2 are uniform on (0,1), then

$$z_1 = \sin(2\pi u_1)\sqrt{-2\ln u_2} \quad \text{and} \quad z_2 = \cos(2\pi u_1)\sqrt{-2\ln u_2} \tag{42.6}$$

are independent and Gaussian distributed with mean 0 and $\sigma = 1$.

There are many variants of this basic algorithm, which may be faster. For example, construct $v_1 = 2u_1 - 1$ and $v_2 = 2u_2 - 1$, which are uniform on (−1,1). Calculate $r^2 = v_1^2 + v_2^2$, and if $r^2 > 1$ start over. If $r^2 < 1$, it is uniform on (0,1). Then

$$z_1 = v_1\sqrt{\frac{-2\ln r^2}{r^2}} \quad \text{and} \quad z_2 = v_2\sqrt{\frac{-2\ln r^2}{r^2}} \tag{42.7}$$

are independent numbers chosen from a normal distribution with mean 0 and variance 1. $z_i' = \mu + \sigma z_i$ distributes with mean μ and variance σ^2.

For a multivariate Gaussian with an $n \times n$ covariance matrix V, one can start by generating n independent Gaussian variables, $\{\eta_j\}$, with mean 0 and variance 1 as above. Then the new set $\{x_i\}$ is obtained as $x_i = \mu_i + \sum_j L_{ij}\eta_j$, where μ_i is the mean of x_i, and L_{ij} are the components of L, the unique lower triangular matrix that fulfils $V = LL^T$. The matrix L can be easily computed by the following recursive relation (Cholesky's method):

$$L_{jj} = \left(V_{jj} - \sum_{k=1}^{j-1} L_{jk}^2\right)^{1/2} \ , \tag{42.8a}$$

$$L_{ij} = \frac{V_{ij} - \sum_{k=1}^{j-1} L_{ik}L_{jk}}{L_{jj}} \ , \ j = 1,...,n \, ; \ i = j+1,...,n, \tag{42.8b}$$

where $V_{ij} = \rho_{ij}\sigma_i\sigma_j$ are the components of V. For $n = 2$ one has

$$L = \begin{pmatrix} \sigma_1 & 0 \\ \rho\sigma_2 & \sqrt{1-\rho^2}\,\sigma_2 \end{pmatrix} \ , \tag{42.9}$$

and therefore the correlated Gaussian variables are generated as $x_1 = \mu_1 + \sigma_1\eta_1$, $x_2 = \mu_2 + \rho\sigma_2\eta_1 + \sqrt{1-\rho^2}\,\sigma_2\eta_2$.

42.4.5 $\chi^2(n)$ distribution

To generate a variable following the χ^2 distribution for n degrees of freedom, use the Gamma distribution with $k = n/2$ and $\lambda = 1/2$ using the method of Sec. 42.4.6.

42.4.6 *Gamma distribution*

All of the following algorithms are given for $\lambda = 1$. For $\lambda \neq 1$, divide the resulting random number x by λ.

- If $k = 1$ (the *exponential* distribution), accept $x = -\ln u$. (See also Sec. 42.4.1.)

- If $0 < k < 1$, initialize with $v_1 = (e+k)/e$ (with $e = 2.71828...$ being the natural log base). Generate u_1, u_2. Define $v_2 = v_1u_1$.

  Case 1: $v_2 \leq 1$. Define $x = v_2^{1/k}$. If $u_2 \leq e^{-x}$, accept x and stop, else restart by generating new u_1, u_2.

  Case 2: $v_2 > 1$. Define $x = -\ln([v_1 - v_2]/k)$. If $u_2 \leq x^{k-1}$, accept x and stop, else restart by generating new u_1, u_2. Note that, for $k < 1$, the probability density has a pole at $x = 0$, so that return values of zero due to underflow must be accepted or otherwise dealt with.

- Otherwise, if $k > 1$, initialize with $c = 3k - 0.75$. Generate u_1 and compute $v_1 = u_1(1-u_1)$ and $v_2 = (u_1 - 0.5)\sqrt{c/v_1}$. If $x = k + v_2 - 1 \leq 0$, go back and generate new u_1; otherwise generate u_2 and compute $v_3 = 64v_1^3u_2^2$. If $v_3 \leq 1 - 2v_2^2/x$ **or** if $\ln v_3 \leq 2\{[k-1]\ln[x/(k-1)] - v_2\}$, accept x and stop; otherwise go back and generate new u_1.

42.4.7 *Binomial distribution*

Begin with $k = 0$ and generate u uniform in $[0,1)$. Compute $P_k = (1-p)^n$ and store P_k into B. If $u \leq B$ accept $r_k = k$ and stop. Otherwise, increment k by one; compute the next P_k as $P_k \cdot (p/(1-p)) \cdot (n-k)/(k+1)$; add this to B. Again, if $u \leq B$, accept $r_k = k$ and stop, otherwise iterate until a value is accepted. If $p > 1/2$, it will be more efficient to generate r from $f(r; n, q)$, *i.e.*, with p and q interchanged, and then set $r_k = n - r$.

42.4.8 *Poisson distribution*

Iterate until a successful choice is made: Begin with $k = 1$ and set $A = 1$ to start. Generate u. Replace A with uA; if now $A < \exp(-\mu)$, where μ is the Poisson parameter, accept $n_k = k - 1$ and stop. Otherwise increment k by 1, generate a new u and repeat, always starting with the value of A left from the previous try.

Note that the Poisson generator used in ROOT's `TRandom` classes before version 5.12 (including the derived classes `TRandom1, TRandom2, TRandom3`) uses a Gaussian approximation when μ exceeds a given threshold. This may be satisfactory (and much faster) for some applications. To do this, generate z from a Gaussian with zero mean and unit standard deviation; then use $x = \max(0, [\mu + z\sqrt{\mu} + 0.5])$ where $[\,]$ signifies the greatest integer $\leq$ the expression. The routines from Numerical Recipes [13] and CLHEP's routine `RandPoisson` do not make this approximation (see, *e.g.*, Ref. [11]).

42.4.9 *Student's t distribution*

Generate u_1 and u_2 uniform in $(0,1)$; then $t = \sin(2\pi u_1)[n(u_2^{-2/n} - 1)]^{1/2}$ follows the Student's t distribution for $n > 0$ degrees of freedom (n not necessarily an integer).

Alternatively, generate x from a Gaussian with mean 0 and $\sigma^2 = 1$ according to the method of 42.4.4. Next generate y,

an independent gamma random variate, according to 42.4.6 with $\lambda = 1/2$ and $k = n/2$. Then $z = x/\sqrt{y/n}$ is distributed as a t with n degrees of freedom.

For the special case $n = 1$, the Breit-Wigner distribution, generate u_1 and u_2; set $v_1 = 2u_1 - 1$ and $v_2 = 2u_2 - 1$. If $v_1^2 + v_2^2 \leq 1$ accept $z = v_1/v_2$ as a Breit-Wigner distribution with unit area, center at 0.0, and FWHM 2.0. Otherwise start over. For center M_0 and FWHM Γ, use $W = z\Gamma/2 + M_0$.

42.4.10 *Beta distribution*

The choice of an appropriate algorithm for generation of beta distributed random numbers depends on the values of the parameters α and β. For, *e.g.*, $\alpha = 1$, one can use the transformation method to find $x = 1 - u^{1/\beta}$, and similarly if $\beta = 1$ one has $x = u^{1/\alpha}$. For more general cases see, *e.g.*, Refs. [17, 18] and references therein.

42.5 Importance sampling and weighted Monte Carlo

Often the goal of a Monte Carlo calculation is to determine an expectation value of a function $h(x)$, where x is a (single or vector) random variable that follows a pdf $f(x)$,

$$E_f[h(x)] = \int h(x) f(x)\, dx \equiv \mu \,. \tag{42.10}$$

A Monte-Carlo estimator $\hat{\mu}_{\rm MC}$ for μ is the average of N values of $h(x)$ where x is sampled (generated) from $f(x)$, i.e., $\hat{\mu}_{\rm MC} = \frac{1}{N}\sum_{i=1}^{N} h(x_i)$. This has a variance

$$V[\hat{\mu}_{\rm MC}] = \frac{1}{N} V_f[h(x)] = \frac{1}{N}\left(E_f[h^2(x)] - \mu^2\right) \,. \tag{42.11}$$

By using the method of *importance sampling*, one can achieve a reduction in this variance and thus a more accurate determination of the expectation value for a given number of random values generated. The key idea is to rewrite the expectation value in Eq. (42.10) as

$$\mu = \int h(x) f(x)\, dx = \int \frac{h(x) f(x)}{g(x)}\, g(x)\, dx = E_g\left[\frac{h(x) f(x)}{g(x)}\right] \,, \tag{42.12}$$

where $g(x)$ is any other pdf of x with the same support as $f(x)$ (i.e., nonzero for the same region of x). Thus the desired quantity μ is the expectation value with respect to g of $h(x)f(x)/g(x)$. It can be estimated by generating N values of x sampled from g and computing

$$\hat{\mu}_{\rm IS} = \frac{1}{N}\sum_{i=1}^{N} \frac{h(x_i) f(x_i)}{g(x_i)} \,. \tag{42.13}$$

The variance of $\hat{\mu}_{\rm IS}$ is given by

$$V[\hat{\mu}_{\rm IS}] = \frac{1}{N} V_g\left[\frac{h(x) f(x)}{g(x)}\right] = \frac{1}{N}\left(E_g\left[\frac{h^2(x) f^2(x)}{g^2(x)}\right] - \mu^2\right) \,, \tag{42.14}$$

By choosing $g(x)$ such that $h(x)f(x)/g(x)$ is as constant as possible, the variance of $\hat{\mu}_{\rm IS}$ can be substantially reduced. One can show (see, e.g., Refs. [19,20]) that the variance is minimized when $g(x) \propto |h(x)|f(x)$.

An alternative importance sampling estimator can be constructed by replacing the number of generated values N in Eq. (42.13) by the sum $\sum_{i=1}^{N} f(x_i)/g(x_i)$. This can given an even smaller variance at the price of a small bias. It can be of further advantage in problems where the pdf $f(x)$ is known only up to a normalization constant, which then cancels (see Refs. [19, 20]).

A closely related application of importance sampling is the use of weighted Monte Carlo to compute the probability $P_f(x \in A)$ for x to be in a specified region A:

$$P_f(x \in A) = \int_A f(x)\, dx \,. \tag{42.15}$$

It may be, however, that one does not have an MC model capable of generating $x \sim f(x)$, but rather one can generate x according to a different density $g(x)$. The probability $P_f(x \in A)$ can be written

$$\begin{aligned} P_f(x \in A) &= \frac{\int_A \frac{f(x)}{g(x)}\, g(x)\, dx}{\int_A g(x)\, dx} \int_A g(x)\, dx \\ &= E_g[w(x) | x \in A]\, P_g(x \in A) \,, \end{aligned} \tag{42.16}$$

where $w(x) = f(x)/g(x)$ is the *weight function* and $P_g(x \in A) = \int_A g(x)\, dx$ is the probability to find $x \in A$ assuming $x \sim g(x)$. That is, $P_f(x \in A)$ is the conditional expectation value of $w(x)$ with respect to $g(x)$ given $x \in A$ multiplied by the probability to find $x \in A$ under assumption of $g(x)$.

Suppose N values of x are generated according to $g(x)$ and m of them are found in the region A. Then the probability to be in A for $x \sim g(x)$ can be estimated by m/N, and the expectation value above can be obtained from the average of the weights in A. Therefore the desired probability $P_f(x \in A)$ can be estimated using

$$\hat{P}_f(x \in A) = \frac{1}{m}\sum_{i=1}^{m} w_i \times \frac{m}{N} = \frac{1}{N}\sum_{i=1}^{m} w_i \,, \tag{42.17}$$

where $w_i = w(x_i)$ and the sum includes only the m values of x found in A. That is, when generating the x values according to $g(x)$ instead of $f(x)$, the number of events m found in A is replaced by the corresponding sum of weights. The variance of $\hat{P}_f(x \in A)$ can be found from

$$\widehat{V}[\hat{P}_f(x \in A)] = \frac{1}{N^2}\sum_{i=1}^{m} w_i^2 \,. \tag{42.18}$$

By choosing $g(x)$ so that a larger fraction of x values are sampled in the "important" region A, one can reduce the variance of the estimated probability for a given total number of generated values.

42.6 Markov Chain Monte Carlo

In applications involving generation of random numbers following a multivariate distribution with a high number of dimensions, the transformation method may not be possible and the acceptance-rejection technique may have too low of an efficiency to be practical. If it is not required to have independent random values, but only that they follow a certain distribution, then Markov Chain Monte Carlo (MCMC) methods can be used. In depth treatments of MCMC can be found, *e.g.*, in the texts by Robert and Casella [19], Liu [20], and the review by Neal [21]. HEP-oriented software for MCMC is available from the Bayesian Analysis Toolkit (BAT) [22, 23].

MCMC is particularly useful in connection with Bayesian statistics, where a p.d.f. $p(\boldsymbol{\theta})$ for an n-dimensional vector of parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_n)$ is obtained, and one needs the marginal distribution of a subset of the components. Here one samples $\boldsymbol{\theta}$ from $p(\boldsymbol{\theta})$ and simply records the marginal distribution for the components of interest.

A simple and broadly applicable MCMC method is the Metropolis-Hastings algorithm, which allows one to generate multidimensional points $\boldsymbol{\theta}$ distributed according to a target p.d.f. that is proportional to a given function $p(\boldsymbol{\theta})$. It is not necessary to have

$p(\boldsymbol{\theta})$ normalized to unit area, which is useful in Bayesian statistics, as posterior probability densities are often determined only up to an unknown normalization constant.

To generate points that follow $p(\boldsymbol{\theta})$, one first needs a proposal p.d.f. $q(\boldsymbol{\theta}; \boldsymbol{\theta}_0)$, which can be (almost) any p.d.f. from which independent random values $\boldsymbol{\theta}$ can be generated, and which contains as a parameter another point in the same space $\boldsymbol{\theta}_0$. For example, a multivariate Gaussian centered about $\boldsymbol{\theta}_0$ can be used. Beginning at an arbitrary starting point $\boldsymbol{\theta}_0$, the Hastings algorithm iterates the following steps:

1. Generate a value $\boldsymbol{\theta}$ using the proposal density $q(\boldsymbol{\theta}; \boldsymbol{\theta}_0)$;
2. Form the Hastings test ratio, $\alpha = \min\left[1, \frac{p(\boldsymbol{\theta})q(\boldsymbol{\theta}_0;\boldsymbol{\theta})}{p(\boldsymbol{\theta}_0)q(\boldsymbol{\theta};\boldsymbol{\theta}_0)}\right]$;
3. Generate a value u uniformly distributed in $[0, 1]$;
4. If $u \leq \alpha$, take $\boldsymbol{\theta}_1 = \boldsymbol{\theta}$. Otherwise, repeat the old point, *i.e.*, $\boldsymbol{\theta}_1 = \boldsymbol{\theta}_0$.
5. Set $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_1$ and return to step 1.

If one takes the proposal density to be symmetric in $\boldsymbol{\theta}$ and $\boldsymbol{\theta}_0$, then this is the *Metropolis*-Hastings algorithm, and the test ratio becomes $\alpha = \min[1, p(\boldsymbol{\theta})/p(\boldsymbol{\theta}_0)]$. That is, if the proposed $\boldsymbol{\theta}$ is at a value of probability higher than $\boldsymbol{\theta}_0$, the step is taken. If the proposed step is rejected, the old point is repeated.

Methods for assessing and optimizing the performance of the algorithm are discussed in, *e.g.*, Refs. [19–21]. One can, for example, examine the autocorrelation as a function of the lag k, *i.e.*, the correlation of a sampled point with that k steps removed. This should decrease as quickly as possible for increasing k.

Generally one chooses the proposal density so as to optimize some quality measure such as the autocorrelation. For certain problems it has been shown that one achieves optimal performance when the acceptance fraction, that is, the fraction of points with $u \leq \alpha$, is around 40%. This can be adjusted by varying the width of the proposal density. For example, one can use for the proposal p.d.f. a multivariate Gaussian with the same covariance matrix as that of the target p.d.f., but scaled by a constant.

43. Monte Carlo Event Generators

Revised Oct 2023 by P. Nason (INFN, Milano-Bicocca; Milano-Bicocca U.) and P. Skands (Monash U.).

General-purpose Monte Carlo (GPMC) generators like HERWIG [1–3], PYTHIA [4,5], and SHERPA [6], provide detailed simulations of high-energy collisions. They play an essential role in QCD modeling (in particular for aspects beyond fixed-order perturbative QCD) and in data analysis and the planning of new experiments, where they are used together with detector simulation to estimate signals and backgrounds in high-energy processes. They are built from several components, that describe the physics starting from very short distance scales, up to the typical scale of hadron formation and decay. Since QCD is weakly interacting at short distances (below a femtometer), the components of the GPMC dealing with short-distance physics are based upon perturbation theory. At larger distances, all soft hadronic phenomena, like hadronization and the formation of the underlying event in hadron collisions, cannot be computed from first principles at present, and one must rely upon QCD-inspired models.

The purpose of this review is to illustrate the main components of these generators. It is divided into four sections. The first one deals with short-distance, perturbative phenomena. The basic concepts leading to the simulations of the dominant QCD processes are illustrated here. In the second section, the nonperturbative transition from partons to hadrons ("hadronization") is treated. The two most popular hadronization models, the string and cluster models, are illustrated. The basics of the implementation of decay chains of unstable "primary" hadrons into stable "secondaries" is also illustrated here. In the third section, models for soft hadron physics are discussed. These include models for the underlying event and for low-$p_\perp$ ("minimum-bias") interactions. Aspects of collective effects, such as Bose-Einstein and color-reconnection effects, are also discussed here. The fourth section briefly introduces the challenges of MC uncertainty estimates and tuning.

We use natural units throughout, such that $c = 1$ and $\hbar = 1$, with energies, momenta and masses measured in GeV, and times and distances measured in GeV^{-1}.

43.1 Short-distance physics in GPMC generators

The short-distance components of a GPMC generator deal with the computation of the primary process at hand, with decays of short-lived particles, and with the generation of QCD and QED radiation. QCD radiation is computable in perturbation theory as long as the time scales involved are well below $1/\Lambda$, where Λ is a typical hadronic scale of few hundred MeV. Because of the presence of logarithmic enhancements due to both collinear and soft emissions, this description involves an indefinite number of final-state particles that are emitted at time scales below $1/\Lambda$. In e^+e^- annihilation into hadrons, for example, the time scale of the primary process is of the order of the inverse of the annihilation energy Q. Collinear and soft emissions take place at all time scales between $1/Q$ and $1/\Lambda$, Technically, the computation of the dominant collinear and soft radiation is carried out by the so called shower algorithms. Historically, "Parton Shower" algorithms were first developed for resummation of collinear singularities. We will briefly describe this approach in this section. We stress, however, that many modern generators adopt approaches that focus initially upon soft singularities, leading to "Dipole Showers", discussed in Sec. 43.1.3.

Collinear singularities arise when the angle between two emitted light partons becomes small. For example, in a process in which a quark and a gluon are emitted, if the angle θ among them is very small (and is smaller than the angles among all other pairs of light partons in the process) the squared amplitude factorizes as follows

$$|M_{qg}|^2 \mathrm{d}\Phi_{qg} \approx |M_q|^2 \,\mathrm{d}\Phi_q \frac{\alpha_s}{2\pi} P_{q,qg}(z)\mathrm{d}z \frac{\mathrm{d}\phi}{2\pi}\frac{\mathrm{d}\theta^2}{\theta^2} \qquad (43.1)$$

where M_{qg}, $\mathrm{d}\Phi_{qg}$ are the amplitude and phase space describing the emission of both the gluon and the quark; M_q, $\mathrm{d}\Phi_q$ are the amplitude and phase space when only the quark is emitted; $z = E_q/(E_q + E_g)$ is the fraction of energy carried by the quark; ϕ is the azimuth of the splitting plane, and $P_{q,qg}(z) = C_F(1+z^2)/(1-z)$ is the Altarelli-Parisi splitting kernel for gluon emission from a quark line, with color factor $C_F = 4/3$. The factorized form of Eq. (43.1) is due to the fact that for small angle the process is dominated by a single amplitude in which the splitting quark is almost on shell and hence propagates for long distances. We define the energy scale corresponding to the inverse of this distance as the *hardness* of the splitting process, so that larger hardness corresponds to shorter distance. We can define the hardness t as the product $E^2\theta^2$, or as the virtuality of the splitting parton p^2, or as a measure of the relative transverse momentum in the splitting such as the k_t of an emitted parton relative to its parent, defined by

$$\begin{aligned} p^2 &= 2E^2 z(1-z)(1-\cos\theta) \approx z(1-z)E^2\theta^2\,, \\ k_t^2 &= z^2(1-z)^2E^2\theta^2\,. \end{aligned} \qquad (43.2)$$

If the region of small values of z and $1-z$ was not important, these definitions would be equivalent. In QCD we also have soft divergences, arising when soft gluons are emitted. In Eq. (43.1) they appear as $z \to 1$, because of the $1/(1-z)$ singularity of $P_{q,qg}(z)$. Thus, we expect that the choice of the appropriate ordering variable will be relevant when dealing with soft divergences (see Sec. 43.3). The $\mathrm{d}\theta^2/\theta^2$ factor in Eq. (43.1) can be equivalently written in terms of the hardness $\mathrm{d}t/t$. After integration, it gives rise to a logarithmic factor $\log(Q^2/\Lambda^2)$. We can have many subsequent splittings, that we can describe by applying Eq. (43.1) recursively, as long as the splittings are strongly ordered in decreasing hardness. This means that, from a typical final-state configuration, by clustering together final-state parton pairs with the smallest hardness recursively, we can reconstruct a branching tree, that may be viewed as the splitting history of the event. We stress that all hardness values between the hardness of the primary process and the cutoff scale Λ are equally involved here. The collinear approximation is applied recursively to splitting processes that have much smaller hardness with respect to all previous ones.

By integrating over the phase space (and neglecting for the moment soft divergences), a process with n collinear splittings will be of order $(\alpha_S(Q^2)\log(Q^2/\Lambda^2))^n$ with respect to the primary process. Since $\alpha_S(Q^2) \propto 1/\log(Q^2/\Lambda^2)$ [7], these corrections are not small. The so-called KLN theorem [8,9] guarantees that large logarithmic enhancements arising from final-state collinear splitting cancel against the virtual corrections in inclusive cross sections, order by order in perturbation theory. Furthermore, the factorization theorem guarantees that initial-state collinear singularities can be factorized into the parton density functions (PDFs) [7]. Therefore, the cross section for the basic process remains accurate up to corrections of higher orders in $\alpha_S(Q)$, provided it is interpreted as an inclusive cross section, rather than as a bare partonic cross section. For example, the leading order (LO) cross section for $e^+e^- \to q\bar{q}$ is a good estimate of the e^+e^- cross section for the production of a pair of quarks accompanied by an arbitrary number of collinear and soft gluons, but is not a good estimate of the cross section for the production of a $q\bar{q}$ pair with a veto on extra radiation. In summary, perturbation theory at fixed order can yield increasingly accurate predictions for inclusive observables, but cannot be used to describe the indefinite sequence of collinear and soft radiations that accompany the hard partons.

Parton-Shower algorithms are used to compute the cross section for generic hard processes including all dominant collinear radiation. These algorithms begin with the generation of the kinematics of the basic process, performed with a probability proportional to its LO partonic cross section. This is interpreted physically as the inclusive cross section for the basic process, followed by an arbitrary sequence of shower splittings. The algorithm then assigns a probability to each splitting sequence, so that the initial LO cross section is partitioned into the cross sections for a multitude of final states of arbitrary multiplicity, with their sum being equal to the cross section of the primary process. This property of the GPMCs reflects the KLN cancellation mentioned earlier, and it is often called "unitarity of the shower process", a name

that reminds us that the KLN cancellation itself is a consequence of unitarity. The fact that a quantum mechanical process can be described in terms of composition of probabilities, rather than amplitudes, follows from the collinear approximation. In fact, because of strong ordering, a radiated parton cannot be collinear to more than one parton in the amplitude, and this suppresses interference effects.

We now illustrate the basic parton-shower algorithm, as first introduced in Ref. [10]. (For more pedagogical introductions see Ref. [11] and references therein.) For simplicity, we consider the example of e^+e^- annihilation into $q\bar{q}$ pairs, where we only have to deal with final state radiation (FSR). We consider all final states that can be built by dressing the q and $\bar{q}$ partons with an indefinite number of splitting processes. By recursively clustering together final state parton pairs with the smallest relative hardness, from each final state configuration we can construct two trees rooted at the q and $\bar{q}$ partons. The momenta of all intermediate lines of the tree diagrams are then uniquely determined from the final-state momenta. Hardnesses in the trees are ordered. One assigns to each splitting vertex the hardness t, the energy fractions z and $1-z$ of the two generated partons, and the azimuth ϕ of the splitting process with respect to the momentum of the incoming parton. For definiteness, we assume that z and ϕ are defined in the center-of-mass (CM) frame of the e^+e^- collision. The differential cross section for a given final state is given by the product of the differential cross section for the initial $e^+e^- \to q\bar{q}$ process, multiplied by a factor

$$\Delta_i(t_m,t_n)\frac{\alpha_S(t)}{2\pi}P_{i,jk}(z)\frac{dt_m}{t_m}dz\frac{d\phi}{2\pi} \tag{43.3}$$

for each intermediate line arising from the n^{th} and ending in the m^{th} splitting vertex. $\Delta(t_m,t_n)$ is the so-called Sudakov form factor

$$\Delta_i(t_m,t_n)=\exp\left[-\int_{t_m}^{t_n}\frac{dq^2}{q^2}\,\frac{\alpha_S(q^2)}{2\pi}\int dz\frac{d\phi}{2\pi}\sum_{jk}P_{i,jk}(z)\right]. \tag{43.4}$$

The suffixes i and jk represent the parton species of the incoming and final partons, respectively, and $P_{i,jk}(z)$ are the Altarelli-Parisi [12] splitting kernels. Notice that the endpoints on the z integration depend upon the definition of hardness. For example, in case of virtuality or transverse momentum ordering, the z integration is automatically cut-off near the extremes, see eq. (1.2). When this is not the case (as, for example, for angular ordering) an explicit cut-off on z must be introduced, corresponding to the requirement that an emission must have some minimum energy to be distinguishable from no emission. For lines originating at the primary vertex, the scale t_n is replaced by the typical scale of the primary process and for lines ending without any further splitting the scale t_m is replaced by t_0, an infrared cutoff defined by the shower hadronization scale (at which the charges are screened by hadronization) or, for an unstable particle, its width (a source cannot emit radiation with a period exceeding its lifetime).

Eq. (43.3) can be obtained by iterating formula Eq. (43.1) recursively, with two important corrections: a) the strong coupling is evaluated at a scale corresponding to the hardness of the splitting process; b) the presence of the Sudakov form factor. Both these modifications arise from the inclusion of all collinear-dominant virtual corrections.

Notice that the Sudakov form factor for a small hardness interval $\Delta_i(t,t+\delta t)$ is equal to one minus the integrated emission probability of Eq. (43.3), i.e. it can be interpreted as the probability of no emission in the interval $t, t+\delta t$. From this, it immediately follows that $\Delta_i(t_m,t_n)$ can be interpreted as the no-emission probability in the full t_m, t_n interval. This interpretation allows one to formulate the shower process as a probabilistic algorithm. We first notice that $0<\Delta_i(t_m,t_n)\leq 1$, where the upper extreme is reached for $t_m=t_n$, and the lower extreme is approached for $t_m=t_0$. Starting from each of the partons in the primary process (e.g., $e^+e^- \to q\bar{q}$), event generation then proceeds recursively as follows. Given a parton exiting a vertex with hardness t_n, (taken to be of order the annihilation scale Q^2 for the first branching) one seeks a solution of the equation $r=\Delta_i(t_m,t_n)$, with $r\in[0,1]$ a uniform random number, and solves it for the hardness of the next branching t_m. If $t_m\leq t_0$, no splitting is generated and the line is interpreted as a final parton. If $t_m > t_0$, a branching is generated at the scale t_m. Its z value and the final parton species jk are generated with a probability proportional to $P_{i,jk}(z)$. If angular correlations are neglected (see Sec. 43.1.1) the azimuth can be generated uniformly. This procedure is started with each of the primary process partons, and is applied recursively to all generated partons. It may generate an arbitrary number of partons, and it stops when no final-state partons undergo further splitting.

The four-momenta of the final-state partons are reconstructed from the momenta of the initial ones, and from the whole sequence of splitting variables, subject to overall momentum conservation. Different algorithms employ different strategies to treat recoil effects due to momentum conservation, which may be applied either locally for each splitting, or globally for the entire set of partons (a procedure called *momentum reshuffling*).

We emphasize that the shower cross sections described above can be derived from perturbative QCD by keeping only the collinear-dominant real and virtual contributions to the cross section. As such it is unpredictive for large-angle radiation. It is thus unsafe to rely upon Parton Shower Monte Carlo alone to compute backgrounds to new physics signals that are characterized by several widely separated jets.

A Shower Monte Carlo builds its final state as if it developed from an iterative process, often with each intermediate stage made available to the user. It should be remarked that the meaning of these intermediate stages is only relevant within the approximation adopted by the generator, and could also differ in different implementations.

43.1.1 *Angular correlations*

In gluon-splitting processes ($g\to q\bar{q}$, $g\to gg$) in the collinear approximation, the distribution of the split pair is not uniform in azimuth, and the Altarelli-Parisi splitting functions are recovered only after azimuthal averaging. This dependence is due to the interference of positive and negative helicity states for the gluon that undergoes splitting. Spin correlations propagate through the splitting process, and determine acausal correlations of the EPR kind [13]. A method to partially account for these effects was introduced in Ref. [14], in which the azimuthal correlation between two successive splittings is computed by averaging over polarizations. This can then be applied at each branching step. Acausal correlations are argued to be small, and are discarded with this method, that is still used in `PYTHIA` [4]. A method that fully includes spin correlation effects was later proposed [15], and has been implemented in `HERWIG` [3, 16]. For more recent developements, see refs. [17] and references therein.

43.1.2 *Initial-state radiation*

Initial-state radiation (ISR) arises because incoming particles may undergo collinear radiation before entering the hard-scattering process. In doing so, they acquire a non-vanishing transverse momentum, and their virtuality becomes negative (spacelike). In order to efficiently sample the hard collision, it turns out to be convenient to develop the ISR shower starting with the highest hardness (i.e. with the hard process) and ending with the smallest (i.e. with the incoming parton in the hadron). Unlike the case of FSR, however, hardness ordering is opposite to time ordering in the ISR case. A corresponding backwards-evolution algorithm was formulated by Sjöstrand [18], and was basically adopted in all shower models. It can be illustrated by considering a primary interaction initiated by a quark where no collinear emissions of hardness $\geq t$ have taken place, and the same process where the quark also emits a collinear gluon of hardness t. The respective cross sections are proportional to

$$\begin{aligned}&|M_q(x)|^2\mathrm{d}x f_q(x,t), \quad \text{and}\\ &|M_q(x)|^2\,\mathrm{d}x\frac{\alpha_s(t)}{2\pi}f_q(x/z,t)P_{q,qg}(z)\mathrm{d}z\frac{\mathrm{d}\phi}{2\pi}\frac{\mathrm{d}t}{t}\,.\end{aligned} \tag{43.5}$$

Here f_q is the quark PDF in the incoming hadron, x is the fraction of momentum of the incoming quark that enters the basic

process, while x/z is the fraction of momentum of the incoming quark *before* it emits the collinear gluon. The elementary *emission probability* is the ratio of the second over the first expression in Eq. (43.5). In analogy with the final state radiation case, this ratio will appear in the exponent of the Sudakov form factor, that (after the inclusion of all splitting subprocesses) is given by

$$\Delta_i^{\mathrm{ISR}}(t,t') = \exp\left[-\int_{t'}^{t}\frac{dt''}{t''}\frac{\alpha_{\mathrm{S}}(t'')}{2\pi}\int_x^1\frac{dz}{z}\sum_{jk}P_{j,ik}(z)\frac{f_j(t'',x/z)}{f_i(t'',x)}\right]. \tag{43.6}$$

Notice that there are two uses of the PDFs: they are used to compute the cross section for the basic hard process, and they control ISR via backward evolution. Since the evolution is generated with leading-logarithmic accuracy, it is acceptable to use two different PDF sets for these two tasks, provided they agree at the LO level.

In the context of GPMC evolution, each ISR emission generates a finite amount of transverse momentum. Details on how the recoils generated by these transverse "kicks" are distributed among other partons in the event, in particular the ones involved in the hard process, constitute one of the main areas of difference between existing algorithms, see Ref. [11]. An additional $\mathcal{O}(1\,\mathrm{GeV})$ of "primordial k_T" is typically added, to represent the sum of unresolved and/or non-perturbative motion below the shower cutoff scale.

43.1.3 *Soft emissions and QCD coherence*

Soft singularities arise in QCD due to the real or virtual emission of soft gluons. For example, the cross section for the emission of a soft gluon in e^+e^- annihilation into hadrons is given by

$$\begin{aligned}\mathrm{d}\sigma_{q\bar{q}g} &\approx \mathrm{d}\sigma_{q\bar{q}}C_F(4\pi\alpha_s)\left[\frac{2\,p_q\cdot p_{\bar{q}}}{p_q\cdot l\;p_{\bar{q}}\cdot l}\right]\frac{\mathrm{d}^3 l}{2l^0(2\pi)^3}\\ &= \mathrm{d}\sigma_{q\bar{q}}\frac{\alpha_s}{2\pi}C_F\frac{\mathrm{d}l^0}{l^0}\frac{\mathrm{d}\phi}{2\pi}\frac{\mathrm{d}\cos\theta}{1-\cos^2\theta},\end{aligned} \tag{43.7}$$

where p_q, $p_{\bar{q}}$ and l are the quark, antiquark and gluon momentum, and θ and ϕ are the polar and azimuthal angle of the gluon momentum with respect to the quark direction. Since the gluon is soft, we may assume that p_q and $p_{\bar{q}}$ are unaffected by the gluon emission. The soft singularity is manifest in the $\mathrm{d}l^0/l^0$ factor. Notice that also collinear singularities are present at the same time when $\theta\to 0$ and $\theta\to\pi$, corresponding to the gluon becoming collinear to either the quark or the antiquark. It is easy to check that in the collinear limits Eq. (43.7) becomes equivalent to Eq. (43.1) with $P_{q,qg}(z) = C_F 2/(1-z)$, i.e. the limiting form of $P_{q,qg}(z)$ when z approaches 1. Thus, soft singularities coexist with collinear ones, so that two potentially large logarithms can arise simultaneously due to gluon emission.

Unlike the case of collinear emission, soft emission is not tied to a single emitting particle. The amplitude for the emission of a soft gluon from an external (incoming or outgoing) line with momentum p is proportional to $p\cdot\epsilon/p\cdot l$. When squaring the amplitude, products like the one appearing in the square bracket of Eq. (43.1) arise for all pairs of external particles, with the product of a single emission amplitude with itself appearing only if $p^2>0$, i.e. for massive colored particles. Thus, interference plays here a crucial role. This is unlike the case of collinear singularities, where because of strong ordering a radiated parton cannot be collinear to more than one other parton.

It was shown in a set of publications (see Ref. [19]) that, within the conventional parton-shower formalism based on collinear factorization, the region of collinear and soft emissions can be correctly described by using the angle of the emissions as the ordering variable, rather than the virtuality, and by setting the argument of α_{S} at the splitting vertex equal to the relative parton transverse momentum after the splitting. Physically, the ordering in angle approximates the coherent interference arising from large-angle soft emission from a bunch of collinear partons. Without this effect, the particle multiplicity would grow too rapidly with energy, in conflict with e^+e^- data. For this reason, angular ordering is used as the default evolution variable in all versions of `HERWIG` (see Ref. [20]). To partially account for soft interference effects, an angular veto is imposed on the virtuality-ordered evolution in `PYTHIA` 6 [21]. In modern designs this type of fix is avoided, the soft problem being addressed from the start.

A radical alternative formulation of QCD cascades first proposed in Ref. [22] focuses upon soft emission, rather than collinear emission, as the basic splitting mechanism. It then becomes natural to consider a branching process where it is a parton pair (i.e. a dipole) rather than a single parton, that emits a soft parton. Adding a suitable correction for non-soft, collinear partons, one can simultaneously achieve the correct logarithmic structure for both the collinear and soft emissions in the so called leading color approximation, i.e. when terms suppressed by a power of the number of colors are neglected. The `ARIADNE` [23] and `VINCIA` [24] programs are based on this approach. Dipole-type showers [25] are also used by default in `SHERPA` [26] and exist as an option in `HERWIG` [27]. An alternative dipole-based model is available in `PYTHIA` and `SHERPA` via the `DIRE` [28] plugin. The $p_\perp$-ordered showers in `PYTHIA` 6 and 8 represent a hybrid, combining collinear splitting kernels with dipole kinematics [29].

43.1.4 *Resummation*

Shower Monte Carlo generators perform resummation of all-order collinear- and/or soft-enhanced perturbative contributions, and it is thus natural to compare them to QCD resummation calculations [7]. The latter start from the definition of specific infrared-safe observables, that develop towers of large logarithms in certain regions of phase space, typically organized as

$$A(\alpha_{\mathrm{S}})\exp[Lg_0(\alpha_{\mathrm{S}}L)+g_1(\alpha_{\mathrm{S}}L)+\alpha_{\mathrm{S}}g_2(\alpha_{\mathrm{S}}L)+\ldots] \tag{43.8}$$

where L is the large logarithm, α_{S} is the strong coupling constant evaluated at some hard scale. The functions A has a power expansion in α_{S} starting with a constant, and the functions g_i have a power series expansion in their argument starting with the linear term. We talk about $\mathrm{N}^n\mathrm{LL}$ accuracy if all g_i functions for $i\le n$ are fully included in the resummation formula, and the A function is given up to the order $n-1$ in α_{S}. In particular we talk about LL accuracy if the function g_0 is included, NLL accuracy if also g_1 is included. In both cases only the constant term in A is needed, while for $\mathrm{N}^2\mathrm{LL}$ (or NNLL) g_0, g_1 and g_2 are included and A is given up to order α_{S}.

In general, a dedicated resummation calculation must be performed for each new observable. The predictions of shower MCs, on the other hand, are cast in terms of complete sets of final-state momenta, on which one can evaluate any observable; i.e., the shower algorithm itself is normally independent of the specific observable(s) under study. Because of this, it is not easy to qualifying the accuracy of a shower MC using the same criteria adopted in resummation calculation. In spite of this fact, shower MCs perform generally quite well in the description of observables that require resummation. This is related to their inclusion of several universal but formally subleading aspects. There is no guarantee, however, that the shower MC should perform to a certain level of accuracy for all distributions that require resummation. Thus, a more systematic treatment of subleading effects is quite desirable.

Several studies have appeared in the literature, aiming at either improving the current shower algorithms or formulate totally new ones, in such a way that the theoretical accuracy can be discussed in more precise terms [17, 30–35]. In particular, in refs [17, 30, 31] (the PanScales collaboration), it was shown that criteria for defining the accuracy of Shower Generators can indeed be given on a quite general ground. They identified two such criteria: the first one regards the approximations to multi-parton real matrix elements generated by the shower algorithm, that are required to be accurate in the region of phase space that are relevant for $\mathrm{N}^n\mathrm{LL}$ accuracy. The second one regards the implementation of the virtual corrections, and it requires that for a large class of shape variables the shower MC must agree with the resummed calculation at the $\mathrm{N}^n\mathrm{LL}$ level. The PanScales collaboration has constructed shower algorithms that are (with some restrictions) NLL accurate according to these criteria for e^+e^- annihilation,

hadronic collisions, Deep Inelastic Scattering and Vector Boson Fusion processes (see [36] and references therein). Other NLL accurate (according to the same criteria) shower algorithms have been proposed in refs. [32] and [35].

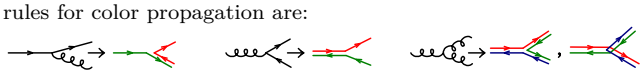
43.1.5 *Massive quarks*

Quark masses act as a cut-off on collinear singularities. If the mass of a quark is below, or of the order of Λ, its effect in the shower is small. For larger quark masses, like in c, b, or t production, it is the mass, rather than the typical hadronic scale, that cuts off collinear radiation. For a quark with energy E and mass m_Q, the divergent behavior $d\theta/\theta$ of the collinear splitting process is regulated for $\theta \leq \theta_0 = m_Q/E$. We thus expect less collinear activity for heavy quarks than for light ones, which in turn is the reason why heavy quarks carry a larger fraction of the momentum acquired in the hard production process.

This feature can be implemented with different levels of sophistication. Using the fact that soft radiation is strongly suppressed at zero emission angle, older parton shower algorithms simply limited the shower emission to be not smaller than the angle θ_0. More modern approaches are used in both `PYTHIA`, where mass effects are included using a kind of matrix-element correction method [37], and in `HERWIG` and `SHERPA`, where a generalization of the Altarelli-Parisi splitting kernel is used for massive quarks [38]. For newer approaches for QCD evolution in processes with massive partons see ref. [39] and references therein.

43.1.6 *Color information*

In event generators, quarks and antiquarks are represented by color lines, with arrows indicating the direction of color flow. In the limit of infinitely many colors (called the leading color approximation), each such line can be associated with a unique label; the probability for two quarks (or antiquarks) to have the same color (anticolor) vanishes. Moreover, in the same limit gluons can be represented by a pair of color lines with opposite arrows, as can be realized e.g. from the SU(3) group relation $8 = 3 \otimes \overline{3} \ominus 1$. The rules for color propagation are:



During the shower development, partons are connected by color lines. We can have a quark directly connected by a color line to an antiquark, or via an arbitrary number of intermediate gluons, as shown in Fig. 43.1. It is also possible for a set of gluons to be connected cyclically in color, as e.g. in the decay $\Upsilon \to ggg$. The color information is used in angular-ordered showers, where

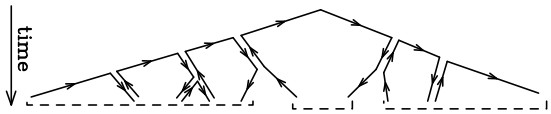


Figure 43.1: Color development of a shower in e^+e^- annihilation. Color-neutral clusters of partons are indicated by the dashed under-brackets.

the angle of color-connected partons (i.e. partons connected by the same color line) determines the initial angle for the shower development, and in dipole showers, where dipoles are formed by color-connected partons. It is also used in hadronization models, where the initial strings or clusters used for hadronization are formed by color-neutral clusters of partons.

43.1.7 *Electromagnetic (and weak) corrections*

The physics of photon emission from charged particles, and of photon splittings to pairs of charged fermions, can also be treated with a shower MC algorithm. High-energy electrons and quarks, for example, are accompanied by bremsstrahlung photons. Also here, similarly to the QCD case, electromagnetic corrections are of order $\alpha_{\rm em} \ln(Q/m)$, where m is the mass of the radiating particle, or even of order $\alpha_{\rm em} \ln(Q/m) \ln(E_\gamma/E)$ for soft γ emissions, so that, especially for the case of electrons, their inclusion in the simulation process is mandatory. This is done in most GPMCs (for a comparative study see [40]), which typically agree in collinear (DGLAP) limits but differ in whether and how soft (multipole) QED interference effects are handled. The specialized generator `PHOTOS` [41] is sometimes used as an afterburner for an improved treatment of QED radiation in non-hadronic resonance decays.

For photon emissions off leptons, the shower can be continued down to virtualities arbitrarily close to the lepton mass shell (unlike the case in QCD). In practice, an infrared cutoff is still required for the shower algorithm to terminate. Therefore, there is always an energy cut-off for emitted photons that depends upon the implementations [40]. In the case of electrons, this energy is typically of the order of its mass. Electromagnetic radiation below this scale is not enhanced by collinear singularities, and is thus bound to be soft, so that the electron momentum is not affected by it.

For photons emitted from quarks, there is instead the obvious limitation that the photon wavelength cannot exceed the typical hadronic size. Longer-wavelength photons are in fact emitted by hadrons, rather than quarks. This last effect is in practice never modeled by existing shower MC implementations. Thus, electromagnetic radiation from quarks is cut off at a typical hadronic scale. Finally, hadron (and τ) decays involving charged particles can produce additional soft bremsstrahlung. In `PYTHIA`, this is done via interfacing with `PHOTOS`, while `HERWIG` and `SHERPA` contain their own dedicated implementations [42, 43] based upon the YFS formalism [44], which is also adopted in the KKMC-hh Monte Carlo [45].

At energies significantly above the electroweak (EW) scale, showers involving emissions (and splittings) of weak gauge and Higgs bosons can also be relevant, with recent implementations based on collinear limits ranging from weak-boson emissions from fermions in `PYTHIA` 8 [46], to triple-boson couplings in `HERWIG` 7 [47], to the full set of EW branching processes in `VINCIA` [48].

43.1.8 *Beyond-the-Standard-Model Physics*

The inclusion of processes for physics beyond the Standard Model (BSM) in event generators is to some extent only a matter of implementing the relevant hard processes and (chains of) decays, with the level of difficulty depending on the complexity of the model and the degree of automation [49, 50]. Notable exceptions are long-lived colored particles [51], particles in exotic color representations, and particles showering under new gauge symmetries, with a growing set of implementations documented in the individual GPMC manuals. Further complications that may be relevant are finite-width effects (discussed in Sec. 43.1.9) and the assumed threshold behavior.

In addition to code-specific implementations [11], there are a few commonly adopted standards that are useful for transferring information and events between codes. Currently, the most important of these is the Les Houches Event File (LHEF) standard [52], normally used to transfer parton-level events from a hard-process generator to a shower generator. Another important standard is the Supersymmetry Les Houches Accord (SLHA) format [53], originally used to transfer information on supersymmetric particle spectra and couplings, but by now extended to apply also to more general BSM frameworks and incorporated within the LHEF standard [54]. Unfortunatly, at present no standard method for handling multiple shower starting scales has been define in the LHEF, so that further code, specific to the given GPMC, needs to be added to the interface in this case.

43.1.9 *Decay Chains and Particle Widths*

In most BSM processes and some SM ones, an important aspect of the event simulation is how decays of short-lived particles, such as top quarks, EW and Higgs bosons, and new BSM resonances, are handled. We here briefly summarize the spectrum of possibilities, but emphasize that there is no universal standard. Users are advised to check whether the treatment of a given code is adequate for the physics study at hand.

The appearance of an unstable resonance as a physical particle at an intermediate stage of the event generation implies that its production and decay processes are treated as being factorized. This is valid up to corrections of order Γ/m_0, with Γ the width and m_0 the pole mass. States whose widths are a substantial fraction of their mass should instead be treated as intrinsically off-shell internal propagator lines.

For states treated as physical particles, two aspects are relevant: the mass distribution of the decaying particle itself and the distributions of its decay products. For the former, matrix-element generators often use a simple δ function at m_0. The next level up, typically used in GPMCs, is to use a Breit-Wigner distribution, which formally resums higher-order virtual corrections to the mass distribution. Note, however, that this still only generates an improved picture for *moderate* fluctuations away from m_0. Similarly to above, particles that are significantly off-shell (in units of Γ) should not be treated as resonant, but rather as internal off-shell propagator lines. In most GPMCs, further refinements are included, for instance by letting Γ be a function of m ("running widths") and by limiting the magnitude of the allowed fluctuations away from m_0. We finally point out that NLO+PS generators have appeared that can deal with resonances including off-shell effects, non-resonance contributions and interference of radiation generated in resonance decay and production, see [55] and references therein. A new "interleaved" shower treatment also allows for interference between production and decay in the `VINCIA` model [48].

For the distributions of the decay products, the simplest treatment is again to assign them their respective m_0 values, with a uniform phase-space distribution. A more sophisticated treatment distributes the decay products according to the differential decay matrix elements, capturing at least the internal dynamics and helicity structure of the decay process, including EPR-like correlations. Further refinements include polarizations of the external states [56] and assigning the decay products their own Breit-Wigner distributions, the latter of which opens the possibility to include also intrinsically off-shell decay channels, like $H \to WW^*$.

GPMC manuals often give instructions on how to include new decay modes, at varying levels of sophistications ranging from simple uniform phase-space sampling (which the user can reweight a posteriori) and step-function thresholds, to fully matrix-element weighted decay implementations including potential off-shell / threshold effects.

During subsequent showering of the decay products, most parton-shower models will preserve the total invariant mass of the decayed resonance, so as not to skew the original resonance shape. In the context of passing externally generated LHEF files [52] to a GPMC for showering, note that this is only possible if the intermediate resonances are present (with status code 2) in the LHEF event record [57].

43.1.10 *Matching and Merging with Fixed-Order Matrix Elements*

Shower algorithms are based upon a combination of the collinear (small-angle) and soft (small-energy) approximations and are thus normally inaccurate for hard, wide-angle emissions (i.e., additional well-resolved jets). They also contain only the leading singular pieces of next-to-leading order (NLO) and higher corrections to the basic process.

Traditional GPMCs, like `HERWIG` and `PYTHIA`, have included for a long time the so called Matrix-Element Corrections (MEC), first formulated in Ref. [58] with later developments summarized in Ref. [11]. They are typically available for $2 \to 1$ or $1 \to 2$ processes, like DIS, vector boson and Higgs production and decays, and top decays. The MEC corrects the emission of the hardest jet at large angles, so that it becomes exact at LO. A generalization of the method to multiple emissions was formulated in [59].

Aside from MECs implemented directly in the GPMCs, the improvements on the parton-shower description of hard collisions have been made in two main directions: the so called Matrix Elements and Parton Shower matching (ME+PS from now on), and the matching of NLO calculations and Parton Showers (NLO+PS). We now discuss each of these, and then briefly summarize techniques becoming available for combining them.

The ME+PS method allows one to use tree-level matrix elements for hard, large-angle emissions. It was first formulated in the so-called CKKW paper [60], and several variants have appeared, including the CKKW-L, MLM, pseudoshower and MESS methods, see Refs. [11, 61, 62] and references therein. So called "Truncated Showers" are required [63] to maintain color coherence when interfacing to angular-ordered parton showers, and care must be taken to use consistent α_S choices for the real (ME-driven) and virtual (PS-driven) corrections [64].

In the ME+PS method one typically starts by generating LO matrix elements for the production of the basic process plus a certain number $\leq n$ of other partons. A minimum separation is imposed on the produced partons, requiring, for example, that the relative transverse momentum in any pair of partons is above a given cut $Q_{\rm cut}$. One then reweights these amplitudes in such a way that, in the strongly ordered region, the virtual effects that are included in the shower algorithm (i.e. running couplings and Sudakov form factors) are also accounted for. At this stage, before parton showers are added, the generated configurations are tree-level accurate at large angle, and at small angle they match the results of the shower algorithm, except that there are no emissions below the scale $Q_{\rm cut}$, and no final states with more than n partons. These kinematic configurations are thus fed into a GPMC, that must generate all splittings with relative transverse momentum below the scale $Q_{\rm cut}$, for initial events with less than n partons, or below the scale of the smallest pair transverse momentum, for events with n partons. The matching parameter $Q_{\rm cut}$ must be chosen to be large enough for fixed-order perturbation theory to hold, but small enough so that the shower is accurate for emissions below it. Notice that the accuracy achieved with MEC is equivalent to that of ME+PS with $n = 1$, where MEC has the advantage of not having a matching parameter $Q_{\rm cut}$.

The popularity of the ME+PS method is due to the fact that processes with many jets often appear as backgrounds to new-physics searches. These jets are typically required to be well separated, and to have large transverse momenta. These kinematic configurations are exactly those for which pure shower algorithms are unreliable, hence it is mandatory to describe them using at least LO matrix elements.

Several ME+PS implementations use existing LO generators, like `ALPGEN` [65], `MADGRAPH` [66], and others summarized in Ref. [61], for the calculation of the matrix elements, and feed the partonic events to a GPMC like `PYTHIA` or `HERWIG` using the Les Houches Interface for User Processes (LHI/LHEF) [52, 57]. `SHERPA` and `HERWIG` also include their own matrix-element generators.

The NLO+PS methods promote the accuracy of the generation of the basic process from LO to NLO in QCD. They must thus include the radiation of one extra parton with tree-level accuracy, since this radiation constitutes a NLO correction to the basic process. They must also include NLO virtual corrections. They can be viewed as an extension of the MEC methods with the inclusion of NLO virtual corrections. They are however more general, since they are applicable to processes of arbitrary complexity. Two of these methods are now widely used: MC@NLO [67] and POWHEG [63,68], with several alternative methods now also being pursued, see [69] and references therein, and the recent method presented in [70].

NLO+PS generators produce NLO accurate distributions for inclusive quantities, and generate the hardest jet with tree-level accuracy. Note also that the optimal tuning of an NLO+PS generator may well be different from that of the pure PS.

Several NLO+PS processes are implemented in the MC@NLO program [67], together with the `AMC@NLO` development [71], and in the POWHEG-BOX framework [68]. `HERWIG` supports its own variants of POWHEG and MC@NLO for several processes. `SHERPA` instead implements a variant of the MC@NLO method.

For applications that require an accurate description of more than one hard, large-angle jet associated with the primary process, ME+PS schemes are still superior to NLO+PS ones. Ideally, one would like to improve NLO generators in such a way that also the production of associated jets achieves NLO accuracy. The FXFX [72], UNLOPS [73], MiNLO [74] and `MEPS@NLO` [75] methods address this problem. The solution of this problem is also a prerequisite for the construction of NNLO+PS generators, i.e. generators that, besides being NLO accurate for the production of an associated jet, are also NNLO accurate for fully inclusive observables. Three different approaches have appeared in the literature for dealing with this problem: the UN^{2}NLOPS, based upon UNLOPS method [76]; methods extending the MiNLO ap-

proach by reweigthting [77] and by the so called MiNNLO$_{\rm PS}$ technique [78]; and the GENEVA method [79]. Several processes have been implemented with the MiNLO related and GENEVA methods, mostly for the production of color singlet systems, with the exception of the recent MiNNLO$_{\rm PS}$ implementation of $t\bar{t}$ production (see refs. [69, 80, 81] for an extensive list of references).

43.2 Hadronization Models

In the context of GPMCs, *hadronization* denotes the process by which a set of colored partons (*after* showering) is transformed into a set of "primary hadrons", which may then subsequently decay further (to "secondary hadrons"). This non-perturbative transition takes place at the *hadronization scale* $Q_{\rm had}$, which by construction is equal to the infrared cutoff of the parton shower. In the absence of a first-principles solution to the relevant dynamics, GPMCs use QCD-inspired phenomenological models to describe this transition.

An important result in "quenched" lattice QCD (see Chap. 17 of PDG book) is that the potential energy between two partons with opposite color charges grows linearly with their separation, at distances greater than about a femtometer. This is known as "linear confinement", and it forms the starting point for the *string model of hadronization*, discussed below in Sec. 43.2.1. Alternatively, a property of perturbative QCD called "preconfinement" is the basis of the *cluster model of hadronization*, discussed in Sec. 43.2.2.

A key difference between MC hadronization models and the fragmentation-function (FF) formalism used to describe inclusive hadron spectra in perturbative QCD (see Chap. 9 and Chap. 19 of PDG book) is that FFs can be defined at an arbitrary perturbative scale Q while MC hadronization models are intrinsically defined at the scale $Q_{\rm had}$. Direct comparisons are therefore only meaningful if the perturbative evolution between Q and $Q_{\rm had}$ is taken into account. FFs are calculable in pQCD, given a non-perturbative initial condition obtained by fits to hadron spectra. In the MC context, one can prove that the correct QCD evolution of the FFs arises from the shower formalism, with the hadronization model providing an explicit parameterization of the non-perturbative component. However, the MC modeling of shower and hadronization includes much more information on the final state since it is fully exclusive (i.e., it addresses all particles in the final state explicitly), while FFs only describe inclusive spectra. This exclusivity also enables MC models to make use of the color-flow information coming from the perturbative shower evolution (see Sec. 43.1.6) to determine between which partons confining potentials should arise. E.g., in the string picture, the nonperturbative limit of a QCD dipole is a string piece [82].

Given an ideal, exact hadronization model, its dependence on the scale $Q_{\rm had}$ should in principle be compensated by the corresponding scale dependence of the shower algorithm, which stops generating branchings at the scale $Q_{\rm had}$. However, due to their complicated and fully exclusive nature, it is generally not possible to enforce this compensation automatically in MC models. One must therefore be aware that the nonperturbative model parameters must be "retuned" by hand if the infrared cutoff is modified. Any other changes to the perturbative part of the calculation, such as matching to further (fixed-order or resummed) coefficients, may also necessitate a retuning. Tuning is discussed briefly in Sec. 43.4.

The impact of hadronization corrections in a GPMC can be estimated by switching off hadronization. It should be emphasized, however, that the so-called "parton level" obtained this way is not a fully universal concept. This is because $Q_{\rm had}$ is typically defined in a model-dependent way, via a cutoff in the respective shower model's evolution variable, sometimes with supplementary cutoffs, e.g., in invariant mass, $p_{\rm T}$, or the like and different tunes possibly using different numerical values for the cutoff(s). Variations of the main shower cutoff scale (e.g., by a factor of 2) may give an indication of the level of model dependence, which may be mild for sufficiently inclusive observables. Nevertheless our recommendation is to avoid correcting experimental measurements to "parton level" as the intrinsic model dependence will always imply a loss of accuracy.

43.2.1 *The String Model*

Starting from early concepts [83], several hadronization models based on strings have been proposed [11]. Of these, the most widely used today is the so-called Lund model [84, 85], implemented in `PYTHIA` [4, 5]. We concentrate on that particular model here, though many of the overall concepts would be shared by any string-inspired method.

Consider a quark and an antiquark that have a large relative momentum and which are in an overall color-singlet state, such as the $\bar{q}q$ pair produced at the end of the shower in the center of Fig. 43.1. As the charges move apart, linear confinement implies that a potential $V(r) = \kappa\, r$ is reached for large distances r. (At short distances, there is a Coulomb term $\propto 1/r$ as well, but this is neglected in the Lund string.) This potential describes a string with tension $\kappa \sim 1\,\text{GeV/fm} \sim 0.2\,\text{GeV}^2$. The physical picture is that of a color flux tube being stretched between the q and the $\bar{q}$. As the string grows, the nonperturbative creation

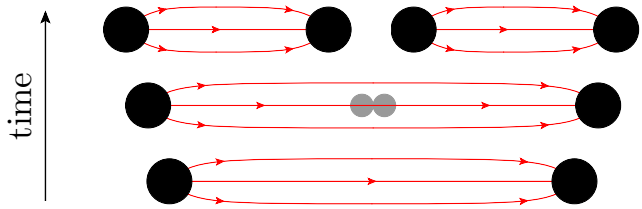

Figure 43.2: Illustration of string breaking by quark pair-creation in the string field.

of quark-antiquark pairs can break the string, via the process illustrated in Fig. 43.2. If either of the resulting string pieces after the break still has a large invariant mass, new breaks will then continue to occur until every piece has a mass of the order of that of a typical hadron. In nature, quantum mechanics ensures that these masses are (Breit-Wigner-distributed around) those of the physical hadron states in QCD, while in an algorithmic implementation, this is less trivial to impose. Within the Lund model, the constraint that each final string piece must have a mass consistent with that of physical hadron is addressed by first noting that each breakup vertex is spacelike separated from all others (the string cannot break again in the forward lightcone of a point where it has already broken); since the breakups are therefore causally disconnected, they do not have to be considered in any particular order. The Lund model exploits this to perform the fragmentation in an outwards-in manner [85], splitting off one physical hadron at a time from either the left or right endpoint (chosen randomly in each step).

The first hadron to be generated (starting either from the left or right) is thus the "outermost" one (sometimes called the "first-rank" hadron), formed by combining the original hadronizing endpoint quark (or antiquark) q_0 with an antiquark (or quark) $\bar{q}_1$ produced by the first breakup. The new leftover quark (or antiquark) q_1 becomes the string endpoint for the next iteration, in a Markov chain which continues, alternating randomly between the left and right ends of the string, until finally a small last bit of string is decayed directly to two hadrons, with no energy left over.

Not only does this allow for the hadron that is split off in each step to be assigned a physical mass, the fact that the fragmentation spectrum should be independent of whether one performs the fragmentation from left to right or vice versa places a strong constraint on the form of the nonperturbative *string fragmentation function*[1], $f(z)$, which governs the probability for the hadron produced in a given step to take a fraction $z \in [0, 1]$ of the remaining energy. Thus, in the Lund model, causality dictates that the

[1] Note that the string fragmentation function differs from the parton-to-hadron fragmentation functions discussed earlier. In principle, the two kinds should be related (with the latter evolved to a low scale of the order of the hadronization scale), but the relationship is not trivial and goes beyond the scope of this review.

fragmentation function should be of the form,

$$f(z) \propto \frac{1}{z}(1-z)^a \exp\left(-\frac{b\,(m_h^2 + p_{\mathrm{T},h}^2)}{z}\right) . \qquad (43.9)$$

This is known as the Lund symmetric fragmentation function (normalized to unit integral). The dimensionless parameter a dampens the hard tail of the fragmentation function, towards $z \to 1$, and may in principle be flavor-dependent, while b, with dimension GeV^{-2}, is a universal constant related to the string tension [85] which determines the behavior in the soft limit, $z \to 0$. Note that the dependence on the hadron mass, m_h, in $f(z)$ implies that heavier hadrons have higher $\langle z \rangle$. We return to the transverse momentum $p_{\mathrm{T},h}$ below.

The model is Lorentz invariant, so considerations involving boosted string systems are straightforward, involving the usual Lorentz effects.

As a by-product, the probability distribution in invariant time τ of $q'\bar{q}$ breakup vertices, or equivalently $\Gamma = (\kappa\tau)^2$, is also obtained, with $dP/d\Gamma \propto \Gamma^a \exp(-b\Gamma)$ implying an area law for the color flux, and the average breakup time lying along a hyperbola of constant invariant time $\tau_0 \sim 10^{-23}$s [85].

For massive endpoints (e.g. c and b quarks), which do not move along straight lightcone sections, the exponential suppression with string area leads to modifications of the form $f(z) \to f(z)/z^{b\,m_Q^2}$, with m_Q the mass of the heavy quark [86]. Although different forms, such as the Peterson formula [87], can also be used to describe inclusive heavy-meson spectra (see Sec 19.8 of PDG book), such choices are not strictly consistent with causality in the string framework.

43.2.1.1 *Strings with Gluons*

In the string model, energetic gluons lead to transverse "kinks" on strings, illustrated in Fig. 43.3. The order of these kinks follows from the color ordering produced by the parton shower, cf. the $\bar{q}gggq$ and $\bar{q}gq$ systems on the left and right part of Fig. 43.1. (Modifications to this order, by possible color reconnection/rearrangement effects, are discussed in Sec. 43.3.2.) Thus gluons

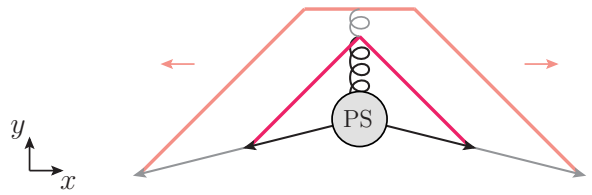

Figure 43.3: Schematic illustration of an $e^+e^- \to qg\bar{q}$ configuration emerging from the parton shower (PS). Snapshots of string positions are shown at two different times (full and shaded lines respectively). The gluon forms a transverse kink which grows in the y direction until all the gluon's kinetic energy has been used up.

effectively build up a transverse structure in the originally one-dimensional object, with infinitely soft ones smoothly absorbed into the string. Note: cyclic topologies made entirely of gluons (closed strings) are also possible, e.g. in decays such as $H \to gg$ or $\Upsilon \to ggg$. The space-time evolution is more involved when kinks are taken into account [85], but no additional free parameters need to be introduced. The main difference between quark and gluon hadronization stems from the fact that gluons are connected to two string pieces (one on either side), while quarks are only connected to a single string piece. Hence, the relative rate of energy loss per unit invariant time — and consequently also the rate of hadron production — is larger by a factor of 2 for gluons (analogously to the ratio of gluon to quark color charges $C_A/C_F = 2.25$).

43.2.1.2 *Transverse Momentum and Flavors*

For each breakup vertex, quantum mechanical tunneling is assumed to control the masses and p_{T} kicks (transverse to the string axis, in a frame in which the string itself has no transverse motion) that can be produced, leading to a Gaussian suppression

$$\mathrm{Prob}(m_q^2, p_{\mathrm{T},q}^2) \;\propto\; \exp\left(\frac{-\pi m_q^2}{\kappa}\right) \exp\left(\frac{-\pi p_{\mathrm{T},q}^2}{\kappa}\right) , \qquad (43.10)$$

where m_q is the mass of the produced quark flavor and p_{T} is the nonperturbative transverse momentum imparted to it by the breakup process, with a universal average value of $\left\langle p_{\mathrm{T},q}^2 \right\rangle = \kappa/\pi \sim (250\,\mathrm{MeV})^2$. The antiquark has the same mass and opposite p_{T}.

In an MC model with a fixed shower cutoff t_0, the effective amount of p_{T} in string breaks may be larger than the purely nonperturbative κ/π above, to account for effects of additional (unresolved) radiation below t_0.

From the mass term in Eq. (43.10), one concludes that charm and bottom quarks are too heavy to be produced in string breaks, while strange quarks will be suppressed relative to up and down ones. Lacking unambiguous and precise mass definitions for light quarks, however, the effective amount of strangeness suppression is normally extracted from experimental data, using observables such as K/π, K^*/ρ, and ϕ/K^* ratios.

Baryon production can also be incorporated, at various levels of sophistication. The simplest option is to allow string breaks to produce a diquark-antidiquark pair, where a diquark is a loosely bound states of two quarks in an overall $\bar{3}$ representation. Again, the relative rate of such pairs is extracted from data, e.g. using p/π or Λ/K ratios. Since the perturbative shower splittings do not produce diquarks, the optimal value for this parameter is mildly correlated with the amount of $g \to q\bar{q}$ splittings in the shower. More sophisticated options, including the so-called "popcorn" mechanism, are discussed in Ref. [85]. Finally, the PYTHIA framework also allows for baryon string junctions [88], in which three string pieces (which can be thought of as red, green, and blue, respectively) join together. These are used, e.g., to model the fragmentation of baryon beam remnants, and can also be created (in pairs of junctions and antijunctions) in some color-reconnection scenarios [89], making the effective baryon-to-meson ratios in such models dependent on the amount and type of color reconnections that occur in each event

The next step of the algorithm is the assignment of the produced quarks within hadron multiplets. Using a nonrelativistic classification of spin states, the hadronizing q may combine with the $\bar{q}'$ from a newly created breakup to produce a hadron of a given spin S and angular momentum L. The lowest-lying pseudoscalar and vector meson multiplets, and spin-1/2 and -3/2 baryons, are assumed to dominate in a string framework[2], but individual rates are not predicted by the model, and hence the ratios of spin-1 to spin-0 mesons and diquarks are free parameters (modulo a factor 3 from spin counting) which must be constrained by data. In that context, it is often advisable to begin with the heaviest states, since so-called feed-down from the decays of higher-lying hadron states complicates the extraction for lighter particles, see Sec. 43.2.3.

43.2.2 *The Cluster Model*

The cluster hadronization model is based on *preconfinement*, i.e., on the observation [90, 91] that the color structure of a perturbative QCD shower evolution at any scale Q_0 is such that color-singlet subsystems of partons (labeled "clusters") occur with a universal invariant mass distribution which is power suppressed at large masses. For any starting scale $Q \gg Q_0 \gg \Lambda_{\mathrm{QCD}}$, only the number of such clusters depends on Q, while the shape of their mass distribution only depends on Q_0 and on Λ_{QCD}.

Following early models based on this universality [10, 92], the cluster model developed by Webber [93] has for many years been a hallmark of the HERWIG generators, with an alternative implementation [94] now available in the SHERPA generator. The key idea, in addition to preconfinement, is to force "by hand" all gluons to split into quark-antiquark pairs at the end of the parton shower.

[2] In PYTHIA, the four $L = 1$ meson multiplets (scalar, tensor, and 2 pseudovectors) are also available but are disabled by default, since many states (and their decays) are poorly known.

Compared with the string description, this effectively amounts to viewing gluons as "seeds" for string breaks, rather than as kinks in a continuous object. After the splittings, a new set of low-mass color-singlet clusters is obtained, formed only by quark-antiquark pairs. These can be decayed to on-shell hadrons in a simple manner, with the relative yields of different hadron species mainly governed by their masses and the size of the phase space.

The algorithm starts by generating the forced $g \to q\bar{q}$ breakups, and by assigning flavors and momenta to the produced quark pairs. For a typical shower cutoff corresponding to a gluon virtuality of $Q_{\rm had} \sim 1\,\text{GeV}$, the $p_{\rm T}$ generated by the splittings can be neglected. The constituent light-quark masses, $m_{u,d} \sim 300\,\text{MeV}$ and $m_s \sim 450\,\text{MeV}$, imply a suppression (typically even an absence) of strangeness production. In principle, the model also allows for diquarks to be produced at this stage, but due to the larger constituent masses this would only become relevant for shower cutoffs larger than 1 GeV.

If a cluster formed in this way has an invariant mass above some cutoff value, typically 3–4 GeV, it is forced to undergo sequential $1 \to 2$ cluster breakups, along an axis defined by the constituent partons of the original cluster, until all sub-cluster masses fall below the cutoff value. Due to the preservation of the original axis in these breakups, this treatment has some resemblance to the string-like picture, though the nonperturbative $p_\perp$ kicks generated in this way are generally larger, up to half the allowed cluster mass.

Next, on the low-mass side of the spectrum, some clusters are allowed to decay directly to a single hadron, with nearby clusters absorbing any excess momentum. This improves the description of the high-z part of the spectrum — where the hadron carries almost all the momentum of its parent jet — at the cost of introducing one additional parameter, controlling the probability for single-hadron cluster decay.

Having obtained a final distribution of small-mass clusters, now with a strict cutoff at 3–4 GeV and with the component destined to decay to single hadrons already removed, the remaining clusters are interpreted as a smoothed-out spectrum of excited mesons, each of which decays isotropically to two hadrons, with relative probabilities proportional to the available phase space for each possible two-hadron combination that is consistent with the cluster's internal flavors, including spin degeneracy. It is important that all the light members (containing only uds) of each hadron multiplet be included, as the absence of members can lead to unphysical isospin or SU(3) flavor violation. Typically, the lightest pseudoscalar, vector, scalar, even and odd charge conjugation pseudovector, and tensor multiplets of light mesons are included. In addition, some excited vector multiplets of light mesons may be available. For baryons, usually only the lightest flavor-octet, -decuplet and -singlet baryons are present, although both the `HERWIG` and `SHERPA` implementations now include some heavier baryon multiplets as well.

Differently from the string model, the mechanism of phase-space suppression employed here leads to a natural enhancement of the lighter pseudoscalars, and no parameters beyond the spectrum of hadron masses need to be introduced at this point. The phase space also limits the transverse momenta of the produced hadrons relative to the jet axis.

Note that, since the masses and decays of excited heavy-flavor hadrons in particular are not well known, there is some freedom in the model to adjust these, which in turn will affect their relative phase-space populations.

43.2.3 *Hadron and τ Decays*

Of the so-called primary hadrons, originating directly from string breaks and/or cluster decays (see above), many are unstable and so decay further, until a set of particles is obtained that can be considered stable on time scales relevant to the given measurement. (A typical hadron-collider definition of a "stable particle" $c\tau \geq 10\,\text{mm}$ includes weakly-decaying strange hadrons K, Λ, $\Sigma^\pm$, $\bar{\Sigma}^\pm$, Ξ, Ω.) The decay modeling can therefore have a significant impact on final particle yields and spectra, especially for the lowest-lying hadronic states, which receive the largest relative contributions from decays (feed-down). This interplay also implies that hadronization parameters may need to be retuned if significant changes to the decay treatment are made.

Particle summary tables, such as those given elsewhere in this *Review*, represent a condensed summary of the available experimental measurements and hence may be incomplete and/or exhibit inconsistencies within the experimental precision. In an MC decay package, on the other hand, all information must be quantified and consistent, with all branching ratios summing to unity. When adapting particle summary information for use in a decay package, a number of choices must therefore be made. The amount of ambiguity increases as more excited hadron multiplets are added to the simulation, about which less and less is known from experiment, with each GPMC making its own choices.

A related choice is how to distribute the decay products differentially in phase space, in particular which matrix elements to use. Historically, MC generators contained matrix elements only for selected (generator-specific) classes of hadron and τ decays, coupled with a Breit-Wigner smearing of the masses, truncated at the edges of the physical decay phase space (the treatment of decay thresholds can be important for certain modes [11]). A more sophisticated treatment can then be obtained by reweighting the generated events using the obtained particle four-momenta and/or by using specialized external packages such as `EVTGEN` [95] for hadron decays and `TAUOLA` [96] for τ decays.

More recently, `HERWIG` and `SHERPA` include helicity-dependence in τ decays [6, 97], with a more limited treatment available in `PYTHIA` 8 [5]. The `HERWIG` and `SHERPA` generators have also included significantly improved internal simulations of hadronic decays, which include spin correlations between those decays for which matrix elements are used. Photon-bremsstrahlung effects are discussed in Sec. 43.1.7.

`HERWIG` and `PYTHIA` include the probability for B mesons to oscillate into $\bar{B}$ ones before decay. `SHERPA` and `EVTGEN` also include CP-violating effects and, for common decay modes of the neutral meson and its antiparticle, the interference between the direct decay and oscillation followed by decay.

We end on a note of warning on double counting. This may occur if a particle can decay via an intermediate on-shell resonance. An example is $a_1 \to \pi\pi\pi$ which may proceed via $a_1 \to \rho\pi$, $\rho \to \pi\pi$. If these decay channels of the a_1 are both included, each with their full partial width, a double counting of the on-shell $a_1 \to \rho\pi$ contribution would result. Such cases are normally dealt with consistently in the default MC generator packages, so this warning is mostly for users that wish to edit decay tables on their own.

43.3 Models for Soft Hadron-Hadron Physics

43.3.1 *Underlying Event*

In the GPMC context, "underlying event" (UE) denotes any additional activity *beyond* the basic process and its associated ISR and FSR activity. The UE is thus only defined in the context of events selected with a "hard" (i.e., high-$p_\perp$) trigger which defines the basic process at hand. The dominant contribution to the UE is believed to come from additional color exchanges between the colliding hadronic states. These multiple exchanges can be modeled either as additional perturbative (mainly t-channel gluon) exchanges, called multiple parton-parton interactions (MPI), or nonperturbatively using so-called cut pomerons (roughly equivalent to exchange of gluons with $p_\perp \to 0$). The experimental observation that events with a hard trigger are accompanied by a higher-than-average level of associated activity is called the "jet pedestal" effect.

The most clearly identifiable consequence of MPI is arguably the possibility of observing several hard parton-parton interactions in one and the same hadron-hadron event. Typically, these are QCD $2 \to 2$ interactions, which produce additional back-to-back jet pairs, with each pair having a small value of $\text{sum}(\vec{p}_\perp)$. The fraction of MPI that give rise to additional reconstructible jets is, however, small. Soft interactions, that exchange color and a small amount of momentum without giving rise to observable jets, are much more plentiful, and can give significant corrections to the color flow and total scattered energy of the event. This affects the final-state activity in a more global way, increasing hadron-multiplicity and summed E_T distributions, and contribut-

ing to the break-up of the beam remnants in the forward direction.

The first detailed Monte Carlo model for perturbative MPI was proposed in Ref. [98], and with some variation this still forms the basis for most modern implementations. Some useful additional references can be found in Ref. [11]. The first crucial observation is that the t-channel propagators appearing in perturbative QCD $2 \to 2$ scattering almost go on shell at low p_{T}, causing the differential cross sections to behave roughly as

$$d\sigma_{2\to 2} \propto \frac{dt}{t^2} \sim \frac{dp_{\mathrm{T}}{}^2}{p_{\mathrm{T}}{}^4} . \tag{43.11}$$

This cross section represents the inclusive scattering of partons against partons in perturbative QCD, summed over all partons. Thus, if a single hadron-hadron scattering contains *two* parton-parton interactions, that event will contribute twice to the parton-parton cross section $\sigma_{2\to 2}$ but only once to the hadron-hadron one σ_{tot}, and so on. In the limit that all the parton-parton interactions are independent and equivalent, one has

$$\sigma_{2\to 2} = \langle n \rangle \ \sigma_{\mathrm{tot}} , \tag{43.12}$$

with $\langle n \rangle$ the average number of parton-parton interactions, typically defined with some minimal $p_{\mathrm{T}} > p_{\perp \mathrm{min}}$ to render the parton-parton cross section finite. The probability for n parton-parton scatterings then follows a Poisson distribution,

$$\mathcal{P}_n = \langle n \rangle^n \frac{\exp\left(-\langle n \rangle\right)}{n!} . \tag{43.13}$$

This simple argument expresses unitarity; instead of the total hadron-hadron interaction cross section diverging as the parton-parton $p_{\mathrm{T}} \to 0$ (which would violate unitarity), we have restated the problem so that it is now the *number of parton-parton interactions per hadron-hadron collision* that diverges, with the total hadron-hadron cross section remaining finite. At LHC energies, the parton-parton scattering cross sections computed using the LO QCD cross section folded with modern PDFs become larger than the total pp one for $p_{\perp \mathrm{min}}$ values of order 4–5 GeV (see e.g. [99, 100]). One therefore expects the average number of perturbative MPI to exceed unity at around that scale.

Two ingredients remain to fully regulate the remaining divergence. Firstly, the interactions cannot use up more momentum than is available in the parent hadron. This suppresses the large-n tail of the estimate above. In `PYTHIA`-based models, the MPI are ordered in p_{T}, and the parton densities for each successive interaction are explicitly constructed so that the sum of x fractions can never be greater than unity. In the `HERWIG` models, the Poisson estimate of $\langle n \rangle$ above is used as an initial guess, but the generation of actual MPI is stopped once the energy-momentum conservation limit is reached. Both of these approaches generate momentum (conservation) correlations among the MPI.

The second ingredient invoked to suppress the number of interactions, at low p_{T} and x, is color screening; if the wavelength $\sim 1/p_{\mathrm{T}}$ of an exchanged colored parton becomes larger than a typical color-anticolor separation distance, it will only see an *average* color charge that vanishes in the limit $p_{\mathrm{T}} \to 0$. This provides an infrared cutoff for MPI similar to that provided by the hadronization scale for parton showers. A first estimate of the color-screening cutoff would be the proton size, $p_{\perp \mathrm{min}} \approx \hbar / r_p \approx 0.3\,\mathrm{GeV} \approx \Lambda_{\mathrm{QCD}}$, but empirically this appears to be far too low. In current models, one replaces the proton radius r_p in the above formula by a "typical color screening distance," i.e., an average size of a region within which the net compensation of a given color charge occurs. This number is not known from first principles [101] and is perceived of simply as an effective cutoff parameter. The simplest choice is to introduce a step function $\Theta(p_{\mathrm{T}} - p_{\perp \mathrm{min}})$. Alternatively, one may note that the jet cross section is divergent like $\alpha_{\mathrm{S}}^2(p_{\mathrm{T}}{}^2)/p_{\mathrm{T}}{}^4$, cf. Eq. (43.11), and that therefore a factor

$$\frac{\alpha_{\mathrm{S}}^2(p_{\mathrm{T},0}^2 + p_{\mathrm{T}}{}^2)}{\alpha_{\mathrm{S}}^2(p_{\mathrm{T}}{}^2)} \frac{p_{\mathrm{T}}{}^4}{(p_{\mathrm{T},0}^2 + p_{\mathrm{T}}{}^2)^2} \tag{43.14}$$

would smoothly regulate the divergences, now with $p_{\mathrm{T},0}$ as the free parameter. Regardless of whether it is imposed as a smooth (`PYTHIA` and `SHERPA`) or step (`HERWIG`) function, this is effectively the main "tuning" parameter in such models.

Note that the numerical value obtained for the cross section depends upon the PDF set used, and therefore the optimal value to use for the cutoff will also depend on this choice. Note also that the cutoff does not have to be energy-independent. Higher energies imply that parton densities can be probed at smaller x values, where the number of partons rapidly increases. Partons then become closer packed and the color screening distance d decreases. The uncertainty on the energy and/or x scaling of the cutoff is a major concern when extrapolating between different collider energies [102].

We now turn to the origin of the observational fact that hard jets appear to sit on top of a higher "pedestal" of underlying activity than events with no hard jets. This is interpreted as a consequence of impact-parameter-dependence: in peripheral collisions, only a small fraction of events contain any high-p_{T} activity, whereas central collisions are more likely to contain at least one hard scattering; a high-p_{T} triggered sample will therefore be biased towards small impact parameters, b. The ability of a model to describe both the UE in events with a hard trigger as well as the activity in inclusive "minimum-bias" (MB) samples (see below) therefore depends upon its modeling of the b-dependence, and correspondingly the impact-parameter shape constitutes another main tuning parameter.

For each impact parameter b, the number of interactions $\tilde{n}(b)$ can still be assumed to be distributed according to Eq. (43.13), again modulo momentum conservation, but now with the mean value of the Poisson distribution depending on impact parameter, $\langle \tilde{n}(b) \rangle$. This causes the final n-distribution (integrated over b) to be wider than a Poissonian.

Finally, there are two perturbative modeling aspects which go beyond the introduction of MPI themselves: 1) parton showers off the MPI, and 2) perturbative parton-rescattering effects. Without showers, MPI models would generate very sharp peaks for back-to-back MPI jets, caused by unshowered partons passed directly to the hadronization model. However, with the exception of the oldest `PYTHIA6` model, all GPMC models do include such showers [11], and hence should exhibit more realistic (i.e., broader and more decorrelated) MPI jets. On the initial-state side, the main questions are whether and how correlated multi-parton densities are taken into account and, as discussed previously, how the showers are regulated at low p_{T} and/or low x. Although none of the general purpose MC models currently impose a rigorous correlated multi-parton evolution, all of them include some elementary aspects. The most significant for parton-level results is arguably momentum conservation, which is enforced explicitly in all the models. The so-called "interleaved" models [29] attempt to go a step further, generating an explicitly correlated multi-parton evolution in which flavor sum rules are imposed to conserve, e.g. the total numbers of valence and sea quarks [88]. Fully correlated double-parton evolution is so far only available in the more specialised code dShower [103]; see [104] for comparisons between this and Pythia's interleaved model.

Perturbative rescattering in the final state can occur if partons are allowed to undergo several distinct interactions, with showering activity possibly taking place in-between. This has so far not been studied extensively, but a first exploratory model is available [105]. In the initial state, parton rescattering/recombination effects have so far not been included in any of the GPMC models.

43.3.2 *Bose-Einstein and Color-Reconnection Effects*

In the context of e^+e^- collisions, Bose-Einstein (BE) correlations have mostly been discussed as a source of uncertainty on high-precision W mass determinations at LEP [106]. In hadron-hadron (and nucleus-nucleus) collisions, however, BE correlations are used extensively to study the space-time structure of hadronizing matter ("femtoscopy").

In MC models of hadronization, each string break or particle/-cluster decay is normally factorized from all other ones. This reduces the number of variables that must be considered in each step, but also makes it intrinsically difficult to introduce correlations among particles from different breaks/decays. In GPMCs, a few semi-classical models are available within the `PYTHIA` 6 and

8 generators [107], in which the BE effect is mimicked by an attractive interaction between pairs of identical particles in the final state, with no higher correlations included. Variants of this model differ mainly by the assumed shape of the correlation function and how overall momentum conservation is handled.

As discussed in Sec. 43.2, leading-color ("planar") color flows are used to set up the hadronizing systems (clusters or strings) at the hadronization stage. If the systems do not overlap significantly in space and time, subleading-color ambiguities and/or nonperturbative reconnections are expected to be small. However, if the density of displaced color charges is sufficiently high that several systems can overlap significantly, full-color and/or reconnection effects should become progressively larger.

In the specific context of MPI, a crucial question is how color is neutralized *between* different MPI systems, including the remnants. The large rapidity differences involved imply large invariant masses (though normally low $p_{\rm T}$), and hence large amounts of (soft) particle production. Indeed, in the context of soft-inclusive physics, it is these "inter-system" strings/clusters that furnish the dominant particle-production mechanism, and hence their modeling is an essential part of the soft-physics description, affecting topics such as MB/UE multiplicity and $p_{\rm T}$ distributions, rapidity gaps, and precision mass measurements. Reviews of color-reconnection effects can be found in [11, 89].

43.3.3 *Minimum-Bias Events and Diffraction*

The term "minimum bias" (MB) originates from the experimental requirement of a minimal number of tracks (or hits) in a given instrumented region. In order to make MC predictions for such observables, all possible contributions to the relevant phase-space region must be accounted for. There are essentially four types of physics processes, which together make up the total hadron-hadron (hh) cross section: 1) elastic scattering[3]: $hh \to hh$, 2) single diffractive dissociation: $hh \to h + \text{gap} + X$, with X denoting anything that is not the original beam particle, and "gap" denoting a rapidity region devoid of observed activity; 3) double diffractive dissociation: $hh \to X + \text{gap} + X$, and 4) inelastic non-diffractive scattering: everything else. A fifth class may also be defined, called central diffraction ($hh \to h + \text{gap} + X + \text{gap} + h$). Note that different terminologies exist [108]: in experimental settings, diffraction is typically defined by an observable gap, of some minimal size in rapidity, while in the MC context, each diffractive physics process produces a whole spectrum of gaps, with small ones suppressed but not excluded.

The inelastic non-diffractive part of the cross section is typically modeled either by smoothly regulating and extending the perturbative QCD scattering cross sections all the way to zero $p_\perp$ [98] (`PYTHIA` and `SHERPA`), or by regulating the QCD cross sections with a sharp cutoff [109] and adding a separate class of nonperturbative scatterings below that scale [110] (`HERWIG`). See also Sec. 43.3.1. In all cases, the most important ingredients are: 1) the IR regularization of the perturbative scattering cross sections, including their PDF dependence, 2) the assumed matter distribution of the colliding hadrons, possibly including multi-parton correlations [88] and/or x dependence [111], and 3) additional soft-QCD effects such as color reconnections, discussed in Sec. 43.3.2.

Currently, there are essentially three methods for simulating diffraction in the main MC models: 1) in `PYTHIA` 6, one picks a diffractive mass according to parameterized cross sections $\propto \mathrm{d}M^2/M^2$ [112]. This mass is represented as a string, which is hadronized as described in Sec. 43.2.1, though differences in the effective scale of the hadronization may necessitate a (re)tuning of the hadronization parameters for diffraction; 2) in `PYTHIA` 8, the high-mass tail beyond $M \sim 10\,\text{GeV}$ is augmented by a partonic description in terms of pomeron PDFs [113], allowing diffractive jet production including showers and underlying event [114]; 3) the `PHOJET` and `DPMJET` programs also include central diffraction and rely directly on a formulation in terms of pomerons (color-singlet multi-gluon states) [115–117]. Cut pomerons correspond to exchanges of soft gluons while uncut ones give elastic and diffractive topologies as well as virtual corrections that help preserve unitarity. So-called "hard pomerons" provide a transition to the perturbative regime. Hadronization is still handled using the Lund string model, so there is some overlap with the above models at the hadronization stage. In addition, a pomeron-based package exists for `HERWIG` [118], and an effort is underway to construct an MC implementation of the "KMR" model [101] within the `SHERPA` generator. Color reconnections (Sec. 43.3.2) may also play a role in creating rapidity gaps and the underlying event (Sec. 43.3.1) in filling them.

[3]The QED elastic cross section diverges and is normally a non-default option.

43.4 Uncertainties and Tuning

The accuracy that can be achieved by a GPMC model depends on the sophistication of the theory models it incorporates, on the available constraints on its free parameters, and on the nature of the observable(s) under study. Using existing data to constrain the model parameters is referred to as generator tuning. Although tuned models do tend to yield improved results also for observables that they have not been tuned to, the question of evaluating the remaining uncertainties reliably is still far from solved. It is worth noting, however, that all of the GPMCs now provide options for automatic evaluation of perturbative shower uncertainties (e.g., via renormalization-scale variations), in the form of vectors of alternative event weights [119–121]. One must be aware that these variations are not necessarily exhaustive and significant weight fluctuations can be a problem for processes with large shower phase spaces. Nonperturbative uncertainties are normally still evaluated by varying salient model parameters by hand, though this looks set to change with a new method based on reweighting [122]. A general method called eigentunes [123] is also available, based on global fits to data.

Typically, the overall event properties are determined by only a few, very important parameters, such as the effective value of $\alpha_{\rm S}$, for perturbative corrections, and the shape of the fragmentation functions, for nonperturbative ones. More parameters may then be introduced to describe successively more detailed aspects (e.g., the rates and decays of individual hadron species), but these should have progressively less impact on the overall modeling. One may therefore take a factorized approach, first constraining the perturbative parameters and thereafter the nonperturbative ones, in order of decreasing significance to the overall modeling. Furthermore, by identifying which measurements are most sensitive to each parameter, this ordering can be reflected in the way that data is selected and applied to constrain the models. Thus, measurements sensitive to global event properties would typically be applied first, to constrain the most inclusive parameters, and so on for progressively more exclusive aspects. For high-$p_{\rm T}$ processes, one should be aware that if the perturbative modelling is not adequate, there is a risk that one may end up effectively mistuning nonperturbative parameters to compensate for perturbative deficiencies. This is obviously wrong and care must be taken to avoid it. E.g., it would not make sense to tune to get the right total number of hadrons unless one also gets the right total number of jets. In this context, it may be more desirable to use ratios like the number of hadrons *per jet*.

Note also that the unitarity of shower and hadronization models implies that the Born-level cross-section normalization is not tunable, hence in tuning contexts one tends to focus on the shapes of distributions rather than their normalizations.

At LO×(N)LL, perturbation theory is doing well if it agrees with an IR safe shape measurement within $\sim 10\%$. It would therefore not make much sense to tune a GPMC to agree with individual data points beyond this level. To reflect this, and to protect against overfitting, a 5% sanity limit has sometimes been enforced in tuning studies [99, 124]. The advent of NLO Monte Carlos may reduce this number slightly, but only for quantities for which one expects NLO precision. For quantities governed by nonperturbative physics, uncertainties are larger. For some quantities, e.g. ones for which the underlying modeling is known to be poor, an order-of-magnitude agreement or worse may have to be accepted.

In the context of LO×LL GPMC tuning, subleading aspects of coupling-constant and PDF choices are relevant. In particular, one should be aware that the choice of QCD Λ parameter $\Lambda_{\rm MC} = 1.569\Lambda_{\overline{\rm MS}}$ (for 5 active flavors) improves the predictions

of coherent shower algorithms at the NLL level for a class of relevant observables [125]. The question of LO vs. NLO PDFs is more involved [11], but it should be emphasized that the gluon PDF at (very) low x is important for determining the level of the underlying event in MPI models (Sec. 43.3.1), and hence the MB/UE tuning (and energy scaling [102]) is linked to the choice of PDF in such models. Further issues and an example of a specific recipe that could be followed in a realistic set-up can be found in Ref. [99]. A useful online resource can be found at the mcplots.cern.ch website [126], based on the RIVET tool [127].

Recent years have seen the emergence of automated tools to reduce the amount of both computer and manpower required for tuning [123,128,129]. Automating the human expert input is more difficult. In the tools currently on the market, this is addressed by a combination of input solicited from the GPMC authors (e.g., which parameters and ranges to consider, which observables constitute a complete set, etc) and a set of weights determining the relative priority given to each bin in each distribution. The final result is therefore still subjective but at least reproducible. Backed by careful demonstrations of sensitivities, correlations, and uncertainties, competitive tunes can be produced. The field is still burgeoning, with future sophistications to be expected.

44. Monte Carlo Neutrino Generators

Revised September 2021 by H. Gallagher (Tufts U.) and Y. Hayato (Kamioka Observatory, ICRR, UTokyo; Kavli IPMU (WPI), UTokyo).

Monte Carlo neutrino generators are programs or libraries which simulate neutrino interactions with electrons, nucleons and nuclei. In this capacity their usual task is to take an input neutrino and nucleus and produce a set of 4-vectors for particles emerging from the interaction, which are then input to full detector simulations. Since these generators have to simulate not only the initial interaction of neutrinos with target particles, but reinteractions of the generated particles in the nucleus, they contain a wide range of elementary particle and nuclear physics. Viewed more broadly, they are the access point for neutrino experimentalists to the theory inputs needed for analysis. Examples include cross section libraries for event rate calculations and parameter uncertainties and reweighting tools for systematic error evaluation.

Neutrino experiments typically operate in neutrino beams that are neither completely pure nor mono-energetic. Generators are a crucial component in the convolution of beam flux, neutrino interaction physics, and detector response that is necessary to make predictions about observable quantities. Generated events are used to define experimental analyses, like event selection criteria, for efficiency determination and background subtraction. Similarly they are used to relate reconstructed quantities back to true quantities. In these various capacities they are used from the detector design stage through the extraction of physics measurements from reconstructed observable. Monte Carlo neutrino generators play unique and important roles in the experimental study of neutrino interactions and oscillations.

There are several neutrino event generators available, such as ANIS [1], GENIE [2, 3], GiBUU [4, 5], MARLEY [6], NEGN [7], NEUT [8], NUANCE [9], the FLUKA routines NUNDIS/-NUNRES [10, 11], and NuWro [12], as well as tools to facilitate cross-generator comparisons, such as NUISANCE [13]. Historically, experiments would develop their own generators. This was often because they were focused on a particular measurement, energy range, or target, and wanted to ensure that the best physics was included for them. These 'home-grown' generators were often tuned primarily or exclusively to the neutrino data most similar to the data that the experiment would be collecting. A major advance in the field was the introduction of conference series devoted to the topic of neutrino interaction physics, NuINT (https://indico.cern.ch/event/703880/) and NuFACT (https://indico.cern.ch/event/855372/) in particular. Event generator comparisons have been a regular staple of the NuINT conference series from its inception, and a great deal of information on this topic can be found in the Proceedings of these meetings. These meetings have facilitated experiment-theory discussions leading to the first generator developed by a theory group (NuWro) [12], the extension of established nuclear interaction codes (FLUKA and GiBUU) to include neutrino-nuclear processes [4,5,10,11], and inclusion of theorists in existing generator development teams.

These activities have led to more careful scrutiny of the crucial hadron and nuclear theory inputs to these generators, which is evaluated in particular through comparisons to electron-scattering data. At this point in time all simulation codes face challenges in describing the full extent of the lepton scattering data, and the tension between incorporating the best available theory versus obtaining the best agreement with the data plays out in a variety of ways within the field. For the field to make progress, inclusion of state of the art theory needs to be coupled to global analyses that correctly incorporate correlations between measurements. Given the rapid pace of new data and the complexity of analyses, this is a significant challenge for the field in the coming years.

There are many neutrino experiments which use various sources of neutrinos, from reactors, accelerators, the atmosphere, and astrophysical sources, thereby covering a range of energies from MeV to TeV. Much of the emphasis has been on the few-GeV region in the generators, as this is the relevant energy range for short- and long-baseline neutrino oscillation experiments. These generators use the impulse approximation, which treats the nucleus as a collection of independent nucleons and the primary interaction occurs between the probe and a single nucleon, for most of the initial interaction, and subsequently simulates the interactions of secondary particles in the nucleus in semi-classical ways. Semi-classical hadron transport approaches are commonly used as they are able simulate a variety of nuclei in a single model, fully describe complex multi-particle final states, and for practical considerations as these approaches are fast. However, there are several challenges facing these simulations coming mainly from the complexity of the nuclear physics, and the need to avoid double counting in combining perturbative and non-perturbative models for the neutrino-nucleon scattering processes. The overall validity of this impulse approximation-based scheme, and in particular the importance of scattering channels that involve more than one nucleon, is a crucial question that is the topic of much current work. While generators share many common ingredients, differences in implementation, parameter values, and approaches to avoid double counting can yield dramatically different predictions [14]. In the following sections, interaction models and their implementations, including final-state interactions of hadrons produced in the nuclei, are described.

In order to assure their validity, neutrino event generators are tuned and validated against a wide variety of data. This means that the quality of the outputs from generators is limited by the quality of experimental data. The existing neutrino-nucleon and neutrino-nucleus scattering data sets are not restrictive enough to eliminate many approaches. On the other hand, there are various precise data sets, which use photon, charged lepton, and hadron probes. These data sets are extensively used to validate the generators. The results from these external data tuning exercises are important for experiments as they quantify the uncertainty on model parameters, needed by experiments in the evaluation of generator-related systematic errors. Electron scattering data plays an important role in determining the vector contribution to the form-factors and structure functions, as well as in evaluating specific aspects of the nuclear model [15, 16]. Hadron scattering data is used in validating the nuclear model, in particular of interactions between hadrons produced in the primary interaction and the residual target nucleus (final state interactions). As mentioned, tuning of neutrino-nucleon scattering and hadronization models relies heavily on the previous generation of high energy neutrino scattering and hydrogen and deuterium bubble chamber experiments. More recent data from the K2K, MiniBooNE, NOMAD, SciBooNE, MINOS, T2K, ArgoNEUT, MINERvA, NOvA, MicroBooNE, ICARUS, SBND and Ninja experiments has been, or will be, used for this purpose, although caution is advisable due to possible biases that mismodeled nuclear effects might introduce. In practice, there are often choices to be made about which models to include in an overall simulation, and which data sets to use for tuning. The process of developing a comprehensive tune in GENIE is discussed in Ref. [3].

However, all the recent experiments use nuclear targets and it is challenging to disentangle the neutrino-nucleon interaction from the effects of the nuclear environment. For example, it is difficult to separate charged current quasi-elastic scattering from the multi-nucleon quasi-elastic like scattering or single pion production, in which a pion is absorbed in the nucleus. Sometimes, there are tensions between the data sets from different experiments. Data on multi-pion and meson production are limited, but are anticipated to be measured in the near future experiments. Next generation experiments are expected to provide better detection capabilities with higher statistics and these data will help in evaluating and validating the models implemented in the generators.

44.1 Neutrino-Nucleon Scattering

Event generators typically begin with free-nucleon cross sections which are then embedded into a nuclear physics model. The most important processes are quasi-elastic (elastic for neutral current (NC)) scattering, resonance production, and non-resonant inelastic scattering, which make comparable contributions for few-GeV interactions. The neutrino cross sections in this energy range can be seen in Figure 52.1 of this *Review*.

44.1.1 *Quasi-Elastic Scattering*

The cross section for the neutrino nucleon charged current quasi-elastic scattering is described in terms of the leptonic and hadronic weak currents, where dominant contributions to the hadronic current come from the vector (V) and axial-vector (A) form factors. Contributions from the pseudo-scalar form factor (P) are typically small for muon and electron neutrinos and are related to the axial form factor (A) assuming partially conserved axial currents (PCAC). Owing to isospin symmetry, the vector form factors are related to those measured by precise electron scattering experiments [17]. Therefore, most of the generators use parametrizations of these form factors taken directly from the data. For the axial form factor there is no such precise experiment, and most of the generators use a dipole form [18]. Generally, the value of axial form factor at $q^2 = 0$ (q is the four-momentum transfer) is extracted from the polarized nucleon beta decay experiment. However, the selection of the axial vector mass parameter depends on each generator, with values typically around 1.00 GeV/c^2. Recently, there are several attempts to use the other functions for the axial form factors [19, 20] and some generators have already implemented these form factors [8, 21].

44.1.2 *Inelastic Production*

Most generators use the prescriptions of Rein-Sehgal [22] to simulate neutrino-induced single pion production, or updated versions that incorporate lepton mass terms and pion pole contributions [23,24]. To obtain the cross section for a particular channel, they calculate the amplitude for the production of each resonance multiplied by the probability for the decay of that resonance into that particular channel. Implementation differences include the number of resonances included, whether the amplitudes are added coherently or incoherently, the invariant mass range over which the model is used, how non-resonant backgrounds are included, inclusion of lepton mass terms, and the model parameter values (in particular the axial mass). In this model it is also possible to calculate the cross-sections of single photon, and η production by changing the decay probability of the resonances, which are included in some of the programs. However, it is known that discrepancies exist between the recent pion electro/photo-production data and the results from the simulation data with the same framework, i.e. vector part of this model. There are several attempts to overcome this issue [25] and some of the generators started using more appropriate form factors. Recently, there are approaches that improve the theoretical description of non-resonant contributions in the resonance region, [26–28], and which account for interference between resonant and non-resonant amplitudes. This work is expected to be implemented in the generators soon. GiBUU and NuWro generators do not use the Rein-Sehgal model, and instead rely directly on electro-production data for the vector contribution and fit bubble chamber data to determine the remaining parameters for the axial contribution [29–32]. The dynamical coupled-channel model, which has been developed to simulate various electro- and photo-meson productions, was extended to simulate the neutrino single pion production [33]. In this approach pion-nucleon scattering is used to fix the form of the axial current at $q^2 = 0$. This model is also being implemented and expected to be available in some of the generators in future.

44.1.3 *Deep and Shallow Inelastic Scattering*

For this process the fundamental target shifts from the nucleon to its quark constituents. Therefore, the generators construct the nucleon structure functions F_2 and xF_3 from parton distributions for high Q^2 (the DIS regime: $W \gtrsim 2$ GeV/c^2 and $Q^2 \gtrsim 1$ GeV^2) to calculate the direction and momentum of the lepton. The first challenge is in extending this picture to the lower values of Q^2 and W that dominate the available phase space for few-GeV interactions (the so-called 'shallow inelastic scattering', or SIS regime). GRV98LO parton distribution functions [34] with the corrections proposed in [35, 36] are widely used, while others [10] implement their own modifications to the parton distributions at low Q^2. Both DIS and SIS generate hadrons but their production depends on each generator's implementation of a hadronization model as described in the next section. There are various difficulties not only in the actual hadronization but the relation with the single meson production. It is necessary to avoid double counting between the resonance and SIS/DIS models, and all generators are different in this regard. The scheme chosen can have a significant impact on the results of simulations at a few-GeV neutrino energies. For simulating ultra-high energy interactions currently being studied with neutrino telescopes, fully partonic descriptions, which utilize beyond-leading-order pQCD calculations [37,38] are the norm [39].

44.2 Hadronization Models

For hadrons produced via baryonic resonances, the underlying model amplitudes and resonance branching fractions can be used to fully characterize the hadronic system. For shallow- and deep-inelastic scattering, a hadronization model is required. Most generators use PYTHIA [40] for this purpose, although some with modified parameters. In addition some implement their own models to handle invariant masses that are too low for PYTHIA, typically somewhere around 2.0 GeV/c^2. Such models rely heavily on measurements of neutrino hadro-production in high-resolution devices, such as bubble chambers and the CHORUS [41] and NOMAD experiments [42], to construct empirical parametrizations that reproduce the key features of the data [43, 44]. The basic ingredients are the empirical observations that average charged particle multiplicities increase logarithmically with the invariant mass of the hadronic system, and that the distribution of charged particle multiplicities about this average are described by a single function (an observation known as KNO scaling [45]). The multiplicity of the neutral particles are usually obtained by scaling the charged particle multiplicity. Simple parametrizations to more accurately reproduce differences observed in the forward/backward hemispheres of hadronic systems are included in GENIE, NEUT, and NuWro.

44.3 Nuclear Physics

The nuclear physics relevant to neutrino-nucleus scattering at few-GeV energies is complicated, involving Fermi motion, nuclear binding, Pauli blocking, in-medium modifications of form factors and hadronization, intranuclear rescattering of hadrons, and many-body scattering mechanisms including long- and short-range nucleon-nucleon correlations.

44.3.1 *Treatment of nuclear effects*

In order to obtain the cross-section off nucleons in the nucleus, it is necessary to take into account various in-medium effects. Most of the models used for neutrino-nuclear scattering kinematics were developed in the context of few-GeV inclusive electron scattering, by experiments going back nearly 50 years. The basic models employed in event generators rely on impulse approximation schemes, the most simple of which is the Relativistic Fermi Gas Model. The most common implementations have been the Smith-Moniz [46] and Bodek-Ritchie [47] models. However, the results from neutrino-nucleus scattering experiments in 2000 and afterwards, beginning with K2K, MiniBooNE have shown large discrepancies from the naive expectation from the models. Most striking differences are a suppression of forward going muons (low Q^2), a high Q^2 enhancement in the event rate, and an overall larger than expected number of observed events. In order to reproduce the data, the quasi-elastic axial mass was used as the effective parameter and increased by roughly 20% from the nominal values obtained by an earlier generation of bubble chamber experiments using hydrogen or deuterium [18]. This inconsistency between nucleon and nucleus targets suggests that the simple nuclear model is not appropriate in describing the data. Moreover, these simple Fermi-Gas models are not expected to describe the kinematical distributions of final state nucleons. Therefore, several generators have to implement better models, such as local Fermi-Gas model or more sophisticated models. Within the electron scattering community, the analogous calculations have for decades relied on spectral functions, which incorporate information about nucleon momenta and binding energies in the impulse approximation scheme [15]. Therefore, most of the generators have implemented the realistic spectral functions in their latest releases.

Actually, the discrepancies in small q^2 could not be solved alone

by just introducing the local Fermi-gas model nor spectral function models. This implies that the additional medium correction effects are needed to be taken into account. One of the implemented solutions is the local Fermi-Gas model with medium correction calculated using the random phase approximation, which is known to give large suppression in small q^2 [48, 49]. Although, the fundamental parts of the models are same, actual implementations are quite different between the generators. Especially, the constructions of the final state hadron kinematics are quite different. Especially for the quasi-elastic scattering case, treatment of the nucleon masses in the nucleus, the binding and the separation energies are sometimes quite different [50]. Recently, Super-Scaling model with relativistic mean field theory effects (SuSAv2) [51, 52] is implemented in some of the generators. Indications of the suppression in small q^2 in the single pion productions were also observed in K2K and MiniBooNE and it is clearly observed at the MINERνA and NOνA experiments. However, the models to explain the suppression have not been implemented, other than the phenomenological ones. Also, q^2 dependence of the cross-section is largely model and parameter dependent. Further studies of newly implemented single pion models may give new insights. The cause of the discrepancy of small q^2 seems to be identified but the issue of the observed interaction rates are not solved. This implies that there must be some interaction channels which are missing and not considered in the generators.

These led to a revisitation of the role played by excitation of multiple particle-hole states in the nucleus, and the experimental study of these scattering channels is an area of intense experimental interest [53]. The contribution of these scattering processes is an extremely active area of theoretical research as well, with significant implications for generators and analyses [54]. Several approaches, ranging from strictly phenomenological descriptions to full theoretical calculations, have recently been incorporated into generators [55–57]. One example of a phenomenological approach utilizes an Effective Spectral Function [58] and a Transverse Enhancement Model [59], which together encapsulate information derived from electron scattering experiments at relevant kinematics. The microscopic model of Nieves and collaborators is now available in GENIE and NEUT [60, 61]. SuSAv2 model [52] also has capability to simulate this multi-nucleon quasi-elastic like interaction and is also implemented in GENIE.

One of the challenges in incorporating full theoretical models of these processes is that they are typically slow, so generators have developed new approaches whereby much of the computation is done offline, and the generators simply read in the hadronic tensor components. This allows for a full prediction of the lepton kinematics, however the ability to simulate the hadronic component of these multinucleon states then relies on separate models. The other challenge is that the theoretical models are not designed to describe exclusive final states. These approaches, while making simulations computationally tractable, neglect correlations between the lepton and hadron kinematics. Also, there are limitations of the model itself to describe some of the kinematic regions. However, the generators need to simulate final all the state particles and thus, several assumptions are made by authors of the generators from time to time.

Also, it is known from photo and electro-nuclear scattering that the Delta width is affected by Pauli blocking and collisional broadening. These effects are included in some, but not all generators.

The remnant nucleus after the scattering is usually in an excited state. Therefore, the remnant may emit gamma-rays, additional nucleons or an alpha particle during the de-excitation process. This de-excitation gamma-ray is used in searching for proton decay in water Cherenkov detectors. Some generators have implemented this process. NEUT implemented the de-excitation process but only for Oxygen. Recently, GENIE has de-excitation processes for various nuclei.

When scattering from a nucleus, coherent scattering of various kinds is possible. Most simulations incorporate, at least, coherent neutral and charged single pion production. While the interaction rate for these interactions is typically around a percent of the total yield, the unique kinematic features of these events can make them potential backgrounds for oscillation searches. Implemented in Monte Carlo are several PCAC-based methods [62, 63]. Microscopic models, valid at lower neutrino energies [64–67], have also been implemented in several generators. One commonly used model by Rein and Sehgal [62] predicts a cross section for charged-current coherent pion production that is much larger than what is observed by K2K, MINERvA and T2K. However, the cross-section is sensitive to the pion cross-section used in the model as parameters and improved models with lepton mass correction [63] give better agreement with the recent data. This improved model is implemented in most of the generators. In addition to coherent pion production, some generators can simulate coherent single photon production [68] and coherent elastic neutrino-nucleus scattering.

44.3.2 *Hadron Production in Nuclei*

Neutrino pion production is one of the dominant neutrino scattering mechanisms in the few-GeV region and the pions produced in the nucleus have quite large interaction cross sections. Therefore, pion intranuclear scattering can have sizable effects on the results of simulations at these energies. Also, recent neutrino oscillation experiments use the observed information of protons and pions more extensively, in addition to the charged leptons. Therefore, most generators implement this physics through an intranuclear cascade simulation. In generators which utilize cascade models, a hadron, which has been formed in the nucleus, is moved step by step until it interacts with a nucleon or escapes from the nucleus. The probabilities of each interaction in nucleus are usually given as the mean free paths and used to determine whether the hadron has interacted or not. If the hadron is found to have interacted, appropriate final states are selected. Usually, absorption, elastic, charge exchange, and inelastic scatterings including particle productions are simulated as intranuclear interactions. The determination method of the kinematics for the final state particles heavily depends on the generators but most of them use experimentally validated models to simulate hadron interactions in nucleus. No two intranuclear cascade simulations implemented in neutrino event generators are the same [69]. In all cases hadrons propagate from an interaction vertex chosen based on the density distribution of the target nucleus. In determining the generated position of the hadrons in nucleus, the concept of the formation length is sometimes employed. Based on this idea, the hadronization process is not instantaneous and it takes some time before generating the hadrons [12]. The basis for formation times are measurements at relatively high energy and Q^2, and most generators that employ the concept do not apply them to resonance interactions.

GiBUU does not employ an intranuclear cascade simulation, instead, it utilizes a semi-classical transport model in coupled channels that describes the space-time evolution of a many body system in the presence of potentials and a collision term [4]. This approach assures consistency between nuclear effects in the initial state, such as Fermi motion, Pauli blocking, hadron self-energies [70], and modified cross sections, and the final state, such as particle re-interactions, since the two are derived from the same model. This model has been previously used to describe a wide variety of nuclear interaction data. Similarly, the hadronic simulation of the NUNDIS/NUNRES programs are handled by the well-established FLUKA hadronic simulation package [10]. Recently, GENIE included the interface to the external hadronic simulation package INCL++ [71].

45. Monte Carlo Particle Numbering Scheme

Revised August 2023 by A. Buckley (Glasgow U.), F. Krauss (Durham U.), S. Navas (Granada U.) and P. Richardson (Durham U.).

The Monte Carlo particle numbering scheme presented here is intended to facilitate interfacing between matrix-element generators, event generators, detector simulators, and analysis packages used in particle physics, and is widely accepted as the "industry standard". The numbering scheme was introduced in 1988 [1], and has since been revised and expanded in the light of new information on hadronic resonances, and to encompass as yet undiscovered and hypothetical particles.[1]

The general form is a 7–digit number:

$$\pm n\, n_r\, n_L\, n_{q_1}\, n_{q_2}\, n_{q_3}\, n_J\ .$$

This encodes information about the particle's spin, flavor content, and internal quantum numbers. A 9–digit extension is used specifically for tetra- and penta-quark states, and a distinct 10-digit scheme is used for encoding (hyper)nuclear states. The details are as follows:

1. Particles are given positive numbers, antiparticles negative numbers. The PDG convention for mesons is used, so that K^+ and B^+ are particles.
2. Quarks and leptons are numbered consecutively starting from 1 and 11 respectively; to do this they are first ordered by family and within families by weak isospin.
3. In composite quark systems (diquarks, mesons, and baryons) $n_{q_{1-3}}$ are quark numbers used to specify the quark content, while the rightmost digit $n_J = 2J+1$ gives the system's spin (except for the K^0_S and K^0_L). The scheme does not cover particles of spin $J > 4$.
4. Diquarks have 4-digit numbers with $n_{q_1} \geq n_{q_2}$ and $n_{q_3} = 0$.
5. The numbering of mesons is guided by the nonrelativistic (L–S decoupled) quark model, as listed in Tables 15.2, 15.3, and 15.4.
   (a) The numbers specifying the meson's quark content conform to the convention $n_{q_1} = 0$ and $n_{q_2} \geq n_{q_3}$. The special case K^0_L is the sole exception to this rule.
   (b) The quark numbers of flavorless, light (u, d, s) mesons are: 11 for the member of the isotriplet $(\pi^0, \rho^0, \ldots)$, 22 for the lighter isosinglet $(\eta, \omega, \ldots)$, and 33 for the heavier isosinglet $(\eta', \phi, \ldots)$. Since isosinglet mesons are often large mixtures of $u\bar{u} + d\bar{d}$ and $s\bar{s}$ states, 22 and 33 are assigned by mass and do not necessarily specify the dominant quark composition.
   (c) The special numbers 310 and 130 are given to the K^0_S and K^0_L respectively.
   (d) The fifth digit n_L is reserved to distinguish mesons of the same total (J) but different spin (S) and orbital (L) angular momentum quantum numbers. For $J > 0$ the numbers are: $(L, S) = (J-1, 1)$ $n_L = 0$, $(J, 0)$ $n_L = 1$, $(J, 1)$ $n_L = 2$ and $(J+1, 1)$ $n_L = 3$. For the exceptional case $J = 0$ the numbers are $(0, 0)$ $n_L = 0$ and $(1, 1)$ $n_L = 1$ (*i.e.* $n_L = L$). See Table 45.1.
   (e) If a set of physical mesons correspond to a (non-negligible) mixture of basis states, differing in their internal quantum numbers, then the lightest physical state gets the smallest basis state number. For example the $K_1(1270)$ is numbered 10313 (1^1P_1 K_{1B}) and the $K_1(1400)$ is numbered 20313 (1^3P_1 K_{1A}).
   (f) The sixth digit n_r is used to label mesons radially excited above the ground state.
   (g) Numbers have been assigned for complete $n_r = 0$ S- and P-wave multiplets, even where states remain to be identified.
   (h) In some instances assignments within the $q\bar{q}$ meson model are only tentative; here best guess assignments are made.
   (i) Many states appearing in the Meson Listings are not yet assigned within the $q\bar{q}$ model. Here $n_{q_{2-3}}$ and n_J are assigned according to the state's likely flavors and spin; all such unassigned light isoscalar states are given the flavor code 22. Within these groups $n_L = 0, 1, 2, \ldots$ is used to distinguish states of increasing mass. These states are flagged using $n = 9$. It is to be expected that these numbers will evolve as the nature of the states are elucidated. Codes are assigned to most mesons that are listed in the one-page table at the end of the Meson Summary Table as long as they have a preferred or established spin. Additional heavy meson states expected from heavy quark spectroscopy are also assigned codes.
6. The numbering of baryons is again guided by the nonrelativistic quark model, see Table 15.6. This numbering scheme is illustrated through a few examples in Table 45.2.
   (a) The numbers specifying a baryon's quark content are such that in general $n_{q_1} \geq n_{q_2} \geq n_{q_3}$.
   (b) Two states exist for $J = 1/2$ baryons containing 3 different types of quarks. In the lighter baryon $(\Lambda, \Xi, \Omega, \ldots)$ the light quarks are in an antisymmetric ($J = 0$) state while for the heavier baryon $(\Sigma^0, \Xi', \Omega', \ldots)$ they are in a symmetric ($J = 1$) state. In this situation n_{q_2} and n_{q_3} are reversed for the lighter state, so that the smaller number corresponds to the lighter baryon.
   (c) For excited baryons a scheme is adopted, where the n_r label is used to denote the excitation bands in the harmonic oscillator model, see Sec. 15.5. Using the notation employed there, n_r is given by the N-index of the D_N band identifier.
   (d) Further degeneracies of excited hadron multiplets with the same excitation number n_r and spin J are lifted by labelling such multiplets with the n_L index according to their mass, as given by its N or Δ-equivalent.
   (e) In such excited multiplets extra singlets may occur, the $\Lambda(1520)$ being a prominent example. In such cases the ordering is reversed such that the heaviest quark label is pushed to the last position: $n_{q_3} > n_{q_1} > n_{q_2}$.
7. The gluon, when considered as a gauge boson, has official number 21. In codes for glueballs, however, 9 is used to allow a notation in close analogy with that of hadrons.
8. The pomeron and odderon trajectories and a generic reggeon trajectory of states in QCD are assigned codes 990, 9990, and 110 respectively, where the final 0 indicates the indeterminate nature of the spin, and the other digits reflect the expected "valence" flavor content. We do not attempt a complete classification of all reggeon trajectories, since there is currently no need to distinguish a specific such trajectory from its lowest-lying member.
9. Two-digit numbers in the range 21–30 are provided for the Standard Model gauge and Higgs bosons.
10. Codes 81–100 are reserved for generator-specific pseudoparticles and concepts. Codes 901–930, 1901–1930, 2901–2930, and 3901–3930 are for additional components of Standard Model parton distribution functions: the latter three ranges

Table 45.1: Meson numbering logic. Here qq stands for $n_{q2}\, n_{q3}$.

	$L = J-1$, $S = 1$			$L = J$, $S = 0$			$L = J$, $S = 1$			$L = J+1$, $S = 1$		
J	code	J^{PC}	L	code	J^{PC}	L	code	J^{PC}	L	code	J^{PC}	L
0	—	—	—	00qq1	0^{-+}	0	—	—	—	10qq1	0^{++}	1
1	00qq3	1^{--}	0	10qq3	1^{+-}	1	20qq3	1^{++}	1	30qq3	1^{--}	2
2	00qq5	2^{++}	1	10qq5	2^{-+}	2	20qq5	2^{--}	2	30qq5	2^{++}	3
3	00qq7	3^{--}	2	10qq7	3^{+-}	3	20qq7	3^{++}	3	30qq7	3^{--}	4
4	00qq9	4^{++}	3	10qq9	4^{-+}	4	20qq9	4^{--}	4	30qq9	4^{++}	5

[1] The scheme was substantially updated and extended in 2012. Certain excited baryons follow the pre-2012 scheme. A further revision and/or extension of the numbering scheme is anticipated in the near future.

Table 45.2: Some examples of octet (top) and decuplet (bottom) members for the numbering scheme for excited baryons. Here qqq stands for $n_{q1}n_{q2}n_{q3}$. See the text for the definition of the notation. The numbers in parenthesis correspond to the mass of the baryons. The states marked as (?) are not experimentally confirmed.

are intended to distinguish left/ right/ longitudinal components. Codes 998 and 999 are reserved for GEANT tracking purposes.

11. The search for physics beyond the Standard Model is an active area, so these codes are also standardized as far as possible.
    (a) A standard fourth generation of fermions is included by analogy with the first three.
    (b) The graviton and the boson content of a two-Higgs-doublet scenario and of additional SU(2)×U(1) groups are found in the range 31–40.
    (c) "One-of-a-kind" exotic particles are assigned numbers in the range 41–80. The subrange 61-80 can be used for new heavier fermions in generic models, where partners to the SM fermions would have codes offset by 60. If required, however, other assignments could be made.
    (d) Fundamental supersymmetric particles are identified by adding a nonzero n to the particle number. The superpartner of a boson or a left-handed fermion has $n = 1$ while the superpartner of a right-handed fermion has $n = 2$. When mixing occurs, such as between the winos and charged Higgsinos to give charginos, or between left and right sfermions, the lighter physical state is given the smaller basis state number.
    (e) Technicolor states have $n = 3$, with technifermions treated like ordinary fermions. States which are ordinary color singlets have $n_r = 0$. Color octets have $n_r = 1$. If a state has non-trivial quantum numbers under the topcolor groups $\mathrm{SU}(3)_1 \times \mathrm{SU}(3)_2$, the quantum numbers are specified by tech,ij, where i and j are 1 or 2. n_L is then $2i + j$. The coloron, V_8, is a heavy gluon color octet and thus is 3100021.
    (f) Excited (composite) quarks and leptons are identified by setting $n = 4$ and $n_r = 0$.
    (g) Within several scenarios of new physics, it is possible to have colored particles sufficiently long-lived for color-singlet hadronic states to form around them. In the context of supersymmetric scenarios, these states are called R-hadrons, since they carry odd R-parity. R-hadron codes, defined here, should be viewed as templates for corresponding codes also in other scenarios, for any long-lived particle that is either an unflavored color octet or a flavored color triplet. The R-hadron code is obtained by combining the SUSY particle code with a code for the light degrees of freedom, with as many intermediate zeros removed from the former as required to make place for the latter at the end. (To exemplify, a sparticle $n00000n_{\tilde{q}}$ combined with quarks q_1 and q_2 obtains code $n00n_{\tilde{q}}n_{q_1}n_{q_2}n_J$.) Specifically, the new-particle spin decouples in the limit of large masses, so that the final n_J digit is defined by the spin state of the light-quark system alone. An appropriate number of n_q digits is used to define the ordinary-quark content. As usual, 9 rather than 21 is used to denote a gluon/gluino in composite states. The sign of the hadron agrees with that of the constituent new particle (a color triplet) where there is a distinct new antiparticle, and else is defined as for normal hadrons. Particle names are R with the flavor content as lower index.
    (h) A black hole in models with extra dimensions has code 5000040. Kaluza-Klein excitations in models with extra dimensions have $n = 5$ or $n = 6$, to distinquish excitations of left- or right-handed fermions or, in case of mixing, the lighter or heavier state (cf. 11d). The nonzero n_r digit gives the radial excitation number, in scenarios where the level spacing allow these to be distinguished. Should the model also contain supersymmetry, excited SUSY states would be denoted by an $n_r > 0$, with $n = 1$ or 2 as usual. Should some colored states be long-lived enough that hadrons would form around them, the coding strategy of 11g applies, with the initial two nn_r digits preserved in the combined code.
    (i) Magnetic monopoles and dyons are assumed to have one unit of Dirac monopole charge and a variable integer number $n_{q1}n_{q2}n_{q3}$ units of electric charge. Codes $411n_{q1}n_{q2}n_{q3}0$ are then used when the magnetic and electrical charge sign agree and $412n_{q1}n_{q2}n_{q3}0$ when they disagree, with the overall sign of the particle set by the magnetic charge. For now no spin information is provided.
    (j) The nature of Dark Matter (DM) is not known, and therefore a definitive classification is too early. Candidates within specific scenarios are classified therein, such as 1000022 for the lightest neutralino. Generic fundamental states can be given temporary codes in the range 51 - 60, with 51, 52 and 53 reserved for spin 0, 1/2 and 1 ones (this could also be an axion state). Generic mediators of s-channel DM pair creation of annihilation can be given codes 54 and 55 for spin 0 or 1 ones. Separate antiparticles, with negative codes, may or may not exist. More elaborate new scenarios should be constructed with $n = 5$ and $n_r = 9$.
    (k) Hidden Valley particles have $n = 4$ and $n_r = 9$, and trailing numbers in agreement with their nearest-analog standard particles, as far as possible. Thus 4900021 is the gauge boson g_v of a confining gauge field, $490000n_{q_v}$ and $490001n_{\ell_v}$ fundamental constituents charged or not under this, 4900022 is the γ_v of a non-confining field, and $4900n_{q_{v1}}n_{q_{v2}}n_J$ a Hidden Valley meson.
12. Occasionally program authors add their own states. To avoid confusion, these should be flagged by setting $nn_r = 99$.
13. Concerning the non-99 numbers, it may be noted that only quarks, excited quarks, squarks, and diquarks have $n_{q_3} = 0$; only diquarks, baryons, and the odderon have $n_{q_1} \neq 0$; and only mesons, the reggeon, and the pomeron have $n_{q_1} = 0$ and $n_{q_2} \neq 0$. Concerning mesons (not antimesons), if n_{q_1} is odd

then it labels a quark and an antiquark if even.

14. The 9-digit tetra-quark codes are $\pm 1 n_r n_L n_{q_1} n_{q_2} 0 n_{q_3} n_{q_4} n_J$. For the particle $q_1 q_2$ is a diquark and $\bar{q}_3 \bar{q}_4$ an antidiquark, sorted such that $n_{q_1} \geq n_{q_2}$, $n_{q_3} \geq n_{q_4}$, $n_{q_1} \geq n_{q_3}$, and $n_{q_2} \geq n_{q_4}$ if $n_{q_1} = n_{q_3}$. For the antiparticle, given with a negative sign, $\bar{q}_1 \bar{q}_2$ is an antidiquark and $q_3 q_4$ a diquark, with the same sorting except that either $n_{q_1} > n_{q_3}$ or $n_{q_2} > n_{q_4}$ (so that flavour-diagonal states are particles). The n_r, n_L, and n_J numbers have the same meaning as for ordinary hadrons.
15. The 9-digit penta-quark codes are $\pm 1 n_r n_L n_{q_1} n_{q_2} n_{q_3} n_{q_4} n_{q_5} n_J$, sorted such that $n_{q_1} \geq n_{q_2} \geq n_{q_3} \geq n_{q_4}$. In the particle the first four are quarks and the fifth an antiquark while the opposite holds in the antiparticle, which is given with a negative sign. The n_r, n_L, and n_J numbers have the same meaning as for ordinary hadrons.
16. Nuclear codes are given as 10-digit numbers $\pm 10 L Z Z Z A A A I$. For a (hyper)nucleus consisting of n_p protons, n_n neutrons and n_Λ Λ's, $A = n_p + n_n + n_\Lambda$ gives the total baryon number, $Z = n_p$ the total charge and $L = n_\Lambda$ the total number of strange quarks. I gives the isomer level, with $I = 0$ corresponding to the ground state and $I > 0$ to excitations, see [2], where states denoted m, n, p, q translate to $I = 1$–4. As examples, the deuteron is 1000010020 and ^{235}U is 1000922350. To avoid ambiguities, nuclear codes should not be applied to a single hadron, like p, n or Λ^0, where quark-contents-based codes already exist.

Footnotes to the tables:

$*$) Numbers or names in bold face are new or have changed since the 2020 *Review*.

a) Particulary in the third generation, the left and right sfermion states may mix, as shown.

The lighter mixed state is given the smaller number.

b) The physical $\widetilde{\chi}$ states are admixtures of the pure $\widetilde{\gamma}$, $\widetilde{Z}^0$, $\widetilde{W}^+$, $\widetilde{H}_1^0$, $\widetilde{H}_2^0$, and $\widetilde{H}^+$ states.

c) Σ^* and Ξ^* are alternate names for $\Sigma(1385)$ and $\Xi(1530)$.

47. SU(3) Isoscalar Factors and Representation Matrices

Revised August 2019 by R. Kelly (LBNL).

The most commonly used SU(3) isoscalar factors, corresponding to the singlet, octet, and decuplet content of $8 \otimes 8$ and $10 \otimes 8$, are shown at the right. The notation uses particle names to identify the coefficients, so that the pattern of relative couplings may be seen at a glance. We illustrate the use of the coefficients below. See J.J de Swart, Rev. Mod. Phys. **35**, 916 (1963) for detailed explanations and phase conventions.

A $\sqrt{\ }$ is to be understood over every integer in the matrices; the exponent 1/2 on each matrix is a reminder of this. For example, the $\Xi \to \Omega K$ element of the $10 \to 10 \otimes 8$ matrix is $-\sqrt{6}/\sqrt{24} = -1/2$.

Intramultiplet relative decay strengths may be read directly from the matrices. For example, in decuplet $\to$ octet + octet decays, the ratio of $\Omega^* \to \Xi\overline{K}$ and $\Delta \to N\pi$ partial widths is, from the $10 \to 8 \times 8$ matrix,

$$\frac{\Gamma\,(\Omega^* \to \Xi\overline{K})}{\Gamma\,(\Delta \to N\pi)} = \frac{12}{6} \times \text{ (phase space factors)} \,. \tag{47.1}$$

Including isospin Clebsch-Gordan coefficients, we obtain, *e.g.*,

$$\frac{\Gamma(\Omega^{*-} \to \Xi^0 K^-)}{\Gamma(\Delta^+ \to p\,\pi^0)} = \frac{1/2}{2/3} \times \frac{12}{6} \times p.s.f. = \frac{3}{2} \times p.s.f. \tag{47.2}$$

Partial widths for $8 \to 8 \otimes 8$ involve a linear superposition of 8_1 (symmetric) and 8_2 (antisymmetric) couplings. For example,

$$\Gamma(\Xi^* \to \Xi\pi) \sim \left(-\sqrt{\frac{9}{20}}\, g_1 + \sqrt{\frac{3}{12}}\, g_2 \right)^2 \,. \tag{47.3}$$

The relations between g_1 and g_2 (with de Swart's normalization) and the standard D and F couplings that appear in the interaction Lagrangian,

$$\mathscr{L} = -\sqrt{2}\; D\; Tr\,(\{\overline{B}, B\}M) + \sqrt{2}\; F\; Tr\,([\overline{B}, B]\,M) \;\;, \tag{47.4}$$

where $[\overline{B}, B] \equiv \overline{B}B - B\overline{B}$ and $\{\overline{B}, B\} \equiv \overline{B}B + B\overline{B}$, are

$$D = \frac{\sqrt{30}}{40}\; g_1 \;, \qquad F = \frac{\sqrt{6}}{24}\; g_2 \;. \tag{47.5}$$

Thus, for example,

$$\Gamma(\Xi^* \to \Xi\pi) \sim (F - D)^2 \sim (1 - 2\alpha)^2 \;, \tag{47.6}$$

where $\alpha \equiv F/(D + F)$. (This definition of α is de Swart's. The alternative $D/(D + F)$, due to Gell-Mann, is also used.)

The generators of SU(3) transformations, λ_a ($a = 1, 8$), are 3×3 matrices that obey the following commutation and anticommutation relationships:

$$[\lambda_a,\ \lambda_b] \equiv \lambda_a\lambda_b - \lambda_b\lambda_a = 2if_{abc}\lambda_c \tag{47.7}$$

$$\{\lambda_a,\ \lambda_b\} \equiv \lambda_a\lambda_b + \lambda_b\lambda_a = \frac{4}{3}\delta_{ab}I + 2d_{abc}\lambda_c \;, \tag{47.8}$$

where I is the 3×3 identity matrix, and δ_{ab} is the Kronecker delta symbol. The f_{abc} are odd under the permutation of any pair of indices, while the d_{abc} are even. The nonzero values are:

$\mathbf{1} \to \mathbf{8} \otimes \mathbf{8}$

$$\begin{pmatrix} \Lambda \end{pmatrix} \to \begin{pmatrix} N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \end{pmatrix} = \frac{1}{\sqrt{8}} \begin{pmatrix} 2 & 3 & -1 & -2 \end{pmatrix}^{1/2}$$

$\mathbf{8_1} \to \mathbf{8} \otimes \mathbf{8}$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \to \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ & N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ & & \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{20}} \begin{pmatrix} 9 & -1 & -9 & -1 \\ -6 & 0 & 4 & 4 & -6 \\ 2 & -12 & -4 & -2 \\ 9 & -1 & -9 & -1 \end{pmatrix}^{1/2}$$

$\mathbf{8_2} \to \mathbf{8} \otimes \mathbf{8}$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \to \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ & N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ & & \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} 3 & 3 & 3 & -3 \\ 2 & 8 & 0 & 0 & -2 \\ 6 & 0 & 0 & 6 \\ 3 & 3 & 3 & -3 \end{pmatrix}^{1/2}$$

$\mathbf{10} \to \mathbf{8} \otimes \mathbf{8}$

$$\begin{pmatrix} \Delta \\ \Sigma \\ \Xi \\ \Omega \end{pmatrix} \to \begin{pmatrix} N\pi & \Sigma K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ & \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \\ & & \Xi\overline{K} \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} -6 & 6 \\ -2 & 2 & -3 & 3 & 2 \\ 3 & -3 & 3 & 3 \\ 12 \end{pmatrix}^{1/2}$$

$\mathbf{8} \to \mathbf{10} \otimes \mathbf{8}$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \to \begin{pmatrix} \Delta\pi & \Sigma K \\ \Delta\overline{K} & \Sigma\pi & \Sigma\eta & \Xi K \\ & \Sigma\pi & \Xi K \\ \Sigma\overline{K} & \Xi\pi & \Xi\eta & \Omega K \end{pmatrix} = \frac{1}{\sqrt{15}} \begin{pmatrix} -12 & 3 \\ 8 & -2 & -3 & 2 \\ & -9 & 6 \\ 3 & -3 & -3 & 6 \end{pmatrix}^{1/2}$$

$\mathbf{10} \to \mathbf{10} \otimes \mathbf{8}$

$$\begin{pmatrix} \Delta \\ \Sigma \\ \Xi \\ \Omega \end{pmatrix} \to \begin{pmatrix} \Delta\pi & \Delta\eta & \Sigma K \\ \Delta\overline{K} & \Sigma\pi & \Sigma\eta & \Xi K \\ \Sigma\overline{K} & \Xi\pi & \Xi\eta & \Omega K \\ & \Xi\overline{K} & \Omega\eta \end{pmatrix} = \frac{1}{\sqrt{24}} \begin{pmatrix} 15 & 3 & -6 \\ 8 & 8 & 0 & -8 \\ 12 & 3 & -3 & -6 \\ & 12 & -12 \end{pmatrix}^{1/2}$$

abc	f_{abc}	abc	d_{abc}	abc	d_{abc}

367	−1/2	338	$1/\sqrt{3}$	778	$-1/(2\sqrt{3})$
458	$\sqrt{3}/2$	344	1/2	888	$-1/\sqrt{3}$
678	$\sqrt{3}/2$				

The λ_a's are

$$\lambda_1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_2 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

$$\lambda_4 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad \lambda_5 = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix} \quad \lambda_6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$

$$\lambda_7 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix} \quad \lambda_8 = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}$$

Equation (47.7) defines the Lie algebra of SU(3). A general d-dimensional representation is given by a set of $d \times d$ matrices satisfying Eq. (47.7) with the f_{abc} given above. Equation (47.8) is specific to the defining 3-dimensional representation.

48. SU(n) Multiplets and Young Diagrams

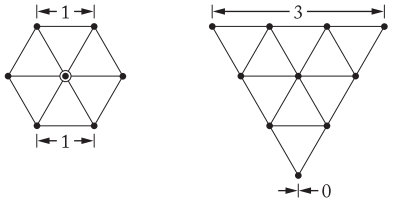
Revised August 2019 by C.G. Wohl (LBNL).

This note tells (1) how SU(n) particle multiplets are identified or labeled, (2) how to find the number of particles in a multiplet from its label, (3) how to draw the Young diagram for a multiplet, and (4) how to use Young diagrams to determine the overall multiplet structure of a composite system, such as a 3-quark or a meson-baryon system.

In much of the literature, the word "representation" is used where we use "multiplet," and "tableau" is used where we use "diagram."

48.1 Multiplet labels

An SU(n) multiplet is uniquely identified by a string of (n−1) nonnegative integers: $(\alpha, \beta, \gamma, \ldots)$. Any such set of integers specifies a multiplet. For an SU(2) multiplet such as an isospin multiplet, the single integer α is the number of *steps* from one end of the multiplet to the other (*i.e.*, it is one fewer than the number of particles in the multiplet). In SU(3), the two integers α and β are the numbers of steps across the top and bottom levels of the multiplet diagram. Thus the labels for the SU(3) octet and decuplet



are (1,1) and (3,0). For larger n, the interpretation of the integers in terms of the geometry of the multiplets, which exist in an (n−1)-dimensional space, is not so readily apparent.

The label for the SU(n) singlet is $(0, 0, \ldots, 0)$. In a flavor SU(n), the n quarks together form a $(1, 0, \ldots, 0)$ multiplet, and the n antiquarks belong to a $(0, \ldots, 0, 1)$ multiplet. These two multiplets are *conjugate* to one another, which means their labels are related by $(\alpha, \beta, \ldots) \leftrightarrow (\ldots, \beta, \alpha)$.

48.2 Number of particles

The number of particles in a multiplet, $N = N(\alpha, \beta, \ldots)$, is given as follows (note the pattern of the equations). In SU(2), $N = N(\alpha)$ is

$$N = \frac{(\alpha + 1)}{1} \ . \tag{48.1}$$

In SU(3), $N = N(\alpha, \beta)$ is

$$N = \frac{(\alpha + 1)}{1} \cdot \frac{(\beta + 1)}{1} \cdot \frac{(\alpha + \beta + 2)}{2} \ . \tag{48.2}$$

In SU(4), $N = N(\alpha, \beta, \gamma)$ is

$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\gamma+1)}{1} \cdot \frac{(\alpha+\beta+2)}{2} \cdot \frac{(\beta+\gamma+2)}{2} \cdot \frac{(\alpha+\beta+\gamma+3)}{3} \ . \tag{48.3}$$

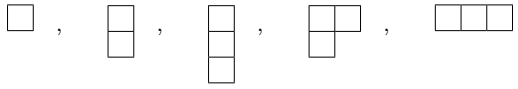
Note that in Eq. (48.3) there is no factor with $(\alpha + \gamma + 2)$: only a *consecutive* sequence of the label integers appears in any factor. One more example should make the pattern clear for any SU(n). In SU(5), $N = N(\alpha, \beta, \gamma, \delta)$ is

$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\gamma+1)}{1} \cdot \frac{(\delta+1)}{1} \cdot \frac{(\alpha+\beta+2)}{2} \cdot \frac{(\beta+\gamma+2)}{2} \times \frac{(\gamma+\delta+2)}{2} \cdot \frac{(\alpha+\beta+\gamma+3)}{3} \cdot \frac{(\beta+\gamma+\delta+3)}{3} \cdot \frac{(\alpha+\beta+\gamma+\delta+4)}{4} \ . \tag{48.4}$$

From the symmetry of these equations, it is clear that multiplets that are conjugate to one another have the same number of particles, but so can other multiplets. For example, the SU(4) multiplets (3,0,0) and (1,1,0) each have 20 particles. Try the equations and see.

48.3 Young diagrams

A Young diagram consists of an array of boxes (or some other symbol) arranged in one or more *left-justified* rows, with each row being *at least as long* as the row beneath. The correspondence between a diagram and a multiplet label is: The top row juts out α boxes to the right past the end of the second row, the second row juts out β boxes to the right past the end of the third row, *etc.* A diagram in SU(n) has at most n rows. There can be any number of "completed" columns of n boxes buttressing the left of a diagram; these don't affect the label. Thus in SU(3) the diagrams



represent the multiplets (1,0), (0,1), (0,0), (1,1), and (3,0). In any SU(n), the quark multiplet is represented by a single box, the antiquark multiplet by a column of (n−1) boxes, and a singlet by a completed column of n boxes.

48.4 Coupling multiplets together

The following recipe tells how to find the multiplets that occur in coupling two multiplets together. To couple together more than two multiplets, first couple two, then couple a third with each of the multiplets obtained from the first two, *etc.*

First a definition: A sequence of the letters $a, b, c, \ldots$ is *admissible* if at any point in the sequence at least as many a's have occurred as b's, at least as many b's have occurred as c's, *etc.* Thus *abcd* and *aabcb* are admissible sequences and *abb* and *acb* are not. Now the recipe:

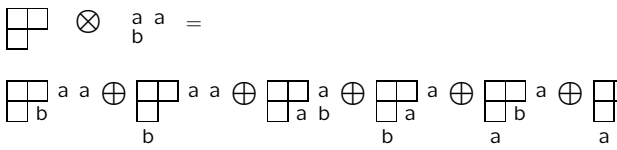
(a) Draw the Young diagrams for the two multiplets, but in one of the diagrams replace the boxes in the first row with a's, the boxes in the second row with b's, *etc.* Thus, to couple two SU(3) octets (such as the π-meson octet and the baryon octet), we start with  and  . The *unlettered* diagram forms the *upper left-hand corner* of all the enlarged diagrams constructed below.

(b) Add the a's from the lettered diagram to the right-hand ends of the rows of the unlettered diagram to form all possible legitimate Young diagrams that have no more than one a per column. In general, there will be several distinct diagrams, and all the a's appear in each diagram. At this stage, for the coupling of the two SU(3) octets, we have:

(c) Use the b's to further enlarge the diagrams already obtained, subject to the same rules. Then throw away any diagram in which the full sequence of letters formed by reading *right to left* in the first row, then the second row, *etc.*, is not admissible.

(d) Proceed as in (c) with the c's (if any), *etc.*

The final result of the coupling of the two SU(3) octets is:



Here only the diagrams with admissible sequences of a's and b's and with fewer than four rows (since $n = 3$) have been kept. In terms of multiplet labels, the above may be written

$$(1, 1) \otimes (1, 1) = (2, 2) \oplus (3, 0) \oplus (0, 3) \oplus (1, 1) \oplus (1, 1) \oplus (0, 0) \ .$$

In terms of numbers of particles, it may be written

$$\mathbf{8} \otimes \mathbf{8} = \mathbf{27} \oplus \mathbf{10} \oplus \overline{\mathbf{10}} \oplus \mathbf{8} \oplus \mathbf{8} \oplus \mathbf{1} \ .$$

The product of the numbers on the left here is equal to the sum on the right, a useful check. (See also Sec. 15 on the Quark Model.)

Kinematics, Cross-Section Formulae, and Plots

49. Kinematics

Reviewed August 2021 by D. Miller (Glasgow), D.R. Tovey (Sheffield), written January 2000 by J.D. Jackson (LBNL).

Throughout this section units are used in which $\hbar = c = 1$. The following conversions are useful: $\hbar c = 197.3$ MeV fm, $(\hbar c)^2 = 0.3894$ (GeV)^2 mb.

49.1 Lorentz transformations

The energy E and 3-momentum $\boldsymbol{p}$ of a particle of mass m form a 4-vector $p = (E, \boldsymbol{p})$ whose square $p^2 \equiv E^2 - |\boldsymbol{p}|^2 = m^2$. The velocity of the particle is $\boldsymbol{\beta} = \boldsymbol{p}/E$. The energy and momentum $(E^*, \boldsymbol{p}^*)$ viewed from a frame moving with velocity $\boldsymbol{\beta}_f$ are given by

$$\begin{pmatrix} E^* \\ p^*_\parallel \end{pmatrix} = \begin{pmatrix} \gamma_f & -\gamma_f \beta_f \\ -\gamma_f \beta_f & \gamma_f \end{pmatrix} \begin{pmatrix} E \\ p_\parallel \end{pmatrix} , \quad p^*_T = p_T , \tag{49.1}$$

where $\gamma_f = (1 - \beta_f^2)^{-1/2}$ and p_T ($p_\parallel$) are the components of $\boldsymbol{p}$ perpendicular (parallel) to $\boldsymbol{\beta}_f$. Other 4-vectors, such as the space-time coordinates of events, of course transform in the same way. The scalar product of two 4-momenta $p_1 \cdot p_2 = E_1 E_2 - \boldsymbol{p}_1 \cdot \boldsymbol{p}_2$ is invariant (frame independent).

49.2 Center-of-mass energy and momentum

In the collision of two particles of masses m_1 and m_2 the total center-of-mass energy can be expressed in the Lorentz-invariant form

$$\begin{aligned} E_{\rm cm} &= \left[(E_1 + E_2)^2 - (\boldsymbol{p}_1 + \boldsymbol{p}_2)^2\right]^{1/2} , \\ &= \left[m_1^2 + m_2^2 + 2E_1 E_2 (1 - \beta_1 \beta_2 \cos\theta)\right]^{1/2} , \end{aligned} \tag{49.2}$$

where θ is the angle between the particles. In the frame where one particle (of mass m_2) is at rest (lab frame),

$$E_{\rm cm} = (m_1^2 + m_2^2 + 2E_{1\,\rm lab}\, m_2)^{1/2} . \tag{49.3}$$

The velocity of the center-of-mass in the lab frame is

$$\boldsymbol{\beta}_{\rm cm} = \boldsymbol{p}_{\rm lab}/(E_{1\,\rm lab} + m_2) , \tag{49.4}$$

where $\boldsymbol{p}_{\rm lab} \equiv \boldsymbol{p}_{1\,\rm lab}$ and

$$\gamma_{\rm cm} = (E_{1\,\rm lab} + m_2)/E_{\rm cm} . \tag{49.5}$$

The c.m. momenta of particles 1 and 2 are of magnitude

$$p_{\rm cm} = p_{\rm lab} \frac{m_2}{E_{\rm cm}} . \tag{49.6}$$

For example, if a 0.80 GeV/c kaon beam is incident on a proton target, the center of mass energy is 1.699 GeV and the center of mass momentum of either particle is 0.442 GeV/c. It is also useful to note that

$$E_{\rm cm}\, dE_{\rm cm} = m_2\, dE_{1\,\rm lab} = m_2\, \beta_{1\,\rm lab}\, dp_{\rm lab} . \tag{49.7}$$

49.3 Lorentz-invariant amplitudes

The matrix elements for a scattering or decay process are written in terms of an invariant amplitude $-i\mathscr{M}$. As an example, the S-matrix for $2 \to 2$ scattering is related to $\mathscr{M}$ by

$$\langle p_1' p_2' \,|S-1|\, p_1 p_2\rangle = i(2\pi)^4\, \delta^4(p_1 + p_2 - p_1' - p_2')\mathscr{M}(p_1, p_2;\, p_1', p_2') . \tag{49.8}$$

The state normalization is such that

$$\langle p'|p\rangle = (2\pi)^3\, 2E_p\, \delta^3(\boldsymbol{p}' - \boldsymbol{p}) , \tag{49.9}$$

with $E_p = \sqrt{\boldsymbol{p}^2 + m^2}$.

For a $2 \to 2$ scattering process producing unstable particles $1'$ and $2'$ decaying via $1' \to 3'4'$ and $2' \to 5'6'$ the matrix element for the complete process can be written in the narrow width approximation as:

$$\begin{aligned} &\mathscr{M}(12 \to 3'4'5'6') = \\ &\sum_{h_{1'}, h_{2'}} \frac{\mathscr{M}(12 \to 1'2')\mathscr{M}(1' \to 3'4')\mathscr{M}(2' \to 5'6')}{(m^2_{3'4'} - m^2_{1'} + im_{1'}\Gamma_{1'})(m^2_{5'6'} - m^2_{2'} + im_{2'}\Gamma_{2'})} . \end{aligned} \tag{49.10}$$

Here, m_{ij} is the invariant mass of particles i and j, m_k and Γ_k are the mass and total width of particle k, and the sum runs over the helicities of the intermediate particles. This enables the cross section for such a process to be written as the product of the cross section for the initial $2 \to 2$ scattering process with the branching ratios (relative partial decay rates) of the subsequent decays. A more sophisticated treatment, beyond the narrow width approximation, can be found in the review on "Resonances".

49.4 Particle decays

The partial decay rate of a particle of mass M into n bodies in its rest frame is given in terms of the Lorentz-invariant matrix element $\mathscr{M}$ by

$$d\Gamma = \frac{(2\pi)^4}{2M} |\mathscr{M}|^2\, d\Phi_n\, (P;\, p_1, \ldots, p_n), \tag{49.11}$$

where $d\Phi_n$ is an element of n-body phase space given by

$$d\Phi_n(P;\, p_1, \ldots, p_n) = \delta^4\, (P - \sum_{i=1}^n p_i)\, \prod_{i=1}^n \frac{d^3 p_i}{(2\pi)^3 2E_i} . \tag{49.12}$$

This phase space is reduced by combinatoric factors whenever there are identical particles in the final state. The phase space can be generated recursively, viz.

$$\begin{aligned} d\Phi_n(P;\, p_1, \ldots, p_n) &= d\Phi_j(q;\, p_1, \ldots, p_j) \\ &\times\ d\Phi_{n-j+1}\, (P;\, q, p_{j+1}, \ldots, p_n)(2\pi)^3 dq^2 , \end{aligned} \tag{49.13}$$

where $q^2 = (\sum_{i=1}^j E_i)^2 - \left|\sum_{i=1}^j \boldsymbol{p}_i\right|^2$. This form is particularly useful in the case where a particle decays into another particle that subsequently decays.

49.4.1 *Survival probability*

If a particle of mass M has mean proper lifetime τ ($= 1/\Gamma$) and has momentum $(E, \boldsymbol{p})$, then the probability that it lives for a time t_0 or greater before decaying is given by

$$P(t_0) = e^{-t_0\, \Gamma/\gamma} = e^{-Mt_0\, \Gamma/E} , \tag{49.14}$$

and the probability that it travels a distance x_0 or greater is

$$P(x_0) = e^{-Mx_0\, \Gamma/|\boldsymbol{p}|} . \tag{49.15}$$

49.4.2 *Two-body decays*

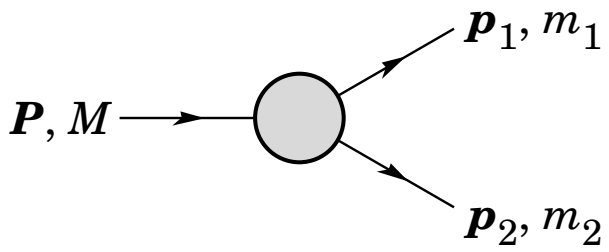


Figure 49.1: Definitions of variables for two-body decays.

In the rest frame of a particle of mass M, decaying into 2 particles labeled 1 and 2,

$$E_1 = \frac{M^2 - m_2^2 + m_1^2}{2M} , \tag{49.16}$$

$$|\boldsymbol{p}_1| = |\boldsymbol{p}_2| = \frac{1}{2M} \sqrt{\lambda(M^2, m_1^2, m_2^2)} , \tag{49.17}$$

and

$$d\Gamma = \frac{1}{32\pi^2}\,|\mathscr{M}|^2\,\frac{|\boldsymbol{p}_1|}{M^2}\,d\Omega\ , \tag{49.18}$$

where $\lambda(\alpha,\beta,\gamma) = \alpha^2+\beta^2+\gamma^2-2\alpha\beta-2\alpha\gamma-2\beta\gamma$ is the Källén function and $d\Omega = d\phi_1 d(\cos\theta_1)$ is the solid angle of particle 1. The invariant mass M can be determined from the energies and momenta using Eq. (49.2) with $M = E_{\rm cm}$.

49.4.3 *Three-body decays*

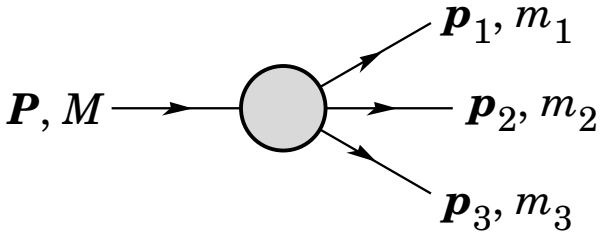

Figure 49.2: Definitions of variables for three-body decays.

Defining $p_{ij} = p_i + p_j$ and $m_{ij}^2 = p_{ij}^2$, then $m_{12}^2+m_{23}^2+m_{13}^2 = M^2+m_1^2+m_2^2+m_3^2$ and $m_{12}^2 = (P-p_3)^2 = M^2+m_3^2-2ME_3$, where E_3 is the energy of particle 3 in the rest frame of M. In that frame, the momenta of the three decay particles lie in a plane. The relative orientation of these three momenta is fixed if their energies are known. The momenta can therefore be specified in space by giving three Euler angles (α,β,γ) that specify the orientation of the final system relative to the initial particle. The direction of any one of the particles relative to the frame in which the initial particle is described can be specified in space by two angles (α,β) while a third angle, γ, can be set as the azimuthal angle of a second particle around the first [1]. Then

$$d\Gamma = \frac{1}{(2\pi)^5}\frac{1}{16M}\,|\mathscr{M}|^2\,dE_1\,dE_3\,d\alpha\,d(\cos\beta)\,d\gamma\ . \tag{49.19}$$

Alternatively

$$d\Gamma = \frac{1}{(2\pi)^5}\frac{1}{16M^2}\,|\mathscr{M}|^2\,|\boldsymbol{p}_1^*|\,|\boldsymbol{p}_3|\,dm_{12}\,d\Omega_1^*\,d\Omega_3\ , \tag{49.20}$$

where $(|\boldsymbol{p}_1^*|,\ \Omega_1^*)$ is the momentum of particle 1 in the rest frame of 1 and 2, and Ω_3 is the angle of particle 3 in the rest frame of the decaying particle. $|\boldsymbol{p}_1^*|$ and $|\boldsymbol{p}_3|$ are given by

$$|\boldsymbol{p}_1^*| = \frac{1}{2m_{12}}\sqrt{\lambda(m_{12}^2,m_1^2,m_2^2)}\ , \tag{49.21a}$$

and

$$|\boldsymbol{p}_3| = \frac{1}{2M}\sqrt{\lambda(M^2,m_{12}^2,m_3^2)}\ . \tag{49.21b}$$

[Compare with Eq. (49.17).]

If the decaying particle is a scalar, or we average over its spin states, then integration over the angles in Eq. (49.19) gives

$$\begin{aligned} d\Gamma &= \frac{1}{(2\pi)^3}\frac{1}{8M}\,\overline{|\mathscr{M}|^2}\,dE_1\,dE_3 \\ &= \frac{1}{(2\pi)^3}\frac{1}{32M^3}\,\overline{|\mathscr{M}|^2}\,dm_{12}^2\,dm_{23}^2\ . \end{aligned} \tag{49.22}$$

This is the standard form for the Dalitz plot.

49.4.3.1 *Dalitz plot*

For a given value of m_{12}^2, the range of m_{23}^2 is determined by its values when $\boldsymbol{p}_2$ is parallel or antiparallel to $\boldsymbol{p}_3$:

$$(m_{23}^2)_{\rm max} = (E_2^*+E_3^*)^2 - \left(\sqrt{E_2^{*2}-m_2^2}-\sqrt{E_3^{*2}-m_3^2}\right)^2\ , \tag{49.23a}$$

$$(m_{23}^2)_{\rm min} = (E_2^*+E_3^*)^2 - \left(\sqrt{E_2^{*2}-m_2^2}+\sqrt{E_3^{*2}-m_3^2}\right)^2\ . \tag{49.23b}$$

Here $E_2^* = (m_{12}^2-m_1^2+m_2^2)/2m_{12}$ and $E_3^* = (M^2-m_{12}^2-m_3^2)/2m_{12}$ are the energies of particles 2 and 3 in the m_{12} rest frame. The scatter plot in m_{12}^2 and m_{23}^2 is called a Dalitz plot. If $\overline{|\mathscr{M}|^2}$ is constant, the allowed region of the plot will be uniformly populated with events [see Eq. (49.22)]. A nonuniformity in the plot gives immediate information on $|\mathscr{M}|^2$. For example, in the case of $D\to K\pi\pi$, bands appear when $m_{(K\pi)} = m_{K^*(892)}$, reflecting the appearance of the decay chain $D\to K^*(892)\pi\to K\pi\pi$.

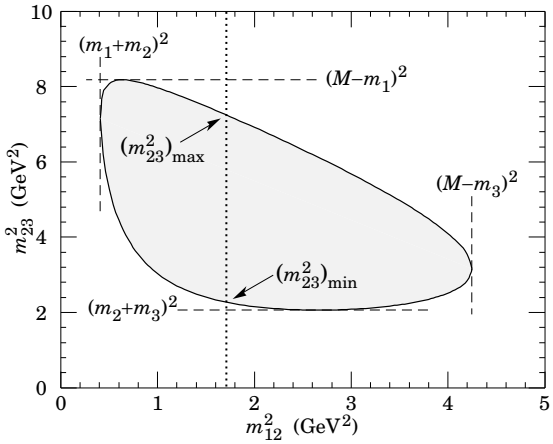

Figure 49.3: Dalitz plot for a three-body final state. In this example, the state is $\pi^+\overline{K}^0 p$ at 3 GeV. Four-momentum conservation restricts events to the shaded region.

49.4.4 *Kinematic limits*

49.4.4.1 *Three-body decays*

In a three-body decay (Fig. 49.2) the maximum of $|\boldsymbol{p}_3|$, [given by Eq. (49.21)], is achieved when $m_{12} = m_1+m_2$, *i.e.*, particles 1 and 2 have the same vector velocity in the rest frame of the decaying particle. If, in addition, $m_3 > m_1, m_2$, then $|\boldsymbol{p}_3|_{\rm max} > |\boldsymbol{p}_1|_{\rm max}$, $|\boldsymbol{p}_2|_{\rm max}$. The distribution of m_{12} values possesses an end-point or maximum value at $m_{12} = M-m_3$. This can be used to constrain the mass difference of a parent particle and one invisible decay product.

49.4.4.2 *Sequential two-body decays*

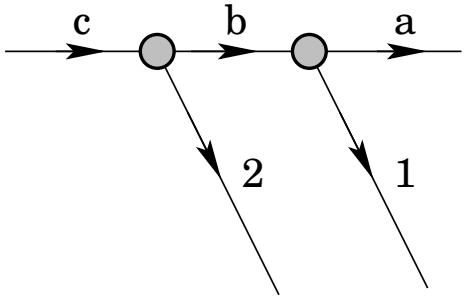

Figure 49.4: Particles participating in sequential two-body decay chain. Particles labeled 1 and 2 are visible while the particle terminating the chain (a) is invisible.

When a heavy particle initiates a sequential chain of two-body decays terminating in an invisible particle, constraints on the masses of the states participating in the chain can be obtained from end-points and thresholds in invariant mass distributions of the aggregated decay products. For the two-step decay chain depicted in Fig. 49.4 the invariant mass distribution of the two visible particles possesses an end-point given by:

$$(m_{12}^{\rm max})^2 = \frac{(m_{\rm c}^2-m_{\rm b}^2)(m_{\rm b}^2-m_{\rm a}^2)}{m_{\rm b}^2}\ , \tag{49.24}$$

provided particles 1 and 2 are massless. If visible particle 1 has non-zero mass m_1 then Eq. (49.24) is replaced by

$$(m_{12}^{\max})^2 = m_1^2 + \frac{(m_{\rm c}^2 - m_{\rm b}^2)}{2m_{\rm b}^2} \times \left(m_1^2 + m_{\rm b}^2 - m_{\rm a}^2 + \sqrt{(-m_1^2 + m_{\rm b}^2 - m_{\rm a}^2)^2 - 4m_1^2 m_{\rm a}^2} \right) \quad (49.25)$$

See Refs. [2] and [3] for other cases.

49.4.5 *Multibody decays*

The above results may be generalized to final states containing any number of particles by combining some of the particles into "effective particles" and treating the final states as 2 or 3 "effective particle" states. Thus, if $p_{ijk\ldots} = p_i + p_j + p_k + \ldots$, then

$$m_{ijk\ldots} = \sqrt{{p^2}_{ijk\ldots}} \ , \quad (49.26)$$

and $m_{ijk\ldots}$ may be used in place of *e.g.*, m_{12} in the relations in Sec. 49.4.3 or Sec. 49.4.4 above.

49.5 Cross sections

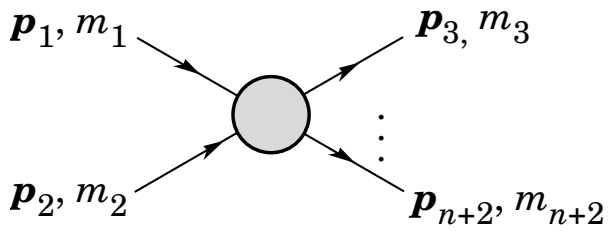

Figure 49.5: Definitions of variables for production of an n-body final state.

The differential cross section is given by

$$d\sigma = \frac{(2\pi)^4 |\mathscr{M}|^2}{4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}} \times \ d\Phi_n(p_1 + p_2;\ p_3,\ \ldots,\ p_{n+2}) \ . \quad (49.27)$$

[See Eq. (49.12).] In the rest frame of m_2(lab),

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = m_2 p_{1\,\rm lab}; \quad (49.28a)$$

while in the center-of-mass frame

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = p_{1\rm cm}\sqrt{s} \ . \quad (49.28b)$$

49.4.1 *Two-body reactions*

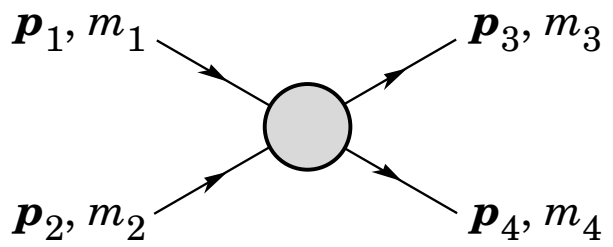

Figure 49.6: Definitions of variables for a two-body final state.

Two particles of momenta p_1 and p_2 and masses m_1 and m_2 scatter to particles of momenta p_3 and p_4 and masses m_3 and m_4; the Lorentz-invariant Mandelstam variables are defined by

$$\begin{aligned} s &= (p_1 + p_2)^2 = (p_3 + p_4)^2 \\ &= m_1^2 + 2E_1E_2 - 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_2 + m_2^2 \ , \quad (49.29) \\ t &= (p_1 - p_3)^2 = (p_2 - p_4)^2 \\ &= m_1^2 - 2E_1E_3 + 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_3 + m_3^2 \ , \quad (49.30) \\ u &= (p_1 - p_4)^2 = (p_2 - p_3)^2 \\ &= m_1^2 - 2E_1E_4 + 2\boldsymbol{p}_1 \cdot \boldsymbol{p}_4 + m_4^2 \ , \quad (49.31) \end{aligned}$$

and they satisfy

$$s + t + u = m_1^2 + m_2^2 + m_3^2 + m_4^2 \ . \quad (49.32)$$

The two-body cross section may be written as

$$\frac{d\sigma}{dt} = \frac{1}{64\pi s} \ \frac{1}{|\boldsymbol{p}_{1\rm cm}|^2} \ |\mathscr{M}|^2 \ . \quad (49.33)$$

In the center-of-mass frame

$$\begin{aligned} t &= (E_{1\rm cm} - E_{3\rm cm})^2 - (p_{1\rm cm} - p_{3\rm cm})^2 - 4p_{1\rm cm}\, p_{3\rm cm}\, \sin^2(\theta_{\rm cm}/2) \\ &= t_0 - 4p_{1\rm cm}\, p_{3\rm cm}\, \sin^2(\theta_{\rm cm}/2) \ , \end{aligned} \quad (49.34)$$

where $\theta_{\rm cm}$ is the angle between particle 1 and 3. The limiting values t_0 ($\theta_{\rm cm} = 0$) and t_1 ($\theta_{\rm cm} = \pi$) for $2 \to 2$ scattering are

$$t_0(t_1) = \left[\frac{m_1^2 - m_3^2 - m_2^2 + m_4^2}{2\sqrt{s}} \right]^2 - (p_{1\,\rm cm} \mp p_{3\,\rm cm})^2 \ . \quad (49.35)$$

In the literature the notation $t_{\min}$ ($t_{\max}$) for t_0 (t_1) is sometimes used, which should be discouraged since $t_0 > t_1$. The center-of-mass energies and momenta of the incoming particles are

$$E_{1\rm cm} = \frac{s + m_1^2 - m_2^2}{2\sqrt{s}} \ , \qquad E_{2\rm cm} = \frac{s + m_2^2 - m_1^2}{2\sqrt{s}} \ , \quad (49.36)$$

For $E_{3\rm cm}$ and $E_{4\rm cm}$, change m_1 to m_3 and m_2 to m_4. Then

$$p_{i\,\rm cm} = \sqrt{E_{i\,\rm cm}^2 - m_i^2} \text{ and } p_{1\rm cm} = \frac{p_{1\,\rm lab}\, m_2}{\sqrt{s}} \ . \quad (49.37)$$

Here the subscript lab refers to the frame where particle 2 is at rest. [For other relations see Eqs. (49.2)–(49.4).]

49.4.2 *Inclusive reactions*

Choose some direction (usually the beam direction) for the z-axis; then the energy and momentum of a particle can be written as

$$E = m_T \cosh y \ , \ p_x \ , \ p_y \ , \ p_z = m_T \sinh y \ , \quad (49.38)$$

where m_T, conventionally called the 'transverse mass', is given by

$$m_T^2 = m^2 + p_x^2 + p_y^2 \ . \quad (49.39)$$

and the rapidity y is defined by

$$\begin{aligned} y &= \frac{1}{2} \ln \left(\frac{E + p_z}{E - p_z} \right) \\ &= \ln \left(\frac{E + p_z}{m_T} \right) = \tanh^{-1} \left(\frac{p_z}{E} \right) \ . \quad (49.40) \end{aligned}$$

Note that the definition of the transverse mass in Eq. (49.39) differs from that used by experimentalists at hadron colliders (see Sec. 49.6.1 below). Under a boost in the z-direction to a frame with velocity β, $y \to y - \tanh^{-1}\beta$. Hence, the shape of the rapidity distribution dN/dy is invariant, as are differences in rapidity. The invariant cross section may also be rewritten

$$E\frac{d^3\sigma}{d^3p} = \frac{d^3\sigma}{d\phi\, dy\, p_T\, dp_T} \Longrightarrow \frac{d^2\sigma}{\pi\, dy\, d(p_T^2)} \ . \quad (49.41)$$

The second form is obtained using the identity $dy/dp_z = 1/E$, and the third form represents the average over ϕ.

Feynman's x variable is given by

$$x = \frac{p_z}{p_{z\,\max}} \approx \frac{E + p_z}{(E + p_z)_{\max}} \quad (p_T \ll |p_z|) \ . \tag{49.42}$$

In the c.m. frame,

$$x \approx \frac{2p_{z\,\mathrm{cm}}}{\sqrt{s}} = \frac{2m_T \sinh y_{\mathrm{cm}}}{\sqrt{s}} \tag{49.43}$$

and

$$= (y_{\mathrm{cm}})_{\max} = \ln(\sqrt{s}/m) \ . \tag{49.44}$$

The invariant mass M of the two-particle system described in Sec. 49.4.2 can be written in terms of these variables as

$$M^2 = m_1^2 + m_2^2 + 2[E_T(1)E_T(2)\cosh \Delta y - \boldsymbol{p}_T(1)\cdot\boldsymbol{p}_T(2)] \ , \tag{49.45}$$

where

$$E_T(i) = \sqrt{|\boldsymbol{p}_T(i)|^2 + m_i^2} \ , \tag{49.46}$$

and $\boldsymbol{p}_T(i)$ denotes the transverse momentum vector of particle i.

For $p \gg m$, the rapidity [Eq. (49.40)] may be expanded to obtain

$$\begin{aligned} y &= \frac{1}{2} \ln \frac{\cos^2(\theta/2) + m^2/4p^2 + \ldots}{\sin^2(\theta/2) + m^2/4p^2 + \ldots} \\ &\approx -\ln \tan(\theta/2) \equiv \eta \end{aligned} \tag{49.47}$$

where $\cos\theta = p_z/p$. The pseudorapidity η defined by the second line is approximately equal to the rapidity y for $p \gg m$ and $\theta \gg 1/\gamma$, and in any case can be measured when the mass and momentum of the particle are unknown. From the definition one can obtain the identities

$$\sinh\eta = \cot\theta \ , \quad \cosh\eta = 1/\sin\theta \ , \quad \tanh\eta = \cos\theta \ . \tag{49.48}$$

49.6 Transverse variables

At hadron colliders, a significant and unknown proportion of the energy of the incoming hadrons in each event escapes down the beam-pipe. Consequently, if invisible particles are created in the final state, their net momentum can only be constrained in the plane transverse to the beam direction. Defining the z-axis as the beam direction, this net momentum is equal to the missing transverse energy vector

$$\boldsymbol{E}_T^{\mathrm{miss}} = -\sum_i \boldsymbol{p}_T(i) \ , \tag{49.49}$$

where the sum runs over the transverse momenta of all visible final state particles.

49.6.1 *Single production with semi-invisible final state*

Consider a single heavy particle of mass M produced in association with visible particles which decays as in Fig. 49.1 to two particles, of which one (labeled particle 1) is invisible. The mass of the parent particle can be constrained with the quantity M_T defined by

$$\begin{aligned} M_T^2 &\equiv [E_T(1) + E_T(2)]^2 - [\boldsymbol{p}_T(1) + \boldsymbol{p}_T(2)]^2 \\ &= m_1^2 + m_2^2 + 2[E_T(1)E_T(2) - \boldsymbol{p}_T(1)\cdot\boldsymbol{p}_T(2)] \ , \end{aligned} \tag{49.50}$$

where

$$\boldsymbol{p}_T(1) = \boldsymbol{E}_T^{\mathrm{miss}} \ . \tag{49.51}$$

This quantity is called the 'transverse mass' by hadron collider experimentalists but it should be noted that it is quite different from that used in the description of inclusive reactions [Eq. (49.39)]. The distribution of event M_T values possesses an end-point at $M_T^{\max} = M$. If $m_1 = m_2 = 0$ then

$$M_T^2 = 2|\boldsymbol{p}_T(1)||\boldsymbol{p}_T(2)|(1 - \cos\phi_{12}) \ , \tag{49.52}$$

where ϕ_{ij} is defined as the angle between particles i and j in the transverse plane.

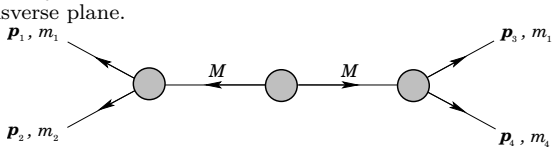

Figure 49.7: Definitions of variables for pair production of semi-invisible final states. Particles 1 and 3 are invisible while particles 2 and 4 are visible.

49.6.2 *Pair production with semi-invisible final states*

Consider two identical heavy particles of mass M produced such that their combined center-of-mass is at rest in the transverse plane (Fig. 49.7). Each particle decays to a final state consisting of an invisible particle of fixed mass m_1 together with an additional visible particle. M and m_1 can be constrained with the variables M_{T2} and M_{CT} which are defined in Refs. [4] and [5].

50. Resonances

Revised August 2023 by D.M. Asner (BNL), C. Hanhart (FZ Jülich) and M. Mikhasenko (Ruhr U. Bochum).

50.1 General Considerations

Perturbative methods can be applied to systems of quarks and gluons only for large momentum transfers (see review on 'Quantum Chromodynamics') and, under certain conditions, to some properties of systems that contain heavy quarks or very large momentum scales (see review on "Heavy-quark and soft-collinear effective theory"). Dealing with Quantum Chromodynamics (QCD) in the low momentum transfer region is a very complicated, non-perturbative problem. Most hadrons are resonances, which means that they appear as poles of the $\mathcal{S}$-matrix in the complex plane on unphysical sheets, a notion further detailed in Sec. 50.2. These resonances can show up either in so-called formation experiments,

$$A + B \to \mathbf{R} \to C_1 + ... + C_n \ ,$$

where they become visible in an energy scan (for example, the R-function measured in e^+e^- annihilation, *cf.* the corresponding plots in the review on "Plots of Cross Sections and Related Quantities"), or together with a spectator particle S in production experiments of the kind

$$\begin{aligned} A + B \to \mathbf{R} + S \to [C_1 + ... + C_n] + S \ , \\ Z \to \mathbf{R} + S \to [C_1 + ... + C_n] + S \ , \end{aligned}$$

where the first reaction corresponds to an associated production, the second is a decay (see "Review of Multibody Charm Analyses"). In the latter case, the resonance properties are commonly extracted from a Dalitz-plot analysis (see review on "Kinematics") or projections thereof.

Resonance phenomena are very rich: while typical hadronic widths are of the order of 100 MeV (*e.g.*, for the meson resonances $\rho(770)$ or $\psi(4040)$ or the baryon resonance $\Delta(1232)$) corresponding to a lifetime of 10^{-23} s, the widths can also be as small as a few MeV (*e.g.* of $\phi(1020)$ or J/ψ) or as large as several hundred MeV (*e.g.* of the meson resonances $f_0(500)$ or $D_1(2430)$ or the baryon resonance $N(2190)$).

Typically, a resonance appears as a peak in the total cross section. If the structure is narrow and if there are no relevant thresholds or other resonances nearby, the resonance properties may be extracted employing a Breit–Wigner parameterization, if necessary improved by using an energy-dependent width (*cf.* Sec. 50.3.1 of this review). However, in general, unitarity and analyticity call for the use of more refined tools as outlined here as well as in recent review articles [1, 2]. When there are overlapping resonances with the same quantum numbers, the resonance terms should not simply be added but combined in a non-trivial way either in a $\mathcal{K}$-matrix approach (*cf.* Sec. 50.3.2 of this review) or using other advanced methods (*cf.* Sec. 50.3.5 of this review). Additional constraints from the $\mathcal{S}$-matrix allow one to build more reliable amplitudes and, in turn, to reduce the systematic uncertainties of the resonance parameters: pole locations and residues. In addition, for broad resonances there is no direct relation between pole location and the total width/lifetime — then, the pole residues need to be used in order to quantify the decay properties.

For simplicity, throughout this review the formulas are given for resonances in a system of distinguishable, scalar particles. The additional complications that appear in the presence of spins can be controlled in the helicity framework developed by Jacob and Wick [3], or in a non-covariant [4] or covariant [5] tensor-operator formalisms. Within these approaches, sequential (cascade) decays are commonly treated as a coherent sum of two-body interactions. Most of the expressions below are given for two-body kinematics.

50.1.1 *Properties of the $\mathcal{S}$-matrix*

The unitary operator that connects asymptotic *in* and *out* states is called the $\mathcal{S}$-matrix. The scattering amplitude is defined as the interacting part of the $\mathcal{S}$-matrix. For a two-particles scattering process, it reads:

$$\begin{aligned} i(2\pi)^4\delta^4(p_1 + p_2 - p_{1'} - p_{2'})\,\mathcal{M}(p_1, p_2; p_{1'}, p_{2'})_{ba} \\ = {}_{\text{out}}\langle p_{1'}p_{2'}, b|\,\mathcal{S} - 1\,|p_1p_2, a\rangle_{\text{in}} \end{aligned} \tag{50.1}$$

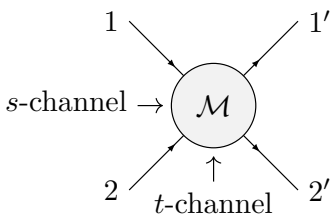

Figure 50.1: Illustration of the relation between s- and t-channel.

where $|p_1p_2, a\rangle$ and $|p_{1'}p_{2'}, b\rangle$ are asymptotic states that can be treated as non-interacting particles in the spirit of the LSZ-reduction [6]. They carry the momenta p_1, p_2 and $p_{1'}$, $p_{2'}$, respectively.

The labels a and b are used to specify the *reaction channels*. In general terms, a reaction channel describes the possible outcome of a scattering event, characterized by the quantum numbers of the particles involved. Note, that in general $\mathcal{M}$ operates as a matrix in channel space, connecting the different asymptotic multi-particle states. For a single-particle state, we employ the relativistic normalization,

$$\left\langle p'|p\right\rangle = (2\pi)^3 2E_p\,\delta^3(\vec{p}\,' - \vec{p}), \tag{50.2}$$

with $E_p = \sqrt{\vec{p}^{\,2} + m^2}$.

Mandelstam variables are defined as $s = (p_1 + p_2)^2$, $t = (p_1 - p_{1'})^2$, and $u = (p_1 - p_{2'})^2$. One finds that the the variables s, t, and u are not independent, since

$$s + t + u = m_1^2 + m_2^2 + m_{1'}^2 + m_{2'}^2$$

holds, where m_i with $i \in 1, 1', 2, 2'$ represents the masses of the involved particles. As a result, the reaction amplitude can be expressed as a function of two variables, $\mathcal{M}(s, t)$.

The Mandelstam variables play a crucial role in characterizing particle scattering. Specifically, the process described in Eq. (50.1) is known as *s-channel*, referring to a reaction, $1, 2 \to 1', 2'$. Here, $\sqrt{s}$ represents the total energy of the interacting system in the center-of-momentum frame. The variable t corresponds to the *momentum transfer*, which is related to the scattering angle, the angle between the momenta of particles 1 and $1'$ in the center-of-momentum frame (see also the review on "Kinematics" in this Review of Particle Physics). The scattering process with particles 1 and the antiparticle of $1'$, denoted by $\overline{1'}$, incoming to the antiparticle of 2, denoted by $\overline{2}$, and $2'$ outgoing represent a different reaction, it is referred to as the *t-channel* reaction. The scattering amplitudes of s- and t-channel are related via the so-called *crossing symmetry*. The *u-channel* is introduced analogously as a reaction with the initial state of particles 1 and $\overline{2'}$ and the final state of particles $1'$ and $\overline{2}$. The t-channel and the u-channel are referred to as the *crossed channels* relative to the reaction in Eq. (50.1). This relationship is illustrated in Fig. 50.1.

The analysis of resonance phenomena requires delving deeper into the complex analysis of the amplitude: $\mathcal{M}(s, t)$ is a multi-valued function due to the complex *branch points* associated with the Mandelstam variables. These branch points emerge whenever a new channel becomes accessible, that is, whenever s exceeds $s_{\text{thr},a} = (m_{1,a} + m_{2,a})^2$, where $m_{i,a}$ denotes the masses of the two particles in channel a. Every two-particle threshold introduces a square-root singularity. The square-root function is inherently double-valued; for instance, the equation $x = y^2$ has two solutions: $\sqrt{x}$ and $-\sqrt{x}$. In the complex plane, these two solutions are represented as separate layers or surfaces, known as *Riemann sheets* or Riemann surfaces. Consequently, each square-root singularity causes the number of Riemann sheets of the scattering amplitude to double. If a channel opens that has an odd number of particles, the branch point at the threshold exhibits a logarithmic singularity [7]. Such a branch point gives rise to an infinite

number of sheets. The branch points come with their associated branch cuts — by convention those are taken from the threshold to infinity along the real axis and accordingly called *right-hand cuts*. To explore a reaction amplitude in the complex energy plane, one can introduce a complex component to the Mandelstam variable s. The section of the complex plane that relates to a positive imaginary component of the relative momentum can be directly accessed from the physical region and is called the first Riemann sheet or the *physical sheet*. The other sheets are called *unphysical sheets*. The *physical axis* of an s-channel scattering amplitude represents a line for real values of the variable s larger than the lowest threshold to be evaluated on the physical sheet.

While the physical Riemann sheet is free of singularities off the real axis, the unphysical sheets may contain resonance poles and branch points. Branch points appear in the complex plane of an unphysical sheet when there is a resonance in a subsystem of involved particles [7, 8]. The branch points related to thresholds in the crossed channels are located in the portion of the complex plane where the real part is negative and, therefore, are referred to as the *left-hand cuts*. An illustrative example for a left-hand cut is the one-pion exchange in nucleon-nucleon scattering that is located in the unphysical domain at $s = 4m_N^2 - m_\pi^2$. Triangle topologies, which are Feynman diagrams characterized by a triangular loop of three propagators, can lead to logarithmic singularities in the scattering amplitude. These singularities, appearing on the unphysical sheets, are often termed *triangle singularities* (TS) [7, 9, 10].

The reaction amplitude has poles that can be categorized as bound states, virtual states, or resonances. Poles corresponding to bound and virtual states manifest at real values of s. Specifically, *bound state* poles are found on the physical sheet, while *virtual state* poles are situated on an unphysical sheet, both being below the threshold. Resonance poles, on the other hand, emerge inside the complex plane of the unphysical sheets. Notably, those resonance poles that are on the unphysical sheet nearest to the physical region exert the most significant influence on experimental observables. Analyticity dictates that for every pole at a specific complex value of s_p, there must be a corresponding pole at its complex conjugate value s_p^*. This relationship is a direct consequence of the *Schwarz reflection principle*, a mathematical technique utilized for analytic continuation within scattering theory. For a single-channel case, the complex structure of an amplitude with a single resonance is illustrated in Fig. 50.2(a)-(c). Among the two poles, symmetrically positioned relative to the real axis on the second sheet, the one exhibiting a negative imaginary part seamlessly connects to the physical axis, which becomes especially clear in panel (c) of the figure where the physical axis is shown as the blue line. It therefore has a more pronounced effect on observables in the vicinity of the resonance region compared to its conjugate counterpart. The shortest continuous path from the physical region to the second sheet pole with the positive imaginary part is via a line that goes around the threshold. However, as the extra path around the threshold diminishes in the near-threshold region, the effective distance to both poles becomes comparable for near threshold kinematics, thereby rendering the influence of both poles on observables similarly significant.

An alternative way to depict the complex structure is through the k-plane, where k denotes the relative momentum of the two scattering particles in their center-of-momentum frame. For particles of equal mass, denoted as m (expression for unequal masses is given in Eq. (50.7)), one finds

$$k = \frac{1}{2}\sqrt{s - 4m}\,. \tag{50.3}$$

Unlike the complex s-plane, the k-plane does not have a two-body threshold cut. Consequently, both the physical and unphysical Riemann sheets, which are linked to the branch point in s are mapped onto the upper and lower half of the complex k-plane, respectively. The k-plane is sketched in Fig. 50.2(d), including possible locations of resonance poles. In this representation it becomes especially clear that only one resonance pole drives the dynamics on the physical axis in the resonance region, while at the threshold, where $k = 0$, both poles are of equal significance.

In situations involving two relevant channels, we encounter four Riemann sheets. These are illustrated in the left panel of Fig. 50.3. For a non-relativistic system with two channels, this four-sheeted Riemann surface can be transformed into a plane represented by a new variable, ω. This variable is defined in relation to the channel-momenta, as detailed in references [11, 12] (for a recent application see Ref. [13])

$$k_1 = \sqrt{\frac{\mu_1 \Delta}{2}}\left(\omega + \frac{1}{\omega}\right)\,, \quad k_2 = \sqrt{\frac{\mu_2 \Delta}{2}}\left(\omega - \frac{1}{\omega}\right)\,, \tag{50.4}$$

where Δ denotes the energy difference between the two thresholds and the μ_a the reduced mass of the particles in channel a, $\mu_a = m_{1,a} m_{2,a}/(m_{1,a} + m_{2,a})$. The lower threshold is located at $\omega = i$, the higher at $\omega = 1$. The mapping of the Riemann sheets and the different areas in the ω-plane is shown in the right panel of Fig. 50.3. The ω-plane nicely shows how the different sheets connect to each other.[1] The solid green line shows the physical axis in the physical regime. The thick black line its analytic continuation below the lowest threshold. The pronounced kinks in this line for the ω plane show the thresholds. Please observe that for $\omega \approx i$ the sheet structure agrees to panel (d) of Fig. 50.2, since in this kinematic regime the second channel does not matter.

In the context of a two-channel scenario, the proximity of a sheet to the physical axis varies with increasing energy. Specifically, for energies that exceed the first threshold, but remain below the second, sheet (21) is the one that smoothly connects to the upper half-plane of the physical sheet (11). Once the energy surpasses the second threshold, sheet (22) assumes this role. As a result, any pole on sheet (21) that lies above the second threshold will manifest in the data solely as a cusp right at the second threshold. Sheet (12), on the other hand, is remote for almost all energies.

Singularities, poles and branch points determine the visible structures in observables. However, it is crucial to note that not every observable bump is indicative of a resonance as discussed in [14]. Under certain kinematic conditions, Triangle Singularities, in particular, can either mimic resonance signals, as suggested in Refs. [15–20], or significantly alter resonance signals [21]. Conversely, not all resonances produce a noticeable bump across all observables. For example, in the baryon sector, there is no clear trace of the $N(1440)1/2^+$, the so called Roper resonance, in the πN observables or phase shifts, although careful analyses reveal a pole [22]. In the meson sector, the $f_0(500)$, also known as σ meson, was firmly established only after the application of very sophisticated theoretical analysis tools (see, *e.g.*, Ref. [23] for a review). This complexity arises because the scalar-isoscalar $\pi\pi$ phase shifts reach 90 degrees near 800 MeV, which is approximately 400 MeV above the resonance mass. At this energy, the onset of the next resonance, the $f_0(980)$, is already observable. The analyticity principle of the $\mathcal{S}$-matrix germane to quantum scattering theories, dictates that only poles and branch points can exist on the real axis of the first Riemann sheet, excluding any singularities in the complex plane. This principle is closely linked to causality, ensuring that effects follow their causes in a chronological order. In non-relativistic scattering, the analyticity finds a solid mathematical base [24]. Similarly, perturbative relativistic theory maintains this analyticity through a series expansion of the $\mathcal{S}$-matrix, each term depicted by a Feynman diagram, representing processes with distinct analytical expressions. A deeper level of analyticity is proposed by the Mandelstam hypothesis, suggesting not only the analytic properties of the scattering amplitude within the complex plane of the first Riemann sheet but also a nuanced interconnection between crossed scattering processes through analytic continuation [25].

Unitarity further constrains the imaginary part of the amplitude on this real axis, a topic we will explore in the subsequent section. Additional constraints are introduced by principles such as crossing symmetry, duality [26] and positivity [27]. Approaches based on analyticity and crossing symmetry have been implemented through dispersion theory. Among the most notable are

[1] An alternative illustration for this two-channel case as well as an extension to three channels can be found in Ref. [2].

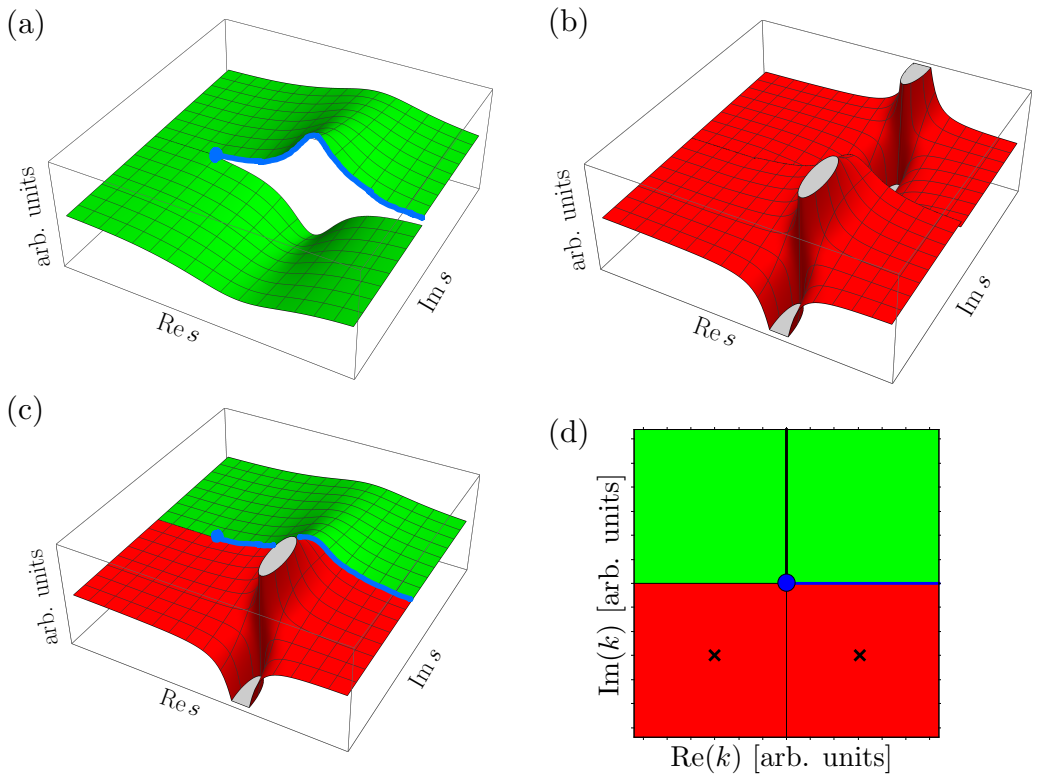

Figure 50.2: (a)-(c): Imaginary part of a typical scattering amplitude with an isolated resonance. The blue line shows the physical range of the Mandelstam variable s: it is real and starts from the threshold shown by the blue dot. Plot (a) shows the imaginary part of the amplitude in the complex s-plane that corresponds to the first or physical sheet (green surface), plot (b) shows the related unphysical or the second sheet (red surface) which contains the resonance poles, and plot (c) shows the analytic continuation of the same amplitude from the upper half plane of the physical sheet to the lower half plane of the unphysical sheet. The two sheets are connected smoothly along the real axis above the threshold. Panel (d) shows the k-plane, which is free of cuts. The upper (lower) half plane maps onto the physical (unphysical) sheet. Also here the blue line corresponds to the physically accessible values of the momentum k, which starts at threshold, where $k = 0$. The thick black line shows the analytic continuation of the on-shell momentum in the below threshold regime. The locations of the resonance poles are indicated by the black crosses.

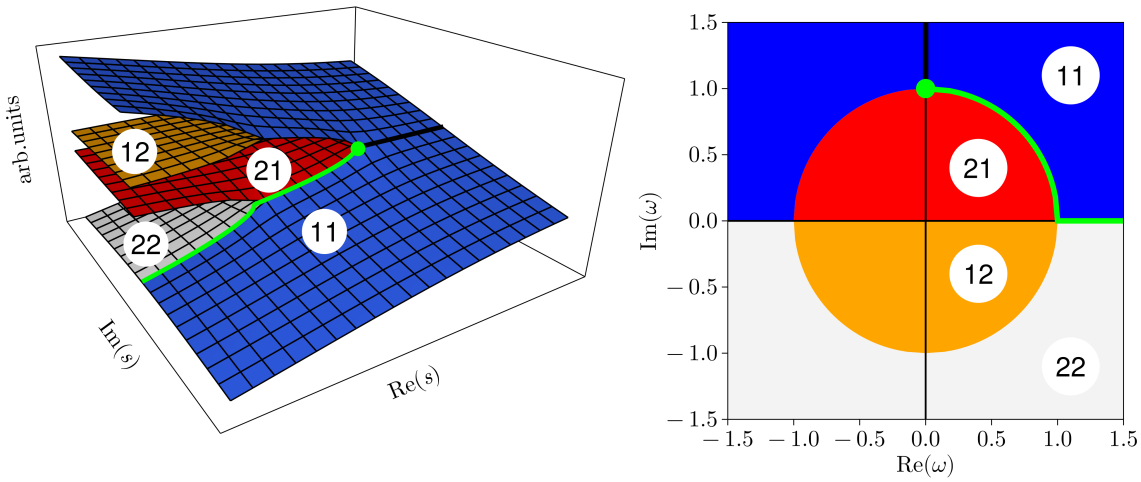

Figure 50.3: Cut structure of the $\mathcal{S}$-matrix with two channels present. The diagrams feature four sheets, labeled (ij), where both i and j can be 1 or 2. These labels indicate the doubling of the sheets at the first and second thresholds. The left panel displays the complex s plane, while the right panel represents the ω plane. The physical axis, along with its analytic continuation below the threshold, is highlighted with a thick solid line, green in the physical regime, black for the analytic continuation below the lowest threshold.

the Roy equations and their variants [28]. These have been applied to a range of processes, including $\pi\pi \to \pi\pi$ [29–31], πK scattering [32], $\gamma\gamma \to \pi\pi$ interactions [33], and pion-nucleon scattering [34, 35].

50.1.2 *Consequences from unitarity*

Scattering amplitudes, denoted as $\mathcal{M}$, and production amplitudes, represented by $\mathcal{A}$, have distinct characteristics due to the different constraints imposed by unitarity. When considering the scattering amplitude, it is assumed that all channels hold similar significance. In contrast, for production amplitudes, it is assumed that for the dynamics of the particles in the final state the initial state does not play a role. Accordingly, the interactions in the final state among the produced particles are described by relevant scattering amplitudes of those particles only. Scattering processes are for example $\pi^+\pi^- \to K\bar{K}$ and $D^0\bar{D}^0 \to D^0\bar{D}^0$. Examples for production processes are $e^+e^- \to \gamma^* \to \pi^+\pi^-$, which provides access to the pion vector form factor, $\tau^- \to K^-\pi^0\nu_\tau$, and $B^0 \to J/\psi\pi^+\pi^-$.

The unitarity of the $\mathcal{S}$-matrix, represented by the equation $S^\dagger S = 1$, ensures the conservation of probability. This principle imposes a specific constraint on the imaginary part of the reaction amplitude. Below the lowest threshold, the amplitude remains real. However, once the energy is higher than the threshold, there is a discontinuity associated with the threshold branch point. The $\mathcal{S}$-matrix unitarity relates the value of the discontinuity, to the amplitude itself [6]:

$$\begin{aligned}\mathrm{Disc}\,\mathcal{M}_{ba} &= \mathcal{M}_{ba} - \mathcal{M}^*_{ab}\ ,\ ,\\ &= i\,(2\pi)^4 \sum_c \int d\Phi_c \mathcal{M}^*_{cb}\mathcal{M}_{ca}\ ,\end{aligned} \tag{50.5}$$

where $d\Phi_c$ denotes the invariant phase space for a given channel, labeled as c. The factor $(2\pi)^4$ aligns with the definition of the phase space expression (see Eq. (12) in the review on "Kinematics"). It is essential to note that the summation only considers open channels, meaning those with a production threshold below the scattered system's energy. In the evaluation of an actual Feynman diagram the discontinuity can be extracted by employing the Cutkosky rule, which comprises replacing the propagators in the pertinent intermediate state by delta-distributions. Eq. (50.5) is illustrated graphically in Fig. 50.4. The left part of the expression yields $2i\,\mathrm{Im}\mathcal{M}_{ba}$ in accordance to analytic properties of reaction amplitude [36]. For the forward scattering, $t = 0$, the right part of Eq. (50.5) resembles the total cross section up to a kinematic factor, a relationship know an the optical theorem:

$$\mathrm{Im}\,\mathcal{M}_{aa}(s,0) = 2q_a\sqrt{s}\,\sigma_{\mathrm{tot}}(a \to \text{anything})\,. \tag{50.6}$$

In this equation, q_a represents the break-up momentum of the particles in the center-of-momentum frame,

$$q_a = \frac{\lambda^{1/2}(s, m^2_{1,a}, m^2_{2,a})}{2\sqrt{s}}\ , \tag{50.7}$$

where $\lambda(x,y,z) = x^2 + y^2 + z^2 - 2xy - 2yz - 2xz$ is the Källén function, and the masses of the two particles in the channel a, $m_{1,a}$ and $m_{2,b}$, *cf.* Eq. (17) of the review on "Kinematics".

The unitarity relation for a production amplitude in channel a is represented by:

$$\begin{aligned}\mathrm{Disc}\,\mathcal{A}_a &= \mathcal{A}_a - \mathcal{A}^*_a\,,\\ &= i\,(2\pi)^4 \sum_c \int d\Phi_c \mathcal{M}^*_{ca}\mathcal{A}_c\,.\end{aligned} \tag{50.8}$$

Equation (50.8) is illustrated graphically in Fig. 50.4. A direct consequence of this equation is that the production amplitude shares its poles with the scattering amplitude. A common method to model the production amplitude that adheres to this unitary relation is to express it as a linear combination of the scattering amplitudes. This approach, known as the $\mathcal{Q}$-vector method (see Sec 50.3.4), has its limitations. Specifically, production amplitude inherits the left-hand singularities of the scattering amplitude, while, in general, it has a different cut structure. To address this drawback, a more sophisticated method, known as *unitarization* is employed. This method, rooted in dispersion theory, offers a more refined approach to the problem and is detailed in [37]. A notable application of this method is the Khuri-Treiman framework [38, 39], which is frequently used to study three-body decays. This framework has been successfully applied to a range of decays, from light mesons [40–52] to heavy-flavour decays [53–55].

50.1.3 *Partial-wave decomposition*

It is often convenient to expand a two-body scattering amplitude of a two-body subsystem of a production amplitude in partial waves. Since resonances have a well-defined spin, they appear only in a specific partial wave of the reaction amplitude. For scalar particles, the expansion reads:

$$\mathcal{M}_{ba}(s,t) = \sum_{j=0}^{\infty}(2j+1)\mathcal{M}^j_{ba}(s)P_j(\cos(\theta))\ , \tag{50.9}$$

where j denotes the total angular momentum and the $P_j(\cos(\theta))$ denotes the Legendre polynomials. In the presence of spins an expansion more complicated than Eq. (50.9) is necessary — for a general discussion on how to handle spins see *e.g.* Ref. [56]. In the absence of spins the parameter j coincides with the orbital angular momentum of the particle pairs in the initial and the final state. To simplify notation and since all amplitudes from here on are understood to be partial wave projected, we drop the label j for the single-argument function $\mathcal{M}_{ba}(s)$. Plugging Eq. (50.9) into Eq. (50.5) one finds the unitarity relation for the partial-wave amplitude $\mathcal{M}_{ba}(s)$, namely

$$\mathrm{Im}\,\mathcal{M}_{ba}(s) = \sum_c \mathcal{M}_{cb}(s)^*\,\rho_c(s)\,\mathcal{M}_{ca}(s) \tag{50.10}$$

with $\rho_c(s)$ being a factor that is related to the two-body phase space in Eq. (12) of the review on "Kinematics",

$$\rho_c(s) = \frac{(2\pi)^4}{2}\int \mathrm{d}\Phi_2 = \frac{1}{16\pi}\frac{2|\vec{q}_c|}{\sqrt{s}}\ , \tag{50.11}$$

with the momentum q_c being defined in Eq. (50.7). Note that in case of the two particles being identical the inclusion of symmetry factors becomes necessary. The partial-wave amplitude $f_{ba}(s)$ is introduced by normalizing scattering amplitude with the phase spaces factors,

$$f_{ba}(s) = \sqrt{\rho_b}\,\mathcal{M}_{ba}(s)\,\sqrt{\rho_a}\,. \tag{50.12}$$

The unitarity condition for f_{ba} follows from Eq. (50.10):

$$\mathrm{Im}\,f_{ba}(s) = \sum_c f^*_{cb}(s) f_{ca}(s)\,. \tag{50.13}$$

It leads us to deduce that the inverse of the imaginary part of f_{ba} is equal to $-\delta_{ba}$. Moreover, $\mathcal{S} = \mathbb{I} + 2if$ is a unitary matrix. Hence, the diagonal elements of f can be parameterized as

$$f_{bb} = (\eta_b \exp(2i\delta_b) - 1)/2i\ , \tag{50.14}$$

where δ_b denotes the phase shift for the scattering from channel b to channel b and η_b is the elasticity parameter, also known as inelasticity. Building upon Eq. (50.13), we can further deduce that,

$$\mathrm{Im}\,f_{bb}(s) = (1 - \eta_b\cos(2\delta_b))/2 = \sum_c |f_{cb}(s)|^2\ . \tag{50.15}$$

Using Eq. (50.14) for the last term in the sum, we obtain a relation highlighting the meaning of the inelasticity,

$$\frac{1}{4}(1-\eta_b^2) = \sum_{c\neq b}|f_{cb}(s)|^2\ . \tag{50.16}$$

It is important to note that the parameter η_b is confined within the range $[0,1]$, where the case, $\eta_b = 1$ is referred to as a purely elastic

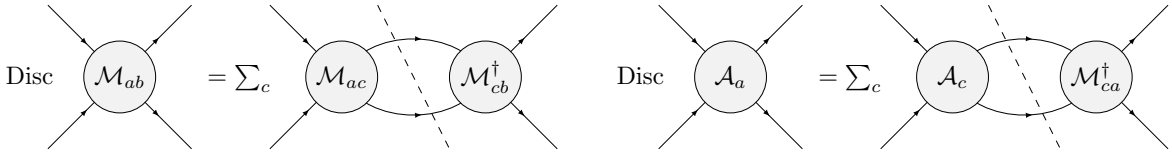

Figure 50.4: Graphical illustration of the discontinuity equations for the scattering and the production amplitude, respectively. The dashed line indicates that the intermediate state is to be put on-shell to find the discontinuity.

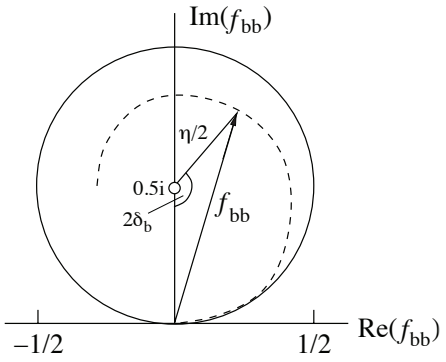

Figure 50.5: Argand plot showing a trajectory of the diagonal element of a partial-wave amplitude, f_{bb}, as a function of energy in the complex plane. As the energy increases the amplitude follows the line counter clockwise. The amplitude leaves the unitary circle (solid line) as soon as inelasticity sets in, $\eta < 1$ (dashed line).

scattering. Thus, the function $\eta_b(s)$ is a direct measure of the contribution of the inelastic channels on the scattering amplitude in a given channel.

The evolution of the partial-wave amplitude f_{bb} with energy can be displayed as a trajectory in the Argand plot, as shown in Fig. 50.5. In case of a two-channel problem, $\eta_1 = \eta_2 = \eta$, and the off-diagonal element is $f_{12} = \sqrt{1-\eta^2}/2\, \exp(i(\delta_1 + \delta_2))$. The unitarity condition Eq. (50.14) sets the limit to the squared amplitude f_{bb}:

$$|f_{bb}|^2 = \frac{1}{4}(\eta_b^2 - 2\eta_b \cos(2\delta_b) + 1) \leq \frac{1}{4}(\eta_b + 1)^2 \ , \qquad (50.17)$$

where the maximum value is reached for $\delta_b = \pi/2$. For the absolute square of the partial-wave-projected scattering amplitude the unitarity bound thus reads:

$$|\mathcal{M}_{bb}| \ \leq \ \frac{1}{2\rho_b}(\eta_b + 1) \ \leq \ \frac{8\pi}{q_b}\sqrt{s}\,, \qquad (50.18)$$

where the second inequality comes from $\eta_b \leq 1$. For energies much larger than the masses of the scattering particles the upper bound for $|\mathcal{M}_{bb}|$ tends to 16π for large s.

The partial-wave projected production amplitude $\mathcal{A}(s)$ (note that the label j has been omitted for consistency) is also constrained by unitarity. As derived from Eq. (50.8):

$$\mathrm{Im}\,\mathcal{A}_a = \sum_b \mathcal{M}^*_{ba}\, \rho_b\, \mathcal{A}_b \ , \qquad (50.19)$$

where the summation encompasses all open channels. In the realm of elastic scattering, solely one channel, denoted by a, contributes to the sum. Consequently, the phase of $\mathcal{A}_a$ must align with the phase of $\mathcal{M}_{aa}$, given that the left-hand side of Eq. (50.19) represents a real value. This principle is recognized as the *Watson theorem* [57]. To illustrate, consider the phase of the pion vector form factor: it agrees to that of $\pi\pi$ scattering in the vector isovector channel (aside from effects of the isospin-violating $\rho - \omega$ mixing) up to about 1 GeV, where inelastic contributions start gaining significance.

50.2 Properties of resonances

A resonance is defined by its *pole position* in the complex s-plane, denoted as s_R, and by the strength parameters of its couplings to various decay channels evaluated at this pole, known as the *pole residues*. The pole mass M_R and pole width Γ_R are defined via the pole parameters

$$\sqrt{s_\mathrm{R}} = M_\mathrm{R} - i\Gamma_\mathrm{R}/2 \ . \qquad (50.20)$$

For states where the relevant thresholds are situated significantly below the resonance location, the lifetime τ_R of the resonance is given by $\tau_\mathrm{R} = 1/\Gamma_\mathrm{R}$ (refer to the review on "Kinematics" and for a recent discussion, see Ref. [58]). It is important to note that the conventional Breit–Wigner parameters M_BW and Γ_BW, introduced in Eq. (50.30), differ from the pole parameters due to finite width effects and the influence of thresholds and background terms. It should be stressed that pole location s_R and pole residues are the only resonance properties that are model and parameterization independent.

When a resonance interacts with multiple channels, each channel contributes to the imaginary part of the pole position. However, these individual imaginary contributions do not necessarily simply sum up, leading to the need for redefining the partial widths. This behavior is discussed on the example of the $f_0(980)$ in Refs. [59, 60].

In the close vicinity of the resonance pole one defines the residues via

$$\lim_{s \to s_\mathrm{R}} (s - s_\mathrm{R})\mathcal{M}_{ba} = -\mathcal{R}_{ba} \ . \qquad (50.21)$$

Those can be conveniently calculated via an integration along a closed contour around the pole using

$$\mathcal{R}_{ba} = -\frac{1}{2\pi i}\oint ds \mathcal{M}_{ba} \ . \qquad (50.22)$$

The residue adheres to the factorization relation, $(\mathcal{R}_{ba})^2 = \mathcal{R}_{aa} \times \mathcal{R}_{bb}$. This factorization emerges as a universal property stemming from the unitarity of scattering processes [7]. Building on this relation, one can define *pole couplings* as follows:

$$\tilde{g}_a = \mathcal{R}_{ba}/\sqrt{\mathcal{R}_{bb}}\,. \qquad (50.23)$$

The pole couplings characterize the transition strength of a given resonance to some channel a independently of how the particular resonance was produced. They are in general complex valued.

In the baryon sector, it is customary to define the residue of the pole for the f_{ba} amplitude (as described in Eq. (50.13)) in terms of the variable $\sqrt{s}$ rather than s. This residue can be related to the residues mentioned earlier by:

$$r_{ba} = \frac{1}{2}\sqrt{\frac{\rho_a(s_\mathrm{R})\rho_b(s_\mathrm{R})}{s_\mathrm{R}}}\,\mathcal{R}_{ba} \ , \qquad (50.24)$$

where the phase-space factors are to be continued analytically to the pole location s_R. The residues quoted in the baryon listings are those for πN scattering ($a = b = \pi N$).

The branching ratio of a resonance decay to a specific channel represents the fraction of the decay probability directed to that channel.

$$\mathrm{Br}_a = N_a/N_\mathrm{tot} \ . \qquad (50.25)$$

Here, N_a is the experimental count of events for the decay channel $R \to a$, while N_tot represents the total number of events produced

in the decay of the resonance. Since the amplitudes of decays to different final states add incoherently, we have $N_{\rm tot} = \sum_b N_b$. We note, however, that both N_a and $N_{\rm tot}$ may exhibit a dependence on the reaction through which the resonance is produced, due to the resonance's finite width. For a narrow resonance, the experimental count is determined by integrating the squared production amplitude over the decay channel's phase space:

$$N_a = N_0 \int |\mathcal{A}_a|^2 \, \mathrm{d}\Phi_a \ , \tag{50.26}$$

where N_0 is a normalization constant associated with the integrated luminosity, and $\mathcal{A}_a$ represents the amplitude of the resonance decay to channel a. When the decay rate's variation across the resonance width becomes significant, the resonance's lineshape must be considered:

$$N_a = N_0 \int_{s_{\rm thr,a}}^{\infty} \mathrm{d}s \sigma_{\rm R}(s) \int |\mathcal{A}_a(s)|^2 \, \mathrm{d}\Phi_a(s) \ . \tag{50.27}$$

Here, $\sigma_{\rm R}(s)$ denotes a proper weight function of the resonance and $s_{\rm thr,a}$ is the threshold value for the channel a. Additionally, the phase space integral, $\Phi_a(s)$, puts the integrand to zero below the energy threshold of the decay channel a. This aspect is particularly crucial for the decays of broad resonances into channels with energy thresholds exceeding the resonance's nominal mass. This methodology is frequently employed in light-meson studies, as demonstrated in Ref. [61], and is also prevalent in light baryon research, as referenced in Ref. [60].

In case of the decay of some heavy state into multi-body final states, the transition amplitude can include resonances within subsystems of particles. When the total amplitude is decomposed as $\mathcal{A}_a = \sum_{\rm R} \mathcal{A}_{a({\rm R})}$, the relative branching fraction for the decay of the given heavy state into final state a via resonance R in some subsystem, denoted as $\mathrm{Br}_{a({\rm R})} \,/\, \mathrm{Br}_a$, is given by:

$$\mathrm{Br}_{a({\rm R})} \,/\, \mathrm{Br}_a = \int \left|\mathcal{A}_{a({\rm R})}\right|^2 \mathrm{d}\Phi_a \Big/ \int |\mathcal{A}_a|^2 \, \mathrm{d}\Phi_a \tag{50.28}$$

It is crucial to recognize that the decomposition of the total amplitude, $\mathcal{A}_a$, into resonance amplitudes, $\mathcal{A}_{a(R)}$, is not a straightforward process. Beyond the differentiation of components based on distinct quantum numbers, this separation is inherently model-dependent. Furthermore, it is essential to be aware that the amplitudes $\mathcal{A}_{a(R)}$ can interfere with one another. As a result, their individual probabilities might not sum up to the total branching fraction of channel a. Nonetheless, in many scenarios, the interference contributions are small, making the fractions $\mathrm{Br}_{a({\rm R})} \,/\, \mathrm{Br}_a$ indicative. For recent applications of these formulas in the context of B-decays see Refs. [62–65].

Lastly, an expression analogous to the branching fraction can be formulated using the pole parameters. For two-particle decays in the S-wave, one writes:

$$\mathrm{Br}_a = \frac{|\tilde{g}_a|^2}{M_{\rm R}\Gamma_{\rm R}} \rho_a(M_{\rm R}^2) \ , \tag{50.29}$$

where $M_{\rm R}$ and $\Gamma_{\rm R}$ have been previously defined in Eq. (50.20). This approach was utilized to define a two-photon width for the broad $f_0(500)$ resonance [66, 67]. Similarly, one should use residues to quantify the coupling of resonances to certain production channels [68]. For an application of this approach to the coupling of the $K_0^*(1430)$ resonance to a leptonic current see Ref. [69]. Equation (50.29) provides a definition of branching fraction that remains independent of the reaction used to derive the quantity. For narrow resonances, this definition aligns well with Eq. (50.25) and Eq. (50.26). However, for broad, overlapping resonances, it is essential to recognize that Eq. (50.29) is primarily used to convert residues into metrics that facilitate a more straightforward comparison of resonance transitions across different channels. For resonances with a coupling to a channel that remains closed at the resonance mass, Eq. (50.29) is not applicable due to the phase-space factor. In such scenarios, modification of the expression is required as elaborated upon in Ref. [60], and at the conclusion of Sec. 50.3.5.

50.3 Common parameterizations

In general, there is no universal, model-independent recipe to build scattering amplitudes. However, a few approaches presented in this section are practical to extract resonance properties in experimental analyses. The systematic theory uncertainties need to be assessed from a range of model variations that provide a sufficient quality of description of the available data and are permitted by general $\mathcal{S}$-matrix principles and the symmetries controlling the system at hand.

50.3.1 *The Breit–Wigner parameterization*

The relativistic Breit–Wigner parameterization represents a dressed propagator for an isolated resonance. The production amplitude for a resonance observed in a channel a, is given by

$$\mathcal{A}_a(s) = \frac{\mathcal{N}_a(s)}{M_{\rm BW}^2 - s - iM_{\rm BW}\Gamma(s)} \tag{50.30}$$

where $M_{\rm BW}$ represents the Breit–Wigner mass, and $\Gamma_{\rm BW} = \Gamma(M_{\rm BW}^2)$ denotes the Breit–Wigner width. The function $\Gamma(s)$ is defined by the channels to which the resonance can decay. The numerator function $\mathcal{N}_a(s)$ is tailored to the production process, encompassing kinematic factors and couplings pertinent to both the production and decay processes.

$$\mathcal{N}_a(s) = \alpha \, g_a \, n_a(s) \tag{50.31}$$

$$\Gamma(s) = \frac{1}{M_{\rm BW}} \sum_b g_b^2 \rho_b(s) n_b^2(s) \ , \tag{50.32}$$

Here the index $b = 1, 2, \ldots$ runs over all decay channels of the resonance. The coupling constants are represented by g_b, and ρ_b is the phase-space factor as defined in Eq. (50.11). The expression for $n_a(s)$ is:

$$n_a = (q_a/q_0)^{l_a} F_{l_a}(q_a/q_0) \, , \tag{50.33}$$

where l_a indicates the orbital angular momentum in channel a, $q_a(s)$ is the break-up momentum as defined in Eq. (50.7), and q_0 is a suitably selected momentum scale. The term $(q_a)^{l_a}$ ensures the amplitude's appropriate threshold behavior. The rapid growth of this factor for angular momenta $l_a > 0$ is offset at specific s values by a phenomenological form factor, represented here by $F_{l_a}(q_a, q_0)$ — the presence of these suppression factors is also a requirement from positivity which demands that the dressed propagator, the denominator of Eq. (50.30) and similar equations below, is not allowed to drop faster than $1/s$ [27]. The Blatt-Weisskopf form factors are frequently employed in the literature [70–72] to model F_j:

$$\begin{aligned} F_0^2(z) &= 1 \, , \\ F_1^2(z) &= 1/(1+z^2) \, , \\ F_2^2(z) &= 1/(9+3z^2+z^4) \, , \end{aligned} \tag{50.34}$$

where $z = q/q_0$, the scale parameter $1/q_0$ typically falls within the range of $1\,\mathrm{GeV}^{-1}$ to $5\,\mathrm{GeV}^{-1}$. Rather than employing coupling constants as in Eq. (50.32), channel partial widths can be used,

$$\Gamma(s) = \sum_b \Gamma_{{\rm BW},b} \frac{\rho_b(s)}{\rho_b(M_{\rm BW}^2)} \left(\frac{q_b}{q_{b\,{\rm R}}}\right)^{2l_b} \frac{F_{l_b}^2(q_b, q_0)}{F_{l_b}^2(q_{b\,{\rm R}}, q_0)} \, . \tag{50.35}$$

Here $q_{b\,{\rm R}}$ is the values of the break-up momenta evaluated at $s = M_{\rm BW}^2$. It is essential to note that this substitution is valid only for channels where the decay channel's threshold is positioned below the nominal resonance mass. In other scenarios, Eq. (50.32) should be applied.

Equation (50.32) incorporates a threshold for each of the coupled channels. The expression is straightforward to use in the physical region above all the thresholds. Its evaluation elsewhere requires a careful analytic continuation. As outlined in Refs. [73, 74], the choice

$$q_c = i\sqrt{-q_c^2} \quad \text{for} \quad q_c^2 < 0 \, , \tag{50.36}$$

leads to an evaluation of the amplitude on the physical sheet below threshold. The *Flatté parameterization* [73] refers to the two

S-wave channels' amplitude near a threshold of a heavier channel in the physical region of the lighter channel computed with Eq. (50.36). When a resonance's coupling to the channel with a higher threshold is notably strong, the parameterization displays scaling invariance. This implies that it is not possible to extract individual partial decay widths; only their ratios can be determined [75].

The Breit–Wigner parameterization is an accurate representation of resonance phenomena strictly in the $\Gamma/\Delta \to 0$ limit, where Γ is the resonance width and Δ is the distance to the closest unaccounted singularity, be it a pole of a higher resonance or a kinematic threshold related to a coupled channel. However, the situation is often more complex due to multiple singularities in the complex plane around the resonance with different importance. For instance, in P-wave $\pi\pi$ scattering, the Breit–Wigner parameterization aptly describes the ρ-meson resonance over an extensive range. Although the closest singularity to the ρ-meson pole is the ω-pole ($\Gamma_\rho/\Delta_\omega \gg 1$), this isospin breaking effect is typically insignificant except few special cases [76, 77]. Subsequent singularities, namely the 3π, 4π, and 6π thresholds, are also generally disregarded. The two-pion threshold is incorporated in the Breit-Wigner parameterization through an energy-dependent width. Finally, the parameterization's efficacy diminishes around 1.2 GeV due to the ρ' resonance, situated approximately at 1.45 GeV.

Once the applicability of the Breit-Wigner parameterization is established, it is crucial to recognize that its parameters will only align with the pole parameters if the width is small. Yet, extracting the pole position from the Breit-Wigner amplitude is a straightforward technical task, achieved through analytic continuation. However, neither the Breit–Wigner parameters nor the corresponding pole parameters should be deemed reliable without justifying the parameterization's applicability. If there is more than one resonance in one partial wave that significantly couples to the same channel, it is generally inappropriate to employ a sum of Breit–Wigner functions. Such an approach often results in a breach of unitarity constraints, potentially introducing an indeterminate bias to the inferred resonance properties from the reaction amplitude. For overlapping resonances in the same partial wave, more sophisticated methods, such as the $\mathcal{K}$-matrix approach detailed in the subsequent section, are recommended.

50.3.2 *$\mathcal{K}$-matrix approach*

The *$\mathcal{K}$-matrix* method offers a comprehensive framework for modelling coupled-channel amplitudes [78]. This method ensures two-particle unitarity. However, it traditionally omits the left-hand cuts. The scattering amplitude $\mathcal{M}_{ba}(s)$ can be derived from the equation:

$$n_b\, \mathcal{M}^{-1}_{ba}\, n_a = \mathcal{K}^{-1}_{ba} - i\delta_{ba}\rho_a n_a^2\,. \tag{50.37}$$

Here, $\mathcal{K}_{ba}$ represents a real function and is subject to modeling. The factor n_a is elaborated upon in Eq. (50.33). Since there is no unique recipe to build $\mathcal{K}$, it is essential to explore various parameterizations to gauge the theoretical systematic uncertainty. A commonly adopted choice for the $\mathcal{K}$-matrix is given by:

$$\mathcal{K}_{ba}(s) = \sum_{\mathrm{R}} \frac{g_b^{\mathrm{R}} g_a^{\mathrm{R}}}{m_{\mathrm{R}}^2 - s} + b_{ba}\,, \tag{50.38}$$

where m_{R} is referred to as the bare mass of the resonance R (not to be confused with the physical mass), and the g_a^{R} represents the bare couplings of the resonance R to the channel a (not to be confused with the residues). The b_{ba} is a matrix that parameterizes the non-pole components of the $\mathcal{K}$-matrix. Provided all parameters in Eq. (50.38) are real, the amplitude $\mathcal{M}_{ba}(s)$ remains unitary. From Eq. (50.37), the scattering amplitude $\mathcal{M}$ can be directly computed using its matrix form:

$$\mathcal{M} = n[1 - \mathcal{K}\, i\rho\, n^2]^{-1}\mathcal{K}\, n\,, \tag{50.39}$$

where n and ρ are diagonal matrices, $n = \mathrm{diag}(n_a, n_b, \dots)$, and $\rho = \mathrm{diag}(\rho_a, \rho_b, \dots)$. As an alternative to Eq. (50.38), the same functional structure on the right side of Eq. (50.38) can be employed to parameterize the inverse $\mathcal{K}$-matrix, termed the M-matrix, by the authors of Ref. [79]. Numerous alternative formulations within the $\mathcal{K}$-matrix framework are utilized for amplitude studies related to lattice-QCD calculations [80–82].

A prevalent method to construct the production amplitude within the $\mathcal{K}$-matrix framework is the *$\mathcal{P}$-vector* parameterization [72,78,83]. The method utilizes the $\mathcal{K}$-matrix poles and bare couplings from Eq. (50.38):

$$\mathcal{A}_a(s) = n_a \sum_c \left[1 - \mathcal{K}\, i\rho n^2\right]^{-1}_{ac} \mathcal{P}_c\,, \tag{50.40}$$

$$\mathcal{P}_c = \sum_{\mathrm{R}} \frac{\alpha^{\mathrm{R}} g_c^{\mathrm{R}}}{m_{\mathrm{R}}^2 - s} + \mathcal{B}_c. \tag{50.41}$$

The production vector, denoted as $\mathcal{P}_c$, comprises two main components. The first component represents a transition driven by the coupling of the bare resonance, R, to the source. This coupling is characterized by a strength parameter, α^{R}. The second component, $\mathcal{B}_c$, signifies the direct transition from the source to the channel c. The formalism ensures that the complete production vector gets dressed via the final state interaction.

The *$\mathcal{Q}$-vector*, as discussed in Ref. [72,79,84], offers an alternative methodology for constructing a production amplitude:

$$\mathcal{A}_a(s) = \sum_c \mathcal{M}_{ac}(s)\mathcal{Q}_c(s)/n_c\,. \tag{50.42}$$

Here, $\mathcal{Q}_c(s)$ represents a smooth function of s and can be parameterized using a polynomial series. The unitarity condition of Eq. (50.19) is satisfied when $\mathcal{Q}_c(s)$ is a real function and in particular does not have singularities above the lowest threshold for all channels c. Besides these conditions $\mathcal{Q}_c(s)$ is arbitrary. In a study of $\gamma\gamma \to \pi\pi$, *cf.* Ref. [66,67] a low-order polynomial is claimed to be sufficient to parameterize the energy dependence of the function $\mathcal{Q}_c(s)$. The $\mathcal{Q}$-vector method is convenient, if the full matrix $\mathcal{M}$ is known, *cf.* Ref. [79]. An important distinction between the $\mathcal{P}$-vector and the $\mathcal{Q}$-vector methods is highlighted in [83]. When the two-particle scattering amplitude approaches zero, the production amplitude in the $\mathcal{Q}$-vector construction unavoidably vanishes for finite values of $\mathcal{Q}_c$, whereas it remains non-zero in the $\mathcal{P}$-vector approach.

Traditionally, amplitudes constructed using the $\mathcal{K}$-matrix technique exclude the left-hand cuts. Nevertheless, these can be customarily incorporated into the function b_{ba} from Eq. (50.38) for the scattering amplitude [85,86]. Similarly, for the production amplitude, the functions $\mathcal{B}_c$ and $\mathcal{Q}_c$ from Eq. (50.40) and Eq. (50.42), respectively, might also encompass the left-hand cuts. Those can often be parameterized by low order polynomials [66,67,87].

The position of the resonance poles can be determined by examining the zeros of the analytic function $\det[1 - \mathcal{K}\, i\rho\, n^2]$. Owing to the ρ factor, this determinant exhibits a complex multisheet structure. Nonetheless, the nearest unphysical sheet usually has the highest influence to the physical region. It is always the one which is determined by the heaviest threshold below the studied point in s (*cf.* Fig. 50.3). If for a given resonance the pole closest to the physical axis is not located on a sheet that connects directly to the physical axis, it is possible that $\mathcal{K}$-matrix fits do not allow one to fix the pole parameters, since a larger distance of the pole to the physical axis can be balanced by increased residues — for a detailed discussion see Ref. [88].

50.3.3 *Further improvements: Chew-Mandelstam function*

The $\mathcal{K}$-matrix framework often enables an accurate fit of physical amplitudes and is straightforward to handle. However, it does present a significant drawback: it breaches constraints imposed by analyticity. For instance, ρ_a, as defined in Eq. (50.11), is not well-defined at $s = 0$. Moreover, in cases of unequal masses, it manifests an unphysical cut, as depicted in the left panel of Fig. 50.6.

A method to improve the analytic properties has been suggested in Refs. [89–93]. This approach replaces the term $i\rho_a(s)n_a^2$ from

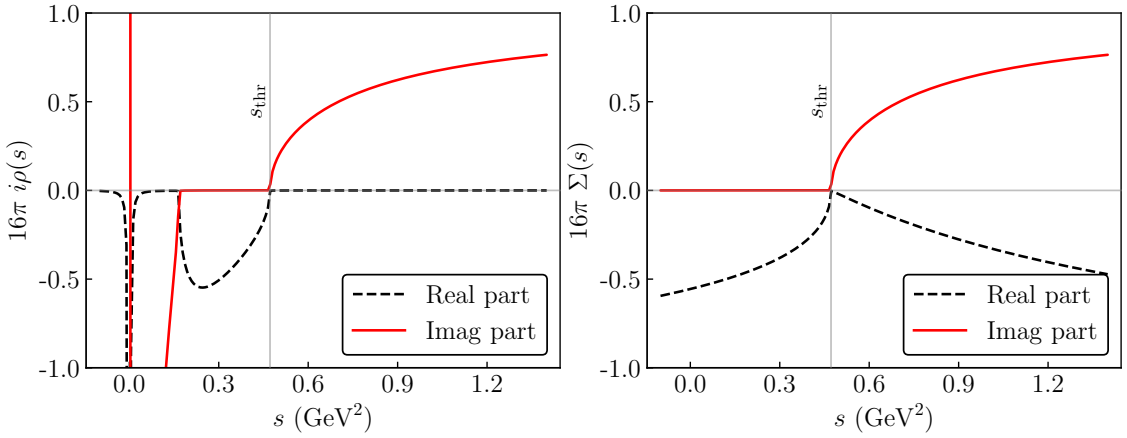

Figure 50.6: Comparison of the $i\rho$ function (left plot) to the *Chew-Mandelstam function* from Eq. (50.44) (right plot), evaluated for the case of S-wave $\eta\pi$ scattering. The values of s are taken slightly above the real axis, $s + i0$. The solid red line shows the imaginary part that is the same for both functions above threshold. The dashed black line presents the real part. One finds indications of the unphysical left-hand singularities of the function $i\rho$ on the left plot, while the Chew-Mandelstam function in analytic below the two-particle threshold.

Eq. (50.37) with the analytic function $\Sigma_a(s)$, known as the Chew-Mandelstam function. This function produces the imaginary part $i\rho_a(s)n_a^2$ on the right-hand cut, while maintaining analyticity on the left-hand side, as represented by the once subtracted dispersion integral:

$$\Sigma_a(s+i0) = \frac{s - s_{\mathrm{thr}_a}}{\pi} \int_{s_{\mathrm{thr}_a}}^{\infty} \frac{\rho_a(s')n_a^2(s')}{(s' - s_{\mathrm{thr}_a})(s' - s - i0)}\,\mathrm{d}s'. \tag{50.43}$$

Here, we chose the channel threshold, s_{thr_a}, as the subtraction point, and assumed that the subtraction constant is absorbed into the other parameters used for the amplitude. For an S-wave where $n_a = 1$, the integral has a closed form [37, 91]:

$$\Sigma_a(s) = \frac{1}{16\pi^2}\left[\frac{2q_a}{\sqrt{s}} \log\frac{m_1^2 + m_2^2 - s + 2\sqrt{s}q_a}{2m_1m_2}\right. ,$$
$$\left. - (m_1^2 - m_2^2)\left(\frac{1}{s} - \frac{1}{(m_1+m_2)^2}\right)\log\frac{m_1}{m_2}\right], \tag{50.44}$$

where m_1 and m_2 are masses of the final-state particles in channel a, with $s_{\mathrm{thr}_a} = (m_1 + m_2)^2$. The function's behavior along the real axis is illustrated in the right panel of Fig. 50.6. A further discussion of the calculation of the Chew-Mandelstam function can be found in Refs. [94, 95].

If there is only a single resonance in a given channel, it is possible to feed the imaginary part of the Breit–Wigner function, Eq. (50.30) with an energy-dependent width, directly into a dispersion integral to get a resonance propagator with the correct analytic structure [96, 97].

50.3.4 *Effective-range expansion and scattering-length approximation*

For elastic scattering, $\eta_b = 1$, Eq. (50.14) simplifies to

$$f_{bb} = e^{i\delta}\sin(\delta) = \frac{q}{q\cot(\delta) - iq}\ , \tag{50.45}$$

where q is the relative momentum of the scattering particles. For S-waves one may then employ the *effective-range expansion* [98, 99] (ERE)

$$q\cot\delta = \frac{1}{a} + \frac{1}{2}rq^2 + O(r^3q^4)\,, \tag{50.46}$$

whose radius of convergence is set by the closest non-analyticity, which may be the next threshold, a left-hand cut or a zero in the amplitude which is equivalent to a pole in $q\cot\delta$. The ERE is understood to be an expansion in $R_f q$, where R_f denotes the range of forces provided by the inverse of the lightest exchange particle allowed. The *scattering length*, a, is then defined as the first term in an expansion of the real part of the inverse scattering amplitude. The sign convention used in Eq. (50.46) is the one commonly employed in particle physics. In this convention a positive scattering length indicates attraction; if, however, the attraction is strong enough to generate a bound state, the scattering length changes sign and turns negative. A negative scattering length also occurs for repulsive interactions. Note that in nuclear physics the leading term in the expansion of Eq. (50.46) is usually defined as $-1/a$ such that *e.g.* a bound state would be related to a positive scattering length. The parameter r is called the *effective range*. Especially in cases where the scattering length is large the ERE not only describes the low energy scattering well but also allows for an analytic continuation to find bound states below threshold by proper analytic continuation. This method was, *e.g.*, employed recently to analyze near threshold scattering phase shifts for $D^{*+}D^0$ scattering found in lattice analyses to extract properties of the $T_{cc}(3875)^+$ [100–102] at unphysical pion masses. It should be stressed that the analyses of the lattice data might call for a modification to account for the nearby left-hand cut which sets the radius of convergence of the ERE [103].

When considering only the scattering length within the ERE, the scattering amplitude is represented as:

$$\mathcal{M}(s) = \frac{8\pi\sqrt{s}}{1/a - iq(s)}\,. \tag{50.47}$$

The scattering length is thus proportional to the value of the amplitude at threshold. It is worth noting that the scattering length approximation is applicable only in a very limited energy range, however, might well be appropriate to analyze the recently discovered narrow near-threshold states [104, 105]. Examples of such analyses can be found in Refs. [106–108]. Moreover, it is possible to introduce the effect of a weakly coupled lower channel [109,110]. Such coupling results in a positive imaginary part of the scattering length. It is also crucial to highlight that for large a values, the amplitude of Eq. (50.47) develops a near-threshold pole located on the physical or unphysical sheet for negative or positive values of a, respectively. For readers interested in a exploration of how close-to-threshold poles interact with remote thresholds, we refer to Ref. [111].

While easy to use, it is important to stress, however, that the approximation in Eq. (50.47) is a specific choice of the dynamic function. This choice results in a single pole close to the physical region, suggesting that the state under study has the characteristics of a hadronic molecule, as discussed in references such as [108, 112–114]. Virtual states are discussed in this context in Ref. [115].

50.3.5 *Two-potential decomposition*

Another advanced technique to construct the scattering amplitude, which is widely used in the literature [69,116–121], is based on the two-potential formalism [122]. While it is possible to formulate this method for the full unprojected amplitude $\mathcal{M}_{ba}(s,t)$, for clarity, we focus on presenting the equations in their partial-wave-projected form.

The scattering amplitude, $\mathcal{M}(s)$, can be broken down into two components: a background part and a pole part. This can be represented as:

$$\mathcal{M}(s) = \mathcal{M}^{\text{b.g.}}(s) + \mathcal{M}^{\text{pole}}(s)\,. \tag{50.48}$$

It is important to note that the division presented in Eq. (50.48) is not unique and model-dependent. This is further discussed in references such as [123,124]. The background scattering matrix is assumed to be unitary by itself. One approach to parameterize it, especially at lower energies, is by using phase shifts and inelasticities, as seen in [69, 120, 121]. Alternatively, it can be computed based on some potential, $V^{\text{b.g.}}$, fed into a proper scattering equation [118, 119].

The complete amplitude, $\mathcal{M}$, from Eq. (50.48) is unitary, if the pole part follows a specific construction. Namely,

$$\mathcal{M}^{\text{pole}}_{ab}(s) = \Omega_{ac}(s)\,[1 - V^{\text{R}}(s)\Sigma^{u}(s)]^{-1}_{cd} V^{\text{R}}_{de}(s)\;\Omega^{T}_{eb}(s)\;. \tag{50.49}$$

In this context, we introduce the vertex functions, denoted as $\Omega_{ab}(s)$, and the resonance potential, represented as $V^{\text{R}}(s)$. This potential operates as a matrix in the channel space and can be expressed as:

$$V^{\text{R}}_{ab}(s) = \sum_{\text{R}} \frac{g^{\text{R}}_a\; g^{\text{R}}_b}{m^2_{\text{R}} - s}\,. \tag{50.50}$$

The term Σ^{u}_{ab} represents the self-energy matrix. Additionally, g^{R}_a denotes the bare coupling of the resonance, labeled as R, to the channel a, and m_{R} is its bare mass. The vertex functions obey a unitarity relation similar to the production amplitude in Eq. (50.8). However, in this case, the final state interaction is determined by $\mathcal{M}^{\text{b.g.}}$. This can be represented as:

$$\text{Disc}\,\Omega_{ab}(s) = 2i \sum_{c} \mathcal{M}^{\text{b.g.}\,*}_{ca}(s)\,\rho_c(s)\,\Omega_{cb}(s)\;. \tag{50.51}$$

When using low-energy phase shifts for the background term, it is practical to express the vertex functions in terms of an Omnès matrix, as discussed in [121]. The matrix reduces to the well-known Omnès function

$$\Omega(s) = \exp\left(\frac{s}{\pi}\int_{s_{\text{thr}}}^{\infty} \text{d}s' \frac{\delta^{\text{b.g.}}(s')}{s'(s'-s-i\epsilon)}\right) \tag{50.52}$$

in the single-channel case [125], where $\delta^{\text{b.g.}}(s)$ denotes the phase of the background scattering matrix $\mathcal{M}^{\text{b.g.}}(s)$. The discontinuity associated with the self-energy matrix, $\Sigma^{u}(s)$, is given by:

$$\text{Disc}\,\Sigma^{u}_{ab}(s) = 2i \sum_{c} \Omega^{*}_{ca}(s)\,\rho_c(s)\,\Omega_{cb}(s)\;. \tag{50.53}$$

To determine the real part of Σ^{u}, one can use Eq. (50.53) with a properly subtracted dispersion integral — *cf.* Eq. (50.43).

When $\mathcal{M}^{\text{b.g.}}$ is unitary, the full amplitude is unitary given Eq. (50.49). However, it is essential to note that the pole term alone is not unitary unless the background amplitude vanishes. Under such conditions, the described amplitude simplifies to the K-matrix construction with improved analytic behavior as detained in Sec. 50.3.3. Neglecting non-pole terms is not a good approximation for certain interactions, such as the scalar-isoscalar $\pi\pi$ at low energies, as discussed in [126]. However, for higher partial waves, this approximation is generally effective.

A production amplitude consistent with Eq. (50.49) reads [120, 121]:

$$\mathcal{A}^{\text{pole}}_{a}(s) = \Omega_{ac}(s)\,[1 - V^{\text{R}}(s)\Sigma^{u}(s)]^{-1}_{cd}\mathcal{P}_d\;, \tag{50.54}$$

with function $\mathcal{P}_d$ given in Eq. (50.40). This form was employed in Refs. [120,121] to treat the pion vector and scalar form factor, respectively, and in Ref. [69] for the scalar πK form factor.

There has been considerable interest in the $3 \to 3$ scattering recently, particularly in light of new data on three-hadron interaction [127] and advancements in lattice calculations [128]. One finds that the methodologies devised for accounting for one-pion exchange bear a resemblance to the two-potential decomposition. For details see Ref. [129], also Eq. (93) in Ref. [130].

51. Cross-Section Formulae for Specific Processes

Revised August 2019 by H. Baer (Oklahoma U.) and R.N. Cahn (LBNL).

PART I: STANDARD MODEL PROCESSES

Setting aside leptoproduction (for which, see Sec. 16 of this *Review*), the cross sections of primary interest are those with light incident particles, e^+e^-, $\gamma\gamma$, $q\overline{q}$, gq , gg, *etc.*, where g and q represent gluons and light quarks. The produced particles include both light particles and heavy ones - t, W, Z, and the Higgs boson H. We provide the production cross sections calculated within the Standard Model for several such processes.

51.1 Resonance Formation

Resonant cross sections are generally described by the Breit-Wigner formula (Sec. 50.3 of this *Review*).

$$\sigma(E) = \frac{2J+1}{(2S_1+1)(2S_2+1)}\frac{4\pi}{k^2}\left[\frac{\Gamma^2/4}{(E-E_0)^2+\Gamma^2/4}\right]B_{in}B_{out}, \tag{51.1}$$

where E is the c.m. energy, J is the spin of the resonance, and the number of polarization states of the two incident particles are $2S_1+1$ and $2S_2+1$. The c.m. momentum in the initial state is k, E_0 is the c.m. energy at the resonance, and Γ is the full width at half maximum height of the resonance. The branching fraction for the resonance into the initial-state channel is B_{in} and into the final-state channel is B_{out}. For a narrow resonance, the factor in square brackets may be replaced by $\pi\Gamma\delta(E-E_0)/2$.

51.2 Production of light particles

The production of point-like, spin-1/2 fermions in e^+e^- annihilation through a virtual photon, $e^+e^- \to \gamma^* \to f\overline{f}$, at c.m. energy squared s is given by

$$\frac{d\sigma}{d\Omega} = N_c\frac{\alpha^2}{4s}\beta\left[1+\cos^2\theta+(1-\beta^2)\sin^2\theta\right]Q_f^2 \ , \tag{51.2}$$

where β is v/c for the produced fermions in the c.m., θ is the c.m. scattering angle, and Q_f is the charge of the fermion. The factor N_c is 1 for charged leptons and 3 for quarks. In the ultrarelativistic limit, $\beta \to 1$,

$$\sigma = N_cQ_f^2\frac{4\pi\alpha^2}{3s} = N_cQ_f^2\frac{86.8\text{ nb}}{s\,(\text{GeV}^2)} \ . \tag{51.3}$$

The cross section for the annihilation of a $q\overline{q}$ pair into a distinct pair $q'\overline{q}'$ through a gluon is completely analogous up to color factors, with the replacement $\alpha \to \alpha_s$. Treating all quarks as massless, averaging over the colors of the initial quarks and defining $t = -s\sin^2(\theta/2)$, $u = -s\cos^2(\theta/2)$, one finds [1]

$$\frac{d\sigma}{d\Omega}(q\overline{q} \to q'\overline{q}') = \frac{\alpha_s^2}{9s}\frac{t^2+u^2}{s^2} \ . \tag{51.4}$$

Crossing symmetry gives

$$\frac{d\sigma}{d\Omega}(qq' \to qq') = \frac{\alpha_s^2}{9s}\frac{s^2+u^2}{t^2} \ . \tag{51.5}$$

If the quarks q and q' are identical, we have

$$\frac{d\sigma}{d\Omega}(q\overline{q} \to q\overline{q}) = \frac{\alpha_s^2}{9s}\left[\frac{t^2+u^2}{s^2}+\frac{s^2+u^2}{t^2}-\frac{2u^2}{3st}\right] \ , \tag{51.6}$$

and by crossing

$$\frac{d\sigma}{d\Omega}(qq \to qq) = \frac{\alpha_s^2}{9s}\left[\frac{t^2+s^2}{u^2}+\frac{s^2+u^2}{t^2}-\frac{2s^2}{3ut}\right]. \tag{51.7}$$

Annihilation of e^+e^- into $\gamma\gamma$ has the cross section

$$\frac{d\sigma}{d\Omega}(e^+e^- \to \gamma\gamma) = \frac{\alpha^2}{2s}\frac{u^2+t^2}{tu} \ . \tag{51.8}$$

The related QCD process also has a triple-gluon coupling. The cross section is

$$\frac{d\sigma}{d\Omega}(q\overline{q} \to gg) = \frac{8\alpha_s^2}{27s}(t^2+u^2)\left(\frac{1}{tu}-\frac{9}{4s^2}\right) \ . \tag{51.9}$$

The crossed reactions are

$$\frac{d\sigma}{d\Omega}(qg \to qg) = \frac{\alpha_s^2}{9s}(s^2+u^2)(-\frac{1}{su}+\frac{9}{4t^2}) \tag{51.10}$$

and

$$\frac{d\sigma}{d\Omega}(gg \to q\overline{q}) = \frac{\alpha_s^2}{24s}(t^2+u^2)(\frac{1}{tu}-\frac{9}{4s^2}) \ . \tag{51.11}$$

Finally,

$$\frac{d\sigma}{d\Omega}(gg \to gg) = \frac{9\alpha_s^2}{8s}(3-\frac{ut}{s^2}-\frac{su}{t^2}-\frac{st}{u^2}) \ . \tag{51.12}$$

Lepton-quark scattering is analogous (neglecting Z exchange)

$$\frac{d\sigma}{d\Omega}(eq \to eq) = \frac{\alpha^2}{2s}e_q^2\frac{s^2+u^2}{t^2} \ . \tag{51.13}$$

where e_q is the charge of the quark. For neutrino scattering with the four-Fermi interaction

$$\frac{d\sigma}{d\Omega}(\nu d \to \ell^- u) = \frac{G_F^2 s}{4\pi^2} \ , \tag{51.14}$$

where the Cabibbo angle suppression is ignored. Similarly

$$\frac{d\sigma}{d\Omega}(\nu\overline{u} \to \ell^-\overline{d}) = \frac{G_F^2 s}{4\pi^2}\frac{(1+\cos\theta)^2}{4} \ . \tag{51.15}$$

To obtain the formulae for deep inelastic scattering (presented in more detail in Section 18) we consider quarks of type i carrying a fraction $x = Q^2/(2M\nu)$ of the nucleon's energy, where $\nu = E-E'$ is the energy lost by the lepton in the nucleon rest frame. With $y = \nu/E$ we have the correspondences

$$1+\cos\theta \to 2(1-y) \ ,$$

$$d\Omega_{cm} \to 4\pi f_i(x)dx\,dy \ , \tag{51.16}$$

where the latter incorporates the quark distribution, $f_i(x)$. In this way we find

$$\frac{d\sigma}{dx\,dy}(eN \to eX) = \frac{4\pi\alpha^2 xs}{Q^4}\frac{1}{2}\left[1+(1-y)^2\right] \times \left[\frac{4}{9}(u(x)+\overline{u}(x)+\ldots)+\frac{1}{9}(d(x)+\overline{d}(x)+\ldots)\right] \tag{51.17}$$

where now $s = 2ME$ is the cm energy squared for the electron-nucleon collision, and we have suppressed contributions from higher mass quarks.

Similarly,

$$\frac{d\sigma}{dx\,dy}(\nu N \to \ell^- X) = \frac{G_F^2 xs}{\pi}[(d(x)+\ldots)+(1-y)^2(\overline{u}(x)+\ldots)] \tag{51.18}$$

and

$$\frac{d\sigma}{dx\,dy}(\overline{\nu}N \to \ell^+ X) = \frac{G_F^2 xs}{\pi}[(\overline{d}(x)+\ldots)+(1-y)^2(u(x)+\ldots)] \ . \tag{51.19}$$

Quasi-elastic neutrino scattering ($\nu_\mu n \to \mu^- p$, $\overline{\nu}_\mu p \to \mu^+ n$) is directly related to the crossed reaction, neutron decay. The formula for the differential cross section is presented, for example, in N.J. Baker *et al.*, Phys. Rev. **D23**, 2499 (1981).

51.3 Hadroproduction of heavy quarks

For hadroproduction of heavy quarks $Q = c,\ b,\ t$, it is important to include mass effects in the formulae. For $q\bar{q} \to Q\bar{Q}$, one has

$$\frac{d\sigma}{d\Omega}(q\bar{q} \to Q\bar{Q}) = \frac{\alpha_s^2}{9s^3}\sqrt{1-\frac{4m_Q^2}{s}} \left[(m_Q^2-t)^2 + (m_Q^2-u)^2 + 2m_Q^2 s\right], \quad (51.20)$$

while for $gg \to Q\bar{Q}$ one has

$$\begin{aligned}\frac{d\sigma}{d\Omega}(gg \to Q\bar{Q}) = \frac{\alpha_s^2}{32s}\sqrt{1-\frac{4m_Q^2}{s}}\Bigg[&\frac{6}{s^2}(m_Q^2-t)(m_Q^2-u) - \\ &-\frac{m_Q^2(s-4m_Q^2)}{3(m_Q^2-t)(m_Q^2-u)} + \\ &\frac{4}{3}\frac{(m_Q^2-t)(m_Q^2-u)-2m_Q^2(m_Q^2+t)}{(m_Q^2-t)^2} \\ &+\frac{4}{3}\frac{(m_Q^2-t)(m_Q^2-u)-2m_Q^2(m_Q^2+u)}{(m_Q^2-u)^2} \\ &-3\frac{(m_Q^2-t)(m_Q^2-u)+m_Q^2(u-t)}{s(m_Q^2-t)} \\ &-3\frac{(m_Q^2-t)(m_Q^2-u)+m_Q^2(t-u)}{s(m_Q^2-u)}\Bigg]. \end{aligned} \quad (51.21)$$

51.4 Production of Weak Gauge Bosons

51.4.1 *W and Z resonant production*

Resonant production of a single W or Z is governed by the partial widths

$$\Gamma(W \to \ell_i \overline{\nu}_i) = \frac{\sqrt{2}G_F m_W^3}{12\pi} \quad (51.22)$$

$$\Gamma(W \to q_i \bar{q}_j) = 3\frac{\sqrt{2}G_F |V_{ij}|^2 m_W^3}{12\pi} \quad (51.23)$$

$$\Gamma(Z \to f\bar{f}) = N_c \frac{\sqrt{2}G_F m_Z^3}{6\pi} \times \left[(T_3 - Q_f \sin^2\theta_W)^2 + (Q_f \sin^2\theta_W)^2\right] \quad (51.24)$$

The weak mixing angle is θ_W. The CKM matrix elements are indicated by V_{ij} and N_c is 3 for $q\bar{q}$ final states and 1 for leptonic final states.

The full differential cross section for $f_i\bar{f}_j \to (W,Z) \to f_{i'}\bar{f}_{j'}$ is given by

$$\begin{aligned}\frac{d\sigma}{d\Omega} = &\frac{N_c^f}{N_c^i}\cdot\frac{1}{256\pi^2 s}\cdot\frac{s^2}{(s-M^2)^2+s\Gamma^2} \\ &\times\Big[(L^2+R^2)(L'^2+R'^2)(1+\cos^2\theta) \\ &+(L^2-R^2)(L'^2-R'^2)2\,cos\theta\Big] \end{aligned} \quad (51.25)$$

where M is the mass of the W or Z. The couplings for the W are $L = (8G_F m_W^2/\sqrt{2})^{1/2} V_{ij}/\sqrt{2}; R = 0$ where V_{ij} is the corresponding CKM matrix element, with an analogous expression for L' and R'. For Z, the couplings are $L = (8G_F m_Z^2/\sqrt{2})^{1/2}(T_3 - \sin^2\theta_W Q); R = -(8G_F m_Z^2/\sqrt{2})^{1/2}\sin^2\theta_W Q$, where T_3 is the weak isospin of the initial left-handed fermion and Q is the initial fermion's electric charge. The expressions for L' and R' are analogous. The color factors $N_c^{i,f}$ are 3 for initial or final quarks and 1 for initial or final leptons.

51.4.2 *Production of pairs of weak gauge bosons*

The cross section for $f\bar{f} \to W^+W^-$ is given in term of the couplings of the left-handed and right-handed fermion f, $\ell = 2(T_3 - Qx_W)$, $r = -2Qx_W$, where T_3 is the third component of weak isospin for the left-handed f, Q is its electric charge (in units of the proton charge), and $x_W = \sin^2\theta_W$:

$$\begin{aligned}\frac{d\sigma}{dt} = &\frac{2\pi\alpha^2}{N_c s^2}\Bigg\{\Bigg[\left(Q + \frac{\ell+r}{4x_W}\frac{s}{s-m_Z^2}\right)^2 \\ &+\left(\frac{\ell-r}{4x_W}\frac{s}{s-m_Z^2}\right)^2\Bigg]A(s,t,u) \\ &+\frac{1}{2x_W}\left(Q + \frac{\ell}{2x_W}\frac{s}{s-m_Z^2}\right) \\ &\qquad(\Theta(-Q)I(s,t,u) - \Theta(Q)I(s,u,t)) \\ &+\frac{1}{8x_W^2}\left(\Theta(-Q)E(s,t,u) + \Theta(Q)E(s,u,t)\right)\Bigg\}, \end{aligned} \quad (51.26)$$

where $\Theta(x)$ is 1 for $x > 0$ and 0 for $x < 0$, and where

$$\begin{aligned} A(s,t,u) &= \left(\frac{tu}{m_W^4} - 1\right)\left(\frac{1}{4} - \frac{m_W^2}{s} + 3\frac{m_W^4}{s^2}\right) + \frac{s}{m_W^2} - 4, \\ I(s,t,u) &= \left(\frac{tu}{m_W^4} - 1\right)\left(\frac{1}{4} - \frac{m_W^2}{2s} - \frac{m_W^4}{st}\right) + \frac{s}{m_W^2} - 2 + 2\frac{m_W^2}{t}, \\ E(s,t,u) &= \left(\frac{tu}{m_W^4} - 1\right)\left(\frac{1}{4} + \frac{m_W^4}{t^2}\right) + \frac{s}{m_W^2}, \end{aligned} \quad (51.27)$$

and s,t,u are the usual Mandelstam variables with $s = (p_f + p_{\bar{f}})^2, t = (p_f - p_{W^-})^2, u = (p_f - p_{W^+})^2$. The factor N_c is 3 for quarks and 1 for leptons.

The analogous cross-section for $q_i\bar{q}_j \to W^\pm Z^0$ is

$$\begin{aligned}\frac{d\sigma}{dt} = &\frac{\pi\alpha^2|V_{ij}|^2}{6s^2x_W^2}\Bigg\{\left(\frac{1}{s-m_W^2}\right)^2\Bigg[\left(\frac{9-8x_W}{4}\right)\left(ut - m_W^2m_Z^2\right) \\ &+(8x_W-6)\,s\left(m_W^2+m_Z^2\right)\Bigg] \\ &+\left[\frac{ut-m_W^2m_Z^2-s(m_W^2+m_Z^2)}{s-m_W^2}\right]\left[\frac{\ell_j}{t} - \frac{\ell_i}{u}\right] \\ &+\frac{ut-m_W^2m_Z^2}{4(1-x_W)}\left[\frac{\ell_j^2}{t^2} + \frac{\ell_i^2}{u^2}\right] + \frac{s(m_W^2+m_Z^2)}{2(1-x_W)}\frac{\ell_i\ell_j}{tu}\Bigg\}, \end{aligned} \quad (51.28)$$

where ℓ_i and ℓ_j are the couplings of the left-handed q_i and q_j as defined above. The CKM matrix element between q_i and q_j is V_{ij}.

The cross section for $q_i\bar{q}_i \to Z^0Z^0$ is

$$\frac{d\sigma}{dt} = \frac{\pi\alpha^2}{96}\frac{\ell_i^4 + r_i^4}{x_W^2(1-x_W^2)^2s^2}\left[\frac{t}{u} + \frac{u}{t} + \frac{4m_Z^2 s}{tu} - m_Z^4\left(\frac{1}{t^2} + \frac{1}{u^2}\right)\right]. \quad (51.29)$$

51.5 Production of Higgs Bosons

51.5.1 *Resonant Production*

The Higgs boson of the Standard Model can be produced resonantly in the collisions of quarks, leptons, W or Z bosons, gluons, or photons. The production cross section is thus controlled by the partial width of the Higgs boson into the entrance channel and its total width. The branching fractions for the Standard Model Higgs boson are shown in Fig. 1 of the "Searches for Higgs bosons" review in the Particle Listings section, as a function of the Higgs boson mass. The partial widths are given by the relations

$$\Gamma(H \to f\bar{f}) = \frac{G_F m_f^2 m_H N_c}{4\pi\sqrt{2}} \left(1 - 4m_f^2/m_H^2\right)^{3/2}, \quad (51.30)$$

$$\Gamma(H \to W^+W^-) = \frac{G_F m_H^3 \beta_W}{32\pi\sqrt{2}} \left(4 - 4a_W + 3a_W^2\right), \quad (51.31)$$

$$\Gamma(H \to ZZ) = \frac{G_F m_H^3 \beta_Z}{64\pi\sqrt{2}} \left(4 - 4a_Z + 3a_Z^2\right), \quad (51.32)$$

where N_c is 3 for quarks and 1 for leptons and where $a_W = 1 - \beta_W^2 = 4m_W^2/m_H^2$ and $a_Z = 1 - \beta_Z^2 = 4m_Z^2/m_H^2$. The decay to two gluons proceeds through quark loops, with the t quark dominating [2]. Explicitly,

$$\Gamma(H \to gg) = \frac{\alpha_s^2 G_F m_H^3}{36\pi^3\sqrt{2}} \left| \sum_q I(m_q^2/m_H^2) \right|^2, \quad (51.33)$$

where $I(z)$ is complex for $z < 1/4$. For $z < 2 \times 10^{-3}$, $|I(z)|$ is small so the light quarks contribute negligibly. For $m_H < 2m_t$, $z > 1/4$ and

$$I(z) = 3\left[2z + 2z(1-4z)\left(\sin^{-1}\frac{1}{2\sqrt{z}}\right)^2\right], \quad (51.34)$$

which has the limit $I(z) \to 1$ as $z \to \infty$.

51.5.2 *Higgs Boson Production in W^* and Z^* decay*

The Standard Model Higgs boson can be produced in the decay of a virtual W or Z ("Higgstrahlung") [3, 4]: In particular, if k is the c.m. momentum of the Higgs boson,

$$\sigma(q_i\bar{q}_j \to WH) = \frac{\pi\alpha^2|V_{ij}|^2}{36\sin^4\theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_W^2}{(s - m_W^2)^2} \quad (51.35)$$

$$\sigma(f\bar{f} \to ZH) = \frac{2\pi\alpha^2(\ell_f^2 + r_f^2)}{48N_c \sin^4\theta_W \cos^4\theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_Z^2}{(s - m_Z^2)^2}, \quad (51.36)$$

where ℓ and r are defined as above.

51.5.3 *W and Z Fusion*

Just as high-energy electrons can be regarded as sources of virtual photon beams, at very high energies they are sources of virtual W and Z beams. For Higgs boson production, it is the longitudinal components of the Ws and Zs that are important [5]. The distribution of longitudinal Ws carrying a fraction y of the electron's energy is [6]

$$f(y) = \frac{g^2}{16\pi^2} \frac{1-y}{y}, \quad (51.37)$$

where $g = e/\sin\theta_W$. In the limit $s \gg m_H \gg m_W$, the partial decay rate is $\Gamma(H \to W_L W_L) = (g^2/64\pi)(m_H^3/m_W^2)$ and in the equivalent W approximation [7]

$$\sigma(e^+e^- \to \overline{\nu}_e\nu_e H) = \frac{1}{16m_W^2}\left(\frac{\alpha}{\sin^2\theta_W}\right)^3 \times \left[\left(1 + \frac{m_H^2}{s}\right)\log\frac{s}{m_H^2} - 2 + 2\frac{m_H^2}{s}\right]. \quad (51.38)$$

There are significant corrections to this relation when m_H is not large compared to m_W [8]. For $m_H = 150$ GeV, the estimate is too high by 51% for $\sqrt{s} = 1000$ GeV, 32% too high at $\sqrt{s} = 2000$ GeV, and 22% too high at $\sqrt{s} = 4000$ GeV. Fusion of ZZ to make a Higgs boson can be treated similarly. Identical formulae apply for Higgs production in the collisions of quarks whose charges permit the emission of a W^+ and a W^-, except that QCD corrections and CKM matrix elements are required. Even in the absence of QCD corrections, the fine-structure constant ought to be evaluated at the scale of the collision, say m_W. All quarks contribute to the ZZ fusion process.

51.6 Inclusive hadronic reactions

One-particle inclusive cross sections $Ed^3\sigma/d^3p$ for the production of a particle of momentum p are conveniently expressed in terms of rapidity y (see above) and the momentum p_T transverse to the beam direction (in the c.m.):

$$E\frac{d^3\sigma}{d^3p} = \frac{d^3\sigma}{d\phi\, dy\, p_T dp_T}. \quad (51.39)$$

In appropriate circumstances, the cross section may be decomposed as a partonic cross section multiplied by the probabilities of finding partons of the prescribed momenta:

$$\sigma_{\rm hadronic} = \sum_{ij} \int dx_1\, dx_2\, f_i(x_1)\, f_j(x_2)\, \widehat{d\sigma}_{\rm partonic}, \quad (51.40)$$

The probability that a parton of type i carries a fraction of the incident particle's that lies between x_1 and $x_1 + dx_1$ is $f_i(x_1)dx_1$ and similarly for partons in the other incident particle. The partonic collision is specified by its c.m. energy squared $\hat{s} = x_1x_2s$ and the momentum transfer squared $\hat{t}$. The final hadronic state is more conveniently specified by the rapidities y_1, y_2 of the two jets resulting from the collision and the transverse momentum p_T. The connection between the differentials is

$$dx_1dx_2d\hat{t} = dy_1dy_2\frac{\hat{s}}{s}dp_T^2, \quad (51.41)$$

so that

$$\frac{d^3\sigma}{dy_1dy_2dp_T^2} = \frac{\hat{s}}{s}\left[f_i(x_1)f_j(x_2)\frac{d\hat{\sigma}}{d\hat{t}}(\hat{s},\hat{t},\hat{u}) + f_i(x_2)f_j(x_1)\frac{d\hat{\sigma}}{d\hat{t}}(\hat{s},\hat{u},\hat{t})\right], \quad (51.42)$$

where we have taken into account the possibility that the incident parton types might arise from either incident particle. The second term should be dropped if the types are identical: $i = j$.

51.7 Two-photon processes

In the Weizsäcker-Williams picture, a high-energy electron beam is accompanied by a spectrum of virtual photons of energies ω and invariant-mass squared $q^2 = -Q^2$, for which the photon number density is

$$dn = \frac{\alpha}{\pi}\left[1 - \frac{\omega}{E} + \frac{\omega^2}{E^2} - \frac{m_e^2\,\omega^2}{Q^2E^2}\right]\frac{d\omega}{\omega}\frac{dQ^2}{Q^2}, \quad (51.43)$$

where E is the energy of the electron beam. The cross section for $e^+e^- \to e^+e^-X$ is then [9]

$$d\sigma_{e^+e^-\to e^+e^-X}(s) = dn_1dn_2d\sigma_{\gamma\gamma\to X}(W^2), \quad (51.44)$$

where $W^2 = m_X^2$. Integrating from the lower limit $Q^2 = m_e^2\frac{\omega_i^2}{E_i(E_i-\omega_i)}$ to a maximum Q^2 gives

$$\sigma_{e^+e^-\to e^+e^-X}(s) = \frac{\alpha^2}{\pi^2}\int_{z_{th}}^1 \frac{dz}{z} \times \left[\left(\ln\frac{Q_{max}^2}{zm_e^2} - 1\right)^2 f(z) + \frac{1}{3}(\ln z)^3\right]\sigma_{\gamma\gamma\to X}(zs), \quad (51.45)$$

where

$$f(z) = \left(1 + \tfrac{1}{2}z\right)^2\ln(1/z) - \tfrac{1}{2}(1-z)(3+z). \quad (51.46)$$

The appropriate value of Q_{max}^2 depends on the properties of the produced system X. For production of hadronic systems,

$Q^2_{max} \approx m^2_\rho$, while for lepton-pair production, $Q^2 \approx W^2$. For production of a resonance with spin $J \neq 1$, we have

$$\sigma_{e^+e^-\to e^+e^- R}(s) = (2J+1)\frac{8\alpha^2 \Gamma_{R\to\gamma\gamma}}{m_R^3} \times \left[f(m_R^2/s)\left(\ln\frac{m_V^2 s}{m_e^2 m_R^2} - 1\right)^2 - \frac{1}{3}\left(\ln\frac{s}{M_R^2}\right)^3 \right], \quad (51.47)$$

where m_V is the mass that enters into the form factor for the $\gamma\gamma \to R$ transition, typically m_ρ.

PART II: PROCESSES BEYOND THE STANDARD MODEL

51.8 Production of supersymmetric particles

In supersymmetric (SUSY) theories (see Supersymmetric Particle Searches in this *Review*), every boson has a fermionic superpartner, and every fermion has a bosonic superpartner. The minimal supersymmetric Standard Model (MSSM) is a direct supersymmetrization of the Standard Model (SM), although a second Higgs doublet is needed to avoid triangle anomalies [10]. Under *soft* SUSY breaking, superpartner masses are lifted above the SM particle masses. In weak scale SUSY, the superpartners are invoked to stabilize the weak scale under radiative corrections, so the superpartners are expected to have masses of order the TeV scale.

51.8.1 *Gluino and squark production*

The superpartners of gluons are the color octet, spin$-\frac{1}{2}$ gluinos ($\tilde{g}$), while each helicity component of quark flavor has a spin-0 *squark* partner, *e.g.* $\tilde{q}_L$ and $\tilde{q}_R$. Third generation left- and right- squarks are expected to have large mixing, resulting in mass eigenstates $\tilde{q}_1$ and $\tilde{q}_2$, with $m_{\tilde{q}_1} < m_{\tilde{q}_2}$ (here, q denotes any of the SM flavors of quarks and $\tilde{q}_i$ the corresponding flavor and type ($i = L, R$ or $1, 2$) of squark). Gluino pair production ($\tilde{g}\tilde{g}$) takes place via either glue-glue or quark-antiquark annihilation [11].

The subprocess cross sections are usually presented as differential distributions in the Mandelstam variables s, t and u. Note that for a $2 \to 2$ scattering subprocess $ab \to cd$, the Mandelstam variable $s = (p_a + p_b)^2 = (p_c + p_d)^2$, where p_a is the 4-momentum of particle a, and so forth. The variable $t = (p_c - p_a)^2$, where c and a are taken conventionally to be the most similar particles in the subprocess. The variable u would then be equal to $(p_d - p_a)^2$. Note that since s, t and u are squares of 4-vectors, they are invariants in any inertial reference frame.

Gluino pair production at hadron colliders is described by:

$$\frac{d\sigma}{dt}(gg \to \tilde{g}\tilde{g}) = \frac{9\pi\alpha_s^2}{4s^2}\left\{ \frac{2(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)}{s^2} + \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) - 2m_{\tilde{g}}^2(m_{\tilde{g}}^2 + t)}{(m_{\tilde{g}}^2 - t)^2} + \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) - 2m_{\tilde{g}}^2(m_{\tilde{g}}^2 + u)}{(m_{\tilde{g}}^2 - u)^2} + \frac{m_{\tilde{g}}^2(s - 4m_{\tilde{g}}^2)}{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)} - \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) + m_{\tilde{g}}^2(u - t)}{s(m_{\tilde{g}}^2 - t)} - \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) + m_{\tilde{g}}^2(t - u)}{s(m_{\tilde{g}}^2 - u)} \right\}, \quad (51.48)$$

where α_s is the strong fine structure constant. Also,

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{g}\tilde{g}) = \frac{8\pi\alpha_s^2}{9s^2}\left\{ \frac{4}{3}\left(\frac{m_{\tilde{g}}^2 - t}{m_{\tilde{q}}^2 - t}\right)^2 + \frac{4}{3}\left(\frac{m_{\tilde{g}}^2 - u}{m_{\tilde{q}}^2 - u}\right)^2 + \frac{3}{s^2}\left[(m_{\tilde{g}}^2 - t)^2 + (m_{\tilde{g}}^2 - u)^2 + 2m_{\tilde{g}}^2 s\right] - 3\frac{\left[(m_{\tilde{g}}^2 - t)^2 + m_{\tilde{g}}^2 s\right]}{s(m_{\tilde{q}}^2 - t)} - 3\frac{\left[(m_{\tilde{g}}^2 - u)^2 + m_{\tilde{g}}^2 s\right]}{s(m_{\tilde{q}}^2 - u)} + \frac{1}{3}\frac{m_{\tilde{g}}^2 s}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)} \right\}. \quad (51.49)$$

Gluinos can also be produced in association with squarks: $\tilde{g}\tilde{q}_i$ production, where $\tilde{q}_i$ represents any of the various types (left, right- or mixed) and flavors of squarks. The subprocess cross section is independent of whether the squark is the right-, left- or mixed type:

$$\frac{d\sigma}{dt}(gq \to \tilde{g}\tilde{q}_i) = \frac{\pi\alpha_s^2}{24s^2}\frac{\left[\frac{16}{3}(s^2 + (m_{\tilde{q}_i}^2 - u)^2) + \frac{4}{3}s(m_{\tilde{q}_i}^2 - u)\right]}{s(m_{\tilde{g}}^2 - t)(m_{\tilde{q}_i}^2 - u)^2} \times \left((m_{\tilde{g}}^2 - u)^2 + (m_{\tilde{q}_i}^2 - m_{\tilde{g}}^2)^2 + \frac{2sm_{\tilde{g}}^2(m_{\tilde{q}_i}^2 - m_{\tilde{g}}^2)}{(m_{\tilde{g}}^2 - t)} \right). \quad (51.50)$$

There are many different subprocesses for production of squark pairs. Since left- and right- squarks generally have different masses and different decay patterns, we present the differential cross section for each subprocess of $\tilde{q}_i$ ($i = L,\ R$ or $1,\ 2$) separately. (In early literature, the following formulae were often combined into a single equation which didn't differentiate the various squark types.) The result for $gg \to \tilde{q}_i\bar{\tilde{q}}_i$ is:

$$\frac{d\sigma}{dt}(gg \to \tilde{q}_i\bar{\tilde{q}}_i) = \frac{\pi\alpha_s^2}{4s^2}\left\{ \frac{1}{3}\left(\frac{m_{\tilde{q}}^2 + t}{m_{\tilde{q}}^2 - t}\right)^2 + \frac{1}{3}\left(\frac{m_{\tilde{q}}^2 + u}{m_{\tilde{q}}^2 - u}\right)^2 + \frac{3}{32s^2}\left(8s(4m_{\tilde{q}}^2 - s) + 4(u - t)^2\right) + \frac{7}{12} - \frac{1}{48}\frac{(4m_{\tilde{q}}^2 - s)^2}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)} + \frac{3}{32}\frac{\left[(t - u)(4m_{\tilde{q}}^2 + 4t - s) - 2(m_{\tilde{q}}^2 - u)(6m_{\tilde{q}}^2 + 2t - s)\right]}{s(m_{\tilde{q}}^2 - t)} + \frac{3}{32}\frac{\left[(u - t)(4m_{\tilde{q}}^2 + 4u - s) - 2(m_{\tilde{q}}^2 - t)(6m_{\tilde{q}}^2 + 2u - s)\right]}{s(m_{\tilde{q}}^2 - u)} + \frac{7}{96}\frac{\left[4m_{\tilde{q}}^2 + 4t - s\right]}{m_{\tilde{q}}^2 - t} + \frac{7}{96}\frac{\left[4m_{\tilde{q}}^2 + 4u - s\right]}{m_{\tilde{q}}^2 - u} \right\}, \quad (51.51)$$

which has an obvious $u \leftrightarrow t$ symmetry.

For $q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_i$ with the same initial and final state flavors, we have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_i) = \frac{2\pi\alpha_s^2}{9s^2}\left\{ \frac{1}{(t - m_{\tilde{g}}^2)^2} + \frac{2}{s^2} - \frac{2/3}{s(t - m_{\tilde{g}}^2)} \right\} \times \left[-st - (t - m_{\tilde{q}_i}^2)^2 \right], \quad (51.52)$$

while if initial and final state flavors are different ($q\bar{q} \to \tilde{q}_i'\bar{\tilde{q}}_i'$) we instead have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i'\bar{\tilde{q}}_i') = \frac{4\pi\alpha_s^2}{9s^4}\left[-st - (t - m_{\tilde{q}_i'}^2)^2 \right]. \quad (51.53)$$

If the two initial state quarks are of different flavors, then we have

$$\frac{d\sigma}{dt}(q\bar{q}' \to \tilde{q}_i\bar{\tilde{q}}_i') = \frac{2\pi\alpha_s^2}{9s^2}\frac{-st-(t-m_{\tilde{q}_i}^2)^2}{(t-m_{\tilde{g}}^2)^2}. \quad (51.54)$$

If the initial quarks are of different flavor and final state squarks are of different type ($i \neq j$) then

$$\frac{d\sigma}{dt}(q\bar{q}' \to \tilde{q}_i\bar{\tilde{q}}_j') = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.55)$$

For same-flavor initial state quarks, but final state unlike-type squarks, we also have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_j) = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.56)$$

There also exist cross sections for quark-quark annihilation to squark pairs. For same flavor quark-quark annihilation to same flavor/same type final state squarks,

$$\frac{d\sigma}{dt}(qq \to \tilde{q}_i\tilde{q}_i) =$$

$$= \frac{\pi\alpha_s^2}{9s^2}m_{\tilde{g}}^2 s\left\{\frac{1}{(t-m_{\tilde{g}}^2)^2}+\frac{1}{(u-m_{\tilde{g}}^2)^2}-\frac{2/3}{(t-m_{\tilde{g}}^2)(u-m_{\tilde{g}}^2)}\right\}, \quad (51.57)$$

while if the final type squarks are different ($i \neq j$), we have

$$\frac{d\sigma}{dt}(qq \to \tilde{q}_i\tilde{q}_j) = \frac{2\pi\alpha_s^2}{9s^2}\times\left\{\frac{[-st-(t-m_{\tilde{q}_i}^2)(t-m_{\tilde{q}_j}^2)]}{(t-m_{\tilde{g}}^2)}\right.$$

$$\left.+\frac{[-su-(u-m_{\tilde{q}_i}^2)(u-m_{\tilde{q}_j}^2)]}{(u-m_{\tilde{g}}^2)}\right\}. \quad (51.58)$$

If initial/final state flavors are different, but final state squark types are the same, then

$$\frac{d\sigma}{dt}(qq' \to \tilde{q}_i\tilde{q}_i') = \frac{2\pi\alpha_s^2}{9s^2}\frac{m_{\tilde{g}}^2 s}{(t-m_{\tilde{g}}^2)^2}. \quad (51.59)$$

If initial quark flavors are different and final squark types are different, then

$$\frac{d\sigma}{dt}(qq' \to \tilde{q}_i\tilde{q}_j') = \frac{2\pi\alpha_s^2}{9s^2}\frac{-st-(t-m_{\tilde{q}_i}^2)(t-m_{\tilde{q}_j}^2)}{(t-m_{\tilde{g}}^2)^2}. \quad (51.60)$$

51.8.2 *Gluino and squark associated production*

In the MSSM, the charged spin-$\frac{1}{2}$ winos and higgsinos mix to make chargino states $\chi_1^\pm$ and $\chi_2^\pm$, with $m_{\chi_1^\pm} < m_{\chi_2^\pm}$. The spin$-\frac{1}{2}$ neutral bino, wino and higgsino fields mix to give four neutralino mass eigenstates $\chi_{1,2,3,4}^0$ ordered according to mass. We sometimes denote the charginos and neutralinos collectively as -inos for notational simplicity

For gluino and squark production in association with charginos and neutralinos [12], the quark-squark-neutralino couplings[1] are defined by the interaction Lagrangian terms

$$\mathcal{L}_{\tilde{f}f\tilde{\chi}_i^0} = \left[iA_{\tilde{\chi}_i^0}^f \tilde{f}_L^\dagger \bar{\tilde{\chi}}_i^0 P_L f + iB_{\tilde{\chi}_i^0}^f \tilde{f}_R^\dagger \bar{\tilde{\chi}}_i^0 P_R f + \text{h.c.}\right],$$

,where $A_{\tilde{\chi}_i^0}^f$ and $B_{\tilde{\chi}_i^0}^f$ are coupling constants involving gauge couplings, neutralino mixing elements and in the case of third generation fermions, Yukawa couplings. Their form depends on the conventions used for setting up the MSSM Lagrangian, and can be found in various reviews [14] and textbooks [13, 15]. P_L and P_R are the usual left- and right- spinor projection operators and f denotes any of the SM fermions u, d, e, $\nu_e, \cdots$. The fermion-sfermion- chargino couplings have the form $\mathcal{L} = \left[iA_{\tilde{\chi}_i^-}^d \tilde{u}_L^\dagger \overline{\tilde{\chi}_i^-} P_L d + iA_{\tilde{\chi}_i^-}^u \tilde{d}_L^\dagger \overline{\tilde{\chi}_i^c} P_L u + \text{h.c.}\right]$ for u and d quarks, where the $A_{\tilde{\chi}_i^-}^d$ and $A_{\tilde{\chi}_i^-}^u$ couplings are again convention-dependent, and can be found in textbooks. The superscript c denotes "charge conjugate spinor", defined by $\psi^c \equiv C\bar{\psi}^T$.

The subprocess cross sections for chargino-squark associated production occur via squark exchange and are given by

$$\frac{d\sigma}{dt}(\bar{u}g \to \tilde{\chi}_i^- \bar{\tilde{d}}_L) = \frac{\alpha_s}{24s^2}|A_{\tilde{\chi}_i^-}^u|^2 \psi(m_{\tilde{d}_L}, m_{\tilde{\chi}_i^-}, t), \quad (51.61)$$

$$\frac{d\sigma}{dt}(dg \to \tilde{\chi}_i^- \tilde{u}_L) = \frac{\alpha_s}{24s^2}|A_{\tilde{\chi}_i^-}^d|^2 \psi(m_{\tilde{u}_L}, m_{\tilde{\chi}_i^-}, t), \quad (51.62)$$

while neutralino-squark production is given by

$$\frac{d\sigma}{dt}(qg \to \tilde{\chi}_i^0 \tilde{q}) = \frac{\alpha_s}{24s^2}\left(|A_{\tilde{\chi}_i^0}^q|^2 + |B_{\tilde{\chi}_i^0}^q|^2\right)\psi(m_{\tilde{q}}, m_{\tilde{\chi}_i^0}, t), \quad (51.63)$$

where

$$\psi(m_1, m_2, t) = \frac{s+t-m_1^2}{2s} - \frac{m_1^2(m_2^2-t)}{(m_1^2-t)^2}$$

$$+\frac{t(m_2^2-m_1^2)+m_2^2(s-m_2^2+m_1^2)}{s(m_1^2-t)}. \quad (51.64)$$

Here, the variable t is given by the square of "squark-minus-quark" four-momentum. The neutralino-gluino associated production cross section also occurs via squark exchange and is given by

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{\chi}_i^0 \tilde{g}) = \frac{\alpha_s}{18s^2}\left(|A_{\tilde{\chi}_i^0}^q|^2 + |B_{\tilde{\chi}_i^0}^q|^2\right)\left[\frac{(m_{\tilde{\chi}_i^0}^2 - t)(m_{\tilde{g}}^2 - t)}{(m_{\tilde{q}}^2 - t)^2}\right.$$

$$\left.+\frac{(m_{\tilde{\chi}_i^0}^2 - u)(m_{\tilde{g}}^2 - u)}{(m_{\tilde{q}}^2 - u)^2} - \frac{2\eta_i\eta_{\tilde{g}} m_{\tilde{g}} m_{\tilde{\chi}_i^0} s}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)}\right], \quad (51.65)$$

where η_i is the sign of the neutralino mass eigenvalue and $\eta_{\tilde{g}}$ is the sign of the gluino mass eigenvalue. We also have chargino-gluino associated production:

$$\frac{d\sigma}{dt}(\bar{u}d \to \tilde{\chi}_i^- \tilde{g}) = \frac{\alpha_s}{18s^2}\left[|A_{\tilde{\chi}_i^-}^u|^2 \frac{(m_{\tilde{\chi}_i^-}^2 - t)(m_{\tilde{g}}^2 - t)}{(m_{\tilde{d}_L}^2 - t)^2}\right.$$

$$\left.+|A_{\tilde{\chi}_i^-}^d|^2 \frac{(m_{\tilde{\chi}_i^-}^2 - u)(m_{\tilde{g}}^2 - u)}{(m_{\tilde{u}_L}^2 - u)^2} + \frac{2\eta_{\tilde{g}} Re(A_{\tilde{\chi}_i^-}^u A_{\tilde{\chi}_i^-}^d) m_{\tilde{g}} m_{\tilde{\chi}_i} s}{(m_{\tilde{d}_L}^2 - t)(m_{\tilde{u}_L}^2 - u)}\right], \quad (51.66)$$

where $\hat{t} = (\tilde{g} - d)^2$ and in the third term one must take the real part of the in general complex coupling constant product.

51.8.3 *Slepton and sneutrino production*

The subprocess cross section for $\tilde{\ell}_L\bar{\tilde{\nu}}_{\ell_L}$ production ($\ell = e$ or μ) occurs via s-channel W exchange and is given by

$$\frac{d\sigma}{dt}(d\bar{u} \to \tilde{l}_L\bar{\tilde{\nu}}_{\ell_L}) = \frac{g^4|D_W(s)|^2}{192\pi s^2}\left(tu - m_{\tilde{\ell}_L}^2 m_{\tilde{\nu}_{\ell_L}}^2\right), \quad (51.67)$$

where $D_W(s) = 1/(s - M_W^2 + iM_W\Gamma_W)$ is the W-boson propagator denominator. The production of $\tilde{\tau}_1\bar{\tilde{\nu}}_\tau$ is given as above, but replacing $m_{\tilde{\ell}_L} \to m_{\tilde{\tau}_1}$, $m_{\tilde{\nu}_{\ell_L}} \to m_{\tilde{\nu}_\tau}$ and multiplying by an overall factor of $\cos^2\theta_\tau$ (where θ_τ is the tau-slepton mixing angle). Similar substitutions hold for $\tilde{\tau}_2\bar{\tilde{\nu}}_\tau$ production, except the overall factor is $\sin^2\theta_\tau$.

[1] The couplings $A_{\tilde{\chi}_i^0}^f$ and $B_{\tilde{\chi}_i^0}^f$ are given explicitly in Ref. [13] in Eq. (8.87). Also, the couplings $A_{\tilde{\chi}_i^-}^d$ and $A_{\tilde{\chi}_i^-}^u$ are given in Eq. (8.93). The couplings X_i^j and Y_i^j are given by Eq. (8.103), while the x_i and y_i couplings are given in Eq. (8.100). Finally, the couplings W_{ij} are given in Eq. (8.101).

Table 51.1: The constants α_f and β_f that appear in in the SM neutral current Lagrangian. Here $t \equiv \tan\theta_W$ and $c \equiv \cot\theta_W$.

f	q_f	α_f	β_f
ℓ	-1	$\frac{1}{4}(3t-c)$	$\frac{1}{4}(t+c)$
ν_ℓ	0	$\frac{1}{4}$(t+c)	$-\frac{1}{4}(t+c)$
u	$\frac{2}{3}$	$-\frac{5}{12}t+\frac{1}{4}c$	$-\frac{1}{4}(t+c)$
d	$-\frac{1}{3}$	$\frac{1}{12}t-\frac{1}{4}c$	$\frac{1}{4}(t+c)$

The subprocess cross section for $\tilde{\ell}_L\bar{\tilde{\ell}}_L$ production occurs via s-channel γ and Z exchange, and depends on the neutral current interaction, with fermion couplings to γ and Z^0 given by $\mathcal{L}_{\rm neutral} = -eq_f\bar{f}\gamma^\mu f A_\mu + e\bar{f}\gamma^\mu(\alpha_f+\beta_f\gamma_5)fZ_\mu$ (with values of q_f, α_f, and β_f given in Table-51.1.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\ell}_L\bar{\tilde{\ell}}_L) = \frac{e^4}{24\pi s^2}\left(tu-m^4_{\tilde{\ell}_L}\right)\times$$
$$\left\{\frac{q_\ell^2 q_q^2}{s^2} + (\alpha_\ell-\beta_\ell)^2(\alpha_q^2+\beta_q^2)|D_Z(s)|^2\right.$$
$$\left. + \frac{2q_\ell q_q\alpha_q(\alpha_\ell-\beta_\ell)(s-M_Z^2)}{s}|D_Z(s)|^2\right\}, \qquad (51.68)$$

where $D_Z(s) = 1/(s-M_Z^2+iM_Z\Gamma_Z)$. The cross section for sneutrino production is given by the same formula, but with α_ℓ, β_ℓ, q_ℓ and $m_{\tilde{\ell}_L}$ replaced by α_ν, β_ν, 0 and $m_{\tilde{\nu}_L}$, respectively. The cross section for $\tilde{\tau}_1\bar{\tilde{\tau}}_1$ production is obtained by replacing $m_{\tilde{\ell}_L}\to m_{\tilde{\tau}_1}$ and $\beta_\ell\to\beta_\ell\cos 2\theta_\tau$. The cross section for $\tilde{\ell}_R\bar{\tilde{\ell}}_R$ production is given by substituting $\alpha_\ell-\beta_\ell\to\alpha_\ell+\beta_\ell$ and $m_{\tilde{\ell}_L}\to m_{\tilde{\ell}_R}$ in the equation above. The cross section for $\tilde{\tau}_2\bar{\tilde{\tau}}_2$ production is obtained from the formula for $\tilde{\ell}_R\bar{\tilde{\ell}}_R$ production by replacing $m_{\tilde{\ell}_R}\to m_{\tilde{\tau}_2}$ and $\beta_\ell\to\beta_\ell\cos 2\theta_\tau$.

Finally, the cross section for $\tilde{\tau}_1\bar{\tilde{\tau}}_2$ production occurs only via Z exchange, and is given by

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\tau}_1\bar{\tilde{\tau}}_2) = \frac{d\sigma}{dt}(q\bar{q}\to\bar{\tilde{\tau}}_1\tilde{\tau}_2) =$$
$$\frac{e^4}{24\pi s^2}(\alpha_q^2+\beta_q^2)\beta_\ell^2\sin^2 2\theta_\tau|D_Z(s)|^2(ut-m^2_{\tilde{\tau}_1}m^2_{\tilde{\tau}_2}). \qquad (51.69)$$

51.8.4 *Chargino and neutralino pair production*

51.8.4.1 $\tilde{\chi}_i^-\tilde{\chi}_j^0$ *production*

The subprocess cross section for $d\bar{u}\to\tilde{\chi}_i^-\tilde{\chi}_j^0$ depends on Lagrangian couplings

$$\mathcal{L}_{W\bar{u}d} = -\frac{g}{\sqrt{2}}\bar{u}\gamma_\mu P_L d W^{+\mu} \ + \text{h.c.},$$
$$\mathcal{L}_{W\tilde{\chi}_i^-\tilde{\chi}_j^0} = -g(-i)^{\theta_j}\overline{\tilde{\chi}^-}_i[X_i^j+Y_i^j\gamma_5]\gamma_\mu\tilde{\chi}_j^0 W^{-\mu} \ + \text{h.c.},$$
$$\mathcal{L}_{q\tilde{q}\tilde{\chi}_i^-} = iA^d_{\tilde{\chi}_i^-}\bar{u}_L^\dagger\overline{\tilde{\chi}_i^-}P_L d + iA^u_{\tilde{\chi}_i^-}\bar{d}_L^\dagger\overline{\tilde{\chi}_i^c}P_L u \ + \text{h.c.}$$

and

$$\mathcal{L}_{q\bar{q}\tilde{\chi}_j^0} = iA^q_{\tilde{\chi}_j^0}\tilde{q}_L^\dagger\overline{\tilde{\chi}^0}_j P_L q \ + \text{h.c.}.$$

Contributing diagrams include W exchange and also $\tilde{d}_L$ and $\tilde{u}_L$ squark exchange. The X_i^j and Y_i^j couplings are new, and again convention-dependent: the cross section formulae works if the interaction Lagrangian is written in the above form, so that the couplings can be suitably extracted. The term $\theta_j = 0$ (1) if $m_{\tilde{\chi}_j^0} > 0$ (< 0); it comes about because the neutralino field must be re-defined by a $-i\gamma_5$ transformation if its mass eigenvalue is negative [13]. The subprocess cross section is given in terms of dot products of four momenta, where particle labels are used to denote their four-momenta; note that all mass terms in the cross section formulae are positive definite, so that the signs of mass eigenstates have been absorbed into the Lagrangian couplings, as for instance in Ref. [13]. We then have

$$\frac{d\sigma}{dt}(d\bar{u}\to\tilde{\chi}_i^-\tilde{\chi}_j^0) = \frac{1}{192\pi s^2}$$
$$\left[T_W + T_{\tilde{d}_L} + T_{\tilde{u}_L} + T_{W\tilde{d}_L} + T_{W\tilde{u}_L} + T_{\tilde{d}_L\tilde{u}_L}\right] \qquad (51.70)$$

where

$$T_W = 8g^4|D_W(s)|^2\left\{[X_i^{j2}+Y_i^{j2}](\tilde{\chi}_j^0\cdot d\tilde{\chi}_i^-\cdot\bar{u}+\tilde{\chi}_j^0\cdot\bar{u}\tilde{\chi}_i^-\cdot d)\right.$$
$$+2(X_i^jY_i^j)(\tilde{\chi}_j^0\cdot d\tilde{\chi}_i^-\cdot\bar{u}-\tilde{\chi}_j^0\cdot\bar{u}\tilde{\chi}_i^-\cdot d)$$
$$\left.+[X_i^{j2}-Y_i^{j2}]m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\}, \qquad (51.71)$$

$$T_{\tilde{d}_L} = \frac{4|A^u_{\tilde{\chi}_i^-}|^2|A^d_{\tilde{\chi}_j^0}|^2}{[(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}]^2}\ d\cdot\tilde{\chi}_j^0\tilde{\chi}_i^-\cdot\bar{u}, \qquad (51.72)$$

$$T_{\tilde{u}_L} = \frac{4|A^d_{\tilde{\chi}_i^-}|^2|A^u_{\tilde{\chi}_j^0}|^2}{[(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}]^2}\ \bar{u}\cdot\tilde{\chi}_j^0\tilde{\chi}_i^-\cdot d \qquad (51.73)$$

$$T_{W\tilde{d}_L} = \frac{-\sqrt{2}g^2 Re[A^{d*}_{\tilde{\chi}_j^0}A^u_{\tilde{\chi}_i^-}(-i)^{\theta_j}](s-M_W^2)|D_W(s)|^2}{(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}}$$
$$\times\left\{8(X_i^j+Y_i^j)\tilde{\chi}_j^0\cdot d\bar{u}\cdot\tilde{\chi}_i^- + 4(X_i^j-Y_i^j)m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\} \qquad (51.74)$$

$$T_{W\tilde{u}_L} = \frac{\sqrt{2}g^2 Re[A^{d*}_{\tilde{\chi}_i^-}A^u_{\tilde{\chi}_j^0}(-i)^{\theta_j}](s-M_W^2)|D_W(s)|^2}{(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}}$$
$$\times\left\{8(X_i^j-Y_i^j)\tilde{\chi}_j^0\cdot\bar{u}d\cdot\tilde{\chi}_i^- + 4(X_i^j+Y_i^j)m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}\right\} \qquad (51.75)$$

and

$$T_{\tilde{d}_L\tilde{u}_L} = -\frac{4Re[A^d_{\tilde{\chi}_j^0}A^{u*}_{\tilde{\chi}_i^-}A^{d*}_{\tilde{\chi}_i^-}A^u_{\tilde{\chi}_j^0}]m_{\tilde{\chi}_i^-}m_{\tilde{\chi}_j^0}d\cdot\bar{u}}{[(\tilde{\chi}_i^- - \bar{u})^2 - m^2_{\tilde{d}_L}][(\tilde{\chi}_j^0 - \bar{u})^2 - m^2_{\tilde{u}_L}]}. \qquad (51.76)$$

51.8.4.2 *Chargino pair production*

The subprocess cross section for $d\bar{d}\to\tilde{\chi}_i^-\tilde{\chi}_i^+$ $(i=1,2)$ depends on Lagrangian couplings $\mathcal{L} = e\overline{\tilde{\chi}_i^-}\gamma_\mu\tilde{\chi}_i^- A^\mu - e\cot\theta_W\overline{\tilde{\chi}_i^-}\gamma_\mu(x_i - y_i\gamma_5)\tilde{\chi}_i^- Z^\mu$ and also $\mathcal{L}\ni iA^d_{\tilde{\chi}_i^-}\bar{u}_L^\dagger\overline{\tilde{\chi}_i^-}P_L d + iA^u_{\tilde{\chi}_i^-}\bar{d}_L^\dagger\overline{\tilde{\chi}_i^{-c}}P_L u + \text{h.c.}$. Contributing diagrams include s-channel γ, Z^0 exchange and t-channel $\tilde{u}_L$ exchange [16, 17]. The couplings x_i and y_i are again new and as usual convention-dependent.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(d\bar{d}\to\tilde{\chi}_i^-\tilde{\chi}_i^+) =$$
$$\frac{1}{192\pi s^2}\left[T_\gamma + T_Z + T_{\tilde{u}_L} + T_{\gamma Z} + T_{\gamma\tilde{u}_L} + T_{Z\tilde{u}_L}\right] \qquad (51.77)$$

where

$$T_\gamma = \frac{32e^4q_d^2}{s^2}\left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}d\cdot\bar{d}\right] \qquad (51.78)$$

$$T_Z = 32e^4\cot^2\theta_W|D_Z(s)|^2$$
$$\left\{(\alpha_d^2+\beta_d^2)(x_i^2+y_i^2)\left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}d\cdot\bar{d}\right]\right.$$

$$\mp 4\alpha_d\beta_d x_i y_i \left[d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- - d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+\right] - 2y_i^2(\alpha_d^2+\beta_d^2)m^2_{\tilde{\chi}_i^-}d\cdot\bar{d}\Bigg\}, \tag{51.79}$$

$$T_{\tilde{u}_L} = \frac{4|A^d_{\tilde{\chi}_i^-}|^4}{[(d-\tilde{\chi}_i^-)^2-m^2_{\tilde{u}_L}]^2}\; d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ \tag{51.80}$$

$$T_{\gamma Z} = \frac{64e^4\cot\theta_W q_d(s-M_Z^2)|D_Z(s)|^2}{s}\times$$
$$\Bigg\{\alpha_d x_i\left(d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^- + d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}d\cdot\bar{d}\right)$$
$$\pm\beta_d y_i\left(d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ - d\cdot\tilde{\chi}_i^+\bar{d}\cdot\tilde{\chi}_i^-\right)\Bigg\} \tag{51.81}$$

$$T_{\gamma\tilde{u}_L} = \mp\frac{8e^2q_d}{s}\frac{|A^d_{\tilde{\chi}_i^-}|^2}{[(d-\tilde{\chi}_i^-)^2-m^2_{\tilde{u}_L}]}\left\{2\bar{d}\cdot\tilde{\chi}_i^+ d\cdot\tilde{\chi}_i^- + m^2_{\tilde{\chi}_i^-}d\cdot\bar{d}\right\} \tag{51.82}$$

and

$$T_{Z\tilde{u}_L} = \mp 8e^2\cot\theta_W|D_Z(s)|^2\frac{|A^d_{\tilde{\chi}_i^-}|^2(s-M_Z^2)}{[(d-\tilde{\chi}_i^-)^2-m^2_{\tilde{u}_L}]}(\alpha_d-\beta_d)$$
$$\times\left\{2(x_i\mp y_i)d\cdot\tilde{\chi}_i^-\bar{d}\cdot\tilde{\chi}_i^+ + m^2_{\tilde{\chi}_i^-}(x_i\pm y_i)d\cdot\bar{d}\right\} \tag{51.83}$$

using the upper of the sign choices.

The cross section for $u\bar{u}\to\tilde{\chi}_i^+\tilde{\chi}_i^-$ can be obtained from the above by replacing $\alpha_d\to\alpha_u$, $\beta_d\to\beta_u$, $q_d\to q_u$, $\tilde{u}_L\to\tilde{d}_L$, $A^d_{\tilde{\chi}_i^-}\to A^u_{\tilde{\chi}_i^-}$, $d\to\bar{u}$, $\bar{d}\to u$ and adopting the lower of the sign choices everywhere.

The cross section for $q\bar{q}\to\tilde{\chi}_1^-\tilde{\chi}_2^+$, $\tilde{\chi}_1^+\tilde{\chi}_2^-$ can occur via Z and $\tilde{q}_L$ exchange. It is usually much smaller than $\tilde{\chi}^-_{1,2}\tilde{\chi}^+_{1,2}$ production, so the cross section will not be presented here. It can be found in Appendix A of Ref. [13].

51.8.4.3 *Neutralino pair production*

Neutralino pair production via $q\bar{q}$ fusion takes place via s-channel Z exchange plus t- and u-channel left- and right- squark exchange (5 diagrams) [17, 18]. The Lagrangian couplings (see previous footnote*) needed include terms given above plus terms of the form $\mathcal{L} = W_{ij}\overline{\tilde{\chi}^0}_i\gamma_\mu(\gamma_5)^{\theta_i+\theta_j+1}\tilde{\chi}^0_j Z^\mu$. The couplings W_{ij} depend only on the *higgsino* components of the neutralinos i and j. The subprocess cross section is given by:

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\chi}_i^0\tilde{\chi}_j^0) = \frac{1}{192\pi s^2}\left[T_Z + T_{\tilde{q}_L} + T_{\tilde{q}_R} + T_{Z\tilde{q}_L} + T_{Z\tilde{q}_R}\right] \tag{51.84}$$

where

$$T_Z = 128e^2|W_{ij}|^2(\alpha_q^2+\beta_q^2)|D_Z(s)|^2$$
$$\left[q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 + q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0}q\cdot\bar{q}\right], \tag{51.85}$$

$$T_{\tilde{q}_L} = 4|A^q_{\tilde{\chi}_i^0}|^2|A^q_{\tilde{\chi}_j^0}|^2\left\{\frac{q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}]^2} + \frac{q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]^2}\right.$$
$$\left. - \eta_i\eta_j\frac{m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0}q\cdot\bar{q}}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}][(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]}\right\} \tag{51.86}$$

$$T_{\tilde{q}_R} = 4|B^q_{\tilde{\chi}_i^0}|^2|B^q_{\tilde{\chi}_j^0}|^2\left\{\frac{q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}]^2} + \frac{q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]^2}\right.$$
$$\left. - \eta_i\eta_j\frac{m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0}q\cdot\bar{q}}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}][(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]}\right\} \tag{51.87}$$

$$T_{Z\tilde{q}_L} = 16e(\alpha_q-\beta_q)(s-M_Z^2)|D_Z(s)|^2$$
$$\left\{\frac{Re(W_{ij}A^{q*}_{\tilde{\chi}_i^0}A^q_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_L}]}\left[2q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0}q\cdot\bar{q}\right]\right.$$
$$\left. + \eta_i\eta_j\frac{Re(W_{ij}A^q_{\tilde{\chi}_i^0}A^{q*}_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_L}]}\left[2q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0}q\cdot\bar{q}\right]\right\} \tag{51.88}$$

$$T_{Z\tilde{q}_R} = 16e(\alpha_q+\beta_q)(s-M_Z^2)|D_Z(s)|^2$$
$$\left\{\frac{Re(W_{ij}B^{q*}_{\tilde{\chi}_i^0}B^q_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_i^0-q)^2-m^2_{\tilde{q}_R}]}\left[2q\cdot\tilde{\chi}_i^0\bar{q}\cdot\tilde{\chi}_j^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0}q\cdot\bar{q}\right]\right.$$
$$\left. - \frac{Re(W_{ij}B^q_{\tilde{\chi}_i^0}B^{q*}_{\tilde{\chi}_j^0})}{[(\tilde{\chi}_j^0-q)^2-m^2_{\tilde{q}_R}]}\left[2q\cdot\tilde{\chi}_j^0\bar{q}\cdot\tilde{\chi}_i^0 - \eta_i\eta_j m_{\tilde{\chi}_i^0}m_{\tilde{\chi}_j^0}q\cdot\bar{q}\right]\right\}. \tag{51.89}$$

As before, $\eta_i = \pm 1$ corresponding to whether the neutralino mass eigenvalue is positive or negative. When $i=j$ in the above formula, one must remember to integrate over just 2π steradians of solid angle to avoid double counting in the total cross section.

51.9 Universal extra dimensions

In the Universal Extra Dimension (UED) model of Ref. [19] (see Ref. [20] for a review of models with extra spacetime dimensions), the Standard Model is embedded in a five dimensional theory, where the fifth dimension is compactified on an S_1/Z_2 orbifold. Each SM chirality state is then the zero mode of an infinite tower of Kaluza-Klein excitations labeled by $n = 0-\infty$. A KK parity is usually assumed to hold, where each state is assigned KK-parity $P = (-1)^n$. If the compactification scale is around a TeV, then the $n=1$ (or even higher) KK modes may be accessible to collider searches.

Of interest for hadron colliders are the production of massive $n \geq 1$ quark or gluon pairs. These production cross sections have been calculated in Ref. [21, 22]. We list here results for the $n=1$ case only with $M_1 = 1/R$ (R is the compactification radius) and s, t and u are the usual Mandelstam variables; more general formulae can be found in Ref. [22]. The superscript $*$ stands for any KK excited state, while $\bullet$ stands for left chirality states and $\circ$ stands for right chirality states.

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2}T \tag{51.90}$$

where

$$T(q\bar{q}\to g^*g^*) = \frac{2g_s^4}{27}\left[M_1^2\left(-\frac{4s^3}{t'^2u'^2} + \frac{57s}{t'u'} - \frac{108}{s}\right)\right.$$
$$\left. + \frac{20s^2}{t'u'} - 93 + \frac{108t'u'}{s^2}\right] \tag{51.91}$$

and

$$T(gg\to g^*g^*) =$$
$$\frac{9g_s^4}{27}\left[3M_1^4\frac{s^2+t'^2+u'^2}{t'^2u'^2} - 3M_1^2\frac{s^2+t'^2+u'^2}{st'u'} + 1\right.$$
$$\left. + \frac{(s^2+t'^2+u'^2)^3}{4s^2t'^2u'^2} - \frac{t'u'}{s^2}\right] \tag{51.92}$$

where $t' = t - M_1^2$ and $u' = u - M_1^2$.

Also,

$$T(q\bar{q}\to q_1^{*\prime}\bar{q}_1^{*\prime}) = \frac{4g_s^4}{9}\left[\frac{2M_1^2}{s} + \frac{t'^2+u'^2}{s^2}\right],$$

$$T(q\bar{q}\to q_1^*\bar{q}_1^*) = \frac{g_2^4}{9}\left[2M_1^2\left(\frac{4}{s} + \frac{s}{t'^2} - \frac{1}{t'}\right)\right.$$
$$\left. + \frac{23}{6} + \frac{2s^2}{t'^2} + \frac{8s}{3t'} + \frac{6t'}{s} + \frac{8t'^2}{s^2}\right],$$

$$T(qq\to q_1^*q_1^*)=\frac{g_s^4}{27}\left[M_1^2\left(6\frac{t'}{u'^2}+6\frac{u'}{t'^2}-\frac{s}{t'u'}\right)\right.$$
$$\left.+2\left(3\frac{t'^2}{u'^2}+3\frac{u'^2}{t'^2}+4\frac{s^2}{t'u'}-5\right)\right],$$
$$T(gg\to q_1^*\bar q_1^*)=g_s^4\left[M_1^4\frac{-4}{t'u'}\left(\frac{s^2}{6t'u'}-\frac{3}{8}\right)\right.$$
$$\left.+M_1^2\frac{4}{s}\left(\frac{s^2}{6t'u'}-\frac{3}{8}\right)+\frac{s^2}{6t'u'}-\frac{17}{24}+\frac{3t'u'}{4s^2}\right],$$
$$T(gq\to g^*q_1^*)=\frac{-g_s^4}{3}\left[\frac{5s^2}{12t'^2}+\frac{s^3}{t'^2u'}+\frac{11su'}{6t'^2}+\frac{5u'^2}{12t'^2}+\frac{u'^3}{st'^2}\right],$$
$$T(q\bar q'\to q_1^*\bar q_1^{*'})=\frac{g_s^4}{18}\left[4M_1^4\frac{s}{t'^2}+5+4\frac{s^2}{t'^2}+8\frac{s}{t'}\right],$$
$$T(qq'\to q_1^*q_1^{*'})=\frac{2g_s^4}{9}\left[-M_1^2\frac{s}{t'^2}+\frac{1}{4}+\frac{s^2}{t'^2}\right],$$
$$T(qq\to q_1^\bullet q_1^\circ)=$$
$$\frac{g_s^4}{9}\left[M_1^2\left(\frac{2s^3}{t'^2u'^2}-\frac{4s}{t'u'}\right)+2\frac{s^4}{t'^2u'^2}-8\frac{s^2}{t'u'}+5\right],$$
$$T(q\bar q'\to q_1^\bullet\bar q_1^{'\circ})=\frac{g_s^4}{9}\left[2M_1^2\left(\frac{1}{t'}+\frac{u'}{t'^2}\right)+\frac{5}{2}+\frac{4u'}{t'}+\frac{2u'^2}{t'^2}\right],$$

and

$$T(qq'\to q_1^\bullet q_1^{'\circ})=\frac{g_s^4}{9}\left[-2M_1^2\left(\frac{1}{t'}+\frac{u'}{t'^2}\right)+\frac{1}{2}+\frac{2u'^2}{t'^2}\right].$$

51.10 Large extra dimensions

In the ADD theory [23] with large extra dimensions (LED), the SM particles are confined to a 3-brane, while gravity propagates in the bulk. It is assumed that the n extra dimensions are compactified on an n-dimensional torus of volume $(2\pi r)^n$, so that the fundamental $4+n$ dimensional Planck scale M_* is related to the usual 4-dimensional Planck scale M_{Pl} by $M_{Pl}^2=M_*^{n+2}(2\pi r)^n$. If $M_*\sim 1$ TeV, then the M_W-M_{Pl} hierarchy problem is just due to gravity propagating in the large extra dimensions.

In these theories, the KK-excited graviton states $G_{\mu\nu}^n$ for $n=1-\infty$ can be produced at collider experiments. The graviton couplings to matter are suppressed by $1/M_{Pl}$, so that graviton emission cross sections $d\sigma/dt\sim 1/M_{Pl}^2$. However, the mass splittings between the excited graviton states can be tiny, so the graviton eigenstates are usually approximated by a continuum distribution. A summation (integration) over all allowed graviton emissions ends up cancelling the $1/M_{Pl}^2$ factor, so that observable cross section rates can be attained. Some fundamental production formulae for a KK graviton (denoted G) of mass m at hadron colliders include the subprocesses

$$\frac{d\sigma_m}{dt}(f\bar f\to\gamma G)=\frac{\alpha Q_f^2}{16N_f}\frac{1}{sM_{Pl}^2}F_1(\frac{t}{s},\frac{m^2}{s}),\qquad(51.93)$$

where Q_f is the charge of fermion f and N_f is the number of QCD colors of f. Also,

$$\frac{d\sigma_m}{dt}(q\bar q\to gG)=\frac{\alpha_s}{36}\frac{1}{sM_{Pl}^2}F_1(\frac{t}{s},\frac{m^2}{s}),\qquad(51.94)$$

$$\frac{d\sigma_m}{dt}(qg\to qG)=\frac{\alpha_s}{96}\frac{1}{sM_{Pl}^2}F_2(\frac{t}{s},\frac{m^2}{s}),\qquad(51.95)$$

$$\frac{d\sigma_m}{dt}(gg\to gG)=\frac{3\alpha_s}{16}\frac{1}{sM_{Pl}^2}F_3(\frac{t}{s},\frac{m^2}{s}),\qquad(51.96)$$

where

$$F_1(x,y)=\frac{1}{x(y-1-x)}\left[-4x(1+x)(1+2x+2x^2)+\right.$$
$$\left.y(1+6x+18x^2+16x^3)-6y^2x(1+2x)+y^3(1+4x)\right]\qquad(51.97)$$

$$F_2(x,y)=-(y-1-x)F_1\left(\frac{x}{y-1-x},\frac{y}{y-1-x}\right)\qquad(51.98)$$

and

$$F_3(x,y)=\frac{1}{x(y-1-x)}\left[1+2x+3x^2+2x^3+x^4\right.$$
$$\left.-2y(1+x^3)+3y^2(1+x^2)-2y^3(1+x)+y^4\right].\qquad(51.99)$$

These formulae must then be multiplied by the graviton density of states formula $dN=S_{n-1}\frac{M_{Pl}^2}{M_*^{n+2}}m^{n-1}dm$ to gain the cross section

$$\frac{d^2\sigma}{dtdm}=S_{n-1}\frac{M_{Pl}^2}{M_*^{n+2}}m^{n-1}\frac{d\sigma_m}{dt}\qquad(51.100)$$

where $S_n=\frac{(2\pi)^{n/2}}{\Gamma(n/2)}$ is the surface area of an n-dimensional sphere of unit radius.

Virtual graviton processes can also be searched for at colliders. For instance, in Ref. [24] the cross section for Drell-Yan production of lepton pairs via gluon fusion was calculated, where it is found that, in the center-of-mass system

$$\frac{d\sigma}{dz}(gg\to\ell^+\ell^-)=\frac{\lambda^2s^3}{64\pi M_*^8}(1-z^2)(1+z^2)\qquad(51.101)$$

where $z=\cos\theta$ and λ is a model-dependent coupling constant ~ 1. Formulae for Drell-Yan production via $q\bar q$ fusion can also be found in Refs. [24, 25].

51.11 Warped extra dimensions

In the Randall-Sundrum model [26] of warped extra dimensions, the arena for physics is a 5-d anti-deSitter (AdS_5) spacetime, for which a non-factorizable metric exists with a metric warp factor $e^{-2\sigma(\phi)}$. It is assumed that two opposite tension 3-branes exist within AdS_5 at the two ends of an S_1/Z_2 orbifold parameterized by co-ordinate ϕ which runs from $0-\pi$. The 4-D solution of the Einstein equations yields $\sigma(\phi)=kr_c|\phi|$, where r_c is the compactification radius of the extra dimension and $k\sim M_{Pl}$. The 4-D effective action allows one to identify $\overline{M}_{Pl}^2=\frac{M^3}{k}(1-e^{-2kr_c\pi})$, where M is the 5-D Planck scale. Physical particles on the TeV scale (SM) brane have mass $m=e^{-kr_c\pi}m_0$, where m_0 is a fundamental mass of order the Planck scale. Thus, the weak scale-Planck scale hierarchy occurs due to the existence of the exponential warp factor if $kr_c\sim 12$.

In the simplest versions of the RS model, the TeV-scale brane contains only SM particles plus a tower of KK gravitons. The RS gravitons have mass $m_n=kx_ne^{-kr_c\pi}$, where the x_i are roots of Bessel functions $J_1(x_n)=0$, with $x_1\simeq 3.83$, $x_2\simeq 7.02$ etc. While the RS zero-mode graviton couplings suppressed by $1/\overline{M}_{Pl}$ and are thus inconsequential for collider searches, the $n=1$ and higher modes have couplings suppressed instead by $\Lambda_\pi=e^{-kr_c\pi}\overline{M}_{Pl}\sim TeV$. The $n=1$ RS graviton should have width $\Gamma_1=\rho m_1x_1^2(k/\overline{M}_{Pl})^2$, where ρ is a constant depending on how many decay modes are open. The formulae for dilepton production via virtual RS graviton exchange can be gained from the above formulae for the ADD scenario via the replacement [27]

$$\frac{\lambda}{M_*^4}\to\frac{i^2}{8\Lambda_\pi^2}\sum_{n=1}^{\infty}\frac{1}{s-m_n^2+im_n\Gamma_n}.\qquad(51.102)$$

52. Neutrino Cross Section Measurements

Revised August 2023 by G.P. Zeller (FNAL).

Neutrino cross sections are an essential ingredient in all neutrino experiments. Interest in neutrino scattering has increased due to the need for such information in the interpretation of neutrino oscillation data [1, 2] and given that uncertainties in neutrino-nucleus scattering remain a dominate source of systematic uncertainty in many neutrino oscillation measurements. Historically, neutrino scattering results on both charged current (CC) and neutral current (NC) channels have been collected over many decades using a variety of targets, analysis techniques, and detector technologies. With the advent of intense neutrino sources constructed for neutrino oscillation investigations, experiments are now remeasuring such interaction cross sections with a renewed appreciation for nuclear effects[1] and the need for more precise neutrino flux estimations [3, 4]. This work summarizes accelerator-based neutrino cross section measurements performed in the $\sim 0.1 - 300$ GeV range with an emphasis on inclusive, quasi-elastic, and pion production processes, areas where we have the most experimental input at present (Table 52.1). For a more comprehensive discussion of neutrino cross sections, including neutrino-electron elastic scattering and lower energy neutrino measurements, the reader is directed to a review of this subject [5]. Here, we survey existing experimental data on neutrino interactions and do not attempt to provide a census of the associated theoretical calculations [6], which are both critical and plentiful. Companion electron-nucleus scattering data [7] are additionally playing an increased role in neutrino interaction predictions through such efforts as the e4ν collaboration [8].

Table 52.1: List of beam properties, targets, and run durations for modern accelerator-based neutrino experiments studying neutrino scattering.

Experiment	beam	$\langle E_\nu \rangle$, $\langle E\overline{\nu} \rangle$ (GeV)	neutrino target(s)	run period
ArgoNeuT	$\nu, \overline{\nu}$	4.3, 3.6	Ar	2009 – 2010
FASERν	$\nu, \overline{\nu}$	> 200	W, emulsion	2021 –
ICARUS (at CNGS)	ν	20	Ar	2010 – 2012
ICARUS (at FNAL)	ν	0.8	Ar	2021 –
K2K	ν	1.3	CH, H_2O	2003 – 2004
MicroBooNE	ν	0.8	Ar	2015 – 2020
MINERvA	$\nu, \overline{\nu}$	3.5 (LE), 5.5 (ME)	He, C, CH, H_2O, Fe, Pb	2009 – 2019
MiniBooNE	$\nu, \overline{\nu}$	0.8, 0.7	CH_2	2002 – 2019
MINOS	$\nu, \overline{\nu}$	3.5, 6.1	Fe	2004 – 2016
NINJA	ν, $\overline{\nu}$	0.6, 0.6	Fe, emulsion	2015 –
NOMAD	$\nu, \overline{\nu}$	23.4, 19.7	C	1995 – 1998
NOvA	$\nu, \overline{\nu}$	2.0, 2.0	CH_2	2010 –
SBND	ν	0.8	Ar	2024 –
SciBooNE	$\nu, \overline{\nu}$	0.8, 0.7	CH	2007 – 2008
T2K	ν, $\overline{\nu}$	0.6, 0.6	CH, H_2O, Fe	2010 –

52.1 Inclusive Scattering

Over the years, many experiments have measured the total inclusive charged current cross section for neutrino ($\nu_\mu N \to \mu^- X$) and antineutrino ($\overline{\nu}_\mu N \to \mu^+ X$) scattering covering a broad range of neutrino energies. As can be seen in Fig. 52.1, which shows this data over decades of time and energy, the inclusive cross section approaches a linear dependence on neutrino energy. This behavior is expected for point-like scattering of neutrinos from quarks, an assumption which breaks down at lower energies. Modern measurements of such inclusive neutrino scattering cross sections and their target nuclei are summarized in Table 52.2. The reader is also referred to a recent review of the status of measurements and calculations in the shallow and deep inelastic scattering regions [9].

[1] Nuclear effects refer to kinematic and final state effects which impact neutrino scattering off nuclei. Such effects can be significant and are particularly relevant given that modern neutrino experiments make use of nuclear targets to increase their event yields.

To provide a more complete picture, differential cross sections for such inclusive scattering processes have also been reported. These include historical measurements on iron from NuTeV [10] and modern measurements on a variety of nuclear targets from ArgoNeuT [11,12], MicroBooNE [13,14], MINERvA [15–18], NINJA [19,20], NOvA [21], and T2K [22,23]. More recently, MINERvA has provided measurements in terms of longitudinal and transverse muon momenta [16,17], MicroBooNE has measured the first triple differential cross sections in argon [24], and T2K has provided the first measurement of the antineutrino inclusive cross section at low energy [25] (Fig. 52.1).

At high energy, the inclusive cross section is dominated by deep inelastic scattering (DIS). Several neutrino experiments have measured DIS cross sections for specific targets and final states, for example, MINERvA has measured ratios of neutrino DIS cross sections on a variety of nuclear targets including lead, iron, and carbon [26, 27]. Other experiments have measured opposite-sign dimuon production, the most recent being from CHORUS [28], NOMAD [29], and NuTeV [30]. Multiple efforts are also now underway to measure inclusive neutrino scattering cross sections at significantly higher neutrino energies, including at the LHC in FASERν [31] and using atmospheric neutrinos in IceCube [32].

Table 52.2: Published measurements of muon neutrino and antineutrino CC inclusive cross sections from modern accelerator-based neutrino experiments.

experiment	measurement	target
ArgoNeuT	ν_μ [11,12], $\overline{\nu}_\mu$ [12]	Ar
MicroBooNE	ν_μ [13,24,33]	Ar
MINERνA	ν_μ [15–18,26,27,34], $\overline{\nu}_\mu$ [34], $\overline{\nu}_\mu/\nu_\mu$ [35]	C, CH, Fe, Pb
MINOS	ν_μ [36], $\overline{\nu}_\mu$ [36]	Fe
NINJA	ν_μ [19,20], $\overline{\nu}_\mu$ [19]	H_2O, Fe
NOMAD	ν_μ [37]	C
NOvA	ν_μ [21]	CH_2
SciBooNE	ν_μ [38]	CH
T2K	ν_μ [22,23,39–41], $\overline{\nu}_\mu/\nu_\mu$ [25]	CH, H_2O, Fe

At lower neutrino energies, the inclusive cross section is an additionally complex combination of quasi-elastic scattering and pion production processes, two areas we discuss next.

52.2 Quasi-elastic scattering

Quasi-elastic (QE) scattering is the dominant neutrino interaction for neutrino energies less than ~ 1 GeV and represents a large fraction of the signal samples in many neutrino oscillation experiments, which is why this process has received considerable attention in recent years. Historically, neutrino (antineutrino) quasi-elastic scattering refers to the process, $\nu_\mu n \to \mu^- p$ ($\overline{\nu}_\mu p \to \mu^+ n$), where a charged lepton and single nucleon are ejected in the elastic interaction of a neutrino (or antineutrino) with a nucleon in the target material. This is the final state one would strictly observe, for example, in scattering off of a *free* nucleon target. There were many early measurements of neutrino QE scattering that span back to the 1970's [5]. In many of these initial measurements, bubble chamber experiments employed light targets (hydrogen or deuterium) and required both the detection of the final state muon and single nucleon[2]; thus the final state was clear and elastic kinematic conditions could be verified. The situation is more complicated, of course, for heavier nuclear targets used in modern neutrino experiments. In this case, nuclear effects can impact the size and shape of the cross section as well as the final state composition, kinematics, and topology. Due to intranuclear hadron rescattering and the effects of correlations between target nucleons, additional particles may be ejected in the final state; hence, a QE interaction on a nuclear target does not necessarily imply the ejection of a lepton and a *single* nucleon. One therefore needs to take care in defining what one means by

[2] In the case of deuterium, many experiments additionally observed the spectator proton.

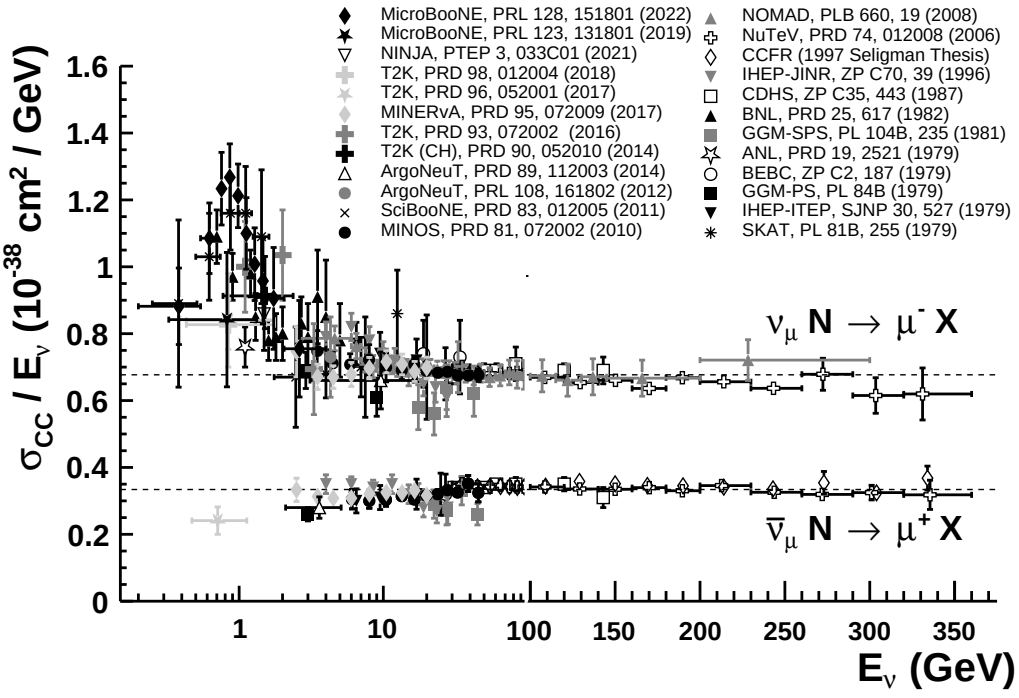

Figure 52.1: Measurements of per nucleon ν_μ and $\overline{\nu}_\mu$ CC inclusive scattering cross sections divided by neutrino energy as a function of neutrino energy. Note the transition between logarithmic and linear scales occurring at 100 GeV. Neutrino cross sections are typically twice as large as their corresponding antineutrino counterparts, although this difference can be larger at lower energies. NC cross sections (not shown) are generally smaller compared to their CC counterparts.

neutrino QE scattering when scattering off targets heavier than hydrogen or deuterium. Because of this, modern experiments tend to instead report cross sections for processes involving pionless (e.g., nucleon-only) final states, often referred to as CC 0π or QE-like reactions in recent literature. Such measurements are summarized in Table 52.3. Many modern experiments have also recently opted to report QE-like cross sections as a function of observed final state particle kinematics. Such measurements can be more difficult to directly compare between experiments but have the advantage of being much less model-dependent and provide more stringent tests of the theory than historical cross sections as a function of derived quantities such as neutrino energy (E_ν) or 4-momentum transfer (Q^2). More recently, new thought has been given to the means for directly comparing experimental measurements produced in these less model-dependent forms [42].

The topic of neutrino QE scattering began drawing considerable attention following the first double differential cross section measurements of this process that revealed a significantly larger cross section than originally anticipated, predominantly in the backwards muon scattering region [64, 65]. Such an enhancement was observed many years prior in transverse electron-nucleus scattering [83] and was attributed to the presence of correlations between nucleons in the target nucleus. As a result, the impact of such nuclear effects on neutrino QE scattering has recently become the subject of intense experimental and theoretical scrutiny with implications on event rates, nucleon emission, neutrino energy reconstruction, and neutrino versus antineutrino cross sections. The reader is referred to reviews of the situation in [6, 84, 85]. To help drive further progress in understanding the underlying nuclear contributions, pionless (e.g., nucleon-only) cross sections have been reported for the first time in the form of double-differential distributions by MiniBooNE [64, 65], MINERvA [51–55, 61], and T2K [73–78]. Such double-differential cross sections in terms of final state particle kinematics reduce the model-dependence of the reported data, provide the most robust measurements available, and allow a more rigorous two-dimensional test of the underlying nuclear theory. MicroBooNE, MINERvA, and T2K have been especially prolific in recent years in probing this interaction process (Table 52.3). Neutrino experiments have also launched dedicated studies of the hadronic side of these interactions, including ArgoNeuT [43, 86], MicroBooNE [45, 46], MINERvA [60, 87], and T2K [82]. MINERvA has been the first modern experiment to measure neutron emission in antineutrino interactions [88] and has simultaneously measured neutrino QE cross sections on a variety of nuclear targets ranging from carbon to lead [55]. ArgoNeuT [43], MicroBooNE [49], and NINJA [70] have explored two-proton final states. T2K has probed ratios of oxygen to carbon [76, 89], asymmetries between neutrino and antineutrino scattering [77], and simultaneous measurements both on and off axis to the neutrino beam [78]. In addition, the exploration of transverse kinematic variables and momentum imbalances in pionless neutrino scattering is allowing better constraints on the various nuclear contributions to the cross section. Such scrutiny includes important evaluations from MicroBooNE [47, 48], MINERvA [51, 52, 56, 57] and T2K [82]. With the MiniBooNE results having first revealed these additional complexities in neutrino-nucleus QE scattering, measurements from multiple neutrino experiments, on multiple targets, and using a variety of kinematic information have been crucial in gaining a better handle on the underlying nuclear physics impacting neutrino-nucleus interactions. What we once thought was "simple" QE scattering is in fact not so simple.

Equally important, neutrino experiments such as MINERvA have revisited the extraction of the axial form factor from light target data using modern higher statistics data sets [63]. In addition to such charged current investigations, measurements of the neutral current counterpart of this channel have also been performed. The most recent NC elastic scattering cross section measurements include those from BNL E734 [90], MiniBooNE [67,68], Super-K [72], and T2K [81]. A number of measurements of the Cabibbo-suppressed antineutrino QE hyperon production cross section have additionally been reported [91, 92], most recently by MicroBooNE [50]. As an exciting new addition, there have also been the first observations of the very challenging-to-detect coherent elastic neutrino-nucleus scattering (CEνNS) process now in multiple nuclei by COHERENT [93, 93, 94].

Table 52.3: Published modern measurements of muon neutrino QE and NC elastic scattering cross sections with pionless final states.

experiment	measurement	target
ArgoNeuT	2p [43]	Ar

52.3 Pion Production

In addition to such elastic scattering processes, neutrinos can also inelastically scatter producing a nucleon excited state (Δ, N^*). Such baryonic resonances quickly decay, most often to a nucleon and single-pion final state. Historically, experiments have measured various exclusive final states associated with these reactions, the majority of which have been on hydrogen and deuterium targets [5]. There have been several recent re-analyses of this data to better understand the consistency between data sets [95], nucleon form factors [96], and non-resonant contributions [97]. Also, modern measurements of neutrino-induced pion production have since been performed on a variety of nuclear targets (Table 52.4).

Table 52.4: Summary of modern measurements of NC and CC scattering cross sections involving a single pion or multiple pions in the final state.

experiment	$\pi^\pm$	π^0	target
ArgoNeuT	CC [98,99]	NC [100]	Ar
K2K	CC[101,102]	CC [103], NC [104]	CH, H_2O
MicroBooNE	–	CC [105], NC [106]	Ar
MINERνA	CC [107–114]	CC [108,115–117], NC [118]	C, CH, H_2O, Fe, Pb
MiniBooNE	CC [119,120]	CC [121], NC [122,123]	CH_2
MINOS	–	NC [124]	Fe
NOMAD	–	NC [125]	C
NOvA	–	NC [126,127]	C
SciBooNE	CC [128]	NC [129,130]	CH
T2K	CC [131–134]	–	CH, H_2O

In addition to resonance production processes, neutrinos can also coherently scatter off of the entire nucleus and produce a distinctly forward-scattered single pion final state. Both CC ($\nu_\mu A \to \mu^- A \pi^+$, $\overline{\nu}_\mu A \to \mu^+ A \pi^-$) and NC ($\nu_\mu A \to \nu_\mu A \pi^0, \overline{\nu}_\mu A \to \overline{\nu}_\mu A \pi^0$) processes are possible in this case. Even though the level of coherent pion production is small compared to their resonant counterpart, observations exist across a broad energy range and on multiple nuclear targets [135]. More recently, several modern neutrino experiments have either measured or set limits on coherent pion production cross sections including ArgoNeuT [98], K2K [102], MINERvA [109,111,113], MiniBooNE [123], MINOS [124], NOMAD [125], NOvA [126], SciBooNE [128,130], and T2K [102].

As with inclusive and quasi-elastic scattering, a new appreciation for the significance of nuclear effects has also surfaced in pion production physics, again due to the use of heavy nuclear targets in modern neutrino experiments. Many experiments have been careful to report cross sections for various detected final states, thereby not correcting for large and uncertain nuclear effects (e.g., pion rescattering, charge exchange, and absorption) which can introduce significant sources of uncertainty and model dependence. Providing the most comprehensive survey of neutrino single-pion production to date, MiniBooNE has published a total of 16 single- and double-differential cross sections for both the final state muon (in the case of CC scattering) and pions in these interactions; thus, providing the first measurements of such final state kinematic distributions [119–122]. At similar neutrino energies, T2K has provided new data [131] including the first measurement of the Adler angles in neutrino-nucleus scattering [133] and the first exploration of transverse kinematic imbalances in pion production processes [134]. MINERvA has produced a similar accompaniment of measurements at higher neutrino energies [108, 110, 112, 116] and uniquely on multiple nuclear targets [114]. Importantly, MINERvA has been working towards an improved nuclear model [117] that can potentially describe all of the pion reaction channels simultaneously, an issue that many experiments have struggled with up until now [108]. ArgoNeuT [99, 100] and MicroBooNE [105, 106] have since been adding new information on single pion production in argon. Regardless of the interaction channel or target material, differential cross section measurements in terms of observed final state particle kinematics are preferred for their reduced model dependence and for the additional kinematic information they provide. Such a new direction has been the focus of modern measurements as opposed to the reporting of more model-dependent, historical cross sections as a function of E_ν or Q^2. Together with similar results for other interaction channels, a better understanding and modeling of nuclear effects will be possible moving forward. MINERvA [136] has already taken a large step in this direction by explicitly tuning the physics in existing neutrino event generators to best fit the experimental data on pion production.

It should be noted that baryonic resonances can also decay to multi-pion, other mesonic (K, η, ρ, etc.), and even photon final states. Experimental results for these channels are typically sparse or non-existent. More recently, MicroBooNE has produced the first measurement of neutrino-induced η production on argon [137]. Photon production processes can comprise an important background for $\nu_\mu \to \nu_e$ appearance searches in some detectors and thus have become the focus of recent experimental investigations, most notably in NOMAD [138] and T2K [139,140]. There have also been several recent measurements of kaon final states produced in neutrino NC and CC scattering in MINERvA [141–143] that are providing needed background constraints for certain nucleon decay searches.

52.4 Electron Neutrino Scattering

The aforementioned cross section measurements are all for either muon neutrino or muon antineutrino scattering. With the production of predominantly muon neutrino beams for neutrino oscillation studies, the availability of electron neutrino scattering data is by construction limited. However, for the first time, measurements of electron neutrino scattering cross sections are being produced by a variety of modern neutrino experiments (Table 52.5). Such measurements are important as they verify our assumptions about lepton universality and validate the use of muon neutrino data to constrain electron neutrino interaction predictions. For lower energy and historical electron neutrino cross section measurements, the reader is directed to reference [5].

Table 52.5: Published measurements of electron neutrino and antineutrino cross sections from modern accelerator-based neutrino experiments.

experiment	CC inclusive	QE-like	π production	target
ArgoNeuT	[144]	-	-	Ar
COHERENT	[145]	-	-	I
MicroBooNE	[146, 147]	[148]	-	Ar
MINERνA	-	[149]	-	CH
NOvA	[150]	-	-	CH_2
T2K	[151–153]	-	-	CH, H_2O

52.5 Outlook

Neutrino experiments continue to produce critical neutrino scattering measurements on nuclei as they accumulate increased statistics and pursue new ways of reporting their measurements. Analysis of a broad energy range of data from MINERvA is providing some of the most detailed analysis of nuclear effects in neutrino interactions by examining multiple nuclei in a single experiment. Data from ArgoNeuT, MicroBooNE, ICARUS and soon also SBND are probing deeper into complex neutrino final states using the superior capabilities of liquid argon time projection chambers, while the T2K and NOvA near detectors continue to collect high statistics samples in intense neutrino beams. Together with dedicated discussions between experiments on how best to report neutrino cross section measurements [154] and with accompanying work being advanced by theorists to further improve nuclear model calculations [6], we are starting to significantly advance our understanding of neutrino-nucleus scattering.

52.6 Acknowledgments

The author thanks Anne Schukraft (Fermilab) for help in preparing the plots and content of this review.

53. Plots of Cross Sections and Related Quantities

Updated in 2023. See various sections for details. For additional cross section results, please see earlier editions of the *Review of Particle Physics (https://pdg.lbl.gov/rpp-archive/).*

53.1 Pseudorapidity Distributions in pp and $\overline{p}p$ Interactions

Revised August 2013 by D.R. Ward (Cavendish Lab.).

Pseudorapidity Distributions in pp and $\bar{p}p$ Interactions

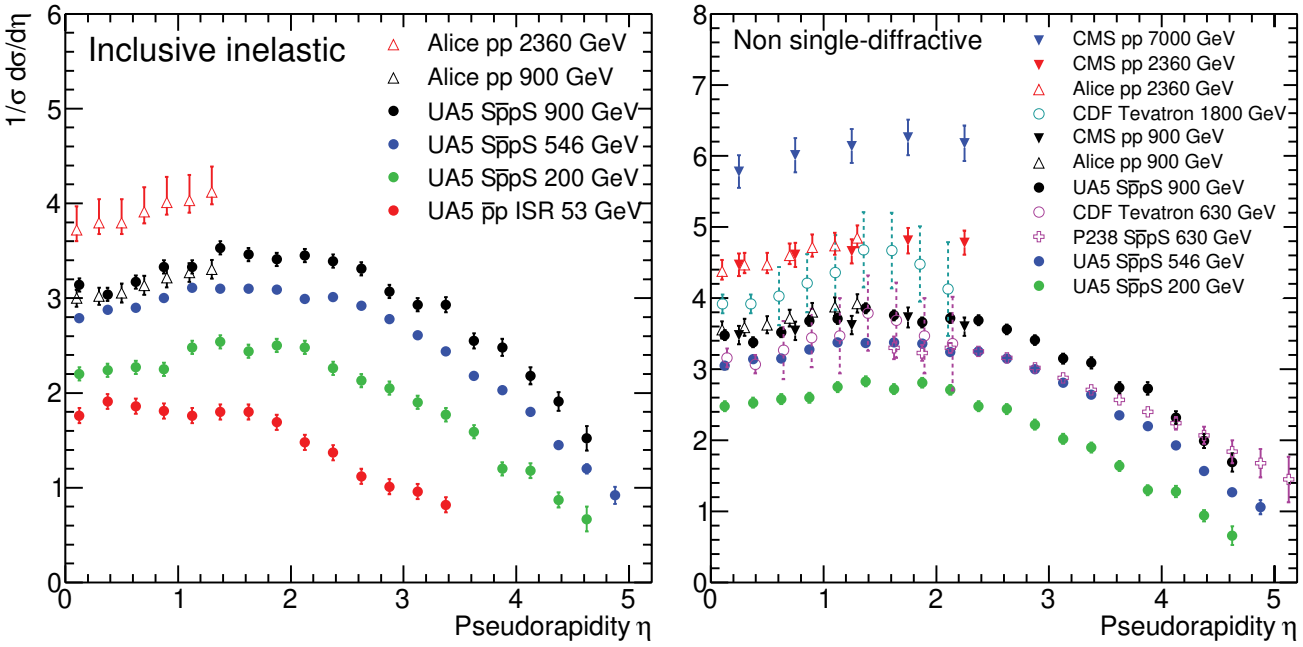

Figure 53.1: Charged particle pseudorapidity distributions in $p\overline{p}$ collisions for 53 GeV $\leq \sqrt{s} \leq$ 1800 GeV. UA5 data from the S$p\overline{p}$S are taken from [1], and from the ISR from [2]. The UA5 data are shown for both the full inelastic cross-section and with singly diffractive events excluded. Additional non single-diffractive measurements are available from CDF at the Tevatron [3] and from P238 at the S$p\overline{p}$S [4]. These may be compared with both inclusive and non single-diffractive measurements in pp collisions at the LHC from ALICE [5] and for non single-diffractive interactions from CMS [6, 7]. (Courtesy of D.R. Ward, Cambridge Univ., 2013)

53.2 Average Hadron Multiplicities in Hadronic e^+e^- Annihilation Events

Revised August 2023 by O. Biebel (Ludwig-Maximilians U.).

Table 53.1: Average hadron multiplicities per hadronic e^+e^- annihilation event at $\sqrt{s} \approx 10$, 29–35, 91, and 130–200 GeV. The rates given include decay products from resonances with $c\tau < 10$ cm, and include the corresponding anti-particle state. Correlations of the systematic uncertainties were considered for the calculation of the averages. Quoted errors are not increased by scale factor S.

Particle	$\sqrt{s} \approx 10$ GeV	$\sqrt{s} = 29$–35 GeV	$\sqrt{s} = 91$ GeV	$\sqrt{s} = 130$–200 GeV	References

(*a*) $\sigma_{\rm had} = 3.33 \pm 0.05 \pm 0.21$ nb (**CLEO**: [99]) has been used in converting the measured cross sections to average hadron multiplicities.
(*b*) B($D_s \to \eta\pi,\ \eta'\pi$) was used (RPP 1994).

(c) Comprises both charged and neutral B meson states.
(d) The Standard Model B($Z \to b\bar{b}$) = 0.217 was used.
(e) $x_p = p/p_{\rm beam} > 0.1$ only.
(f) Both charge states.
(g) B($D^*(2010)^+ \to D^0\pi^+$) × B($D^0 \to K^-\pi^+$) has been used (RPP 2000).
(h) B($D_s^* \to D_S^+\gamma$), B($D_s^+ \to \phi\pi^+$), B($\phi \to K^+K^-$) have been used (RPP 1998).
(i) Any charge state (*i.e.*, B_d^*, B_u^*, or B_s^*).
(j) B($Z \to$ hadrons) = 0.699 was used (RPP 1994).
(k) Any charge state (*i.e.*, B_d^{**}, B_u^{**}, or B_s^{**}).
(ℓ) Assumes B($D_{s1}^+ \to D^{*+}K^0 + D^{*0}K^+$) = 100% and B($D_{s2}^+ \to D^0K^+$) = 45%.
(m) Derived from the production cross section of $\Lambda_c^+ \to p\pi K$ using (a) and using B($\Lambda_c^+ \to p\pi K$) = (6.26 ± 0.29)% (RPP 2022).
(n) Derived from [96], updated with B($\Lambda_c^+ \to p\pi K$) = (6.26 ± 0.29)% (RPP 2022), and complemented by the Λ_c^+ contribution from $g \to c\bar{c}$ of [47].

53.3 Annihilation Cross Section Near M_Z

Courtesy of M. Grünewald and the LEP Electroweak Working Group, 2007.

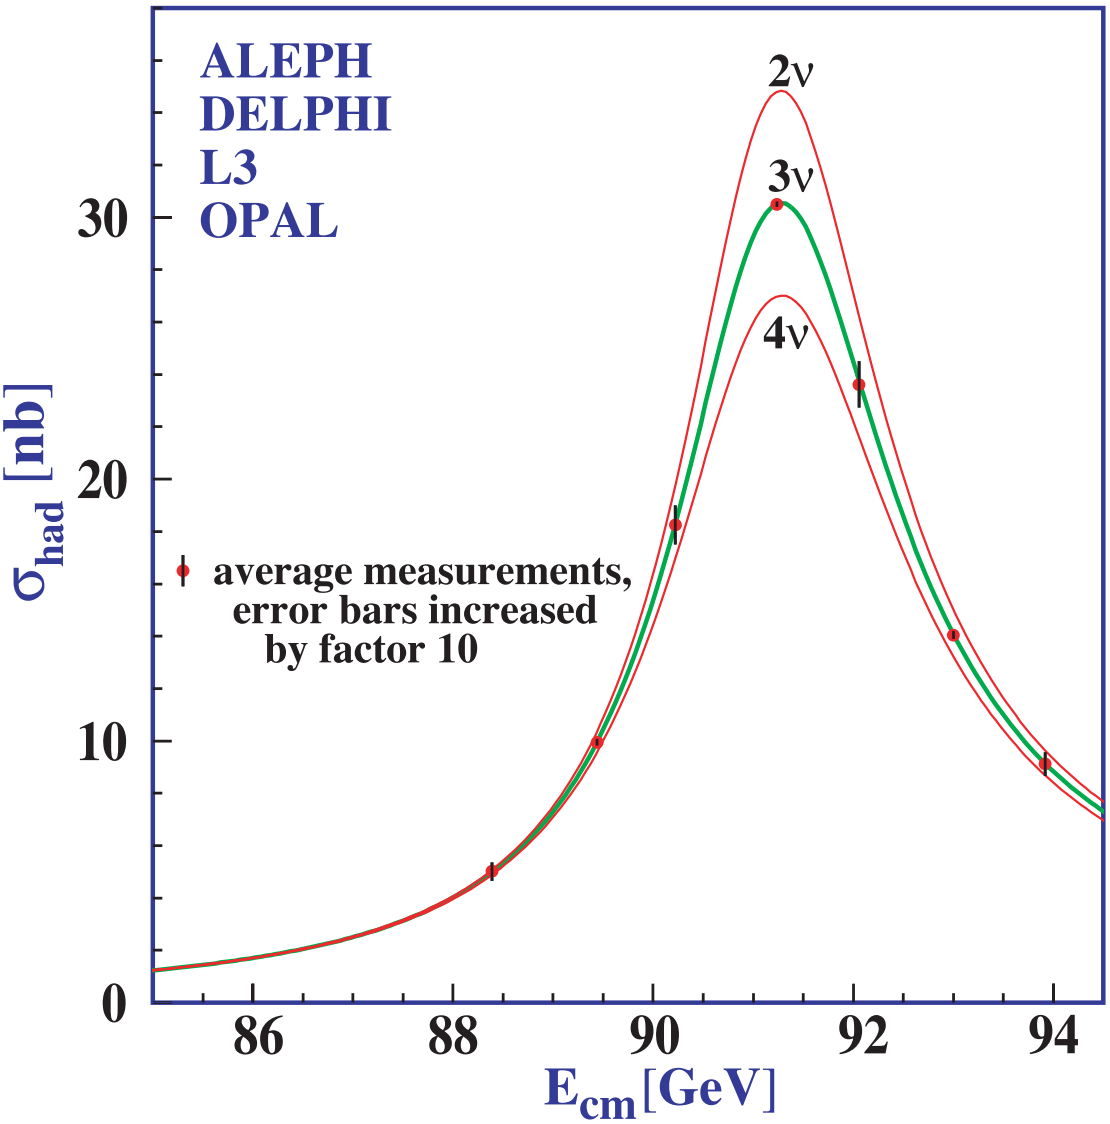

Figure 53.2: Combined data from the ALEPH, DELPHI, L3, and OPAL Collaborations for the cross section in e^+e^- annihilation into hadronic final states as a function of the center-of-mass energy near the Z pole. The curves show the predictions of the Standard Model with two, three, and four species of light neutrinos. The asymmetry of the curve is produced by initial-state radiation. Note that the error bars have been increased by a factor ten for display purposes. References: ALEPH [100], DELPHI [101], L3 [102], OPAL [103], Combination [104],

54. Mass and Width of the W Boson

Revised April 2024 by M. Grünewald (University Coll. Dublin) and A. Gurtu (CERN; TIFR Mumbai).

Precision determination of the W mass is of great importance in testing the internal consistency of the Standard Model. From the time of its discovery in 1983, the W boson has been studied and its mass determined in $p\bar{p}$ and e^+e^- interactions; it is currently studied in pp interactions at the LHC. The mass and width definition used here corresponds to a Breit-Wigner with mass-dependent width.

Production of on-shell W bosons at hadron colliders is tagged by the high p_T charged lepton from its leptonic decay modes. Owing to the unknown parton-parton effective energy and missing energy in the longitudinal direction, the hadron collider experiments reconstruct the transverse mass of the W boson, and derive the W mass from comparing the transverse mass distribution with Monte Carlo predictions as a function of the mass m_W. The transverse momentum of the charged lepton itself and the transverse missing energy (arising from the neutrino in W decay) are also sensitive to the W mass and used in its determination. These analyses use the electron and muon decay modes of the W boson.

At the e^+e^- collider LEP, a precise knowledge of the beam energy enables one to determine the $e^+e^- \to W^+W^-$ cross section as a function of center of mass energy, as well as to reconstruct the W mass precisely from its decay products, even if one of them decays leptonically. Close to the W^+W^- production threshold ($\sqrt{s} = 161$ GeV), the dependence of the W-pair production cross section on m_W is large, and this was used to determine m_W. At higher centre-of-mass energies (172 to 209 GeV) this dependence is much weaker, thus W bosons were directly reconstructed and the mass determined as the invariant mass of the decay products, improving the resolution with a kinematic fit.

To compute the LEP average W mass, each experiment provided its measured W mass for the $q\bar{q}q\bar{q}$ and $q\bar{q}\ell\nu$, $\ell = e, \mu, \tau$ channels at each center-of-mass energy, along with a detailed decomposition of uncertainty contributions: statistical, uncorrelated, partially correlated and fully correlated systematics [1]. This yielded a combined LEP average W mass of $m_W = 80.376 \pm 0.033$ GeV. Errors on m_W due to uncertainties in the LEP beam energy (9 MeV), and possible effect of color reconnection (CR) and Bose-Einstein correlations (BEC) between quarks from different W bosons (8 MeV) are included. Similarly the combined LEP average of the W boson total width is determined to be $\Gamma_W = 2.195 \pm 0.083$ GeV [1].

In the past a similar procedure was followed for the measurements at hadron colliders. The two Tevatron experiments CDF [2] and D0 [3] identified common systematic errors: uncertainties due to the parton distribution functions (PDF), radiative corrections, and choice of mass (width) in the width (mass) measurements were treated as correlated and the resultant mass [4] and width [5] of the W were determined. The W boson total width obtained is $\Gamma_W = 2.046 \pm 0.049$ GeV. Similarly the mass results from the two LHC experiments, ATLAS [6] and LHCb [7] were combined to obtain an LHC average mass of the W, and an overall hadron collider average of the W mass was obtained as well [8].

The results on mass and width published by the experiments are shown in Figures 54.1 and 54.2, respectively. Until 2022, all measurements were in good agreement with each other and with the world average [8]. In April 2022 the CDF collaboration published a result $m_W = 80.4335 \pm 0.0094$ GeV [10], based upon their full Run-II dataset of 8.8 fb^{-1}. The result is of higher precision than the 2022 world average, but the two results disagree significantly.[1]

The LHC-TeV W-mass Working Group, including W-mass experts from all hadron collider experiments, CDF, D0, ATLAS, CMS, LHCb, has been working to understand better the nature of this disagreement and suggest a way forward to obtain a world average value of the W mass. Corrections, uncertainties and their correlations have been evaluated to a greater detail and used in the combination: the central values are corrected to a common theory description and PDF, and the uncertainties, especially due to PDFs, have been re-evaluated to account for correlations properly. The group reports [11] that a combination of all W-mass measurements has a probability of compatibility of 0.5% only, and is therefore disfavoured. A 91% probability of compatibility is obtained when the CDF-II measurement is removed. The corresponding value of the W boson mass is $m_W = 80369.2 \pm 13.3$ MeV, which we quote as the World Average. More details are given in [11].

The Standard Model prediction from an electroweak fit, including Z-pole data and the measured masses of the top quark and of the Higgs boson but excluding results on m_W and Γ_W, implies a W-boson mass of $m_W = 80.353 \pm 0.006$ GeV and a W-boson

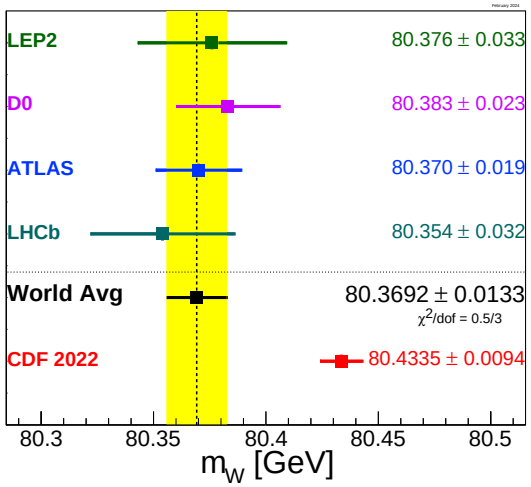

Figure 54.1: Measurements of the W-boson mass by the LEP, Tevatron and LHC experiments. The CDF 2022 result is not used in the world average. In March 2024, after the cut-off of results for this review, the ATLAS Collaboration has submitted for publication a refined analysis of their data used in [6] and obtained a more precise mass value of 80.3665 ± 0.0159 GeV [9].

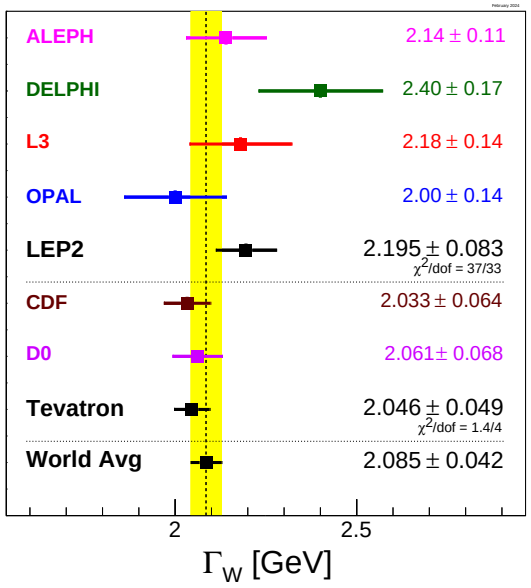

Figure 54.2: Measurements of the W-boson width by the LEP and Tevatron experiments. In March 2024, after the cut-off of results for this review, the ATLAS Collaboration has submitted for publication a refined analysis of their data used in [6] and obtained a width value of 2.202 ± 0.047 GeV [9].

[1] The 2022 CDF result includes the 2.2 fb^{-1} of data used for the previous CDF Run-II result of 80.387 ± 0.019 GeV [2]. Incorporating the improved understanding of PDFs and track reconstruction, the central value of the 2.2 fb^{-1} result is increased by 13.5 MeV to 80,400.5 MeV [10].

width of $\Gamma_W = 2.089 \pm 0.001\,\text{GeV}$; see Section 10, Electroweak Model and Constraints on New Physics, J.Erler and A.Freitas, 2024, this review. Note that the electroweak fit of Section 10 to all measurements uses slightly different measurements of the W boson mass and width as explained there.

55. Z Boson

Revised August 2018 by M. Grünewald (University Coll. Dublin) and A. Gurtu (CERN; TIFR Mumbai).

Precision measurements at the Z-boson resonance using electron–positron colliding beams began in 1989 at the SLC and at LEP. During 1989–95, the four LEP experiments (ALEPH, DELPHI, L3, OPAL) made high-statistics studies of the production and decay properties of the Z. Although the SLD experiment at the SLC collected much lower statistics, it was able to match the precision of LEP experiments in determining the effective electroweak mixing angle $\sin^2\overline{\theta}_W$ and the rates of Z decay to b- and c-quarks, owing to availability of polarized electron beams, small beam size, and stable beam spot.

The Z-boson properties reported in this section may broadly be categorized as:

- The standard 'lineshape' parameters of the Z consisting of its mass, M_Z, its total width, Γ_Z, and its partial decay widths, Γ(hadrons), and $\Gamma(\ell\overline{\ell})$ where $\ell = e, \mu, \tau, \nu$;
- Z asymmetries in leptonic decays and extraction of Z couplings to charged and neutral leptons;
- The b- and c-quark-related partial widths and charge asymmetries which require special techniques;
- Determination of Z decay modes and the search for modes that violate known conservation laws;
- Average particle multiplicities in hadronic Z decay;
- Z anomalous couplings.

The effective vector and axial-vector coupling constants describing the Z-to-fermion coupling are also measured in $p\overline{p}$ and ep collisions at the Tevatron and at HERA. The corresponding cross-section formulae are given in Section 39 (Cross-section formulae for specific processes) and Section 16 (Structure Functions) in this *Review*. In this minireview, we concentrate on the measurements in e^+e^- collisions at LEP and SLC.

The standard 'lineshape' parameters of the Z are determined from an analysis of the production cross sections of these final states in e^+e^- collisions. The $Z \to \nu\overline{\nu}(\gamma)$ state is identified directly by detecting single photon production and indirectly by subtracting the visible partial widths from the total width. Inclusion in this analysis of the forward-backward asymmetry of charged leptons, $A_{FB}^{(0,\ell)}$, of the τ polarization, $P(\tau)$, and its forward-backward asymmetry, $P(\tau)^{fb}$, enables the separate determination of the effective vector ($\overline{g}_V$) and axial vector ($\overline{g}_A$) couplings of the Z to these leptons and the ratio ($\overline{g}_V/\overline{g}_A$), which is related to the effective electroweak mixing angle $\sin^2\overline{\theta}_W$ (see the "Electroweak Model and Constraints on New Physics" review).

Determination of the b- and c-quark-related partial widths and charge asymmetries involves tagging the b and c quarks for which various methods are employed: requiring the presence of a high momentum prompt lepton in the event with high transverse momentum with respect to the accompanying jet; impact parameter and lifetime tagging using precision vertex measurement with high-resolution detectors; application of neural-network techniques to classify events as b or non-b on a statistical basis using event–shape variables; and using the presence of a charmed meson (D/D^*) or a kaon as a tag.

55.1 Z-parameter determination

LEP was run at energy points on and around the Z mass (88–94 GeV) constituting an energy 'scan'. The shape of the cross-section variation around the Z peak can be described by a Breit-Wigner *ansatz* with an energy-dependent total width [1–3]. The **three** main properties of this distribution, viz., the **position** of the peak, the **width** of the distribution, and the **height** of the peak, determine respectively the values of M_Z, Γ_Z, and $\Gamma(e^+e^-) \times \Gamma(f\overline{f})$, where $\Gamma(e^+e^-)$ and $\Gamma(f\overline{f})$ are the electron and fermion partial widths of the Z. The quantitative determination of these parameters is done by writing analytic expressions for these cross sections in terms of the parameters, and fitting the calculated cross sections to the measured ones by varying these parameters, taking properly into account all the errors. Single-photon exchange (σ^0_γ) and γ-Z interference ($\sigma^0_{\gamma Z}$) are included, and the large (∼25 %) initial-state radiation (ISR) effects are taken into account by convoluting the analytic expressions over a 'Radiator Function' [1–5] $H(s, s')$. Thus for the process $e^+e^- \to f\overline{f}$:

$$\sigma_f(s) = \int H(s,s')\ \sigma^0_f(s')\ ds' \tag{55.1}$$

$$\sigma^0_f(s) = \sigma^0_Z + \sigma^0_\gamma + \sigma^0_{\gamma Z} \tag{55.2}$$

$$\sigma^0_Z = \frac{12\pi}{M_Z^2}\ \frac{\Gamma(e^+e^-)\Gamma(f\overline{f})}{\Gamma_Z^2}\ \frac{s\ \Gamma_Z^2}{(s-M_Z^2)^2\ +\ s^2\Gamma_Z^2/M_Z^2} \tag{55.3}$$

$$\sigma^0_\gamma = \frac{4\pi\alpha^2(s)}{3s}\ Q_f^2 N_c^f \tag{55.4}$$

$$\sigma^0_{\gamma Z} = -\ \frac{2\sqrt{2}\alpha(s)}{3}\ (Q_f G_F N_c^f \mathcal{G}_V^e \mathcal{G}_V^f) \times \frac{(s-M_Z^2)M_Z^2}{(s-M_Z^2)^2 + s^2\Gamma_Z^2/M_Z^2} \tag{55.5}$$

where Q_f is the charge of the fermion, $N_c^f = 3$ for quarks and 1 for leptons, and $\mathcal{G}_V^f$ is the vector coupling of the Z to the fermion-antifermion pair $f\overline{f}$.

Since $\sigma^0_{\gamma Z}$ is expected to be much less than σ^0_Z, the LEP Collaborations have generally calculated the interference term in the framework of the Standard Model. This fixing of $\sigma^0_{\gamma Z}$ leads to a tighter constraint on M_Z, and consequently a smaller error on its fitted value. It is possible to relax this constraint and carry out the fit within the S-matrix framework, which is briefly described in the next section.

In the above framework, the QED radiative corrections have been explicitly taken into account by convoluting over the ISR and allowing the electromagnetic coupling constant to run [6]: $\alpha(s) = \alpha/(1-\Delta\alpha)$. On the other hand, weak radiative corrections that depend upon the assumptions of the electroweak theory and on the values of $M_{\rm top}$ and $M_{\rm Higgs}$ are accounted for by **absorbing them into the couplings**, which are then called the *effective* couplings $\mathcal{G}_V$ and $\mathcal{G}_A$ (or alternatively the effective parameters of the $\star$ scheme of Kennedy and Lynn [7].)

$\mathcal{G}_V^f$ and $\mathcal{G}_A^f$ are complex numbers with small imaginary parts. As experimental data does not allow simultaneous extraction of both real and imaginary parts of the effective couplings, the convention $g_A^f = \mathrm{Re}(\mathcal{G}_A^f)$ and $g_V^f = \mathrm{Re}(\mathcal{G}_V^f)$ is used and the imaginary parts are added in the fitting code [4].

Defining

$$A_f = 2\frac{g_V^f \cdot g_A^f}{(g_V^f)^2 + (g_A^f)^2} \tag{55.6}$$

the lowest-order expressions for the various lepton-related asymmetries on the Z pole are [8–10] $A_{FB}^{(0,\ell)} = (3/4)A_eA_f$, $P(\tau) = -A_\tau$, $P(\tau)^{fb} = -(3/4)A_e$, $A_{LR} = A_e$. The full analysis takes into account the energy-dependence of the asymmetries. Experimentally A_{LR} is defined as $(\sigma_L - \sigma_R)/(\sigma_L + \sigma_R)$, where $\sigma_{L(R)}$ are the $e^+e^- \to Z$ production cross sections with left- (right)-handed electrons.

The definition of the partial decay width of the Z to $f\overline{f}$ includes the effects of QED and QCD final-state corrections, as well as the contribution due to the imaginary parts of the couplings:

$$\Gamma(f\overline{f}) = \frac{G_F M_Z^3}{6\sqrt{2}\pi}\ N_c^f\,(\left|\mathcal{G}_A^f\right|^2 R_A^f + \left|\mathcal{G}_V^f\right|^2 R_V^f) + \Delta_{ew/\mathrm{QCD}} \tag{55.7}$$

where R_V^f and R_A^f are radiator factors to account for final state QED and QCD corrections, as well as effects due to nonzero fermion masses, and $\Delta_{ew/\mathrm{QCD}}$ represents the non-factorizable electroweak/QCD corrections.

55.2 S-matrix approach to the Z

While most experimental analyses of LEP/SLC data have followed the 'Breit-Wigner' approach, an alternative S-matrix-based

analysis is also possible. The Z, like all unstable particles, is associated with a complex pole in the S matrix. The pole position is process-independent and gauge-invariant. The mass, $\overline{M}_Z$, and width, $\overline{\Gamma}_Z$, can be defined in terms of the pole in the energy plane via [11–14]

$$\overline{s} = \overline{M}_Z^2 - i\overline{M}_Z\overline{\Gamma}_Z \tag{55.8}$$

leading to the relations

$$\begin{aligned}\overline{M}_Z &= M_Z/\sqrt{1+\Gamma_Z^2/M_Z^2} \\ &\approx M_Z \ - 34.1 \text{ MeV} \end{aligned} \tag{55.9}$$

$$\begin{aligned}\overline{\Gamma}_Z &= \Gamma_Z/\sqrt{1+\Gamma_Z^2/M_Z^2} \\ &\approx \Gamma_Z \ - 0.9 \text{ MeV} \ . \end{aligned} \tag{55.10}$$

The LEP collaborations [15] have analyzed their data using the S–matrix approach as defined in Eq. (55.8), in addition to the conventional one. They observe a downward shift in the Z mass as expected.

55.3 Handling the large-angle e^+e^- final state

Unlike other $f\overline{f}$ decay final states of the Z, the e^+e^- final state has a contribution not only from the s-channel but also from the t-channel and s-t interference. The full amplitude is not amenable to fast calculation, which is essential if one has to carry out minimization fits within reasonable computer time. The usual procedure is to calculate the non-s channel part of the cross section separately using the Standard Model programs ALIBABA [16] or TOPAZ0 [17], with the measured value of $M_{\rm top}$, and $M_{\rm Higgs} = 150$ GeV, and add it to the s-channel cross section calculated as for other channels. This leads to two additional sources of error in the analysis: firstly, the theoretical calculation in ALIBABA itself is known to be accurate to $\sim 0.5\%$, and secondly, there is uncertainty due to the error on $M_{\rm top}$ and the unknown value of $M_{\rm Higgs}$ (100–1000 GeV). These errors are propagated into the analysis by including them in the systematic error on the e^+e^- final state. As these errors are common to the four LEP experiments, this is taken into account when performing the LEP average.

55.4 Errors due to uncertainty in LEP energy determination

The systematic errors related to the LEP energy measurement, see [18–23], can be classified as:

- The absolute energy scale error;
- Energy-point-to-energy-point errors due to the nonlinear response of the magnets to the exciting currents;
- Energy-point-to-energy-point errors due to possible higher-order effects in the relationship between the dipole field and beam energy;
- Energy reproducibility errors due to various unknown uncertainties in temperatures, tidal effects, corrector settings, RF status, *etc.*

Precise energy calibration was done outside normal data-taking using the resonant depolarization technique. Run-time energies were determined every 10 minutes by measuring the relevant machine parameters and using a model which takes into account all the known effects, including leakage currents produced by trains in the Geneva area and the tidal effects due to gravitational forces of the Sun and the Moon. The LEP Energy Working Group has provided a covariance matrix from the determination of LEP energies for the different running periods during 1993–1995 [18].

55.5 Choice of fit parameters

The LEP Collaborations have chosen the following primary set of parameters for fitting:

$$M_Z, \Gamma_Z, \sigma^0_{\rm hadron}, R(\text{lepton}), A_{FB}^{(0,\ell)},$$

where

$$\begin{aligned} R(\text{lepton}) &= \Gamma(\text{hadrons})/\Gamma(\text{lepton}), \sigma^0_{\rm hadron} \\ &= 12\pi\Gamma(e^+e^-)\Gamma(\text{hadrons})/M_Z^2\Gamma_Z^2. \end{aligned}$$

With a knowledge of these fitted parameters and their covariance matrix, any other parameter can be derived. The main advantage of these parameters is that they form a physics motivated set of parameters with much reduced correlations.

Thus, the most general fit carried out to cross section and asymmetry data determines the **nine parameters**: M_Z, Γ_Z, $\sigma^0_{\rm hadron}$, $R(e)$, $R(\mu)$, $R(\tau)$, $A_{FB}^{(0,e)}$, $A_{FB}^{(0,\mu)}$, $A_{FB}^{(0,\tau)}$. Assumption of lepton universality leads to a **five-parameter fit** determining M_Z, Γ_Z, $\sigma^0_{\rm hadron}$, $R(\text{lepton})$, $A_{FB}^{(0,\ell)}$.

55.6 Combining results from LEP and SLC experiments

With a steady increase in statistics over the years and improved understanding of the common systematic errors between LEP experiments, the procedures for combining results have evolved continuously [24]. The Line Shape Sub-group of the LEP Electroweak Working Group investigated the effects of these common errors, and devised a combination procedure for the precise determination of the Z parameters from LEP experiments. Using these procedures, this note also gives the results after combining the final parameter sets from the four experiments, and these are the results quoted as the fit results in the Z listings below. Transformation of variables leads to values of derived parameters like partial decay widths and branching ratios to hadrons and leptons. Finally, transforming the LEP combined nine parameter set to (M_Z, Γ_Z, $\sigma^\circ_{\rm hadron}$, g_A^f, g_V^f, $f = e, \mu, \tau$) using the average values of lepton asymmetry parameters (A_e, A_μ, A_τ) as constraints, leads to the best fitted values of the vector and axial-vector couplings (g_V, g_A) of the charged leptons to the Z.

Brief remarks on the handling of common errors and their magnitudes are given below. The identified common errors are those coming from

(a) LEP energy-calibration uncertainties, and

(b) the theoretical uncertainties in (i) the luminosity determination using small angle Bhabha scattering, (ii) estimating the non-s channel contribution to large angle Bhabha scattering, (iii) the calculation of QED radiative effects, and (iv) the parametrization of the cross section in terms of the parameter set used.

55.7 Common LEP energy errors

All the collaborations incorporate in their fit the full LEP energy error matrix as provided by the LEP energy group for their intersection region [18]. The effect of these errors is separated out from that of other errors by carrying out fits with energy errors scaled up and down by $\sim 10\%$ and redoing the fits. From the observed changes in the overall error matrix, the covariance matrix of the common energy errors is determined. Common LEP energy errors lead to uncertainties on M_Z, Γ_Z, and $\sigma^\circ_{\rm hadron}$ of 1.7, 1.2 MeV, and 0.011 nb, respectively.

55.8 Common luminosity errors

BHLUMI 4.04 [25] is used by all LEP collaborations for small-angle Bhabha scattering leading to a common uncertainty in their measured cross sections of 0.061% [26]. BHLUMI does not include a correction for production of light fermion pairs. OPAL explicitly corrects for this effect and reduces their luminosity uncertainty to 0.054%, which is taken fully correlated with the other experiments. The other three experiments among themselves have a common uncertainty of 0.061%.

55.9 Common non-s channel uncertainties

The same standard model programs ALIBABA [16] and TOPAZ0 [17] are used to calculate the non-s channel contribution to the large angle Bhabha scattering [27]. As this contribution is a function of the Z mass, which itself is a variable in the fit, it is parameterized as a function of M_Z by each collaboration to properly track this contribution as M_Z varies in the fit. The common errors on R_e and $A_{FB}^{(0,e)}$ are 0.024 and 0.0014 respectively, and are correlated between them.

55.10 Common theoretical uncertainties: QED

There are large initial-state photon and fermion pair radiation effects near the Z resonance, for which the best currently available evaluations include contributions up to $\mathcal{O}(\alpha^3)$. To estimate the

remaining uncertainties, different schemes are incorporated in the standard model programs ZFITTER [5], TOPAZ0 [17], and MIZA [28]. Comparing the different options leads to error estimates of 0.3 and 0.2 MeV on M_Z and Γ_Z respectively, and of 0.02% on $\sigma^\circ_{\rm hadron}$.

55.11 Common theoretical uncertainties: parametrization of lineshape and asymmetries

To estimate uncertainties arising from ambiguities in the model-independent parametrization of the differential cross-section near the Z resonance, results from TOPAZ0 and ZFITTER were compared by using ZFITTER to fit the cross sections and asymmetries calculated using TOPAZ0. The resulting uncertainties on M_Z, Γ_Z, $\sigma^\circ_{\rm hadron}$, R(lepton), and $A_{FB}^{(0,\ell)}$ are 0.1 MeV, 0.1 MeV, 0.001 nb, 0.004, and 0.0001 respectively.

Thus, the overall theoretical errors on M_Z, Γ_Z, $\sigma^\circ_{\rm hadron}$ are 0.3 MeV, 0.2 MeV, and 0.008 nb respectively; on each R(lepton) is 0.004 and on each $A_{FB}^{(0,\ell)}$ is 0.0001. Within the set of three R(lepton)'s and the set of three $A_{FB}^{(0,\ell)}$'s, the respective errors are fully correlated.

All the theory-related errors mentioned above utilize Standard Model programs which need the Higgs mass and running electromagnetic coupling constant as inputs; uncertainties on these inputs will also lead to common errors. All LEP collaborations used the same set of inputs for Standard Model calculations: $M_Z = 91.187$ GeV, the Fermi constant $G_F = (1.16637 \pm 0.00001) \times 10^{-5}$ GeV^{-2} [29], $\alpha^{(5)}(M_Z) = 1/128.877 \pm 0.090$ [30], $\alpha_s(M_Z) = 0.119$ [31], $M_{\rm top} = 174.3 \pm 5.1$ GeV [31] and $M_{\rm Higgs} = 150$ GeV. The only observable effect, on M_Z, is due to the variation of $M_{\rm Higgs}$ between 100–1000 GeV (due to the variation of the γ/Z interference term which is taken from the Standard Model): M_Z changes by +0.23 MeV per unit change in $\log_{10} M_{\rm Higgs}/{\rm GeV}$, which is not an error but a correction to be applied once $M_{\rm Higgs}$ is determined. The effect is much smaller than the error on M_Z ($\pm$2.1 MeV).

55.12 Methodology of combining the LEP experimental results

The LEP experimental results actually used for combination are slightly modified from those published by the experiments (which are given in the Listings below). This has been done in order to facilitate the procedure by making the inputs more consistent. These modified results are given explicitly in [24]. The main differences compared to the published results are (a) consistent use of ZFITTER 6.23 and TOPAZ0 (the published ALEPH results used ZFITTER 6.10); (b) use of the combined energy-error matrix, which makes a difference of 0.1 MeV on the M_Z and Γ_Z for L3 only as at that intersection the RF modeling uncertainties are the largest.

Thus, nine-parameter sets from all four experiments with their covariance matrices are used together with all the common errors correlations. A grand covariance matrix, V, is constructed and a combined nine-parameter set is obtained by minimizing $\chi^2 = \Delta^T V^{-1} \Delta$, where Δ is the vector of residuals of the combined parameter set to the results of individual experiments. Imposing lepton universality in the combination results in the combined five-parameter set.

55.13 Study of $Z \to b\bar{b}$ and $Z \to c\bar{c}$

In the sector of c- and b-physics, the LEP experiments have measured the ratios of partial widths $R_b = \Gamma(Z \to b\bar{b})/\Gamma(Z \to$ hadrons), and $R_c = \Gamma(Z \to c\bar{c})/\Gamma(Z \to$ hadrons), and the forward-backward (charge) asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. The SLD experiment at SLC has measured the ratios R_c and R_b and, utilizing the polarization of the electron beam, was able to obtain the final state coupling parameters A_b and A_c from a measurement of the left-right forward-backward asymmetry of $b-$ and $c-$quarks. The high precision measurement of R_c at SLD was made possible owing to the small beam size and very stable beam spot at SLC, coupled with a highly precise CCD pixel detector. Several of the analyses have also determined other quantities, in particular the semileptonic branching ratios, B($b \to \ell^-$), B($b \to c \to \ell^+$), and B($c \to \ell^+$), the average time-integrated $B^0\overline{B}^0$ mixing parameter $\overline{\chi}$ and the probabilities for a c–quark to fragment into a D^+, a D_s, a D^{*+} , or a charmed baryon. The latter measurements do not concern properties of the Z boson, and hence they do not appear in the Listing below. However, for completeness, we will report at the end of this minireview their values as obtained fitting the data contained in the Z section. All these quantities are correlated with the electroweak parameters, and since the mixture of b hadrons is different from the one at the $\Upsilon(4S)$, their values might differ from those measured at the $\Upsilon(4S)$.

All the above quantities are correlated to each other since:

- Several analyses (for example the lepton fits) determine more than one parameter simultaneously;
- Some of the electroweak parameters depend explicitly on the values of other parameters (for example R_b depends on R_c);
- Common tagging and analysis techniques produce common systematic uncertainties.

The LEP Electroweak Heavy Flavour Working Group has developed [32] a procedure for combining the measurements taking into account known sources of correlation. The combining procedure determines fourteen parameters: the six parameters of interest in the electroweak sector, R_b, R_c, $A_{FB}^{b\bar{b}}$, $A_{FB}^{c\bar{c}}$, A_b and A_c and, in addition, B($b \to \ell^-$), B($b \to c \to \ell^+$), B($c \to \ell^+$), $\overline{\chi}$, $f(D^+)$, $f(D_s)$, $f(c_{\rm baryon})$ and $P(c \to D^{*+}) \times {\rm B}(D^{*+} \to \pi^+ D^0)$, to take into account their correlations with the electroweak parameters. Before the fit both the peak and off-peak asymmetries are translated to the common energy $\sqrt{s} = 91.26$ GeV using the predicted energy-dependence from ZFITTER [5].

55.14 Summary of the measurements and of the various kinds of analysis

The measurements of R_b and R_c fall into two classes. In the first, named single-tag measurement, a method for selecting b and c events is applied and the number of tagged events is counted. A second technique, named double-tag measurement, has the advantage that the tagging efficiency is directly derived from the data thereby reducing the systematic error on the measurement.

The measurements in the b- and c-sector can be essentially grouped in the following categories:

- Lifetime (and lepton) double-tagging measurements of R_b. These are the most precise measurements of R_b and obviously dominate the combined result. The main sources of systematics come from the charm contamination and from estimating the hemisphere b-tagging efficiency correlation;
- Analyses with $D/D^{*\pm}$ to measure R_c. These measurements make use of several different tagging techniques (inclusive/exclusive double tag, exclusive double tag, reconstruction of all weakly decaying charmed states) and no assumptions are made on the energy-dependence of charm fragmentation;
- A measurement of R_c using single leptons and assuming B($b \to c \to \ell^+$);
- Lepton fits which use hadronic events with one or more leptons in the final state to measure the asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. Each analysis usually gives several other electroweak parameters. The dominant sources of systematics are due to lepton identification, to other semileptonic branching ratios and to the modeling of the semileptonic decay;
- Measurements of $A_{FB}^{b\bar{b}}$ using lifetime tagged events with a hemisphere charge measurement. These measurements dominate the combined result;
- Analyses with $D/D^{*\pm}$ to measure $A_{FB}^{c\bar{c}}$ or simultaneously $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$;
- Measurements of A_b and A_c from SLD, using several tagging methods (lepton, kaon, D/D^*, and vertex mass). These quantities are directly extracted from a measurement of the left–right forward–backward asymmetry in $c\bar{c}$ and $b\bar{b}$ production using a polarized electron beam.

55.15 Averaging procedure

All the measurements are provided by the LEP and SLD Collaborations in the form of tables with a detailed breakdown of

the systematic errors of each measurement and its dependence on other electroweak parameters.

The averaging proceeds via the following steps:

- Define and propagate a consistent set of external inputs such as branching ratios, hadron lifetimes, fragmentation models *etc.* All the measurements are checked to ensure that all use a common set of assumptions (for instance, since the QCD corrections for the forward–backward asymmetries are strongly dependent on the experimental conditions, the data are corrected before combining);
- Form the full (statistical and systematic) covariance matrix of the measurements. The systematic correlations between different analyses are calculated from the detailed error breakdown in the measurement tables. The correlations relating several measurements made by the same analysis are also used;
- Take into account any explicit dependence of a measurement on the other electroweak parameters. As an example of this dependence, we illustrate the case of the double-tag measurement of R_b, where c-quarks constitute the main background. The normalization of the charm contribution is not usually fixed by the data and the measurement of R_b depends on the assumed value of R_c, which can be written as:

$$R_b = R_b^{\rm meas} + a(R_c)\frac{(R_c - R_c^{\rm used})}{R_c} \ , \qquad (55.11)$$

  where $R_b^{\rm meas}$ is the result of the analysis which assumed a value of $R_c = R_c^{\rm used}$ and $a(R_c)$ is the constant which gives the dependence on R_c;
- Perform a χ^2 minimization with respect to the combined electroweak parameters.

After the fit the average peak asymmetries $A_{FB}^{c\bar{c}}$ and $A_{FB}^{b\bar{b}}$ are corrected for the energy shift from 91.26 GeV to M_Z and for QED (initial state radiation), γ exchange, and γZ interference effects, to obtain the corresponding pole asymmetries $A_{FB}^{0,c}$ and $A_{FB}^{0,b}$.

This averaging procedure, using the fourteen parameters described above, and applied to the data contained in the Z particle listing below, gives the following results (where the last 8 parameters do not depend directly on the Z):

$$\begin{aligned}
R_b^0 &= 0.21629 \pm 0.00066 \\
R_c^0 &= 0.1721 \pm 0.0030 \\
A_{FB}^{0,b} &= 0.0992 \pm 0.0016 \\
A_{FB}^{0,c} &= 0.0707 \pm 0.0035 \\
A_b &= 0.923 \pm 0.020 \\
A_c &= 0.670 \pm 0.027 \\
\\
B(b \to \ell^-) &= 0.1071 \pm 0.0022 \\
{\rm B}(b \to c \to \ell^+) &= 0.0801 \pm 0.0018 \\
B(c \to \ell^+) &= 0.0969 \pm 0.0031 \\
\overline{\chi} &= 0.1250 \pm 0.0039 \\
f(D^+) &= 0.235 \pm 0.016 \\
f(D_s) &= 0.126 \pm 0.026 \\
f(c_{\rm baryon}) &= 0.093 \pm 0.022 \\
P(c \to D^{*+}) \times {\rm B}(D^{*+} \to \pi^+ D^0) &= 0.1622 \pm 0.0048 \qquad (55.12)
\end{aligned}$$

Among the non–electroweak observables, the B semileptonic branching fraction $B(b \to \ell^-)$ is of special interest, since the dominant error source on this quantity is the dependence on the semileptonic decay model for $b \to \ell^-$, with $\Delta B(b \to \ell^-)_{b\to\ell^- {\rm model}} = 0.0012$. Extensive studies have been made to understand the size of this error. Among the electroweak quantities, the quark asymmetries with leptons depend also on the semileptonic decay model, while the asymmetries using other methods usually do not. The fit implicitely requires that the different methods give consistent results and this effectively constrains the decay model, and thus reduces in principle the error from this source in the fit result.

To obtain a conservative estimate of the modelling error, the above fit has been repeated removing all asymmetry measurements. The results of the fit on B–decay related observables are [24]: $B(b \to \ell^-) = 0.1069 \pm 0.0022$, with $\Delta B(b \to \ell^-)_{b\to\ell^- {\rm model}} = 0.0013$, $B(b \to c \to \ell^+) = 0.0802 \pm 0.0019$ and $\overline{\chi} = 0.1259 \pm 0.0042$.

56. Muon Anomalous Magnetic Moment

Revised August 2023 by A. Höcker (CERN) and W.J. Marciano (BNL).

The Dirac equation predicts a muon magnetic moment, $\vec{M} = g_\mu \frac{e}{2m_\mu}\vec{S}$, with gyromagnetic ratio $g_\mu = 2$. Quantum loop effects lead to a small calculable deviation from $g_\mu = 2$, parameterized by the magnetic anomaly[1]

$$a_\mu \equiv \frac{g_\mu - 2}{2} \ . \tag{56.1}$$

That quantity can be accurately measured and, within the Standard Model (SM) framework, precisely predicted. Hence, comparison of experiment and theory tests the SM at its quantum loop level. A deviation in $a_\mu^{\rm exp}$ from the SM expectation would signal effects of new physics, with current sensitivity reaching up to mass scales of $\mathcal{O}$(TeV) [1]. For recent thorough muon $g-2$ reviews, see e.g. Refs. [2–4].

The E821 experiment at Brookhaven National Lab (BNL) studied during the years 1997−2001 the precession of μ^+ and μ^- in a constant external magnetic field as they circulated in a confining storage ring. It found[2] [6]

$$\begin{aligned} a_{\mu^+}^{\rm exp,BNL} &= 116\,592\,040(60)(50) \times 10^{-11} \ , \\ a_{\mu^-}^{\rm exp,BNL} &= 116\,592\,150(80)(30) \times 10^{-11} \ , \end{aligned} \tag{56.2}$$

where the first errors are statistical and the second systematic. Assuming CPT invariance and taking into account correlations between systematic uncertainties, one finds for their average [5,6]

$$a_\mu^{\rm exp,BNL} = 116\,592\,089(54)(33) \times 10^{-11} \ . \tag{56.3}$$

These results represent about a factor of 14 improvement over the classic CERN experiments of the 1970s [7].

Further improvement of the measurement by a factor of four by setting up the E821 storage ring at the Fermilab National Accelerator Laboratory (FNAL), and utilizing a cleaner and more intense muon beam and improved detectors [8] is in progress. After six runs, the experiment has completed data taking in 2023. A first analysis with positive muons based on a fraction of the data collected in 2018 was released in 2021 confirming the BNL result with similar precision [9]. A second analysis released in 2023 was based on a four times larger positive muon data sample collected in 2019 and 2020, and benefitted from instrumental improvements and reduced systematic uncertainties [10]. The result is dominated by statistical uncertainty and consistent with but more precise than the previous one. Their combination yields [10]

$$a_{\mu^+}^{\rm exp,FNAL} = 116\,592\,055(24) \times 10^{-11} \ . \tag{56.4}$$

The ongoing analysis of the remaining 2021–2023 dataset is expected to further reduce the uncertainty by a factor of two.

The FNAL result agrees with the BNL measurement and has improved precision. Their average assuming CPT invariance reads [10]

$$a_\mu^{\rm exp} = 116\,592\,059(22) \times 10^{-11} \ , \tag{56.5}$$

providing a relative precision of 0.19 parts per million.

Another muon $g-2$ experiment with similar sensitivity but using an alternative zero-electric-field technique with a low-emittance and low-momentum muon beam is currently under construction at J-PARC in Japan [11].

The SM prediction $a_\mu^{\rm SM}$ is generally divided into three parts (see Fig. 56.1 for representative Feynman diagrams)

$$a_\mu^{\rm SM} = a_\mu^{\rm QED} + a_\mu^{\rm EW} + a_\mu^{\rm Had} \ . \tag{56.6}$$

[1] Also referred to as *anomalous magnetic moment* despite being dimensionless.

[2] The results reported by the experiment have been updated in Eqs. (56.2) and (56.3) to the newest value for the absolute muon-to-proton magnetic ratio $\lambda = 3.183\,345\,142(71)$ [5]. The change induced in $a_\mu^{\rm exp}$ with respect to the value of $\lambda = 3.183\,345\,39(10)$ used in Ref. [6] amounts to $+10 \times 10^{-11}$.

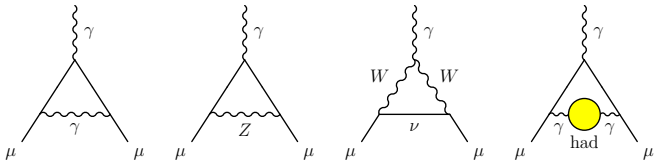

Figure 56.1: Representative diagrams contributing to $a_\mu^{\rm SM}$. From left to right: first order QED (Schwinger term), lowest-order weak, lowest-order hadronic.

In the following discussion we use the numerical estimates provided by the Muon $g-2$ Theory Initiative White Paper [4].

The QED part includes all photonic and leptonic (e, μ, τ) loops starting with the classic $\alpha/2\pi$ Schwinger contribution [12]. It has been computed through five loops [4, 13, 14]

$$\begin{aligned} a_\mu^{\rm QED} =& \frac{\alpha}{2\pi} + 0.765\,857\,420(13)\left(\frac{\alpha}{\pi}\right)^2 + 24.050\,509\,85(23)\left(\frac{\alpha}{\pi}\right)^3 \\ &+ 130.8782(60)\left(\frac{\alpha}{\pi}\right)^4 + 751.0(9)\left(\frac{\alpha}{\pi}\right)^5 + \cdots \end{aligned} \tag{56.7}$$

with little change in the coefficients since our last update of this review. Employing $\alpha^{-1} = 137.035\,999\,046(27)$, obtained from the precise measurements of $h/m_{\rm Cs}$ [15], the Rydberg constant, and $m_{\rm Cs}/m_e$ leads to[3] [13]

$$a_\mu^{\rm QED} = 116\,584\,718.93(0.10) \times 10^{-11} \ , \tag{56.8}$$

where the small error results mainly from the uncertainties in the estimate of the six loop contribution and in α.

Loop contributions involving heavy $W^\pm, Z$ or Higgs particles are collectively labeled as $a_\mu^{\rm EW}$. They are suppressed by at least a factor of $(\alpha/\pi)\cdot(m_\mu^2/m_W^2) \simeq 4 \times 10^{-9}$. At 1-loop order [19]

$$\begin{aligned} &a_\mu^{\rm EW}[\text{1-loop}] = \\ &\frac{G_\mu m_\mu^2}{8\sqrt{2}\pi^2}\left[\frac{5}{3} + \frac{1}{3}\left(1 - 4\sin^2\theta_{\rm W}\right)^2 + \mathcal{O}\left(\frac{m_\mu^2}{M_W^2}\right) + \mathcal{O}\left(\frac{m_\mu^2}{m_H^2}\right)\right] \\ &= 194.8 \times 10^{-11} \ , \end{aligned} \tag{56.9}$$

for $\sin^2\theta_{\rm W} \equiv 1 - M_W^2/M_Z^2 \simeq 0.223$, and where $G_\mu \simeq 1.166 \times 10^{-5}$ GeV^{-2} is the Fermi coupling constant. Two-loop corrections are relatively large and negative [20]. For a Higgs boson mass of 125 GeV it amounts to $a_\mu^{\rm EW}[\text{2-loop}] = -41.2(1.0) \times 10^{-11}$ [20], where the uncertainty stems from quark triangle loops. The 3-loop leading logarithms are negligible, $\mathcal{O}(10^{-12})$ [20, 21]. Overall one finds

$$a_\mu^{\rm EW} = 153.6(1.0) \times 10^{-11} \ . \tag{56.10}$$

A recent complete 2-loop numerical evaluation of the electroweak correction [22] when adjusted for appropriate light quark masses confirmed the result in Eq. (56.10).

Hadronic (quark and gluon) loop contributions to $a_\mu^{\rm SM}$ give rise to its main uncertainty. One traditionally relies on a data-driven dispersion relation approach to evaluate the lowest-order $\mathcal{O}(\alpha^2)$ hadronic vacuum polarization contribution $a_\mu^{\rm Had}$[LO] from corresponding cross section measurements [23]

$$a_\mu^{\rm Had}[\text{LO}] = \frac{1}{3}\left(\frac{\alpha}{\pi}\right)^2 \int_{m_\pi^2}^{\infty} ds\, \frac{K(s)}{s} R^{(0)}(s) \, , \tag{56.11}$$

[3] A recent measurement using Rb-87 atoms [16] resulted in $\alpha^{-1} = 137.035\,999\,206(11)$, which exhibits a larger than 5σ discrepancy with the Cs-133 based result. Using this value in Eq. (56.7) leads to a reduction of $a_\mu^{\rm QED}$ by 0.14×10^{-11}, which is larger than the quoted uncertainty in Eq. (56.8), but still negligible compared to other uncertainties affecting $a_\mu^{\rm SM}$. This discrepancy impacts, however, the SM prediction of the magnetic moment of the electron [14, 17], which differs by respectively -3.9σ and $+2.1\sigma$ from the most recent experimental value [18], depending on whether the Cs-133 or Rb-87 based α value is used.

where $K(s)$ is a QED kernel function [24], and where $R^{(0)}(s)$ denotes the ratio of the bare[4] cross section for e^+e^- annihilation into hadrons to the pointlike muon-pair cross section at center-of-mass energy $\sqrt{s}$. The function $K(s) \sim 1/s$ in Eq. (56.11) emphasizes the low-energy part of the integral so that $a_\mu^{\rm Had}$[LO] is dominated by the $\rho(770) \to \pi^+\pi^-$ resonance.

The analysis of Eq. (56.11) results in the representative value [4, 25–30]

$$a_\mu^{\rm Had}[\rm LO] = 6\,931(40) \times 10^{-11}\,, \qquad (56.12)$$

whose error is dominated by systematic uncertainties in the $e^+e^- \to$ hadrons cross-section data, and also includes a small uncertainty due to perturbative QCD, which is used at intermediate and large energies in the dispersion integral to predict the contribution from the quark-antiquark continuum. The experimental precision of Eq. (56.12) is limited by a discrepancy between the most precise $\pi^+\pi^-$ data from the BABAR and KLOE experiments [27, 29]. Recent preliminary $\pi^+\pi^-$ data from the CMD-3 experiment [31] give a significantly larger contribution to $a_\mu^{\rm Had}$[LO] but disagree with essentially all other datasets. New or updated measurements are expected from several experiments during the next years.

Alternatively, one can use precise vector spectral functions from $\tau \to \nu_\tau +$ hadrons decays [32] that can be related to isovector $e^+e^- \to$ hadrons cross sections by isospin symmetry. Analyses replaced e^+e^- data in the two-pion and four-pion channels by the corresponding isospin- transformed τ data, and applied isospin-violating corrections [33]. Owing to the progress in the precision of the e^+e^- data, the τ data are now less precise and less reliable due to additional theoretical uncertainties, so that recent $a_\mu^{\rm Had}$[LO] evaluations ignored them.

Progress has been achieved on the evaluation of $a_\mu^{\rm Had}$[LO] using lattice QCD, which allows to directly compute the real part of the two-point correlation function without invoking the resonances occurring on the imaginary axis [34–36]. The required sub-percent precision represents a challenge requiring to master systematic and extrapolation uncertainties. A combination of recent lattice QCD evaluations [37, 38] gives [4]

$$a_\mu^{\rm Had}[\rm LO] = 7\,116(184) \times 10^{-11}\,, \qquad (56.13)$$

with an uncertainty that is not yet competitive with the data-driven approach. Another recent lattice QCD calculation with much reduced uncertainty found [39]

$$a_\mu^{\rm Had}[\rm LO] = 7\,075(55) \times 10^{-11}\,, \qquad (56.14)$$

whose error is dominated by systematic uncertainties. It exhibits a 2.1σ tension with the data-driven result, growing up to 3.7σ for the modified observable $a_{\mu,\rm win}$ that has favourable properties for computation on the lattice[5] [38, 39, 41]. Because of the complexity and challenges of such a calculation, it is critical that it is confronted with independent lattice results of comparable precision [38, 41, 42].

Higher order hadronic loop contributions are also obtained from dispersion relations using the same $e^+e^- \to$ hadrons data but with different integration kernels [43]. Recent evaluations found $a_\mu^{\rm Had,Disp}[\rm NLO] = (-98.3 \pm 0.7) \times 10^{-11}$ [4, 30] and $a_\mu^{\rm Had,Disp}[\rm NNLO] = (12.4 \pm 0.1) \times 10^{-11}$ [44]. In the case of hadronic light-by-light scattering contributions, which enter at NLO, recent studies [3, 4, 45, 46] based on short-distance QCD, dispersion relations and lattice QCD calculations lead to the improved prediction $a_\mu^{\rm Had,LBL}[\rm NLO] = 92(18) \times 10^{-11}$ [4].[6] One thus finds for the sum of the three higher order hadronic terms

$$a_\mu^{\rm Had}[\rm N(N)LO] = 6(18) \times 10^{-11}\,, \qquad (56.15)$$

where the error is dominated by the hadronic light-by-light scattering uncertainty.

Adding Eqs. (56.8), (56.10), (56.12) and (56.15) gives the representative SM prediction

$$a_\mu^{\rm SM} = 116\,591\,810(1)(40)(18) \times 10^{-11}\,, \qquad (56.16)$$

whose errors are due to the electroweak, lowest-order hadronic, and higher-order hadronic contributions, respectively. The difference between experiment and theory

$$\Delta a_\mu = a_\mu^{\rm exp} - a_\mu^{\rm SM} = 249(22)(43) \times 10^{-11}\,, \qquad (56.17)$$

where the errors are from experiment and theory prediction (with all errors combined in quadrature, taking into account a small anticorrelation [4] between the data-driven lowest and higher order contributions), exhibits a discrepancy of 5.2σ.[7] The new FNAL measurement has increased the discrepancy with the SM prediction from previously 3.7σ (BNL only) and 4.2σ (including the first FNAL result), respectively. Despite the large significance, the situation remains inconclusive due to the discrepancies in the hadronic cross section data underlying the dispersive $a_\mu^{\rm Had}$[LO] determination.

Figure 56.2 represents the difference between experimental and predicted a_μ values based on the most recent data-driven and lattice QCD based evaluations of $a_\mu^{\rm Had}$[LO].

A leading candidate explanation for the deviation observed in Δa_μ has been supersymmetry particle loop contributions. Such a scenario is quite natural, since generically, supersymmetric models predict [1] an additional contribution to $a_\mu^{\rm SM}$

$$a_\mu^{\rm SUSY} \simeq \pm 130 \times 10^{-11} \cdot \left(\frac{100\ \rm GeV}{m_{\rm SUSY}}\right)^2 \tan\beta\,, \qquad (56.18)$$

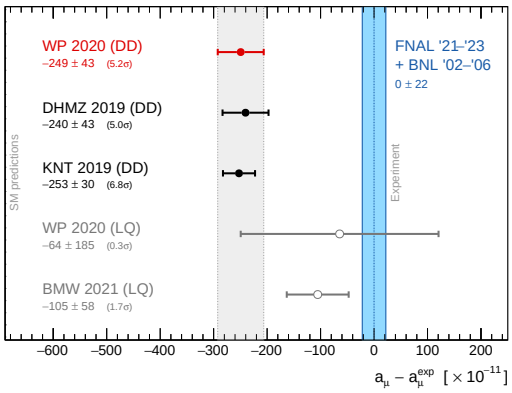

Figure 56.2: Compilation of recent results for a_μ (in units of 10^{-11}), subtracted by the central value of the experimental average (56.3). The light blue vertical band indicates the total experimental uncertainty. The SM predictions shown differ only in the value used for the $a_\mu^{\rm Had}$[LO] contribution. They are taken from: WP 2020 [4] (Eq. (56.16), also indicated by the light grey vertical band), DHMZ 2019 [29], KNT 2019 [30], all three based on the data-driven (DD) $a_\mu^{\rm Had}$[LO] evaluation, and the lattice QCD (LQ) based evaluations WP 2020 [4, 37, 38] and BMW 2021 [39]. Note that the quoted errors in the figure do not include the uncertainty on the subtracted experimental value. To obtain for each theory calculation a result equivalent to Eq. (56.17), the errors from theory and experiment must be added in quadrature.

[4] The bare cross section is defined as the measured cross section corrected for initial-state radiation, electron-vertex loop contributions and vacuum-polarization effects in the photon propagator. However, QED effects in the hadron vertex and final state, as photon radiation, are included.

[5] A dispersive approach similar to that for $a_\mu^{\rm Had}$[LO] is used to determine the hadronic contribution to the running of the electromagnetic fine structure constant at the Z-boson mass $\Delta\alpha_{\rm had}(m_Z)$, which is a critical ingredient of the global electroweak fit. One may therfore ask if the goodness of that fit would break down were $a_\mu^{\rm Had}$[LO] in Eq. (56.12) be brought in compatibility with the result (56.14). However, the difference in the relevant integration kernels (whereas 73% of the contribution to $a_\mu^{\rm Had}$[LO] stems from the $\pi^+\pi^-$ channel, it is only 13% in the case of $\Delta\alpha_{\rm had}(m_Z)$) allows to absorb large effects in $a_\mu^{\rm Had}$[LO] without creating a significant tension in the electroweak fit. Detailed discussions are available in the literature [40].

[6] A very recent lattice QCD based calculation of $a_\mu^{\rm Had,LBL}$[NLO] [47], not included in [4], gives a consistent result with [4, 46] using a different approach.

[7] The probabilistic interpretation of the discrepancy requires caution due to the systematic nature of the $a_\mu^{\rm SM}$ uncertainty.

where $m_{\rm SUSY}$ is a representative supersymmetric mass scale, $\tan\beta \simeq$ 3–40 a potential enhancement factor, and ± 1 corresponds to the sign of the μ term in the supersymmetric Lagrangian. Supersymmetric particles in the mass range 100–500 GeV could be the source of the deviation Δa_μ. If so, those particles should be directly observable at the Large Hadron Collider at CERN. So far, there is however no direct evidence in support of the supersymmetry interpretation.

New physics effects [1] other than supersymmetry could also explain a non-vanishing Δa_μ. A popular scenario involves the "dark photon", a relatively light hypothetical vector boson from the dark matter sector that couples to our world of particle physics through mixing with the ordinary photon [48–50]. As a result, it couples to ordinary charged particles with strength $\varepsilon \cdot e$ and gives rise to an additional muon magnetic anomaly contribution

$$a_\mu^{\text{dark photon}} = \frac{\alpha}{2\pi}\varepsilon^2 F(m_V/m_\mu)\,, \qquad (56.19)$$

where $F(x) = \int_0^1 2z(1-z)^2/[(1-z)^2 + x^2 z]\,dz$. For values of $\varepsilon \sim 1\text{–}2 \times 10^{-3}$ and $m_V \sim 10\text{–}100\,\text{MeV}$, the dark photon, which was originally motivated by cosmology, can provide a viable solution to the muon $g-2$ discrepancy. However, experimental constraints appear to rule out the simplest model in which the dark photon has equal couplings to electrons and muons and decays primarily to e^+e^- pairs [51] or invisible dark particles [52] that give rise to missing event energy. One can expand the dark photon scenario into a more complete theory in which several new particles contribute to the muon $g-2$. Direct searches for a dark photon, therefore, continue to be well motivated, but with primary guidance coming from astrophysics [53].

Recent popular solutions to the muon anomaly discrepancy have also focused on loop contributions induced by relatively light scalar or pseudo scalar particle appendages from physics beyond the SM [54, 55].

57. Muon Decay Parameters

Revised August 2023 by W. Fetscher (ETH Zurich) and H.-J. Gerber (ETH Zurich).

57.1 Introduction:

All measurements in direct muon decay, $\mu^- \to e^- + 2$ neutrals, and its inverse, $\nu_\mu + e^- \to \mu^-$ + neutral, are successfully described by the "V-A interaction," which is a particular case of a local, derivative-free, lepton-number-conserving, four-fermion interaction [1]. As shown below, within this framework, the Standard Model assumptions, such as the V-A form and the nature of the neutrals (ν_μ and $\bar{\nu}_e$), and hence the doublet assignments $(\nu_e\, e^-)_L$ and $(\nu_\mu\, \mu^-)_L$, have been determined from experiments [2,3]. All considerations on muon decay are valid for the leptonic tau decays $\tau^- \to \ell^- + \nu_\tau + \bar{\nu}_\ell$ with the replacements $m_\mu \to m_\tau$, $m_e \to m_{ell}$, $\ell^- = e^-, \mu^-$.

57.2 Parameters:

The differential decay probability to obtain an $e^\pm$ with (reduced) energy between x and $x + \mathrm{d}x$, emitted in the direction $\widehat{\boldsymbol{x}}_3$ at an angle between ϑ and $\vartheta + \mathrm{d}\vartheta$ with respect to the muon polarization vector $\boldsymbol{P}_\mu$, and with its spin parallel to the arbitrary direction $\widehat{\boldsymbol{\zeta}}$, neglecting radiative corrections, is given by

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} = \frac{m_\mu}{4\pi^3}\, W_{e\mu}^4\, G_\mathrm{F}^2\, \sqrt{x^2 - x^{2}_{0}} \times \left(F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta F_\mathrm{AS}(x)\right) \times \left[1 + \widehat{\boldsymbol{\zeta}} \cdot \boldsymbol{P}_e(x,\vartheta)\right] \,. \tag{57.1}$$

Here, $W_{e\mu} = \max(E_e) = (m_\mu^2 + m_e^2)/2m_\mu$ is the maximum $e^\pm$ energy, $x = E_e/W_{e\mu}$ is the reduced energy, $x_0 = m_e/W_{e\mu} = 9.67 \times 10^{-3}$, and $P_\mu = |\boldsymbol{P}_\mu|$ is the degree of muon polarization. $\widehat{\boldsymbol{\zeta}}$ is the direction in which a perfect polarization-sensitive electron detector is most sensitive. The isotropic part of the spectrum, $F_\mathrm{IS}(x)$, the anisotropic part $F_\mathrm{AS}(x)$, and the electron polarization, $\boldsymbol{P}_e(x,\vartheta)$, may be parametrized by the Michel parameter ρ [1], by η [4], by ξ and δ [5,6], *etc.* These are bilinear combinations of the coupling constants $g^\gamma_{\varepsilon\mu}$, which occur in the matrix element (given below).

If the masses of the neutrinos as well as x_0^2 are neglected, the energy and angular distribution of the electron in the rest frame of a muon ($\mu^\pm$) measured by a polarization insensitive detector, is given by

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} \sim x^2 \cdot \left\{ 3(1-x) + \frac{2\rho}{3}(4x-3) + 3\eta\, x_0(1-x)/x \pm P_\mu \cdot \xi \cdot \cos\vartheta \left[1 - x + \frac{2\delta}{3}(4x-3)\right] \right\} \,. \tag{57.2}$$

Here, ϑ is the angle between the electron momentum and the muon spin, and $x \equiv 2E_e/m_\mu$. For the Standard Model coupling, we obtain $\rho = \xi\delta = 3/4$, $\xi = 1$, $\eta = 0$ and the differential decay rate is

$$\frac{\mathrm{d}^2\Gamma}{\mathrm{d}x\,\mathrm{d}\cos\vartheta} = \frac{G_\mathrm{F}^2 m_\mu^5}{192\pi^3}\, [3 - 2x \pm P_\mu \cos\vartheta(2x-1)] \cdot x^2 \,. \tag{57.3}$$

The coefficient in front of the square bracket is the total decay rate.

If only the neutrino masses are neglected, and if the $e^\pm$ polarization is detected, then the functions in Eq. (57.1) become

$$F_\mathrm{IS}(x) = x\,(1-x) + \tfrac{2}{9}\,\rho\,(4x^2 - 3x - x_0^2) + \eta \cdot x_0\,(1-x) \tag{57.4a}$$

$$F_\mathrm{AS}(x) = \tfrac{1}{3}\,\xi\,\sqrt{x^2 - x_0^2} \times \left[(1-x) + \tfrac{2}{3}\delta\left\{(4x-3) + \left(\sqrt{1-x_0^2} - 1\right)\right\}\right] \tag{57.4b}$$

$$\boldsymbol{P}_e(x,\vartheta) = P_{\mathrm{T}_1} \cdot \widehat{\boldsymbol{x}}_1 + P_{\mathrm{T}_2} \cdot \widehat{\boldsymbol{x}}_2 + P_\mathrm{L} \cdot \widehat{\boldsymbol{x}}_3 \tag{57.4c}$$

Here $\widehat{\boldsymbol{x}}_1$, $\widehat{\boldsymbol{x}}_2$, and $\widehat{\boldsymbol{x}}_3$ are orthogonal unit vectors defined as follows:

$\widehat{\boldsymbol{x}}_3$	is along the e momentum $\boldsymbol{p}_e$
$\dfrac{\widehat{\boldsymbol{x}}_3 \times \boldsymbol{P}_\mu}{\lvert\widehat{\boldsymbol{x}}_3 \times \boldsymbol{P}_\mu\rvert} = \widehat{\boldsymbol{x}}_2$	is transverse to $\boldsymbol{p}_e$ and perpendicular to "the decay plane"
$\widehat{\boldsymbol{x}}_2 \times \widehat{\boldsymbol{x}}_3 = \widehat{\boldsymbol{x}}_1$	is transverse to $\boldsymbol{p}_e$ and in the decay plane

The components of $\boldsymbol{P}_e$ then are given by

$$P_{\mathrm{T}_1}(x,\vartheta) = P_\mu \sin\vartheta \cdot F_{\mathrm{T}_1}(x) / \left\{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)\right\} \tag{57.5a}$$

$$P_{\mathrm{T}_2}(x,\vartheta) = P_\mu \sin\vartheta \cdot F_{\mathrm{T}_2}(x) / \left\{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)\right\} \tag{57.5b}$$

$$P_\mathrm{L}(x,\vartheta) = \frac{\pm F_\mathrm{IP}(x) + P_\mu \cos\vartheta \cdot F_\mathrm{AP}(x)}{F_\mathrm{IS}(x) \pm P_\mu \cos\vartheta \cdot F_\mathrm{AS}(x)} \quad , \tag{57.5c}$$

where

$$F_{\mathrm{T}_1}(x) = \tfrac{1}{12}\left\{-2\left[\xi'' + 12\left(\rho - \tfrac{3}{4}\right)\right](1-x)x_0 - 3\,\eta\left(x^2 - x_0^2\right) + \eta''\left(-3x^2 + 4x - x_0^2\right)\right\} \tag{57.6a}$$

$$F_{\mathrm{T}_2}(x) = \tfrac{1}{3}\,\sqrt{x^2 - x_0^2} \cdot \left\{3\,\frac{\alpha'}{A}(1-x) + 2\,\frac{\beta'}{A}\sqrt{1-x_0^2}\right\} \tag{57.6b}$$

$$F_\mathrm{IP}(x) = \tfrac{1}{54}\sqrt{x^2 - x_0^2} \cdot \left\{9\,\xi'\left(-2x + 2 + \sqrt{1-x_0^2}\right) + 4\,\xi\left(\delta - \tfrac{3}{4}\right)\left(4x - 4 + \sqrt{1-x_0^2}\right)\right\} \tag{57.6c}$$

$$F_\mathrm{AP}(x) = \tfrac{1}{6}\left\{\xi''\left(2x^2 - x - x_0^2\right) + 4\left(\rho - \tfrac{3}{4}\right)\left(4x^2 - 3x - x_0^2\right) + 2\,\eta''(1-x)\,x_0\right\}. \tag{57.6d}$$

For the experimental values of the parameters ρ, ξ, ξ', ξ'', δ, η, η'', α/A, β/A, α'/A, β'/A, which are not all independent, see the Data Listings below. Experiments in the past have also been analyzed using the parameters a, b, c, a', b', c', α/A, β/A, α'/A, β'/A (and $\eta = (\alpha - 2\beta)/2A$), as defined by Kinoshita and Sirlin [5,6]. They serve as a model-independent summary of all possible measurements on the decay electron (see Listings below). The relations between the two sets of parameters are

$$\rho - \tfrac{3}{4} = \tfrac{3}{4}\,(-a + 2\,c)/A \tag{57.7a}$$

$$\eta = (\alpha - 2\beta)/A \tag{57.7b}$$

$$\eta'' = (3\,\alpha + 2\,\beta)/A \tag{57.7c}$$

$$\delta - \tfrac{3}{4} = \tfrac{9}{4} \cdot \frac{(a' - 2\,c')\,/A}{1 - [a + 3\,a' + 4\,(b + b') + 6\,c - 14\,c']\,/A} \tag{57.7d}$$

$$1 - \xi\,\frac{\delta}{\rho} = 4\,\frac{[(b + b') + 2\,(c - c')]\,/A}{1 - (a - 2\,c)/A} \tag{57.7e}$$

$$1 - \xi = \left[\left(a + a'\right) + 4\left(b + b'\right) + 6\left(c + c'\right)\right]/A \tag{57.7f}$$

$$1 - \xi'' = (-2\,a + 20\,c)/A \tag{57.7g}$$

$$\text{with} \qquad A = a + 4\,b + 6\,c \tag{57.7h}$$

The differential decay probability to obtain a *left-handed* ν_e with (reduced) energy between y and $y + dy$, neglecting radiative corrections as well as the masses of the electron and of the neutrinos, is given by [7]

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}y} = \frac{m_\mu^5 G_\mathrm{F}^2}{16\,\pi^3} \cdot Q_L^{\nu_e} \cdot y^2 \left\{(1-y) - \omega_L \cdot \left(y - \tfrac{3}{4}\right)\right\} \,. \tag{57.8}$$

Here, $y = 2\ E_{\nu_e}/m_\mu$. $Q_L^{\nu_e}$ and ω_L are parameters. ω_L is the neutrino analog of the spectral shape parameter ρ of Michel. Since in the Standard Model, $Q_L^{\nu_e} = 1$, $\omega_L = 0$, the measurement of $\mathrm{d}\Gamma/\mathrm{d}y$ has allowed a null-test of the Standard Model (see Listings below).

Table 57.1: Coupling constants $g^\gamma_{\varepsilon\mu}$ and some combinations of them. Ninety-percent confidence level experimental limits. The limits on $|g^S_{LL}|$ and $|g^V_{LL}|$ are from [8–10], and the others from a general analysis of muon decay measurements. Top three rows: [11], fourth row: [12], next three rows: [13], last row: [14]. The experimental uncertainty on the muon polarization in pion decay is included. Note that, by definition, $|g^S_{\varepsilon\mu}| \le 2$, $|g^V_{\varepsilon\mu}| \le 1$ and $|g^T_{\varepsilon\mu}| \le 1/\sqrt{3}$.

$\lvert g^S_{RR}\rvert < 0.035$	$\lvert g^V_{RR}\rvert < 0.017$	$\lvert g^T_{RR}\rvert \equiv 0$
$\lvert g^S_{LR}\rvert < 0.050$	$\lvert g^V_{LR}\rvert < 0.023$	$\lvert g^T_{LR}\rvert < 0.015$
$\lvert g^S_{RL}\rvert < 0.420$	$\lvert g^V_{RL}\rvert < 0.105$	$\lvert g^T_{RL}\rvert < 0.105$
$\lvert g^S_{LL}\rvert < 0.550$	$\lvert g^V_{LL}\rvert > 0.960$	$\lvert g^T_{LL}\rvert \equiv 0$
$\lvert g^S_{LR} + 6\,g^T_{LR}\rvert < 0.143$	$\lvert g^S_{RL} + 6\,g^T_{RL}\rvert < 0.418$	
$\lvert g^S_{LR} + 2\,g^T_{LR}\rvert < 0.108$	$\lvert g^S_{RL} + 2\,g^T_{RL}\rvert < 0.417$	
$\lvert g^S_{LR} - 2\,g^T_{LR}\rvert < 0.070$	$\lvert g^S_{RL} - 2\,g^T_{RL}\rvert < 0.418$	
$Q_{RR} + Q_{LR} < 8.2{\times}10^{-4}$		

57.3 Matrix element:

All results in direct muon decay (energy spectra of the electron and of the neutrinos, polarizations, and angular distributions), and in inverse muon decay (the reaction cross section) at energies well below $m_W c^2$, may be parametrized in terms of amplitudes $g^\gamma_{\varepsilon\mu}$ and the Fermi coupling constant G_F, using the matrix element

$$\frac{4G_\mathrm{F}}{\sqrt{2}} \sum_{\substack{\gamma=S,V,T\\ \varepsilon,\mu=R,L}} g^\gamma_{\varepsilon\mu}\, \langle \bar{e}_\varepsilon | \Gamma^\gamma | (\nu_e)_n \rangle\, \langle (\bar{\nu}_\mu)_m | \Gamma_\gamma | \mu_\mu \rangle \tag{57.9}$$

We use the notation of Fetscher *et al.* [2], who in turn use the sign conventions and definitions of Scheck [15]. Here, $\gamma = S, V, T$ indicates a scalar, vector, or tensor interaction; and $\varepsilon, \mu = R, L$ indicate a right- or left-handed chirality of the electron or muon. The chiralities n and m of the ν_e and $\bar{\nu}_\mu$ are then determined by the values of γ, ε, and μ. The particles are represented by fields of definite chirality [16].

As shown by Langacker and London [17], explicit lepton-number nonconservation still leads to a matrix element equivalent to Eq. (57.9). They conclude that it is not possible, even in principle, to test lepton-number conservation in (leptonic) muon decay if the final neutrinos are massless and are not observed.

The ten complex amplitudes $g^\gamma_{\varepsilon\mu}$ (g^T_{RR} and g^T_{LL} are identically zero) and G_F constitute 19 independent (real) parameters to be determined by experiment. The Standard Model interaction corresponds to one single amplitude g^V_{LL} being unity and all the others being zero.

The (direct) muon decay experiments are compatible with an arbitrary mix of the scalar and vector amplitudes g^S_{LL} and g^V_{LL} – in the extreme even with purely scalar $g^S_{LL} = 2$, $g^V_{LL} = 0$. The decision in favour of the Standard Model comes from the quantitative observation of inverse muon decay, which would be forbidden for pure g^S_{LL} [2].

57.4 Experimental determination of V–A:

In order to determine the amplitudes $g^\gamma_{\varepsilon\mu}$ uniquely from experiment, the following set of equations, where the left-hand sides represent experimental results, has to be solved.

$$a = 16\left(|g^V_{RL}|^2 + |g^V_{LR}|^2\right) + \left|g^S_{RL} + 6\,g^T_{RL}\right|^2 + \left|g^S_{LR} + 6\,g^T_{LR}\right|^2 \tag{57.10a}$$

$$a' = 16\left(|g^V_{RL}|^2 - |g^V_{LR}|^2\right) + \left|g^S_{RL} + 6\,g^T_{RL}\right|^2 - \left|g^S_{LR} + 6\,g^T_{LR}\right|^2 \tag{57.10b}$$

$$\alpha = 8\,\mathrm{Re}\left\{g^V_{RL}\left(g^{S*}_{LR} + 6\,g^{T*}_{LR}\right) + g^V_{LR}\left(g^{S*}_{RL} + 6\,g^{T*}_{RL}\right)\right\} \tag{57.10c}$$

$$\alpha' = 8\,\mathrm{Im}\left\{-g^V_{RL}\left(g^{S*}_{LR} + 6\,g^{T*}_{LR}\right) + g^V_{LR}\left(g^{S*}_{RL} + 6\,g^{T*}_{RL}\right)\right\} \tag{57.10d}$$

$$b = 4\left(|g^V_{RR}|^2 + |g^V_{LL}|^2\right) + |g^S_{RR}|^2 + |g^S_{LL}|^2 \tag{57.10e}$$

$$b' = 4\left(|g^V_{RR}|^2 - |g^V_{LL}|^2\right) + |g^S_{RR}|^2 - |g^S_{LL}|^2 \tag{57.10f}$$

$$c = \tfrac{1}{2}\left\{|g^S_{RL} - 2\,g^T_{RL}|^2 + |g^S_{LR} - 2\,g^T_{LR}|^2\right\} \tag{57.10g}$$

$$c' = \tfrac{1}{2}\left\{|g^S_{RL} - 2\,g^T_{RL}|^2 - |g^S_{LR} - 2\,g^T_{LR}|^2\right\} \tag{57.10h}$$

and

$$Q_L^{\nu_e} = 1 - \left\{\tfrac{1}{4}|g^S_{LR}|^2 + \tfrac{1}{4}|g^S_{LL}|^2 + |g^V_{RR}|^2 + |g^V_{RL}|^2 + 3\,|g^T_{LR}|^2\right\}$$

$$\omega_L = \tfrac{3}{4}\,\frac{|g^S_{RR}|^2 + 4\,|g^V_{LR}|^2 + |g^S_{RL} + 2\,g^T_{LR}|^2}{|g^S_{RL}|^2 + |g^S_{RR}|^2 + 4\,|g^V_{LL}|^2 + 4\,|g^V_{LR}|^2 + 12\,|g^T_{RL}|^2}\,. \tag{57.10i}$$

It has been noted earlier by C. Jarlskog [18], that certain experiments observing the decay electron are especially informative if they yield the V-A values. The complete solution is now found as follows. Fetscher *et al.* [2] introduced four probabilities $Q_{\varepsilon\mu}(\varepsilon, \mu = R, L)$ for the decay of a μ-handed muon into an ε-handed electron, and showed that there exist upper bounds on Q_{RR}, Q_{LR}, and Q_{RL}, and a lower bound on Q_{LL}. These probabilities are given in terms of the $g^\gamma_{\varepsilon\mu}$'s by

$$Q_{\varepsilon\mu} = \tfrac{1}{4}|g^S_{\varepsilon\mu}|^2 + |g^V_{\varepsilon\mu}|^2 + 3\,(1 - \delta_{\varepsilon\mu})|g^T_{\varepsilon\mu}|^2 \tag{57.11}$$

where $\delta_{\varepsilon\mu} = 1$ for $\varepsilon = \mu$, and $\delta_{\varepsilon\mu} = 0$ for $\varepsilon \neq \mu$. They are related to the parameters $a,\ b,\ c,\ a', b'$, and c' by

$$Q_{RR} = 2\,(b + b')/A \tag{57.12a}$$

$$Q_{LR} = \left[(a - a') + 6\,(c - c')\right]/2A \tag{57.12b}$$

$$Q_{RL} = \left[(a + a') + 6\,(c + c')\right]/2A \tag{57.12c}$$

$$Q_{LL} = 2\,(b - b')/A \tag{57.12d}$$

with $A = 16$. In the Standard Model, $Q_{LL} = 1$ and the others are zero.

Since the upper bounds on Q_{RR}, Q_{LR}, and Q_{RL} are found to be small, and since the helicity of the ν_μ in pion decay is known from experiment [19, 20] to very high precision to be -1 [21], the cross section S of *inverse* muon decay, normalized to the V-A value, yields [2]

$$|g^S_{LL}|^2 \le 4(1 - S) \tag{57.13a}$$

and

$$|g^V_{LL}|^2 = S\,. \tag{57.13b}$$

Thus the Standard Model assumption of a pure V-A leptonic charged weak interaction of e and μ is derived (within errors) from experiments at energies far below the mass of the $W^\pm$: Eq. (57.13 b) gives a lower limit for V-A, and Eqs. (57.12 a, b, c)

and (57.13 a) give upper limits for the other four-fermion interactions. The existence of such upper limits may also be seen from $Q_{RR}+Q_{RL}=(1-\xi')/2$ (e^+ longitudinal polarization) and $Q_{RR}+Q_{LR}=\frac{1}{2}(1+\xi/3-16\,\xi\delta/9)$ (decay asymmetry). Table 57.1 gives the current experimental limits on the magnitudes of the $g^{\gamma}_{\varepsilon\mu}$'s. More stringent limits on the six coupling constants g^S_{LR}, g^V_{LR}, g^T_{LR}, g^S_{RL}, g^V_{RL}, and g^T_{RL} have been derived from upper limits on the neutrino mass [22]. Limits on the "charge retention" coordinates, as used in the older literature (*e.g.*, Ref. [23]), are given by Burkard *et al.* [24].

58. τ Branching Fractions

Revised April 2024 by Sw. Banerjee (Louisville U.) and A. Lusiani (SNS, Pisa; INFN, Pisa).

58.1 τ Branching Fractions

The τ Listings contains 252 entries that correspond to either a τ partial decay fraction into a specific decay mode (branching fraction) or a ratio of two τ partial decay fractions (branching ratio). Experimental measurements provide values for 148 of these quantities, upper limits for 67 branching fractions to Lepton Family number, Lepton number, or Baryon number violating modes, and 37 additional upper limits for other modes. A total of 129 τ branching fractions and branching ratios are determined with a fit of 170 measurements. 85 quantities have at least one measurement in the fit.

58.2 The constrained fit to τ branching fractions

The τ branching fractions fit uses the reported values, uncertanties and statistical correlations of the τ branching fractions and branching ratios measurements. Asymmetric uncertainties are symmetrized as $\sigma^2_{\rm symm} = (\sigma^2_+ + \sigma^2_-)/2$. If only a few measurements are correlated, the correlation coefficients are listed in the footnote for each measurement (see for example $\Gamma(\text{particle}^- \geq 0\,\text{neutrals} \geq 0\,K^0\nu_\tau$ ("1-prong"))$/\Gamma_{\rm total}$). If a large number of measurements are correlated, then the full correlation matrix is listed in the footnote to the measurement that first appears in the τ Listings. Footnotes to the other measurements refer to the first one. For example, the large correlation matrices for the branching fraction or ratio measurements contained in Refs. [1] [2] are listed in Footnotes to the $\Gamma(e^-\overline{\nu}_e\nu_\tau)/\Gamma_{\rm total}$ and $\Gamma(h^-\nu_\tau)/\Gamma_{\rm total}$ measurements respectively. Additionally, the most precise experimental inputs are treated according to how they depend on external parameters on the basis of their documentation [3]. The τ measurements may depend on parameters such as the τ pair production cross-section in e^+e^- annihilations at the $\Upsilon(4S)$ peak. In some cases, measurements reported in different papers by the same collaboration may depend on common parameters like the estimate of the integrated luminosity or of particle identification efficiencies. For all the significant detected dependencies, the τ measurements and their uncertainties are updated to account for the updated values of the external parameters. The dependencies on common systematic effects are also determined in size and sign, and all the common systematic dependencies of different measurements are used together with the published statistical and systematic uncertainties and correlations in order to compute an updated all-inclusive variance and covariance matrix of the experimental inputs of the fit.

The fit procedure parameters correspond to all measured τ branching fractions and ratios, to some non-measured branching fractions and ratios like for instance $\mathcal{B}(\tau^- \to \pi^- K^0_L K^0_L \nu_\tau)$ and to one nuisance variable. When discussing the fit results in the following, the fit χ^2, the number of degrees of freedom, the residuals and pulls all refer to the subset of fit parameters that correspond to τ branching fractions and ratios, excluding nuisance variables. The fit parameters are optimized while respecting relations described by a series of constraint equations. All the experimental inputs and all the constraint equations are reported in the τ Listings section that follows this review. In some cases, constraints describe approximate relations that nevertheless hold within the present experimental precision. For instance, the constraint $\mathcal{B}(\tau^- \to K^-K^-K^+\nu_\tau) = \mathcal{B}(\tau^- \to K^-\phi\nu_\tau) \times \mathrm{B}(\phi \to K^+K^-)$ is justified within the current experimental evidence. The constraint equations between the τ branching fractions and ratios include quantities other than τ branching fractions and branching ratios, like for instance the branching fractions of the η and ω mesons. We neglect the uncertainties on these values for all quantities except $\mathcal{B}(a_1^- \to \pi^-\gamma)$, whose value and uncertainty were estimated by ALEPH [1] to be $(0.21 \pm 0.08)\cdot 10^{-2}$, relying on a measurement of $\Gamma(a_1^- \to \pi^-\gamma)$ [4]. This quantity is included in the fit parameters as nuisance variable, with a χ^2 term corresponding to its estimate. We assume that $\mathcal{B}(\tau^- \to a_1^-\nu_\tau) = \mathcal{B}(\tau^- \to \pi^-\pi^+\pi^-\nu_\tau$ (ex.K^0,ω)) + $\mathcal{B}(\tau^- \to \pi^-2\pi^0\nu_\tau$ (ex.K^0)) + $\mathcal{B}(\tau^- \to a_1^-(\pi^-\gamma)\nu_\tau)$, neglecting the observed but negligible branching fractions to other modes, and that $\mathcal{B}(\tau^- \to a_1^-(\pi^-\gamma)\nu_\tau) = \mathcal{B}(\tau^- \to a_1^-\nu_\tau)\cdot\mathcal{B}(a_1^- \to \pi^-\gamma)$. The values of all other quantities in the constraint equations are taken from the 2023 edition of the Review of Particle Physics.

In the fit, uncertainty scale factors are applied to the published uncertainties of measurements only if significant inconsistency between different measurements remain after accounting for all relevant uncertainties and correlations. When performing the fit with no scale factors, the two measurements of $\mathcal{B}(\tau^- \to K^-K^-K^+\nu_\tau)$ have pulls exceeding $5\,\sigma$ from the fit values. There are 170 pulls, one per measurement. They are partially correlated, and the effective number of independent pulls is equal to the number of degrees of freedom of the fit, 125. The probability of getting pulls equal or larger than either one of the two very large pulls in a sample of 125 is smaller that the probability of a $3\,\sigma$ deviation for a Normal variable. Therefore, it has been decided to apply an uncertainty scale factor of 5.4 on all measurements of $\mathcal{B}(\tau^- \to K^-K^-K^+\nu_\tau)$ (one by BaBar and one by Belle). The scale factor has been computed according to the standard PDG procedure. After applying the scale factor, the pull distribution of the measurements in figure 58.1 is reasonably Normal and the pull probability distribution in figure 58.2 is reasonably flat.

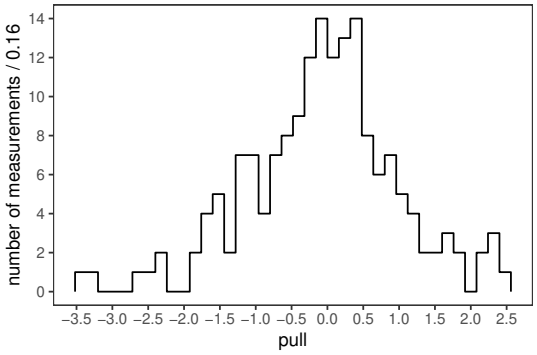

Figure 58.1: Pulls of individual measurements against the respective fitted quantity.

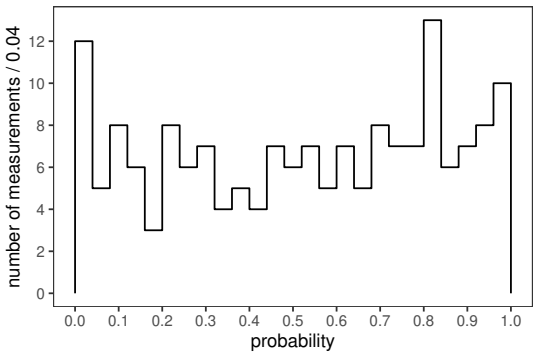

Figure 58.2: Probability of individual measurement pulls against the respective fitted quantity.

Considering only the residuals with respect to τ branching fractions and ratios measurements, the constrained fit has a χ^2 of 135 for 125 degrees of freedom, corresponding to a χ^2 probability of 26.0%. We use 170 measurements and 84 constraints on the branching fractions and ratios to determine 129 quantities, consisting of 112 branching fractions and 17 branching ratios. The constraints include the unitarity constraint on the sum of all the exclusive τ decay modes, $\mathcal{B}_{\rm all} = 1$. If the unitarity constraint is released, the fit result for $\mathcal{B}_{\rm all}$ is consistent with unitarity with $1 - \mathcal{B}_{\rm all} = (0.07 \pm 0.11)\%$.

For the convenience of summarizing the fit results, we list in the following the values and uncertainties for a set of 46 "basis" decay modes, from which all remaining branching fractions and ratios

can be obtained using the constraints. The basis decay modes are not intended to sum up to 1. Since some basis quantities represent multiple branching fractions that are related by constraint equations, the unitarity constraint corresponds to a linear combination of branching fractions, with the coefficients listed in the following. The coefficients of $\mathcal{B}(\tau^- \to \pi^- 2\pi^0 \nu_\tau$ (ex.K^0)) and $\mathcal{B}(\tau^- \to \pi^-\pi^+\pi^-\nu_\tau$ (ex.K^0, ω)) depend on the fitted value of the nuisance variable, $\mathcal{B}(a_1^- \to \pi^-\gamma) = 0.0022 \pm 0.0008$. The correlation matrix between the basis modes is reported in the τ Listings.

In defining the fit constraints and in selecting the modes that sum up to one we made some assumptions and choices. We assume that some channels, like $\tau^- \to \pi^- K^+ \pi^- \geq 0\pi^0\nu_\tau$ and $\tau^- \to \pi^+ K^- K^- \geq 0\pi^0\nu_\tau$, have negligible branching fractions as expected from the Standard Model, even if the experimental limits for these branching fractions are not very stringent. The 95% confidence level upper limits are $\mathcal{B}(\tau^- \to \pi^- K^+ \pi^- \geq 0\pi^0\nu_\tau) < 0.25\%$ and $\mathcal{B}(\tau^- \to \pi^+ K^- K^- \geq 0\pi^0\nu_\tau) < 0.09\%$, values not so different from measured branching fractions for allowed 3-prong modes containing charged kaons. For decays to final states containing one neutral kaon we assume that the branching fraction with the K_L^0 are the same as the corresponding one with a K_S^0. On decays with two neutral kaons we assume that the branching fractions with $K_L^0 K_L^0$ are the same as the ones with $K_S^0 K_S^0$.

58.3 BaBar and Belle measure on average lower branching fractions and ratios.

We compare the BaBar and Belle measurements with the results of a fit where all the B-factories measurements have been excluded. We restrict the comparison to the measurements that are used in the fit, omitting two measurements that are superseeded with other results, and one measurement that is fully correlated with other measurements. We find that BaBar and Belle measure on average lower τ branching fractions and ratios than the other experiments. Figures 58.3 and 58.4 show histograms of the 25 pulls of the differences between B-factory measurements and the respective non-B-factory fit results. The average pull between the two sets of measurements is -0.8σ (-0.7σ for the 14 Belle measurements and -0.9σ for the 11 BaBar measurements).

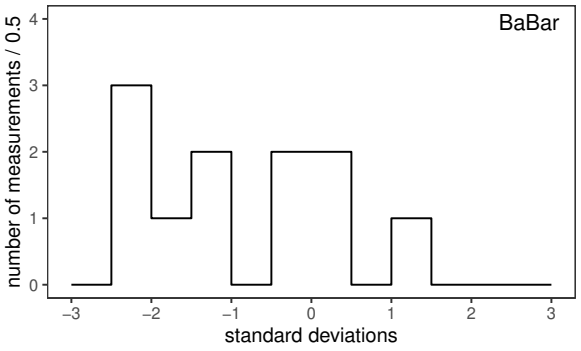

Figure 58.3: Distribution of the normalized difference between 11 measurements of branching fractions and ratios published by the BaBar collaboration and the respective averages computed using only non-B-factory measurements.

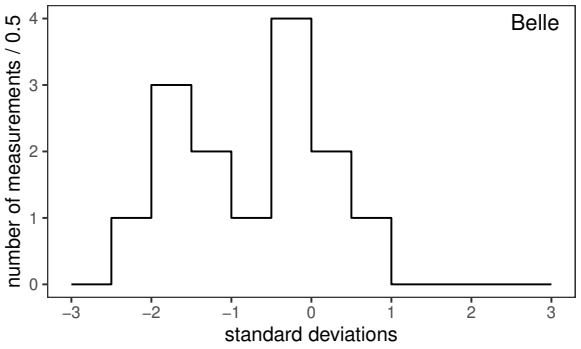

Figure 58.4: Distribution of the normalized difference between 14 measurements of branching fractions and ratios published by the Belle collaboration and the respective averages computed using only non-B-factory measurements.

58.4 Overconsistency of Leptonic Branching Fraction Measurements.

As observed in the previous editions of this review, measurements of the leptonic branching fractions are more consistent with each other than expected from the quoted uncertainties on the individual measurements. The χ^2/n.d.o.f. are 0.34/4 for $\mathcal{B}_e$ and 0.08/4 for $\mathcal{B}_\mu$. The probability of getting a smaller χ^2 is 1.3% for B_e and 0.08% for B_μ.

58.5 Technical implementation of the fit

The fit computes a set of quantities denoted with q_i by minimizing a χ^2 while respecting a series of equality constraints on the q_i. The quantities q_i represent τ branching fractions and branching ratios, and nuisance variables. The fit minimization procedure is equivalent to choosing a set of basis fit variables, using functions of these basis variables to predict measurements, and determining these basis variables by minimizing the measurements' χ^2. The χ^2 is computed using the measurements m_i and their covariance matrix E_{ij} as $\chi^2 = (m_i - A_{ik}q_k)^t E_{ij}^{-1}(m_j - A_{jl}q_l)$, where the model

matrix A_{ij} is used to get the vector of the predicted measurements m'_i from the vector of the fit parameters q_j as $m'_i = A_{ij}q_j$. There is one fit variable for each of the modes that have measurements, therefore $A_{ij} = 1$ when q_j corresponds to the τ branching fraction or branching ratio of the measurement m_i, and $A_{ij} = 0$ otherwise. The constraints are equations involving the fit parameters. The fit does not impose limitations on the functional form of the constraints. In summary, the fit requires:

$$\min\left[\chi^2(q_k)\right] = \min\left[(m_i - A_{ik}q_k)^t E_{ij}^{-1}(m_j - A_{jl}q_l)\right] \ , \quad (58.1)$$

$$\text{subjected to} \quad f_r(q_s) - c_r = 0 \ , \quad (58.2)$$

where the left term of Eq. 58.2 defines the constraint expressions. Using the method of Lagrange multipliers, a set of equations is obtained by taking the derivatives with respect to the fitted quantities q_k and the Lagrange multipliers λ_r of the sum of the χ^2 and the constraint expressions multiplied by the Lagrange multipliers λ_r, one for each constraint:

$$\begin{aligned} \min\left[(A_{ik}q_k - m_i)^t E_{ij}^{-1}(A_{jl}q_l - m_j) + 2\lambda_r(f_r(q_s) - c_r)\right] = \\ = \min\left[\tilde{\chi}^2(q_k, \lambda_r)\right] \ , \\ (\partial/\partial q_k, \partial/\partial\lambda_r)\left[\tilde{\chi}^2(q_k, \lambda_r)\right] = 0 \ . \end{aligned} \quad (58.3)$$

Eq. 58.3 defines a set of equations for the vector of the unknowns (q_k, λ_r), some of which may be non-linear, in case of non-linear constraints. An iterative minimization procedure approximates at each step the non-linear constraint expressions by their first order Taylor expansion around the current values of the fitted quantities, $\bar{q}_s$:

$$f_r(q_s) - c_r = f_r(\bar{q}_s) + \left.\frac{\partial f_r(q_s)}{\partial q_s}\right|_{\bar{q}_s} (q_s - \bar{q}_s) - c_r \ ,$$

which can be written as

$$B_{rs}q_s - c'_r \ ,$$

where c'_r are the resulting constant known terms, independent of q_s at first order. After linearization, the differentiation by q_k and λ_r is trivial and leads to a set of linear equations

$$A^t_{ki}E^{-1}_{ij}A_{jl}q_l + B^t_{kr}\lambda_r = A^t_{ki}E^{-1}_{ij}m_j \ , \quad (58.4)$$

$$B_{rs}q_s = c'_r \ , \quad (58.5)$$

which can be expressed as

$$F_{ij}u_j = v_i \ , \quad (58.6)$$

where $u_j = (q_k, \lambda_r)$ and v_i is the vector of the known constant terms running over the index k and then r in the right terms of Eq. 58.4 and Eq. 58.5, respectively. Solving the equation set in Eq. 58.6 by matrix inversion gives the the fitted quantities and their variance and covariance matrix, using the measurements and their variance and covariance matrix. The fit procedure starts by computing the linear approximation of the non-linear constraint expressions around the quantities seed values. With an iterative procedure, the unknowns are updated at each step by solving the equations and the equations are then linearized around the updated values, until the variation of the fitted unknowns is reduced below a numerically small threshold.

59. τ-Lepton Decay Parameters

Revised February 2024 by A. Stahl (RWTH Aachen U.).

The purpose of the measurements of the decay parameters (also known as Michel parameters) of the τ is to determine the structure (spin and chirality) of the current mediating its decays.

59.1 Leptonic Decays:

The Michel parameters are extracted from the energy spectrum of the charged daughter lepton $\ell = e, \mu$ in the decays $\tau \to \ell\nu_\ell\nu_\tau$. Ignoring radiative corrections, neglecting terms of order $(m_\ell/m_\tau)^2$ and $\left(m_\tau/\sqrt{s}\right)^2$, and setting the neutrino masses to zero, the spectrum in the laboratory frame reads

$$\frac{d\Gamma}{dx} = \frac{G_{\tau\ell}^2\, m_\tau^5}{192\,\pi^3} \times \left\{ f_0\,(x) + \rho f_1\,(x) + \eta \frac{m_\ell}{m_\tau} f_2\,(x) - P_\tau\,[\xi g_1\,(x) + \xi\delta g_2\,(x)] \right\} \tag{59.1}$$

with

$$\begin{aligned} f_0(x) &= 2 - 6\,x^2 + 4\,x^3 \\ f_1(x) &= -\tfrac{4}{9} + 4x^2 - \tfrac{32}{9}x^3 \qquad g_1(x) = -\tfrac{2}{3} + 4x - 6x^2 + \tfrac{8}{3}x^3 \\ f_2(x) &= 12\,(1-x)^2 \qquad\qquad g_2(x) = \tfrac{4}{9} - \tfrac{16}{3}x + 12x^2 - \tfrac{64}{9}\,x^3\,. \end{aligned} \tag{59.2}$$

The quantity x is the fractional energy of the daughter lepton ℓ, *i.e.*, $x = E_\ell/E_{\ell,max} \approx E_\ell/(\sqrt{s}/2)$ and P_τ is the polarization of the tau leptons. The integrated decay width is given by

$$\Gamma = \frac{G_{\tau\ell}^2\, m_\tau^5}{192\,\pi^3} \left(1 + 4\,\eta\,\frac{m_\ell}{m_\tau}\right)\,. \tag{59.3}$$

The situation is similar to muon decays $\mu \to e\nu_e\nu_\mu$. The generalized matrix element with the couplings $g_{\varepsilon\mu}^\gamma$ and their relations to the Michel parameters ρ, η, ξ, and δ have been described in the "Note on Muon Decay Parameters". The Standard Model expectations are 3/4, 0, 1, and 3/4, respectively. For more details, see [1].

More information can be extracted from the decays, if the polarization of the daughter lepton is measured. Belle presented a first result (see [2]). A new parameter ξ' is introduced. Its relation to the couplings is given by (see [3]):

$$\xi' = 1 - 2 \sum_{\omega=L,R} \left(\frac{1}{4} \left| g_{R\omega}^S \right|^2 + \left| g_{R\omega}^V \right|^2 \right) + 3 \left| g_{RL}^T \right|^2\,. \tag{59.4}$$

The new measurement improves the limit on g_{RL}^T by about a factor of two.

Additional Michel parameters can be defined in radiative decays $\tau \to \ell\nu_\ell\nu_\tau\gamma$, see [4]. A first measurement is presented in [5]. The experimental precision does not provide a significant impact on the knowledge about the couplings, yet.

59.2 Hadronic Decays:

In the case of hadronic decays $\tau \to h\nu_\tau$, with $h = \pi$, ρ, or a_1, the ansatz is restricted to purely vectorial currents. The matrix element is

$$\frac{G_{\tau h}}{\sqrt{2}} \sum_{\lambda=R,L} g_\lambda \,\langle\, \overline{\Psi}_\omega(\nu_\tau) \mid \gamma^\mu \mid \Psi_\lambda(\tau) \,\rangle\;\; J_\mu^h \tag{59.5}$$

with the hadronic current J_μ^h. The neutrino chirality ω is uniquely determined from λ. The spectrum depends only on a single parameter ξ_h

$$\frac{d^n\Gamma}{dx_1 dx_2 \ldots dx_n} = f\,(\vec{x}) + \xi_h P_\tau\, g\,(\vec{x})\;\;, \tag{59.6}$$

with f and g being channel-dependent functions of the n observables $\vec{x} = (x_1, x_2, \ldots, x_n)$ (see [6]). The parameter ξ_h is related to the couplings through

$$\xi_h = |g_L|^2 - |g_R|^2\,. \tag{59.7}$$

ξ_h is the negative of the chirality of the τ neutrino in these decays. In the Standard Model, $\xi_h = 1$. Also included in the Data Listings for ξ_h are measurements of the neutrino helicity which coincide with ξ_h, if the neutrino is massless (ASNER 00 [7], ACKERSTAFF 97R [8], AKERS 95P [9], ALBRECHT 93C [10], and ALBRECHT 90I [11]).

59.3 Combination of Measurements:

The individual measurements are combined, taking into account the correlations between the parameters. In a first fit, universality between the two leptonic decays, and between all hadronic decays, is assumed. A second fit is made without these assumptions. The results of the two fits are provided as OUR FIT in the Data Listings below in the tables whose title includes "(e or mu)" or "(all hadronic modes)", and "(e)", "(mu)" *etc.*, respectively. The measurements show good agreement with the Standard Model. The χ^2 values with respect to the Standard model predictions are 24.1 for 41 degrees of freedom and 26.8 for 56 degrees of freedom, respectively. The correlations are reduced through this combination to less than 20%, with the exception of ρ and η which are correlated by +23%, for the fit with universality and by +70% for $\tau \to \mu\nu_\mu\nu_\tau$.

59.4 Model-independent Analysis:

From the Michel parameters, limits can be derived on the couplings $g_{\varepsilon\lambda}^\kappa$ without further model assumptions. In the Standard model $g_{LL}^V = 1$ (leptonic decays), and $g_L = 1$ (hadronic decays) and all other couplings vanish. First, the partial decay widths have to be compared to the Standard Model predictions to derive limits on the normalization of the couplings $A_x = G_{\tau x}^2/G_F^2$ with Fermi's constant G_F:

$$\begin{aligned} A_e &= 1.0022 \pm 0.0041\,, \\ A_\mu &= 0.983 \pm 0.017\,, \\ A_\pi &= 0.9957 \pm 0.0049\,. \end{aligned} \tag{59.8}$$

Then limits on the couplings (95% CL) can be extracted (see [12] and [13]). Without the assumption of universality, the limits given in Table 59.1 are derived.

Table 59.1: Coupling constants $g_{\varepsilon\mu}^\gamma$. 95% confidence level experimental limits. The limits include the quoted values of A_e, A_μ, and A_π and assume $A_\rho = A_{a_1} = 1$.

$\tau \to e\nu_e\nu_\tau$		
$\lvert g_{RR}^S\rvert < 0.70$	$\lvert g_{RR}^V\rvert < 0.17$	$\lvert g_{RR}^T\rvert \equiv 0$
$\lvert g_{LR}^S\rvert < 0.99$	$\lvert g_{LR}^V\rvert < 0.13$	$\lvert g_{LR}^T\rvert < 0.082$
$\lvert g_{RL}^S\rvert < 2.01$	$\lvert g_{RL}^V\rvert < 0.52$	$\lvert g_{RL}^T\rvert < 0.51$
$\lvert g_{LL}^S\rvert < 2.01$	$\lvert g_{LL}^V\rvert < 1.004$	$\lvert g_{LL}^T\rvert \equiv 0$
$\tau \to \mu\nu_\mu\nu_\tau$		
$\lvert g_{RR}^S\rvert < 0.72$	$\lvert g_{RR}^V\rvert < 0.18$	$\lvert g_{RR}^T\rvert \equiv 0$
$\lvert g_{LR}^S\rvert < 0.95$	$\lvert g_{LR}^V\rvert < 0.12$	$\lvert g_{LR}^T\rvert < 0.079$
$\lvert g_{RL}^S\rvert < 2.01$	$\lvert g_{RL}^V\rvert < 0.52$	$\lvert g_{RL}^T\rvert < 0.27$
$\lvert g_{LL}^S\rvert < 2.01$	$\lvert g_{LL}^V\rvert < 1.006$	$\lvert g_{LL}^T\rvert \equiv 0$
$\tau \to \pi\nu_\tau$		
$\lvert g_R^V\rvert < 0.15$	$\lvert g_L^V\rvert > 0.984$	
$\tau \to \rho\nu_\tau$		
$\lvert g_R^V\rvert < 0.10$	$\lvert g_L^V\rvert > 0.995$	
$\tau \to a_1\nu_\tau$		
$\lvert g_R^V\rvert < 0.16$	$\lvert g_L^V\rvert > 0.987$	

59.5 Model-dependent Interpretation:

More stringent limits can be derived assuming specific models. For example, in the framework of a two Higgs doublet model, the measurements correspond to a limit of $m_{H^\pm} > 2.0$ GeV $\times \tan\beta$ on the mass of the charged Higgs boson, or a limit of 500 GeV on the mass of the second W boson in left-right symmetric models for arbitrary mixing (both 95% CL). See [13] and [14].

60. Quark Masses

Revised August 2023 by R.M. Barnett (LBNL), L.P. Lellouch (CNRS & Aix-Marseille U.) and A.V. Manohar (UC San Diego).

60.1 Introduction

This note discusses some of the theoretical issues relevant for the determination of quark masses, which are fundamental parameters of the Standard Model of particle physics. Unlike the leptons, quarks are confined inside hadrons and are not observed as physical particles. Quark masses therefore cannot be measured directly, but must be determined indirectly through their influence on hadronic properties. Although one often speaks loosely of quark masses as one would of the mass of the electron or muon, any quantitative statement about the value of a quark mass must make careful reference to the particular theoretical framework that is used to define it. It is important to keep this *scheme dependence* in mind when using the quark mass values tabulated in the data listings.

Historically, the first determinations of quark masses were performed using quark models. These are usually called constituent quark masses and are of order 350 MeV for the u and d quarks. Constituent quark masses model the effects of dynamical chiral symmetry breaking discussed below, and are not directly related to the quark mass parameters m_q of the QCD Lagrangian of Eq. (60.1). The resulting masses only make sense in the limited context of a particular quark model, and cannot be related to the quark mass parameters, m_q, of the Standard Model. In order to discuss quark masses at a fundamental level, definitions based on quantum field theory must be used, and the purpose of this note is to discuss these definitions and the corresponding determinations of the values of the masses.

60.2 Mass parameters and the QCD Lagrangian

The QCD [1] Lagrangian is

$$\mathcal{L} = \sum_{q=u,d,s,\ldots,t} \overline{q}\,(i\not{D} - m_q)\,q - \tfrac{1}{2}\mathrm{tr}\,G_{\mu\nu}G^{\mu\nu}, \tag{60.1}$$

where the sum runs over the quark flavors u, d, s, c, b and t. $\not{D} = (\partial_\mu - igA_\mu)\,\gamma^\mu$ is the gauge covariant derivative, A_μ is the SU(3)-valued gluon field, $G_{\mu\nu} = \frac{i}{g}[D_\mu, D_\nu]$ is the gluon field strength, m_q is the mass parameter of quark flavor q, and q is the quark Dirac field. After renormalization, the QCD Lagrangian Eq. (60.1) gives finite values for physical quantities, such as scattering amplitudes. Renormalization is a procedure that invokes a subtraction scheme to render the amplitudes finite, and requires the introduction of a dimensionful scale parameter μ. The mass parameters in the QCD Lagrangian Eq. (60.1) depend on the renormalization scheme used to define the theory, and also on the scale parameter μ. The most commonly used renormalization scheme for QCD perturbation theory is the $\overline{\mathrm{MS}}$ scheme.

The QCD Lagrangian has a chiral symmetry in the limit that the quark masses vanish. This symmetry is spontaneously broken by dynamical chiral symmetry breaking, and explicitly broken by the quark masses. The nonperturbative scale of dynamical chiral symmetry breaking, Λ_χ, is around 1 GeV [2]. It is conventional to call quarks heavy if $m_q > \Lambda_\chi$, so that explicit chiral symmetry breaking dominates (c, b, and t quarks are heavy), and light if $m_q < \Lambda_\chi$, so that spontaneous chiral symmetry breaking dominates (the u and d are light and the s is considered to be light when using $\mathrm{SU}(3)_L \times \mathrm{SU}(3)_R$ chiral perturbation theory). The determination of light- and heavy-quark masses is considered separately in Sec. 60.5 and Sec. 60.6 below.

At high energies or short distances, nonperturbative effects, such as chiral symmetry breaking, become small and one can, in principle, determine quark masses by analyzing mass-dependent effects using QCD perturbation theory. Such computations are conventionally performed using the $\overline{\mathrm{MS}}$ scheme at a scale $\mu \gg \Lambda_\chi$, and give the $\overline{\mathrm{MS}}$ "running" mass $\overline{m}(\mu)$. We use the $\overline{\mathrm{MS}}$ scheme when reporting quark masses; one can readily convert these values into other schemes using perturbation theory.

The μ dependence of $\overline{m}(\mu)$ at short distances can be calculated using the renormalization group (RG) equation,

$$\mu^2 \frac{\mathrm{d}\overline{m}\,(\mu)}{\mathrm{d}\mu^2} = -\gamma(\overline{\alpha}_s\,(\mu))\;\overline{m}\,(\mu)\,, \tag{60.2}$$

where γ is the anomalous dimension which is now known to four-loop order in perturbation theory [3] [4]. $\overline{\alpha}_s$ is the coupling constant [1] in the $\overline{\mathrm{MS}}$ scheme. Defining the expansion coefficients γ_r by

$$\gamma\,(\overline{\alpha}_s) \equiv \sum_{r=1}^{\infty} \gamma_r \left(\frac{\overline{\alpha}_s}{4\pi}\right)^r, \tag{60.3}$$

the first four coefficients are given by

$$\begin{aligned}
\gamma_1 &= 4,\\
\gamma_2 &= \frac{202}{3} - \frac{20N_L}{9},\\
\gamma_3 &= 1249 + \left(-\frac{2216}{27} - \frac{160}{3}\zeta\,(3)\right) N_L - \frac{140}{81}N_L^2,\\
\gamma_4 &= \frac{4603055}{162} + \frac{135680}{27}\zeta\,(3) - 8800\zeta\,(5)\\
&\quad + \left(-\frac{91723}{27} - \frac{34192}{9}\zeta\,(3) + 880\zeta\,(4) + \frac{18400}{9}\zeta\,(5)\right) N_L\\
&\quad + \left(\frac{5242}{243} + \frac{800}{9}\zeta\,(3) - \frac{160}{3}\zeta\,(4)\right) N_L^2\\
&\quad + \left(-\frac{332}{243} + \frac{64}{27}\zeta\,(3)\right) N_L^3,
\end{aligned}$$

where N_L is the number of active light quark flavors at the scale μ, i.e. flavors with masses $\leq \mu$, and ζ is the Riemann zeta function ($\zeta(3) \simeq 1.2020569$, $\zeta(4) \simeq 1.0823232$, and $\zeta(5) \simeq 1.0369278$). Eq. (60.2) must be solved in conjunction with the RG equation for $\overline{\alpha}_s\,(\mu)$ given in [1]. In addition, as the renormalization scale crosses quark mass thresholds one needs to match the scale dependence of $\overline{m}$ below and above the threshold. There are finite threshold corrections; the necessary formulae can be found in Ref. [5].

60.3 Lattice QCD

Ab initio lattice QCD calculations of the fundamental parameters of QCD, i.e. the coupling constant and quark masses (except for the top-quark mass), has become a precision science (see also the sections on Lattice Quantum Chromodynamics and on Quantum Chromodynamics in this *Review*). Here we only briefly recall those features which are required for the determination of quark masses. For more details on lattice QCD, please see the section on Lattice Quantum Chromodynamics.

The inputs into lattice calculations are bare, dimensionless versions of the fundamental parameters of QCD: the bare strong coupling and the bare quark masses in lattice units, i.e. multiplied by the lattice spacing a, the distance between neighboring points of the lattice. The physical values of the quark masses are determined by computing as many physical quantities as there are parameters, including one for the gauge coupling. In practice, the computations are performed for multiple lattice spacings, determined by the bare coupling via dimensional transmutation, and a number of bare quark masses. After renormalizing these masses and converting them to physical units, the resulting renormalized masses are interpolated to their physical values. This is achieved by requiring that the computed physical quantities reproduce their measured values as the $a \to 0$ limit to our continuum world is taken. Such a tuning of fundamental parameters is required in any regularization of QCD: lattice QCD is simply a tool to perform QCD calculations in the low-energy, nonperturbative domain.

As discussed in the previous paragraph, one must renormalize the bare quark masses of lattice QCD simulations. The values of these bare masses refer to a particular discretization of QCD with the lattice spacing as the ultraviolet cut-off. In order for the resulting physical masses to be useful in phenomenological applications, it is necessary to give their values in some standard

renormalization scheme such as $\overline{\rm MS}$. Provided that both the ultraviolet cut-off a^{-1} and the renormalization scale μ are much greater than $\Lambda_{\rm QCD}$, the bare masses can be renormalized in perturbation theory. However, in order to avoid uncertainties due to the unknown higher-order coefficients in lattice perturbation theory, most results obtained recently use *nonperturbative renormalization*. This procedure relates the bare masses to those defined in renormalization schemes which can be realized directly in lattice and continuum QCD, e.g. those obtained from quark and gluon Green functions at specified momenta in the Landau gauge [6] or those defined using finite-volume techniques and the Schrödinger functional [7], but not $\overline{\rm MS}$ that is only defined for dimensional regularization. These methods require $\mu \gg \Lambda_{\rm QCD}$ so that unwanted (nonperturbative) corrections proportional to inverse powers of μ, which appear in some approaches, remain small corrections that can be identified and removed. This condition is also necessary so that matching to other schemes can be performed reliably in perturbation theory. Moreover these methods require $a^{-1} \gg \mu$ so that cutoff effects are small enough to be extrapolated away when the continuum limit is taken. The conversion to the $\overline{\rm MS}$ scheme is then performed using continuum perturbation theory, which is more readily obtained to higher orders and is usually better behaved than its lattice counterpart.

It is important to note that the final renormalized values for the quark masses must be the same in the continuum limit for any valid discretization of QCD and for any sensible choice of the physical quantities used for calibration, as long as the calculation is performed with a sufficient number of sea-quark flavors and with the relevant electromagnetic and strong-isospin breaking corrections for the claimed precision. It is also worth noting that issues surrounding the renormalization of quark masses disappear when considering pairwise ratios of these masses in QCD alone. Indeed, if the same renormalization scheme and scale are implemented, also for the definition of QCD in the absence or electromagnetism,[1] QCD renormalization factors are identical for all quark flavors, and these factors therefore cancel exactly in quark-mass ratio [2]. In particular, this means that these ratios are scheme and scale independent up to possible QED corrections. Moreover these ratios may suffer less from the uncertainties in the determination of the lattice scale, in particular in cases where the quantities used to fix the two quarks masses depend on these masses in a similar way, because these ratios are dimensionless. Thus, quark-mass ratios are often determined with significantly higher precision using lattice QCD than are the individual masses.

The determination of quark masses using lattice simulations is well established and the current emphasis is on the reduction and control of uncertainties. With better methods, improved algorithms and access to more powerful computing resources, the precision of the results has improved significantly in recent years. Vacuum polarization effects are included with $N_f = 2,\ 2+1$ or $N_f = 2+1+1$ flavors of sea quarks. The number 2 here indicates that the up and down quarks are degenerate. The first $+1$ corresponds to the inclusion of strange sea-quark effects and the second $+1$ to those of the charm. Simulations with $2+1$ and $2+1+1$ flavors represent controlled approximations to physical QCD at the low energies considered for quark mass determinations, up to corrections of $O((\Lambda_{\rm QCD}/m_c)^2/N_c)$ and $O((\Lambda_{\rm QCD}/m_b)^2/N_c)$, respectively. This is not the case for simulations with $N_f = 2$ or in which vacuum polarization effects are treated as a mean field (this is the so-called *quenched* approximation) and results obtained in those frameworks will not enter the discussion here.

Particularly pleasing is the observation that different formulations of lattice QCD and different approaches, with different systematic uncertainties, yield results which are largely consistent with each other. This gives us broad confidence in the estimates of the systematic errors. As the precision of the results approaches (or even exceeds in some cases) 1%, isospin breaking effects, including electromagnetic corrections need to be considered and this is beginning to be done as will be discussed below. In particular, a reliable estimate of these effects is required for determining the individual u and d quark masses.

Members of the lattice QCD community have organized a Flavour Lattice Averaging Group (FLAG) which, against stated quality criteria, critically reviews quantities computed in lattice QCD that are relevant to flavor physics and presents its view of the current status of the results. This includes the determination of quark masses. The latest edition reviews lattice results that appeared in print before April 30th 2021 [8]. Since that deadline and the writing of the previous edition of the present review, the only new results on quark masses that have been published are those of Ref. [9].

60.4 Averaging procedure for lattice QCD results

In this review we present summary numbers for each quark mass which are solely based on averages of lattice results. Those summary numbers differ from those presented in the particle listings, for three reasons. The first is that they do not include non-lattice estimates of the quark masses. The second is that they may differ slightly in the lattice results retained, as made explicit here and in the listings. The third difference comes from the averaging procedures, which are described in the listings and below. In the listings, summary numbers are obtained from averages of the individual quark-mass estimates, weighted by their total errors. Moreover, the resulting one-standard-deviation errors are rescaled by the usual $\sqrt{\chi^2/\text{dof}}$ factor, which is further multiplied by 1.645 to obtain the uncertainty corresponding to a 90% confidence interval. Nevertheless, the averages presented here and in the listings are fully consistent, with comparable uncertainties, signalling the robustness of the two combination procedure.

The results on which the lattice summary numbers presented here are those used in the FLAG reviews, supplemented by any new calculations that satisfy their selection criteria. The methodology that we use is also close to that of FLAG, but here we make an attempt to separate uncertainties into their statistical and systematic components, to provide some idea of what the relative weight of each is for different quark masses. In some cases, also, slightly different choices are also made. Thus, agreement between the results obtained is a further sign of the robustness of the combination procedures used here, as well as in FLAG.

We now lay out our averaging procedure. For each of m_{ud}, m_s or m_s/m_{ud}, and for each of $N_f = 2+1$ or $N_f = 2+1+1$, we perform averages of the relevant, individual lattice results with weights that include the sum in quadrature of the statistical and systematic uncertainties. The weights also account for correlations by assuming that they are 100% on any uncertainty components that may be correlated. This procedure yields a central value and a total error for each of the quantities of interest. The total uncertainty is rescaled by the usual factor of $\sqrt{\chi^2/\text{dof}}$ if that factor is larger than 1, where χ^2 is the one corresponding to the weighted average procedure. To isolate the statistical component of the uncertainty on any given average, like for the total uncertainty we use the standard error formula for correlated data, this time only taking into account the statistical uncertainties on the different collaborations' results. If the total error has been rescaled, this statistical uncertainty is multiplied by the same factor. The candidate systematic error on an average is then obtained by subtracting in quadrature the statistical uncertainty from the total one. For each quantity, the final systematic error on the average is the largest of two uncertainties: the candidate systematic error and the minimum of the systematic uncertainties on the individual lattice determinations. This guarantees that the final systematic error is no smaller than the one of any given calculation. We then repeat this whole procedure to average the $N_f = 2+1$ and $N_f = 2+1+1$ averages, for reasons discussed below. In cases where the error separation is not explicit in a particular collaboration's result, we assume that the quoted error is statistical and take, as the minimum of systematic error, the smallest non-vanishing one among those of the other individual results. While this procedure may change the balance between statistical and systematic errors, it does change the average (which

[1] Since QCD without QED is not the real world, it makes a difference, for example, which hadron mass is used to tune a quark mass and the QED correction will differ for different choices.

[2] The same remains true in the presence of QED if the two quarks in the ratio have the same charge.

is weighted by the total errors of the individual entries and the correlations between them) and does not decrease the total error. When quantities involving m_c or m_b are averaged, we consider only the averages of $N_f = 2+1+1$ calculations, for reasons also explained below.

The values of the individual results used in the averages obtained below can be found in the quark properties listings of this *Review*.

60.5 Light quarks

In this section we review the determination of the masses of the light quarks u, d and s from lattice simulations and then discuss the consequences of the approximate chiral symmetry.

60.5.1 *Lattice QCD results*

The most reliable determinations of the strange quark mass, m_s, and of the up and down quark masses, m_u and m_d, are obtained from lattice simulations. This is reflected in part by the uncertainties of individual determinations of these masses given in this *Review's* listings of quark properties: lattice results typically have smaller error bars than phenomenological extractions. As explained in the previous section, the simulations are generally performed in the isospin-symmetric limit of QCD, i.e. with degenerate up and down quarks ($m_u = m_d$) and the electromagnetic coupling α set to zero. Thus, it is initially $m_{ud} = (m_u + m_d)/2$ which is obtained from the computations. The numerical values of these masses depend on the choice of renormalization scale and scheme. [3]

Below we discuss the derivation of m_u and m_d separately, but we start by briefly presenting our estimates for m_{ud}, m_s and their ratio, using the latest lattice results. FLAG [8] bases its summary numbers on references that the authors consider to have the most reliable estimates of systematic uncertainties, i.e. [12–18] for $N_f = 2+1$ and [19–24] for $N_f = 2+1+1$ flavors of sea quarks. Note that the $N_f = 2+1+1$ results of Ref. [9] did not make the FLAG deadline. In the estimates given below, we use the fact that Ref. [9] supersedes Ref. [22].

Applying the averaging procedure described in the previous section and the results of Refs. [12–18], for $N_f = 2+1$ we obtain $\overline{m}_{ud} = (3.382 \pm 0.026 \pm 0.040[\pm 0.050])$ MeV, $\overline{m}_s = (92.24 \pm 0.24 \pm 1.00[\pm 1.03])$ MeV and $(\overline{m}_s/\overline{m}_{ud}) = 27.42 \pm 0.05 \pm 0.12[\pm 0.12]$. These numbers are $\overline{m}_{ud} = (3.421 \pm 0.035 \pm 0.049[\pm 0.060])$ MeV, $\overline{m}_s = (92.93 \pm 0.51 \pm 0.37[\pm 0.063])$ MeV and $(\overline{m}_s/\overline{m}_{ud}) = 27.25 \pm 0.03 \pm 0.07[\pm 0.08]$ using the latest $N_f = 2+1+1$ calculations [9, 19–21, 23, 24]. The masses are given in the $\overline{\rm MS}$ scheme at a renormalization scale of 2 GeV. In these averages, the first error is statistical, the second systematic and the third one in brackets is the sum in quadrature of the first two. Also, QED corrections have been accounted for only to the extent that they have been removed from the hadron mass inputs phenomenologically.

A few comments are in order concerning the compatibility of the results which enter these averages. We begin with the case of $N_f = 2+1$. For m_{ud} the results show a good degree of compatibility with a $\chi^2/\text{dof} = 5.7/4$ and the final systematic uncertainty is given by the one of Ref. [17]. The level of compatibility is similar in the case of m_s and the final systematic uncertainty is also given by the one of Ref. [17]. For m_s/m_{ud} the results are even more compatible and here the final systematic error is derived from the averaging procedure. In the case of $N_f = 2+1+1$, there are only two results for m_{ud} [9, 20] and their level of compatibility is poor, with $\chi^2/\text{dof} = 6.4/1$. This is due to the value of Ref. [9], $m_{ud} = (3.636 \pm 0.066 \pm 0.059)$ MeV, which is significantly larger than all other determinations, including those obtained in $N_f = 2+1$ determinations. The scenario repeats for m_s, but is diluted by the fact that there are four results [9, 19–21] which enter the average. However, compatibility is recovered for m_s/m_{ud}, suggesting a problem in the determination of the renormalization constants or the lattice spacing in at least one of the calculations. Since the different collaborations use different formulations of lattice QCD, the (relatively) small variations of the results between the groups provides important information about the reliability of the estimates. Furthermore, the conservative nature of our method for estimating uncertainties is confirmed by the excellent agreement of the averages obtained for $N_f = 2+1$ and $N_f = 2+1+1$ calculations.

Despite being reported in the $\overline{\rm MS}$ scheme at a renormalization scale of 2 GeV, the schemes in simulations with $2+1$ and $2+1+1$ sea-quark flavors actually differ. This is because the former are renormalized with $N_L = 3$ and the latter with $N_L = 4$. Thus for a comparison one should convert the results to the same scheme. That is not the case for (m_s/m_{ud}), where renormalization factors cancel in the absence of electromagnetic corrections. The conversion of the $N_f = 2+1$ results to the $N_L = 4$ scheme can be performed, for instance, by running them down to the charm threshold in the $N_L = 3$ theory, matching the results to the $N_L = 4$ theory at that scale, and running them back up to 2 GeV with four active flavors. Such a conversion leads to an upward shift in the values of the quark masses of only around 0.3%, well within the quoted uncertainties on the quark masses themselves. Quark-mass ratios are not concerned by this upward shift, because it is identical for the numerator and denominator. There are also nonperturbative contributions to this procedure, of $O((\Lambda_{\rm QCD}/m_c)^2/N_c) \sim 2\%$. However lattice QCD studies of these effects have shown that they are typically an order of magnitude smaller on hadronic quantities or on $\Lambda_{\rm QCD}$ [25, 26]. Given that the total errors on the $N_f = 2+1$ results for $\overline{m}_{ud}$ and $\overline{m}_s$ are larger than 1%, we consider these matching effects negligible. In addition, for m_{ud} in particular there are six $N_f = 2+1$ calculations in which all sources of uncertainty have been accounted for, while there are only two for $N_f = 2+1+1$. Thus, we average the averages from the two frameworks in the same way as above (see Sec. 60.4), yielding as a final lattice QCD estimate in the $\overline{\rm MS}$ scheme at $\mu = 2$ GeV in the $N_L = 4$ theory:

$$\overline{m}_{ud} = (3.397 \pm 0.021 \pm 0.040[\pm 0.045])\ \text{MeV}, \qquad (60.4)$$

$$\overline{m}_s = (92.74 \pm 0.22 \pm 0.49[\pm 0.54])\ \text{MeV}, \qquad (60.5)$$

and

$$r_s \equiv \frac{\overline{m}_s}{\overline{m}_{ud}} = 27.30 \pm 0.03 \pm 0.07[\pm 0.08]. \qquad (60.6)$$

In these averages, the first error is statistical, the second systematic and the third one in brackets is the sum in quadrature of the first two. QED corrections have been accounted for only to the extent that they have been removed from the hadron mass inputs phenomenologically. It is worth noting that the result for r_s in Eq. (60.6) is identical to the ratio of m_s and m_{ud} from Eqs. (60.4) and (60.5), within the four digits for r_s given in Eq. (60.6), albeit with a significantly smaller total uncertainty.

To obtain the individual values of $\overline{m}_u$ and $\overline{m}_d$ requires the introduction of isospin breaking effects, including electromagnetism. This is now being done completely using lattice field theory, albeit neglecting electromagnetic effects in the sea in most cases (for an exception, see Ref. [27] which includes a calculation of the valence and sea QED contributions to $\Delta M_K^2 = M_{K^0}^2 - M_{K^+}^2$ that is critical for determining $\overline{m}_d - \overline{m}_u$). The effect of neglecting QED contributions from the sea on the u and d quark masses has been estimated in Ref. [28] to induce a contribution to the uncertainty that ranges from about 3% in $\overline{m}_u/\overline{m}_d$ to less than 1% in $\overline{m}_d$. FLAG has also reviewed results for these masses [8]. Again, they separate results obtained from $N_f = 2+1$ and $N_f = 2+1+1$ simulations. For the former, they use the results of Ref. [28] and for the latter, those of Refs. [20, 29, 30].

To obtain our estimates, we proceed as for the light quark masses above. For $N_f = 2+1$, our estimates are the results

[3] If QED is not included, then quark masses also depend on the conditions used to match isospin-symmetric QCD to the low energy effective theory of the Standard Model, which includes QCD and QED with $m_u \neq m_d$. Those matching conditions, which define a matching scheme, are quite similar in the calculations reported on below. Moreover, they have been designed to minimize the impact of isospin-breaking effects on isospin-symmetric combinations of quark masses, such m_{ud} and m_s here, and m_c and m_b below. Thus, as does FLAG [8], we generally assume that any remaining differences between schemes are within the quoted errors. Such an assumption is certainly true for $\overline{m}_c(\overline{m}_c)$ [10], where QED effects have been studied explicitly. On the other hand, in the case of m_b/m_c, where the effects of QED have also been studied explicitly [11] and where uncertainties are less than 0.3%, these effects are no longer negligible.

of the only calculation in which all sources of uncertainty are accounted for [28]. These are $\overline{m}_u = (2.27 \pm 0.06 \pm 0.06[\pm 0.09])$ MeV, $\overline{m}_d = (4.67 \pm 0.06 \pm 0.06[\pm 0.09])$ MeV and $\overline{m}_u/\overline{m}_d = (0.485 \pm 0.011 \pm 0.016[\pm 0.020])$. For $N_f = 2+1+1$, they rely on Refs. [20, 29, 30]. Our estimates are $\overline{m}_u = (2.14 \pm 0.04 \pm 0.07[\pm 0.08])$ MeV, $\overline{m}_d = (4.70 \pm 0.03 \pm 0.04[\pm 0.05])$ MeV and $\overline{m}_u/\overline{m}d = (0.460 \pm 0.008 \pm 0.018[\pm 0.020])$. These masses are given the the $\overline{\rm MS}$ scheme at 2 GeV in the $N_L = 3$ and 4 theories, respectively. Given the size of the uncertainties on these averages, tiny corrections due to QED effects in the renormalization constants have been neglected.

In obtaining the $N_f = 2+1+1$ averages, there is a significant $\chi^2/1 = 4.7$ tension between the two results for m_u [20, 29] and a $\chi^2/1 = 3.4$ one between those for m_u/m_d [29, 30]. These tensions are accounted for by the usual rescaling of uncertainties. However, agreement is found between the two results for m_d [20, 29]. Moreover, at the level of our conservative uncertainties, agreement is found with the $N_f = 2+1$ results.

Again, given the small number of results and the few percent uncertainties, we average the $N_f = 2+1$ and $N_f = 2+1+1$ results, as explained in Sec. 60.4, to obtain our final estimates:

$$\overline{m}_u = (2.20 \pm 0.04 \pm 0.06[\pm 0.07])\,\text{MeV}, \tag{60.7}$$

$$\overline{m}_d = (4.69 \pm 0.03 \pm 0.04[\pm 0.05])\,\text{MeV}, \tag{60.8}$$

$$r \equiv \frac{\overline{m}_u}{\overline{m}_d} = (0.473 \pm 0.007 \pm 0.016[\pm 0.017]), \tag{60.9}$$

where the three uncertainties have the same meaning as described after Eq. 60.6. r in Eq. (60.9) is the combination of direct lattice computations of that ratio in which some systematics cancel. The averages are given in the $\overline{\rm MS}$ scheme at 2 GeV in the $N_L = 4$ theory and, as above, tiny corrections due to QED effects in the renormalization constants have been neglected. Within one standard deviation it agrees with the ratio of $\overline{m}_u$ over $\overline{m}_d$ from Eqs. (60.7) and (60.8).

It is also worth noting that m_u differs from zero by more than 30 times the quoted error, making a scenario in which $m_u = 0$ very unlikely. This is important because there would be no strong CP problem if m_u were to vanish.

60.5.2 *Chiral Perturbation Theory*

For light quarks, one can use the techniques of chiral perturbation theory [31–33] to extract quark mass ratios. The mass term for light quarks in the QCD Lagrangian is

$$\overline{\Psi} M \Psi = \overline{\Psi}_L M \Psi_R + \overline{\Psi}_R M^\dagger \Psi_L, \tag{60.10}$$

where M is the light quark mass matrix,

$$M = \begin{pmatrix} m_u & 0 & 0 \\ 0 & m_d & 0 \\ 0 & 0 & m_s \end{pmatrix}, \tag{60.11}$$

$\Psi = (u, d, s)$, and L and R are the left- and right-chiral components of Ψ given by $\Psi_{L,R} = P_{L,R}\Psi$, $P_L = (1-\gamma_5)/2$, $P_R = (1+\gamma_5)/2$. The mass term is the only term in the QCD Lagrangian that mixes left- and right-handed quarks. In the limit $M \to 0$, there is an independent SU(3)×U(1) flavor symmetry for the left- and right-handed quarks. The vector U(1) symmetry is baryon number; the axial U(1) symmetry of the classical theory is broken in the quantum theory due to the anomaly. The remaining $G_\chi = {\rm SU(3)}_L \times {\rm SU(3)}_R$ chiral symmetry of the QCD Lagrangian is spontaneously broken to ${\rm SU(3)}_V$, which, in the limit $M \to 0$, leads to eight massless Goldstone bosons, the π's, K's, and η.

The symmetry G_χ is only an approximate symmetry, since it is explicitly broken by the quark mass matrix M. The Goldstone bosons acquire masses which can be computed in a systematic expansion in M, in terms of low-energy constants, which are unknown nonperturbative parameters of the effective theory, and are not fixed by the symmetries. One treats the quark mass matrix M as a uniform, external field that transforms under G_χ as $M \to LMR^\dagger$, where $\Psi_L \to L\Psi_L$ and $\Psi_R \to R\Psi_R$ are the ${\rm SU(3)}_L$ and ${\rm SU(3)}_R$ transformations, and writes down the most general Lagrangian invariant under G_χ. Then one sets M to its given constant value Eq. (60.11), which implements the symmetry breaking. To first order in M one finds that [34]

$$\begin{aligned} m^2_{\pi^0} &= B\,(m_u + m_d)\,, \\ m^2_{\pi^\pm} &= B\,(m_u + m_d) + \Delta_{\rm em}, \\ m^2_{K^0} &= m^2_{\overline{K}^0} = B\,(m_d + m_s)\,, \\ m^2_{K^\pm} &= B\,(m_u + m_s) + \Delta_{\rm em}, \\ m^2_\eta &= \frac{1}{3} B\,(m_u + m_d + 4m_s)\,, \end{aligned} \tag{60.12}$$

with two unknown constants B, related to the light quark condensate, and $\Delta_{\rm em}$, the electromagnetic mass difference. From Eq. (60.12), one can determine the quark mass ratios [34]

$$\begin{aligned} \frac{m_u}{m_d} &= \frac{2m^2_{\pi^0} - m^2_{\pi^+} + m^2_{K^+} - m^2_{K^0}}{m^2_{K^0} - m^2_{K^+} + m^2_{\pi^+}} = 0.56, \\ \frac{m_s}{m_d} &= \frac{m^2_{K^0} + m^2_{K^+} - m^2_{\pi^+}}{m^2_{K^0} + m^2_{\pi^+} - m^2_{K^+}} = 20.2, \end{aligned} \tag{60.13}$$

to lowest order in chiral perturbation theory, with an error which will be estimated below. Since the mass ratios extracted using chiral perturbation theory use the symmetry transformation property of M under the chiral symmetry G_χ, it is important to use a renormalization scheme for QCD that does not change this transformation law. Any mass-independent subtraction scheme such as $\overline{\rm MS}$ is suitable. The ratios of quark masses are scale independent in such a scheme (up to electromagnetic corrections), and Eq. (60.13) can be taken to be the ratio of $\overline{\rm MS}$ masses. Chiral perturbation theory cannot determine the overall scale of the quark masses, since it uses only the symmetry properties of M, and any multiple of M has the same G_χ transformation law as M.

Chiral perturbation theory is a systematic expansion in powers of the light quark masses. The typical expansion parameter is $m^2_K/\Lambda^2_\chi \sim 0.25$ if one uses SU(3) chiral symmetry, and $m^2_\pi/\Lambda^2_\chi \sim 0.02$ if instead one uses SU(2) chiral symmetry. Electromagnetic effects at the few percent level also break SU(2) and SU(3) symmetry. The mass formulæ Eq. (60.12) were derived using SU(3) chiral symmetry, and are expected to have approximately a 25% uncertainty due to second order corrections. This estimate of the uncertainty yields results consistent with the lattice results summarized in Eq. (60.5)–(60.6).

There is a subtlety which arises when one tries to determine quark mass ratios at second order in chiral perturbation theory. The second order quark mass term [35]

$$\left(M^\dagger\right)^{-1} \det M^\dagger \tag{60.14}$$

(which can be generated by instantons) transforms in the same way under G_χ as M. Chiral perturbation theory cannot distinguish between M and $(M^\dagger)^{-1} \det M^\dagger$; one can make the replacement $M \to M(\lambda) = M + \lambda M (M^\dagger M)^{-1} \det M^\dagger$ in the chiral Lagrangian,

$$\begin{aligned} M(\lambda) &= \text{diag}\,(m_u(\lambda),\ m_d(\lambda),\ m_s(\lambda)) \\ &= \text{diag}\,(m_u + \lambda m_d m_s,\ m_d + \lambda m_u m_s,\ m_s + \lambda m_u m_d)\,, \end{aligned} \tag{60.15}$$

and leave all observables unchanged.

The combination

$$\left(\frac{m_u}{m_d}\right)^2 + \frac{1}{Q^2}\left(\frac{m_s}{m_d}\right)^2 = 1 \tag{60.16}$$

where

$$Q^2 = \frac{m^2_s - m^2_{ud}}{m^2_d - m^2_u}, \qquad m_{ud} = \frac{1}{2}(m_u + m_d)\,,$$

is insensitive to the transformation in Eq. (60.15). Eq. (60.16) gives an ellipse in the m_u/m_d-m_s/m_d plane. The ellipse is well-determined by chiral perturbation theory, but the location on the

ellipse, and the absolute normalization of the quark masses, have larger uncertainties.

A leading-order result for Q in SU(3) chiral perturbation theory can be derived using Eq. (60.12) and the values for the relevant meson masses. This result actually holds to next-to-leading order, yielding $Q \overset{\text{NLO}}{=} 24.3$. Phenomenologically, the preferred way to determine Q is from $\eta \to 3\pi$ decay, giving the smaller value $Q = 22.1(7)$ [36]. Lattice QCD collaborations have also reported determinations of Q. Using $N_f = 2+1$ simulations, Ref. [28] obtains $Q = 23.4 \pm 0.6$ and Ref. [29] determines $Q = 23.8 \pm 1.1$ with $N_f = 2+1+1$ simulations, results which are fully compatible. These results are also compatible with $Q = 23.4 \pm 0.5$, obtained from $Q^2 = (r_s^2 - 1)(1+r)/[4(1-r)]$ and from our lattice averages for r_s and r from Eqs. (60.6) and (60.9), respectively. Given the size of the uncertainties on the lattice results for Q, it is safe to neglect effects due to the definition of isosymmetric QCD (see footnote 3). On the whole, the lattice results are larger than the one from phenomenology [36]. This difference could be due to surprisingly large corrections to the NLO substitution of meson masses by Q in the phenomenological determination, as suggested by the authors of [36].

The absolute normalization of the quark masses cannot be determined using chiral perturbation theory. Other methods, such as lattice simulations discussed above, or spectral function sum rules [37,38] for hadronic correlation functions reviewed next, are necessary.

60.5.3 *Sum rules*

Sum rule methods have been used extensively to determine quark masses and for illustration we briefly discuss here their application to hadronic τ decays [39]. Other applications involve very similar techniques.

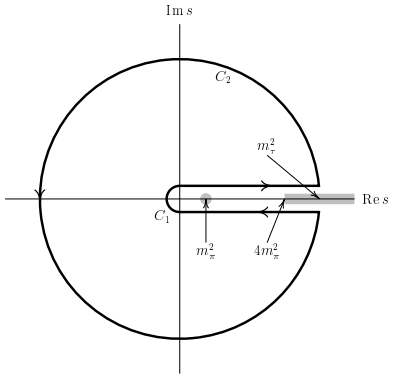

Figure 60.1: The analytic structure of $\Pi(s)$ in the complex s-plane. The contours C_1 and C_2 are the integration contours discussed in the text, and the integral over the closed contour C_1+C_2 vanishes. m_τ^2 has not been drawn to scale; $m_\tau^2 \sim 40(4m_\pi^2)$.

The experimentally measured quantity is R_τ,

$$\frac{\mathrm{d}R_\tau}{\mathrm{d}s} = \frac{\mathrm{d}\Gamma/\mathrm{d}s\left(\tau^- \to \text{hadrons} + \nu_\tau(\gamma)\right)}{\Gamma\left(\tau^- \to e^-\overline{\nu}_e\nu_\tau(\gamma)\right)} \tag{60.17}$$

the hadronic invariant mass spectrum in semihadronic τ decay, normalized to the leptonic τ decay rate. It is useful to define q as the total momentum of the hadronic final state, so $s = q^2$ is the hadronic invariant mass. The total hadronic τ decay rate R_τ is then given by integrating $\mathrm{d}R_\tau/\mathrm{d}s$ over the kinematically allowed range $0 \le s \le M_\tau^2$.

R_τ can be written as

$$R_\tau = 12\pi \int_0^{M_\tau^2} \frac{\mathrm{d}s}{M_\tau^2}\left(1 - \frac{s}{M_\tau^2}\right)^2 \times \left[\left(1 + 2\frac{s}{M_\tau^2}\right)\mathrm{Im}\,\Pi^T(s) + \mathrm{Im}\,\Pi^L(s)\right] \tag{60.18}$$

where the hadronic spectral functions $\Pi^{L,T}$ are defined from the time-ordered correlation function of two weak currents ($j^\mu(x)$ and $j^\nu(0)$) by

$$\Pi^{\mu\nu}(q) = i\int \mathrm{d}^4x\; e^{iq\cdot x}\,\langle 0|\,T\left(j^\mu(x)j^\nu(0)^\dagger\right)|0\rangle\,, \tag{60.19}$$

$$\Pi^{\mu\nu}(q) = (-g^{\mu\nu} + q^\mu q^\nu)\,\Pi^T(s) + q^\mu q^\nu \Pi^L(s), \tag{60.20}$$

and the decomposition Eq. (60.19) is the most general possible structure consistent with Lorentz invariance.

By the optical theorem, the imaginary part of $\Pi^{\mu\nu}$ is proportional to the total cross-section for the current to produce all possible states. A detailed analysis including the phase space factors leads to Eq. (60.18). The spectral functions $\Pi^{L,T}(s)$ are analytic in the complex s plane, with singularities along the real axis. There is an isolated pole at $s = m_\pi^2$, and single- and multi-particle singularities for $s \ge 4m_\pi^2$, the two-particle threshold. The discontinuity along the real axis is $\Pi^{L,T}(s+i0^+) - \Pi^{L,T}(s-i0^+) = 2i\mathrm{Im}\,\Pi^{L,T}(s)$. As a result, Eq. (60.18) can be rewritten with the replacement $\mathrm{Im}\,\Pi^{L,T}(s) \to -i\Pi^{L,T}(s)/2$, and the integration being over the contour C_1. Finally, the contour C_1 can be deformed to $-C_2$ without crossing any singularities, and so leaving the integral unchanged, i.e. the integral over the closed contour $C_1 + C_2$ vanishes. One can derive a series of sum rules analogous to Eq. (60.18) by weighting the differential τ hadronic decay rate by different powers of the hadronic invariant mass [40],

$$R_\tau^{kl} = \int_0^{M_\tau^2} \mathrm{d}s\;\left(1 - \frac{s}{M_\tau^2}\right)^k \left(\frac{s}{M_\tau^2}\right)^l \frac{\mathrm{d}R_\tau}{\mathrm{d}s}\;. \tag{60.21}$$

This leads to the final form of the sum rule(s),

$$R_\tau^{kl} = -6\pi i \int_{C_2} \frac{\mathrm{d}s}{M_\tau^2}\left(1 - \frac{s}{M_\tau^2}\right)^{2+k}\left(\frac{s}{M_\tau^2}\right)^l \times \left[\left(1 + 2\frac{s}{M_\tau^2}\right)\Pi^T(s) + \Pi^L(s)\right]. \tag{60.22}$$

The manipulations so far are completely rigorous and exact, relying only on the general analytic structure of quantum field theory. The left-hand side of the sum rule Eq. (60.22) is obtained from experiment. The right hand-side can be computed for s far away from any physical cuts using the operator product expansion (OPE) for the time-ordered product of currents in Eq. (60.18), and QCD perturbation theory. The OPE is an expansion in a series of local operators, and is an expansion about the $q \to \infty$ limit. It gives $\Pi^{L,T}(s)$ as an expansion in powers of $\alpha_s(s)$ and Λ_{QCD}^2/s, and is valid when s is far (in units of Λ_{QCD}^2) from any singularities in the complex s-plane.

The OPE gives $\Pi^{L,T}(s)$ as a series in α_s, quark masses, and various nonperturbative vacuum matrix elements. By computing $\Pi^{L,T}(s)$ theoretically, and comparing with the experimental values of R_τ^{kl}, one determines various parameters such as α_s and the quark masses. The theoretical uncertainties in using Eq. (60.22) arise from neglected higher order corrections (both perturbative and nonperturbative), and because the OPE is no longer valid near the real axis, where $\Pi^{L,T}$ have singularities. The contribution of neglected higher order corrections can be estimated as for any other perturbative computation. The error due to the failure of the OPE is more difficult to estimate. In Eq. (60.22), the OPE fails on the endpoints of C_2 that touch the real axis at $s = M_\tau^2$. The weight factor $(1 - s/M_\tau^2)$ in Eq. (60.22) vanishes at this point, so the importance of the endpoint can be reduced by choosing larger values of k.

Light quark masses are often determined using QCD sum rules [38], which are similar to the τ sum rules. One takes the correlator of two light-quark-bilinear operators (e.g. an axial vector current), as in Eq. (60.18), and computes their Laplace transforms or moments

$$\mathcal{L}_n(\tau) = \int_0^\infty \mathrm{d}s\, s^n\, e^{-\tau s}\,\mathrm{Im}\,\Pi(s),$$

$$\mathcal{M}_n(Q^2) = \int_0^\infty \frac{\mathrm{d}s}{(s+Q^2)^n}\,\mathrm{Im}\,\Pi(s)$$

to get Laplace or moment sum rules, respectively. The quark masses are extracted by comparing the theoretical and experimental values of $\mathcal{L}_n(\tau)$ and $\mathcal{M}_n(Q^2)$. Considerable theoretical effort has gone into optimizing n and Q^2 to improve the precision of the resulting light quark masses.

60.6 Heavy quarks

60.6.1 *Continuum approaches and results*

For heavy quark physics one can exploit the fact that $m_Q \gg \Lambda_{\rm QCD}$ to construct effective theories (m_Q is the mass of the heavy quark Q). The masses and decay rates of hadrons containing a single heavy quark, such as the B and D mesons can be determined using the heavy quark effective theory (HQET) [41]. The theoretical calculations involve radiative corrections computed in perturbation theory with an expansion in $\alpha_s(m_Q)$ and nonperturbative corrections with an expansion in powers of $\Lambda_{\rm QCD}/m_Q$. Due to the asymptotic nature of the QCD perturbation series, the two kinds of corrections are intimately related; an example of this are renormalon effects in the perturbative expansion which are associated with nonperturbative corrections.

Systems containing two heavy quarks such as the Υ or J/Ψ are treated using non-relativistic QCD (NRQCD) [42]. The typical momentum and energy transfers in these systems are $\alpha_s m_Q$, and $\alpha_s^2 m_Q$, respectively, so these bound states are sensitive to scales much smaller than m_Q. However, smeared observables, such as the cross-section for $e^+e^- \to \bar{b}b$ averaged over some range of s that includes several bound state energy levels, are better behaved and only sensitive to scales near m_Q. For this reason, most determinations of the c, b quark masses using perturbative calculations compare smeared observables with experiment [43–45]. The method is similar to that outlined for τ decays. The current correlator in Eq. (60.18) is the electromagnetic current, and the experimental data is the value of $R(s)$ in the threshold region for $e^+e^- \to Q\overline{Q}$. The theoretical values for the moments are computed using renormalization group improved calculations in non-relativistic QCD.

There are many continuum extractions of the c and b quark masses, some with quoted errors of 10 MeV or smaller. There are systematic effects of comparable size, which are typically not included in these error estimates. Reference [46], for example, shows that even though the error estimate of m_c using the rapid convergence of the α_s perturbation series is only a few MeV, the central value of m_c can differ by a much larger amount depending on which algorithm (all of which are formally equally good) is used to determine m_c from the data. This leads to a systematic error from perturbation theory of around 20 MeV for the c quark and 25 MeV for the b quark. Electromagnetic effects, which also are important at this precision, are often not included. For this reason, we inflate the errors on the continuum extractions of m_c and m_b. The average values of m_c and m_b from continuum determinations are (see Sec. 60.7 for the 1S scheme)

$$\overline{m}_c(\overline{m}_c) = (1.280 \pm 0.025)\text{GeV},$$

$$\overline{m}_b(\overline{m}_b) = (4.18 \pm 0.03)\,\text{GeV}, \quad m_b^{\rm 1S} = (4.65 \pm 0.03)\,\text{GeV}.$$

60.6.2 *Lattice approaches and results*

Lattice QCD simulations of a heavy quark Q, described in a relativistic fermion formulation, lead to potentially large discretization errors which are powers of am_Q (modulated by logarithms); the leading power depends on the formulation of lattice QCD being used and in most cases is quadratic. Clearly those errors can be reduced by performing simulations at smaller lattice spacings a, but also by using *improved* discretizations of the theory, in which the leading discretization errors are systematically eliminated. Recently, with more powerful computing resources, better algorithms and improved discretizations of QCD, it has become possible to perform simulations with quarks more massive than the charm and even up to the b [11], decreasing or eliminating the extrapolation which has to be performed to reach the m_b. It is worth noting that computations using a relativistic fermion formulation for the valence charm with $N_f = 2+1$ sea-quark flavors, or with $N_f = 2+1+1$ flavors and a relativistic b, suffer from partial-quenching effects. This is because the heavy valence quarks are absent from the sea. While these effects are not expected to be large in $N_f = 2+1+1$ computations, they should be investigated when quoting results below the percent level in the case of $N_f = 2+1$ sea-quark flavors. For that reason we will omit heavy-quark results obtained with $N_f = 2+1$ sea-quark flavors from our averages and, more generally focus on $N_f = 2+1+1$ results. Note that these partial-quenching effects are accounted for systematically in lattice calculations in which the heavy valence quarks are described by HQET or NRQCD.

Traditionally the charm quark mass is obtained by tuning its bare, simulation input value to reproduce the physical mass of charmonium mesons or of the D, D_s mesons (requiring a more precise tuning of the light quark masses and the computation of larger QED effects in some cases). This mass can then be renormalized and matched to the $\overline{\rm MS}$ scheme using the methods discussed for the light quarks.

An alternative approach for obtaining the $\overline{\rm MS}$ mass was proposed in [47]. Euclidean-time moments of pseudoscalar, two-point functions of $c\overline{c}$ quark-bilinear operators can readily be computed on the lattice and extrapolated to the continuum limit where they can be compared to perturbative calculations of the same quantities at 4-loop order. In this way, both the strong coupling constant and the charm quark mass can be determined with remarkably small errors. As this approach uses the same perturbative expressions for two-point correlators as the continuum determinations discussed in Sec. 60.6.1, it suffers from similar perturbation-theory, systematic errors. FLAG [8] has reviewed lattice determinations of the charm-quark mass obtained using both approaches. For their $N_f = 2+1$ average they retain the results [13, 48–50], with [51] being published after their deadline. As stated above, we focus here on $N_f = 2+1+1$ results. For these, FLAG uses the results of Refs. [10, 19, 20, 22, 52].

Since the FLAG review, Refs. [22, 52] have been superseded by Ref. [9]. In that reference, only $\overline{m}_c(3\,\text{GeV})$ is given and we multiply it by the running factor 0.7739 ± 0.0060 from $\mu = 3\,\text{GeV}$ to $\overline{m}_c$ [8]. With this substitution and using the combination method described in Sec. 60.4, we obtain:

$$\overline{m}_c(\overline{m}_c) = (1.275 \pm 0.004 \pm 0.008[\pm 0.009])\,\text{GeV} \qquad (60.23)$$

where the three uncertainties have the same meaning as described after Eq. (60.6). This result is in good agreement with the continuum result given above, but with a smaller error.

It is worth noting that three [10, 19, 20] of the four results entering this average agree, while the other [9] is over 2 standard deviations larger than the average. This is taken into account by stretching errors in the usual way, but the total uncertainty on the lattice average of $\overline{m}_c$ will not significantly be reduced until this discrepancy is resolved. It should also be noted that [10] includes QED directly in the lattice calculation, albeit only for valence quarks, while some of the other computations account for these effects using phenomenology. For $\overline{m}_c(\overline{m}_c)$ considered above, these effects are below the permil [10] and are therefore neglected here.

Historically, the main approach to controlling the discretization errors in lattice studies of b-quark physics was to perform simulations of effective theories such as HQET and NRQCD. This remains an important technique, both in its own right and in providing additional information for extrapolations from lower masses to the bottom region. Using effective theories, m_b is obtained from what is essentially a computation of the difference of $M_{H_b} - m_b$, where M_{H_b} is the mass of a hadron H_b containing a b quark. The relative error on m_b is therefore much smaller than that for $M_{H_b} - m_b$. The principal systematic errors are the matching of the effective theories to QCD and the presence of power divergences in a^{-1} in the $1/m_b$ corrections which have to be subtracted numerically. A procedure for performing these subtractions fully nonperturbatively was proposed and implemented for the first time in [53].

The most recent $N_f = 2+1+1$ lattice QCD determinations of the b quark mass rely on a variety of approaches, including Euclidean-time moments of correlation functions with [54] or without NRQCD [19] and interpolations [55, 56] (using results from HQET simulations) or extrapolations [11, 20] from above the

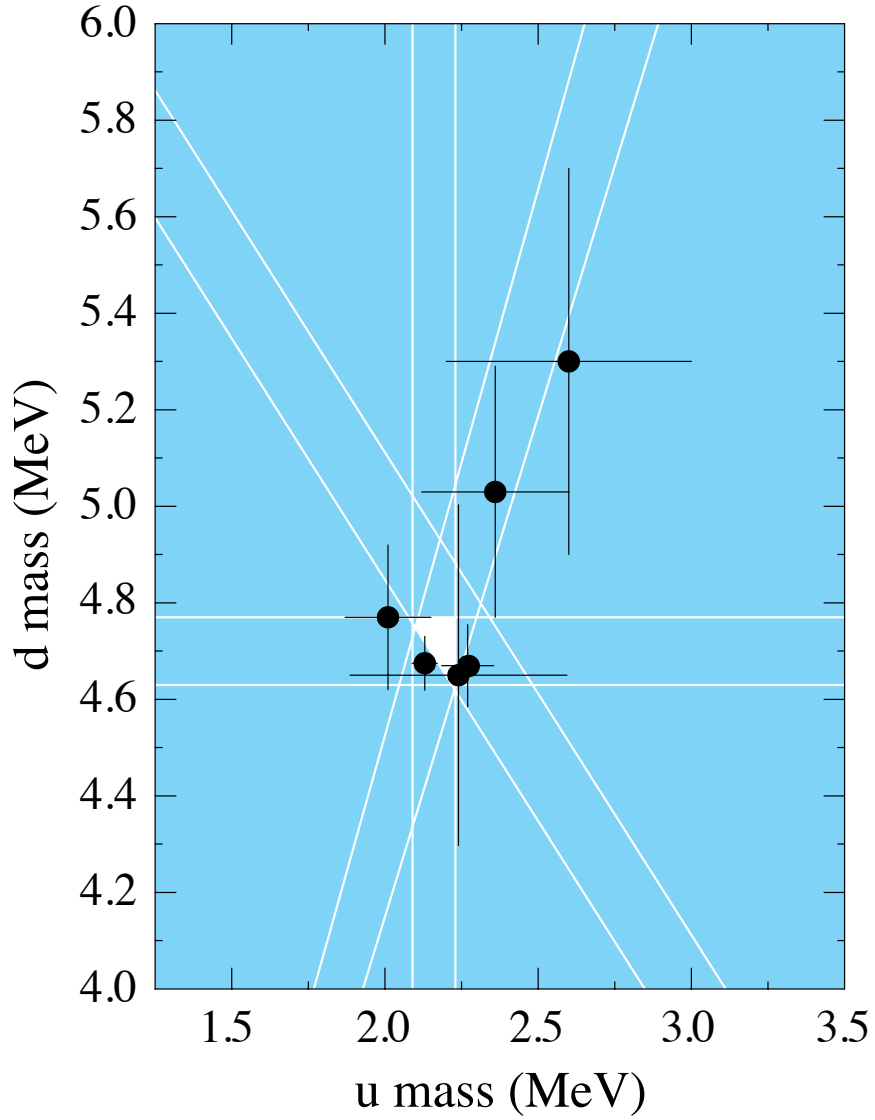

Figure 60.2: The allowed region (shown in white) for up quark and down quark masses renormalized in the $\overline{\rm MS}$ scheme at 2 GeV, determined from the allowed ranges of mass parameters (see Fig. 60.3). The parameter $(m_u + m_d)/2$ yields the two downward-sloping white lines, while m_u/m_d yields the two rising white lines originating at $(0, 0)$. The white region is the remaining allowed parameter space after applying the limits on m_u, m_d, $(m_u + m_d)/2$ and m_u/m_d, where those limits are 90% confidence levels including the scale factors shown in the ideograms in the Data Listings.

charm mass to that of the b. One calculation [11] even includes simulations performed with a heavy quark whose mass is very near that of the b quark. The overall agreement of the results obtained using these very different approaches, which have different systematic errors, is a confirmation that the various groups control these uncertainties. As the range of heavy-quark masses which can be used in numerical simulations increases, the extrapolation or interpolation of results to the physical b mass, possibly including some obtained directly at that mass, are becoming ever more reliable (see e.g. Refs. [11, 20]).

Using the results from Refs. [11, 19, 20, 55, 56], converting those given in the $N_L = 4$ theory to the $N_L = 5$ one and applying the averaging method described in Sec. 60.4, we obtained the estimate:

$$\overline{m}_b(\overline{m}_b) = (4.196 \pm 0.009 \pm 0.009[\pm 0.012])\,\text{GeV}\ , \qquad (60.24)$$

where the three uncertainties have the same meaning as in the estimates given above for light-quark masses.

Among the results entering this average, only one [11] accounts for electromagnetic effects. Using Refs. [10, 11], it is straightforward to show that QED effects on the value of $\overline{m}_b$ at $\mu = 3\,\text{GeV}$, and thus at $\mu = \overline{m}_b$, are smaller than one permil in the separation scheme of those two references. Assuming that the same is true for the other results, we neglect these corrections here.

The lattice result of Eq. (60.24) is compatible with the average value of continuum results, but with a significantly smaller uncertainty. Note that FLAG [8] also provides an average of $N_f = 2+1$ results, taken from [13, 50]. It is about one combined, standard deviations lower that the result quoted above.

As explained in Sec. 60.3, ratios of quark masses can have significantly smaller errors than the individual masses if they are determined within the same lattice QCD framework. This led HPQCD to leverage their precise determination of m_c [47] to determine m_s and m_{ud} [57], through a precise computation of m_c/m_s [57] and of m_s/m_{ud} [58]. The $N_f = 2 + 1$ calculation [57] was updated using $N_f = 2 + 1 + 1$ simulations in [19]. The ratio m_c/m_s was also computed in Refs [48, 59] with $N_f = 2 + 1$ simulations and in Refs. [20, 22] with $N_f = 2 + 1 + 1$ ones. On the basis of those references, FLAG [8] gives average results from $N_f = 2 + 1$ and $N_f = 2+1+1$ simulations. Here we focus on $N_f = 2+1+1$ results and we replace the results of Ref. [22] by the collaboration's update [9]. Applying to the modern $N_f = 2+1+1$ computations of

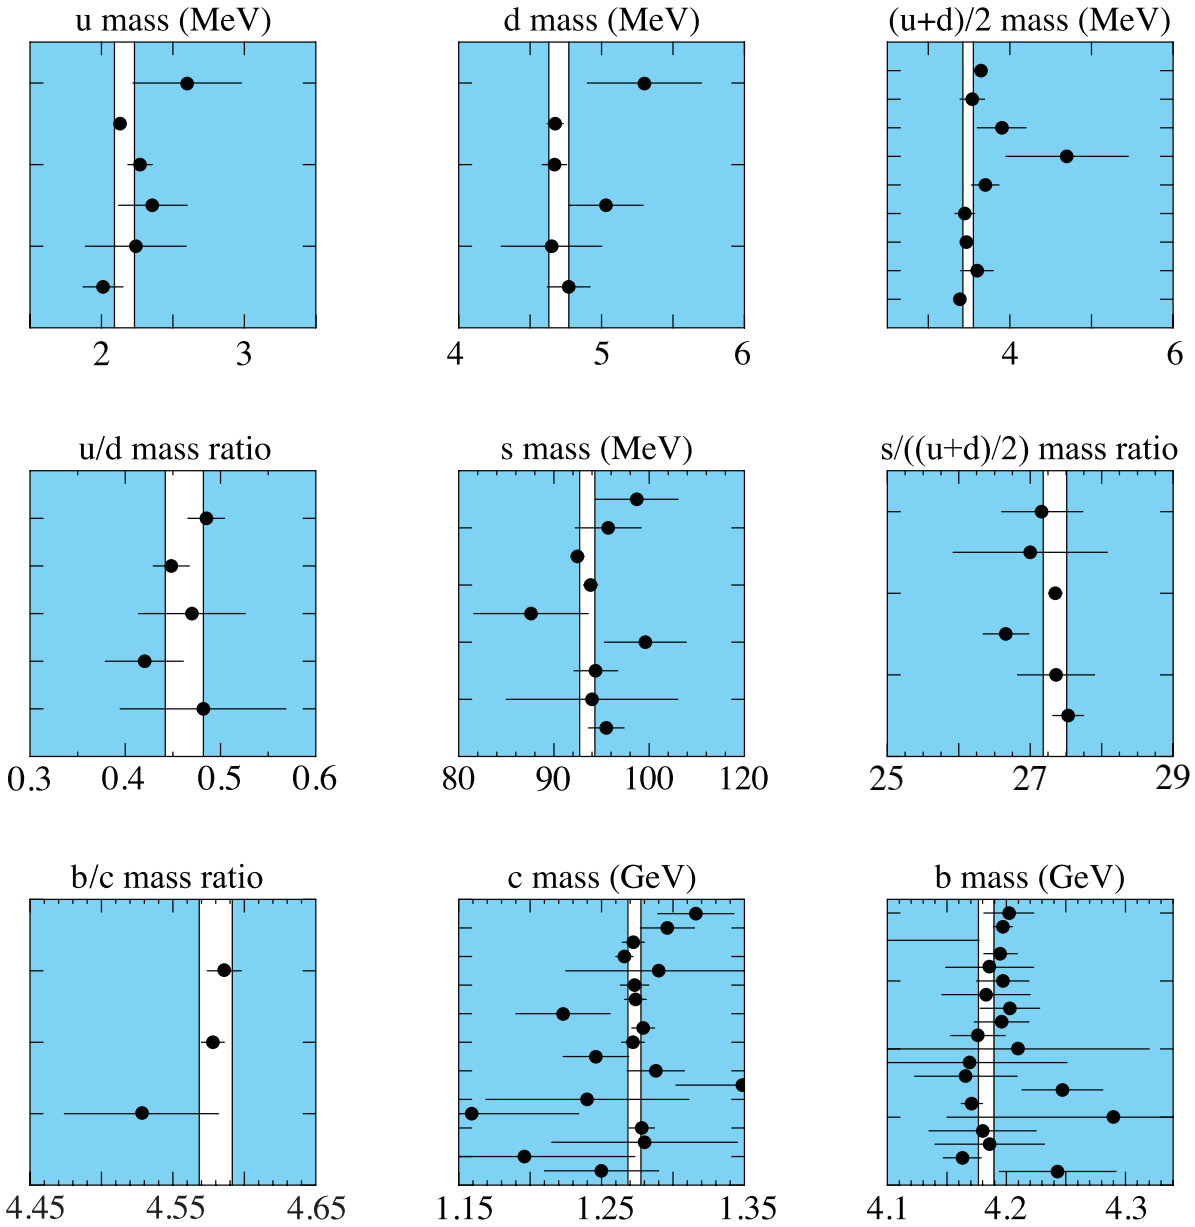

Figure 60.3: The allowed regions (shown in white) for quark masses renormalized in the $\overline{\rm MS}$ scheme at 2 GeV. The points (taken from the Data Listings) are in chronological order with the more recent measurements shown at the top. The white regions indicate values allowed at the 90% confidence level including the scale factors shown in the ideograms in the Data Listings.

Refs. [9, 19, 20] the combination procedure described in Sec. 60.4, we obtain the following lattice average:

$$\overline{m}_c/\overline{m}_s = 11.769 \pm 0.021 \pm 0.028[\pm 0.035],$$

where the three uncertainties have the some meaning as described after Eq. 60.6. The average is dominated by Ref. [20] that has a substantially smaller error than the other results. The result of Ref. [9] is a little more that 1 standard deviation below that average and the one of Ref. [19] close to 2σ above, for a total $\chi^2/\text{dof} = 5.0/2$ and a rescaling factor of ~ 1.6 in the statistical and systematic errors.

The above ratio is renormalization scheme and scale independent, in the absence of electromagnetic corrections. None of the calculations above estimates the size of those corrections. Nevertheless, they are expected to still be smaller than the total uncertainty quoted above in a standard scheme for defining QCD in the isospin limit.

The ratio m_b/m_c has also been computed on the lattice. The two $N_f = 2+1$ results which satisfy FLAG's criteria are [13, 50]. As explained above, we focus on $N_f = 2+1+1$ calculations [11, 20, 55]. Ref. [11] is the only calculation which accounts for QED directly in the lattice simulations, albeit only for valence quarks, and thus must specify the renormalization scheme and scale of its result, which it chooses to be $\overline{\rm MS}$ at 3 GeV. Here we correct the results of Refs. [20, 55] by the QED factor 1.0017 obtained in Ref. [11], and ascribe to it a 100% systematic uncertainty with 100% correlation. This means that we assume that the differences due to the separation schemes used in each calculation lies within that error. Averaging the resulting numbers, as prescribed in Sec. 60.4, yields

$$\overline{m}_b/\overline{m}_c = 4.584 \pm 0.006 \pm 0.010[\pm 0.012],$$

where exceptionally the bar indicates that the masses are renormalized in the $\overline{\rm MS}$ at 3 GeV in the four-flavor theory. Here a scale factor of $\sqrt{\chi^2/\text{dof}} = 1.30$ has been applied to the error bar. Indeed, [55] contributes 3.3 to the total χ^2.

60.6.3 *Warnings concerning the use of the pole mass*

For an observable particle such as the electron, the position of the pole in the propagator is the definition of its mass. In QCD this definition of the quark mass is known as the pole mass. It is known that the on-shell quark propagator has no infrared divergences in perturbation theory [60,61], so this provides a perturbative definition of the quark mass. However, the pole mass cannot be used to arbitrarily high accuracy because of nonperturbative infrared effects in QCD. In fact the full quark propagator has no pole because the quarks are confined, so that the pole mass cannot be defined outside of perturbation theory. The relation between the pole mass m_Q and the $\overline{\rm MS}$ mass $\overline{m}_Q$, used throughout this review, is known to three loops [62–65]

$$m_Q = \overline{m}_Q(\overline{m}_Q)\Bigg\{1 + \frac{4\overline{\alpha}_s(\overline{m}_Q)}{3\pi} + \left[-1.0414\sum_q\left(1-\frac{4}{3}\frac{\overline{m}_q}{\overline{m}_Q}\right)+13.4434\right]\left[\frac{\overline{\alpha}_s(\overline{m}_Q)}{\pi}\right]^2 + \left[0.6527N_L^2 - 26.655N_L + 190.595\right]\left[\frac{\overline{\alpha}_s(\overline{m}_Q)}{\pi}\right]^3\Bigg\}, \tag{60.25}$$

where $\overline{\alpha}_s(\mu)$ is the strong interaction coupling constants in the $\overline{\rm MS}$ scheme, and the sum over q extends over the N_L flavors lighter than Q. The complete mass dependence of the α_s^2 term can be found in [62]; the mass dependence of the α_s^3 term is not known. For the b-quark, Eq. (60.25) reads

$$m_b = \overline{m}_b\,(\overline{m}_b)\,[1 + 0.10 + 0.05 + 0.03]\,, \tag{60.26}$$

where the contributions from the different orders in α_s are shown explicitly. The two and three loop corrections are comparable in size and have the same sign as the one loop term. This is a signal of the asymptotic nature of the perturbation series (there is a renormalon in the pole mass [66]). Such a badly behaved perturbation expansion can be avoided by directly extracting, from data, the mass defined in the $\overline{\rm MS}$ (used in this review) or other short-distance schemes (see below), without invoking the pole mass as an intermediate step.

60.7 Numerical values and caveats

The quark masses in the particle data listings have been obtained by using a wide variety of methods. Each method involves its own set of approximations and uncertainties. In most cases, the errors are an estimate of the size of neglected higher-order corrections or other uncertainties. The expansion parameters for some of the approximations are not very small (for example, they are $m_K^2/\Lambda_\chi^2 \sim 0.25$ for the SU(3) chiral expansion and $\Lambda_{\rm QCD}/m_b \sim 0.1$ for the heavy-quark expansion), so an unexpectedly large coefficient in a neglected higher-order term could significantly alter the results. Thus, before using a particular result, it is important to understand the possible limitations of the approach used to obtain it. It is also important to note that the quark mass values can be significantly different in the different schemes.

We have specified all masses in the $\overline{\rm MS}$ scheme. For light quarks, the renormalization scale has been chosen to be $\mu = 2\,{\rm GeV}$. Quoting these masses at smaller values of μ, where perturbative corrections become significantly larger, would introduce unnecessary uncertainties in the results. In fact, as lattice calculations, performed on finer and finer lattices, allow to determine quark masses, fully nonperturbatively, at larger and larger values of μ, it may become advantageous to quote quark mass results at renormalization scales above 2 GeV, where perturbative uncertainties are smaller.

The heavy quark masses obtained using HQET, QCD sum rules, or lattice gauge theory are consistent with each other if they are all converted into the same scheme and scale. For these quarks it is conventional to choose the renormalization scale equal to the quark mass, so we have quoted $\overline{m}_Q(\mu)$ at $\mu = \overline{m}_Q$ for the c and b quarks. Given the small size of the charm quark mass, in the future it may become advantageous to quote its value at larger values of μ so as not to introduce unnecessary perturbative uncertainties (see discussion above). Analyses of inclusive B meson decays have shown that other mass definitions lead to a better behaved perturbation series than for the $\overline{\rm MS}$ mass, and hence to more accurate mass values [67–70]. Thus, we have chosen to also give values for one of these, the b quark mass in the 1S scheme [67, 68]. Other schemes that have been proposed are the PS-scheme [69], the kinetic scheme [71] and, most recently, the minimal renormalon-subtracted mass (MRS) [70] used in the lattice calculation [20].

If necessary, we have converted values in the original papers to our chosen scheme using two-loop formulæ. It is important to realize that our conversions introduce significant additional errors. In converting to the $\overline{\rm MS}$ b-quark mass, for example, the three-loop conversions from the 1S and pole masses give values about 35 MeV and 135 MeV lower than the two-loop conversions. The uncertainty in $\alpha_s(M_Z) = 0.1179 \pm 0.0010$ [1] gives an uncertainty of ± 9 MeV and ± 21 MeV respectively in the same conversions. We have not added these additional errors when we do our conversions. The α_s value in the conversion is correlated with the α_s value used in determining the quark mass, so the conversion error is not a simple additional error on the quark mass.

61. Top Quark

Revised September 2023 by T.M. Liss (City Coll. of New York), F. Maltoni (CP3 U. catholique de Louvain; Bologna U.) and A. Quadt (Göttingen U.).

61.1 Introduction and SM theory overview

In the Standard Model (SM), the left-handed top quark is the $Q = 2/3$, $T_3 = +1/2$ member of the weak-isospin doublet containing the bottom quark, while the right-handed top is an $SU(2)_L$ singlet (see, e.g., the review "Electroweak Model and Constraints on New Physics" here). Its phenomenology is driven by its large mass, $m_t \simeq \frac{v}{\sqrt{2}}$, where $v = 246$ GeV is the vacuum expectation value of the Higgs field, i.e., it is the only quark whose Yukawa coupling to the Higgs boson is of order unity. As it is heavier than the W boson, it is the only quark that decays semi-weakly into a real W boson and a b quark. This results in a lifetime that is shorter than the time that is needed for strong interactions to modify its properties or to bind it into a hadron. In this respect, the top is the only quark that, in its brief life, behaves as a free one. Because of its large mass and Yukawa coupling to the Higgs boson, it also gives important contributions (via loops) to Standard Model precision observables measured at lower scales.

For these reasons, the top quark provides a unique laboratory to test our understanding of matter and fundamental interactions at the ElectroWeak (EW) symmetry-breaking scale and beyond. In addition, since it is abundantly produced at the Large Hadron Collider (LHC), a precise knowledge of its properties (mass, couplings, production cross sections, decay branching ratios, *etc.*) can be achieved. This review provides a concise discussion of the experimental and theoretical issues involved in the determination of the top-quark properties.

61.1.1 *Properties*

61.1.1.1 *Mass*

The top quark mass determines to a large extent the unique phenomenology of this quark. In the SM quark masses are derived parameters from the Yukawa coupling and the vacuum expectation value. At the loop level, with the Higgs boson discovery and per mil measurement of its mass, the values of the W-boson and top quark mass are correlated, so that their precise determinations provides a strong test of the SM (see Section 10 "Electroweak Model and constraints on new physics" of this *Review*). At present there is some tension at the $1.7\,\sigma$ level, between the indirect top quark (pole) mass determination from electroweak precision data (176.12 ± 1.9 GeV) and the combination of direct measurements at the LHC that yields $172.52 \pm 0.14(\mathit{stat.}) \pm 0.30(\mathit{syst.})$ GeV [1].

The top mass value is also critical in the issue of vacuum stability in the SM [2–4]. At high scales, the Higgs quartic coupling λ evolves to increasingly small values as m_t grows. Above $m_t = 171$ GeV, i.e., very close to the most precise measurements, λ becomes negative at the Planck scale leading to a meta-stable electroweak vacuum, while for slightly larger values, $m_t > 176$ GeV the electroweak vacuum would become unstable. Current top-quark measurements therefore point to a Higgs quartic coupling which is nearly vanishing at the Planck scale. While being quite suggestive, in absence of a clear UV picture this argument allows only to conclude that comparison between our best SM predictions and the data does not imply new physics below the Planck scale (see Section 11.2.3 of "Status of Higgs Boson Physics" in this *Review*).

Given its importance and the large samples of top quarks produced at the LHC, the top mass determination has been one of the most important goals in the precision measurement campaign of the ATLAS and CMS collaborations. The basic methodology rests on the idea of fitting m_t-dependent kinematic distributions to fully-exclusive (Monte Carlo) predictions, via the full or partial reconstruction of the system of the t and $\bar{t}$ decay products. These are called "direct measurements" and aim at a target accuracy in the permil range. With an absolute uncertainty of order or better than $\Lambda_{\rm QCD}$, however, a clear relation between the extracted mass and a well defined quantum field theory parameter of the underlying theory has become necessary.

Several mass parameter definitions exist with a precise field-theoretical meaning, that can be organised in two broad classes, the long-distance ones, such as the "pole mass", and short-distance masses, such as $\overline{\rm MS}$ mass. A mass definition, the MSR mass [5], exists that interpolates between the two. The one measured through direct measurements is sometimes referred to as "Monte Carlo" mass. Several other observables have been put forward that could be expressed in terms of well-defined masses and then overcome the problems of the direct measurements, yet with a target accuracy not quite competitive with the direct determination.

A top mass cannot be defined solely in terms of the mass of the system of its decay products: the top quark is a colored object, therefore it cannot be an asymptotic state of the theory and no final-state hadronic system can be unambiguously associated with it. On the other hand, final state observables such as those arising from its decay, can be related to the top mass through computations, which have perturbative as well as non-perturbative components, as Monte Carlo generators.

From a purely theoretical (calculational) point of view, the top mass parameter is defined within a given renormalization scheme, since divergent perturbative corrections arise order by order in perturbation theory, and need to be subtracted. The pole mass scheme prescribes to subtract the divergent mass corrections so that the pole in the quark propagator remains fixed order by order in perturbation theory. The $\overline{\rm MS}$ scheme prescribes to employ dimensional regularization and subtract the pure $1/\epsilon$ pole in the divergent mass correction. In doing so, the corresponding mass becomes scale dependent. In this scheme the pole in the top propagator receives corrections at all orders in perturbation theory. This scheme has the advantage that it makes the relation between the mass and the Yukawa coupling straightforward in the SM and is independent from non-perturbative corrections.

The relation between the top pole mass $m_t^{\rm pole}$ and $m_t^{\overline{\rm MS}}$ up to four loops reads [6]

$$m_t^{\rm pole} = m_t^{\overline{\rm MS}}(m_t)[1 + 0.4244\,\alpha_s + 0.8345\,\alpha_s^2 + 2.375\,\alpha_s^3 + (8.49 \pm 0.25)\,\alpha_s^4]\,, \tag{61.1}$$

which for $\alpha_s = \alpha_s^{(6)}(m) = 0.1088$ and $m_t^{\rm pole} = 172.5$ GeV gives $m_t^{\overline{\rm MS}}(m_t) = 162.69 \pm 0.006$ GeV. The two definitions lead to perturbatively equivalent theories: a perturbative expression of the pole mass in terms of the $\overline{m}^{\rm MS}$ mass can be translated to a physical result in the pole mass scheme into the corresponding physical result in the $\overline{\rm MS}$ scheme. However, the relation above has only a perturbative meaning, as the two masses differ by non-perturbative, long-distance effects. The difference between the top pole mass and the mass extracted in direct measurements, $\Delta m_{\rm MC}$, arises due to non-perturbative effects, that are currently modelled by shower Monte Carlo programs. It is expected to be of order $Q_0 \cdot \alpha_s(Q_0)$ with $Q_0 \sim 1$ GeV and estimated of order 0.5 GeV. An overview on the on-going efforts to precisely define and to estimate the uncertainties of the top mass can be found in Refs. [7, 8].

61.1.1.2 *Couplings*

The SM couplings involving top quarks are of two types: gauge couplings, which are universal, and Yukawa couplings, which instead depend on the generation. Following the notation of Sections 9 and 10 of this *Review*, after EWSB and in the mass eigenstate basis, top quark interactions read

$$\begin{aligned}\mathcal{L}_t^{\rm SM} = {} & \bar{\psi}_t \left[i\partial\!\!\!/ - m_t \right] \psi_t - g_s \bar{\psi}_t \gamma^\mu t^C \psi_t \mathcal{A}_\mu^C - eQ_t \bar{\psi}_t \gamma^\mu \psi_t A_\mu \\ & - \frac{g}{2\sqrt{2}} \bar{\Psi} \gamma^\mu (1-\gamma^5)(T^+ W_\mu^+ + T^- W_\mu^-) \Psi \\ & - \frac{g}{2\cos\theta_W} \bar{\psi}_t \gamma^\mu \left(g_V^t - g_A^t \gamma^5 \right) \psi_t Z_\mu \frac{m_t}{v} H \bar{\psi}_t \psi_t \,, \end{aligned} \tag{61.2}$$

where in the first line we include the coupling to the $SU(3)$ field $\mathcal{A}_\mu$, and $\Psi = (t, b')$ with $b' = V_{tb}\, b + V_{ts}\, s + V_{td}\, d$. There are no neutral flavor changing interactions in the SM at tree level.

In absence of evidence for physics beyond the SM at the weak scale or below, the Standard Model Effective Field Theory (SMEFT) [9–11] provides a simple and consistent framework

Table 61.1: List of SMEFT operators at dimension six, assuming $U(2)_q \times U(2)_u \times U(2)_d$ flavor symmetry. For more details on notation and conventions, see reference in the text.

Operator	Field content	Operator	Field content
Four-quark		Two-quark-two-lepton	
$O_{qq}^{1(ijkl)}$	$(\bar{q}_i\gamma^\mu q_j)(\bar{q}_k\gamma_\mu q_l)$	$O_{lq}^{1(ijkl)}$	$(\bar{l}_i\gamma^\mu l_j)(\bar{q}_k\gamma^\mu q_l)$

to systematically parameterise possible deviations from the SM predictions in the interactions among the known particles, using minimal theoretical assumptions. It amounts to extend the Lagrangian of the SM, by all higher-dimensional operators that respect the gauge symmetry

$$\mathcal{L}^{\text{SMEFT}} = \mathcal{L}^{\text{SM}} + \sum_{D>4}\sum_{i}^{N_D}\frac{C_i^{(D)}O_i^{(D)}}{\Lambda^{D-4}}\,, \tag{61.3}$$

where D is the dimension of the operator $O_i^{(D)}$ and Λ provides an upper bound for the scale of new physics. An EFT model is generally characterised by power counting rules that identify a hierarchy among operators. In the case of the SMEFT, a minimal approach is considered where the large scale Λ provides a universal suppression factor for the higher dimensional operators.

The currently adopted parametrization for SMEFT interpretations of top quark measurements relies on the Warsaw basis of gauge-invariant dimension-six operators [11] and it is presented in Tab. 61.1 as detailed in Ref. [12] (see [13, 14] for early discussions of top-quark related operators). For convenience, often specific degrees of freedom are identified from combinations of Warsaw-basis operator coefficients aligned with the directions of the EFT parameter space which appear in given processes, in interferences with SM amplitudes, and in top-quark interactions with some of the gauge boson mass eigenstates. Model implementations are available for tree-level and even one-loop Monte Carlo simulations.

The definitions of the SMEFT operators can be organised in four categories: Four-quark, two-quark, two-quark-two-lepton, and baryon-lepton-number violating operators. The overwhelming number of four-fermion operators is tamed by adopting simplifying assumptions about beyond-the-standard-model flavor structures. A baseline flavor scenario in the quark sector and motivated by the minimal flavor violation (MFV) ansatz [15–17] corresponds to imposing a $U(2)_q \times U(2)_u \times U(2)_d$ symmetry among the first two generations. In this case the following numbers of degrees of freedom are produced for the operators of each category of field content:

four heavy quarks	$11 + 2$ CPV
two light and two heavy quarks	14
two heavy quarks and bosons	$9 + 6$ CPV
two heavy quarks and two leptons	$(8 + 3$ CPV$) \times 3$ lepton flavors

where we counted separately CP-conserving and CP-violating (CPV) parameters. They are collected in Table 61.1. Other less restricted scenarios, such as that obtained by imposing $U(2)_{q+u+d}$ symmetry featuring additional $10 + 10$ CPV degrees of freedom, or more restricted ones, such as *top-philic* scenario where it is assumed that new physics couples dominantly to the left-handed doublet and right-handed up-type quark singlet of the third generation as well as to bosons, featuring only 19+6 (CPV) degrees of freedom, are often considered. It is also customary to analyse top-quark flavor-changing neutral currents (FCNCs) separately as, at the tree level, they enter only quadratically. More details can be found in Ref. [12].

61.1.2 *Decay*

As other unstable elementary particles, the lifetime of the top quark, and therefore its width, is perturbatively calculable within the SM. With a mass above the Wb threshold, and $|V_{tb}| \gg |V_{td}|$, $|V_{ts}|$, the decay width of the top quark is expected to be dominated by the two-body channel $t \to Wb$. Neglecting terms of order m_b^2/m_t^2, α_s^2, and $(\alpha_s/\pi)M_W^2/m_t^2$, the width predicted in the SM at NLO is [18]:

$$\Gamma_t = \frac{G_F m_t^3}{8\pi\sqrt{2}}\left(1-\frac{M_W^2}{m_t^2}\right)^2\left(1+2\frac{M_W^2}{m_t^2}\right)\left[1-\frac{2\alpha_s}{3\pi}\left(\frac{2\pi^2}{3}-\frac{5}{2}\right)\right], \tag{61.4}$$

where m_t refers to the top-quark pole mass. The order α_s^2 QCD corrections to Γ_t as well as the EW NLO corrections are known [19,20], thereby improving the overall theoretical accuracy to better than 1%. As a result, between $m_t = 170$ GeV and 175 GeV the width changes from 1.258 GeV to 1.394 GeV, with a linear dependence ($\alpha_s(M_Z) = 0.1179$ and $m_W = 80.377$ GeV). At the reference value of $m_t = 172.5$ GeV, $\Gamma_t = 1.326$ GeV.

With its correspondingly short lifetime of about 0.5×10^{-24} s, the top quark is expected to decay before top-flavored hadrons

or $t\bar{t}$-quarkonium-bound states can form [21]. In fact, since the decay time is close to the would-be-resonance binding time, a peak will be visible in e^+e^- scattering at the $t\bar{t}$ threshold [22] and it is in principle present (yet very difficult to measure) in hadron collisions too [23, 24].

As mentioned above, flavor changing neutral interactions are allowed starting at one loop. The branching ratios to charm final state are estimated to be [25, 26]:

$$\mathrm{Br}^{\mathrm{SM}}(t \to gc) = 5 \cdot 10^{-12},\ \mathrm{Br}^{\mathrm{SM}}(t \to gu) = 4 \cdot 10^{-14},$$
$$\mathrm{Br}^{\mathrm{SM}}(t \to \gamma c) = 5 \cdot 10^{-14},\ \mathrm{Br}^{\mathrm{SM}}(t \to \gamma u) = 4 \cdot 10^{-16},$$
$$\mathrm{Br}^{\mathrm{SM}}(t \to Zc) = 1 \cdot 10^{-14},\ \mathrm{Br}^{\mathrm{SM}}(t \to Zu) = 7 \cdot 10^{-17},$$
$$\mathrm{Br}^{\mathrm{SM}}(t \to Hc) = 3 \cdot 10^{-15},\ \mathrm{Br}^{\mathrm{SM}}(t \to Hu) = 2 \cdot 10^{-17}.$$

61.1.3 *Production*

61.1.3.1 *Pair production*

In hadron collisions, top quarks are produced dominantly in pairs through the processes $q\bar{q} \to t\bar{t}$ and $gg \to t\bar{t}$, at leading order in QCD. At the Tevatron ($p\bar{p}$ at 1.96 TeV) approximately 85% of the production cross section is from $q\bar{q}$ annihilation, with the remainder from gluon-gluon fusion. Conversely, at the LHC about 90% (80%) of $t\bar{t}$ production is from gluon-gluon fusion at $\sqrt{s} = 13$ TeV ($\sqrt{s} = 7$ TeV).

Predictions for the top-quark production total cross sections are available at next-to-next-to leading order (NNLO) [27,28], also including next-to-next-to-leading-log (NNLL) soft gluon resummation. Assuming a top-quark mass of 173.3 GeV, close to the Tevatron + LHC combination [29], the resulting theoretical prediction of the top-quark pair cross-section at NNLO+NNLL accuracy at the Tevatron at $\sqrt{s} = 1.96$ TeV is $\sigma_{t\bar{t}} = 7.16^{+0.11+0.17}_{-0.20-0.12}$ pb where the first uncertainty is from scale dependence and the second from parton distribution functions. At the LHC, assuming a top-quark mass of 172.5 GeV the cross sections are: $\sigma_{t\bar{t}} = 179.6^{+4.8+6.1}_{-6.2-6.1}$ pb at $\sqrt{s} = 7$ TeV, $\sigma_{t\bar{t}} = 256.0^{+6.7+8.0}_{-8.9-8.0}$ pb at $\sqrt{s} = 8$ TeV, $\sigma_{t\bar{t}} = 833.9^{+20.5+21.0}_{-30.0-21.0}$ pb at $\sqrt{s} = 13$ TeV, $\sigma_{t\bar{t}} = 923.6^{+22.6+22.8}_{-33.4-22.8}$ pb at $\sqrt{s} = 13.6$ TeV, and $\sigma_{t\bar{t}} = 985.7^{+24.1+24.1}_{-35.7-24.1}$ pb at $\sqrt{s} = 14$ TeV [27], where the first uncertainty is from scale dependence and the second from parton distribution functions and α_s.

The identification of $t\bar{t}$ events at a collider has to take into account that top quarks decay at microscopic scales and only their decay products can be detected. The final states for the leading pair-production process can be divided into three classes:

A. $t\bar{t} \to W^+ b\, W^- \bar{b} \to q\bar{q}'\, b q''\, \bar{q}'''\, \bar{b}$, (45.7%)
B. $t\bar{t} \to W^+ b\, W^- \bar{b} \to q\bar{q}'\, b \ell^- \bar{\nu}_\ell\, \bar{b} + \ell^+ \nu_\ell\, b\, q''\bar{q}'''\, \bar{b}$, (43.8%)
C. $t\bar{t} \to W^+ b\, W^- \bar{b} \to \ell^+ \nu_\ell\, b\, \ell'^- \bar{\nu}_{\ell'}\, \bar{b}$. (10.5%)

The quarks in the final state evolve into jets of hadrons. A, B, and C are referred to as the all-hadronic, lepton+jets (ℓ+jets), and dilepton ($\ell\ell$) channels, respectively. Their relative contributions, including hadronic corrections, are given in parentheses assuming lepton universality. While ℓ in the above processes refers to e, μ, or τ, most of the analyses distinguish the e and μ from the τ channel, which is more difficult to reconstruct. Therefore, in what follows, we will use ℓ to refer to e or μ, unless otherwise noted. Here, typically leptonic decays of τ are included. In addition to the quarks resulting from the top-quark decays, extra QCD radiation (quarks and gluons) from the colored particles in the event can lead to extra jets.

The number of jets reconstructed in the detectors depends on the decay kinematics, as well as on the algorithm for reconstructing jets used by the analysis. Information on the transverse momenta, p_T of the neutrinos is obtained from the imbalance in transverse momentum measured in each event, the missing p_T, whose magnitude is also called missing transverse energy, E_T.

61.1.3.2 *Single top production*

Electroweak single top-quark production mechanisms, namely from $q\bar{q}' \to t\bar{b}$ [30], $qb \to q't$ [31], mediated by virtual s-channel and t-channel W-bosons, and Wt-associated production, through $bg \to W^- t$, lead to somewhat smaller cross sections. For example, t-channel production, while suppressed by the weak coupling with respect to the strong pair production, is kinematically enhanced, resulting in a sizeable cross section both at Tevatron and LHC energies. At the Tevatron, the t- and s-channel cross sections for top quarks are identical to those for antitop quarks, while at the LHC they are not, due to the charge-asymmetric initial state. NNLO cross sections for t-channel single top-quark production ($t + \bar{t}$) are calculated for $m_t = 173.2$ GeV to be $2.08^{+0.04+0.08}_{-0.03-0.10}$ pb in $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV, where the first uncertainty is from scale dependence and the second from parton distribution functions. [32]. A calculation at NNLO accuracy for the t-channel cross section at the LHC has first appeared in [33], superseded by more recent calculations [32, 34] which predict ($m_t = 172.5$ GeV): $\sigma_{t+\bar{t}} = 30.3^{+0.4+0.6}_{-0.3-0.4}$ pb at $\sqrt{s} = 5.02$ TeV, $\sigma_{t+\bar{t}} = 63.7^{+0.9+1.1}_{-0.5-0.7}$ pb at $\sqrt{s} = 7$ TeV, $\sigma_{t+\bar{t}} = 84.3^{+1.1+1.4}_{-0.7-0.9}$ pb at $\sqrt{s} = 8$ TeV, $\sigma_{t+\bar{t}} = 214.2^{+2.4+3.3}_{-1.7-2.0}$ pb at $\sqrt{s} = 13$ TeV, $\sigma_{t+\bar{t}} = 232.2^{+2.6+3.4}_{-1.7-2.2}$ pb at $\sqrt{s} = 13.6$ TeV, and $\sigma_{t+\bar{t}} = 244.5^{+2.7+3.5}_{-2.0-2.5}$ pb at $\sqrt{s} = 14$ TeV, where the first uncertainty is from scale dependence and the second from parton distribution functions and α_s. The corresponding fraction of top quarks are 67%, 65%, 65%, 63%, 62%, and 62%. For the s-channel, NNLO approximated calculations yield $1.03^{+0.05}_{-0.05}$ pb for the Tevatron [35]. An NNLO calculation gives ($t + \bar{t}$), $3.00^{+0.03}_{-0.03}$ pb, $3.61^{+0.03}_{-0.03}$ pb, $6.84^{+0.06}_{-0.03}$ pb, and $7.25^{+0.06}_{-0.04}$ pb, for $\sqrt{s} = 7, 8, 13, 13.6$ TeV at the LHC, respectively, where the uncertainty is from scale dependence only. While negligible at the Tevatron, at LHC energies Wt-associated production becomes relevant. At $\sqrt{s} = 7, 8, 13, 13.6, 14$ TeV, an NLO+NLL calculation gives ($t + \bar{t}$), $17.1^{+0.4+0.7}_{-0.3-0.7}$ pb, $24.4^{+0.6+0.9}_{-0.5-0.9}$ pb, $79.3^{+1.9+2.2}_{-1.8-2.2}$ pb, $87.9^{+2.0+2.3}_{-1.9-2.4}$ pb, and $93.8^{+2.2+2.5}_{-2.1-2.5}$ pb, respectively, where the first uncertainty is from scale dependence and the second from parton distribution functions and α_s. In this process, an equal proportion of top and anti-top quarks is foreseen. [36].

Assuming $|V_{tb}| \gg |V_{td}|, |V_{ts}|$ (see the Section "The CKM Quark-Mixing Matrix" in this *Review* for more information), the cross sections for single top production are proportional to $|V_{tb}|^2$, and no extra hypothesis is needed on the number of quark families or on the unitarity of the CKM matrix in extracting $|V_{tb}|$. Separate measurements of the s- and t-channel processes provide sensitivity to physics beyond the Standard Model [37].

The identification of top quarks in the electroweak single top channel is much more difficult than in the QCD $t\bar{t}$ channel, due to a less distinctive signature and significantly larger backgrounds, mostly due to $t\bar{t}$ and W+jets production.

61.1.3.3 *Monte Carlo predictions*

Fully exclusive predictions via Monte Carlo generators for the $t\bar{t}$ and single top production processes at NLO accuracy in QCD, including top-quark decays and possibly off-shell effects are available [38,39] through the MC@NLO [40] and POWHEG [41] methods. Recently, the first Monte Carlo implementation of the NNLO QCD computation has become available [42].

61.1.3.4 *Associated production*

Besides fully inclusive QCD or EW top-quark production, more exclusive final states can be accessed at hadron colliders, whose cross sections are typically much smaller, yet can provide key information on the properties of the top quark. For all relevant final states (*e.g.*, $t\bar{t}V$, $t\bar{t}VV$ with $V = \gamma, W, Z$, $t\bar{t}H$, $t\bar{t}$+jets, $t\bar{t}b\bar{b}$, $t\bar{t}t\bar{t}$) automatic or semi-automatic predictions at NLO accuracy both in QCD and EW expansions, also in the form of event generators are available (see the review "Monte Carlo event generators" for more information). Results for total cross sections at NLO+NLL in QCD and NLO EW, are available for $t\bar{t}Z$, $t\bar{t}W$, $t\bar{t}H$ [43] and for $t\bar{t}t\bar{t}$ [44]. Recently, approximate NNLO QCD predictions for and $t\bar{t}H$ and $t\bar{t}W$ have become available [45, 46].

61.2 Top-quark and precision SM tests

Since the discovery of the top quark, direct measurements of $t\bar{t}$ production have been made at seven center-of-mass energies in pp or $p\bar{p}$ and in pPb or $PbPb$ collisions, providing stringent tests of QCD and electroweak theory including parton distribution functions, the strong coupling α_s and the dependence on the top-quark mass m_{top}. The first measurements were made in Run I at the Tevatron at $\sqrt{s} = 1.8$ TeV. In Run II at the Tevatron

relatively precise measurements were made at $\sqrt{s} = 1.96$ TeV. Finally, beginning in 2010, measurements have been made at the LHC at $\sqrt{s} = 7$ TeV, $\sqrt{s} = 8$ TeV, and $\sqrt{s} = 13$ TeV, later also in dedicated low energy runs at $\sqrt{s} = 5.02$ TeV in pp and at $\sqrt{s} = 5.02$ TeV in $PbPb$ collisions and at 8.16 TeV in pPb collisions and recently at $\sqrt{s} = 13.6$ TeV in pp. With the enormous number of over 120 million top quark pairs produced at the LHC, we are entering the era of high precision measurements in the top quark sector.

Production of single top quarks through electroweak interactions has now been measured with good precision at the Tevatron at $\sqrt{s} = 1.96$ TeV, and at the LHC at $\sqrt{s} = 5$ TeV, $\sqrt{s} = 7$ TeV, $\sqrt{s} = 8$ TeV, and also at $\sqrt{s} = 13$ TeV. Measurements at the Tevatron have managed to separate the s- and t-channel production cross sections, and at the LHC, the tW mechanism as well, though the t-channel is measured with best precision to date. The measurements allow an extraction of the CKM matrix element V_{tb}. Also more exclusive production modes and top-quark properties have been measured in single-top production.

With approximately 10 fb^{-1} of Tevatron data, and 255 pb^{-1} at 5 TeV, almost 5 fb^{-1} at 7 TeV, 20 fb^{-1} at 8 TeV, 139 fb^{-1} at 13 TeV and 29 fb^{-1} at 13.6 TeV at the LHC, many properties of the top quark have been measured with high precision. These include properties related to the production mechanism, such as $t\bar{t}$ spin correlations, forward-backward or charge asymmetries, and differential production cross sections, as well as properties related to the tWb decay vertex, such as the helicity of the W-bosons from the top-quark decay. Also studies of the $t\bar{t}b\bar{b}$, $t\bar{t}t\bar{t}$, $t\bar{t}\gamma$, $t\bar{t}Z$, $t\bar{t}h$, th, tZq, $t\gamma q$ or tWZ processes and the corresponding vertices as well as contact interactions have been made, most yielding observations, while first evidence for tWZ has been found and th is still far from evidence. Those processes probe genuinely new aspects of the top-quark such as electroweak couplings to neutral gauge bosons or possibly four-top-quark production via contact interactions. Recently, also first studies for the very fundamental concept of quantum entanglement in top-quark production were pursued. In addition, many searches for physics beyond the Standard Model are being performed with increasing reach in both production and decay channels.

In the following sections we review the current status of measurements of the characteristics of the top quark.

61.2.1 *Top-quark production*

61.2.1.1 $t\bar{t}$ *production*

Fig. 61.1 summarizes the $t\bar{t}$ production cross-section measurements from both, the Tevatron and LHC. Please note that some cross section measurements at the LHC have luminosity-related uncertainties which have improved in the meantime [47]. The latest measurement from DØ [48] ($p\bar{p}$ at $\sqrt{s} = 1.96$ TeV), combining the measurements from the dilepton and lepton plus jets final states in 9.7 fb^{-1}, is 7.26 ± 0.13 (stat.)$^{+0.57}_{-0.50}$ (syst.) pb (7.5%). From CDF the most precise measurement made [49] is in 8.8 fb^{-1} in the dilepton channel requiring at least one b-tag, yielding 7.09 ± 0.84 pb. Both of these measurements assume a top-quark mass of 172.5 GeV/c^2. The dependence of the cross-section measurements on the value chosen for the mass is less than that of the theory calculations because it only affects the determination of the acceptance. In some analyses also the shape of topological variables might be modified.

Combining the recent cross section measurements with older ones in other channels yields $\sigma_{t\bar{t}} = 7.63 \pm 0.50$ pb (6.6%) for CDF, $\sigma_{t\bar{t}} = 7.56 \pm 0.59$ pb (7.8%) for DØ and $\sigma_{t\bar{t}} = 7.60 \pm 0.41$ pb (5.4%) for the Tevatron combination [50]. The contributions to the uncertainty are 0.20 pb from statistical sources, 0.29 pb from systematic sources, and 0.21 pb from the uncertainty on the integrated luminosity. The combined result is in good agreement with the SM expectation of $7.35^{+0.28}_{-0.33}$ pb at NNLO+NNLL in perturbative QCD [27] for a top mass of 172.5 GeV/c^2.

CDF has measured the $t\bar{t}$ production cross section in the dilepton channel with one hadronically decaying tau in 9.0 fb^{-1}, yielding $\sigma_{t\bar{t}} = 8.1 \pm 2.1$ pb. By separately identifying the single-tau and the ditau components, they measure the branching fraction of the top quark into the tau lepton, tau neutrino, and bottom quark to be (9.6 ± 2.8)% [51]. CDF has also performed measurements of the $t\bar{t}$ production cross section normalized to the Z production cross section in order to reduce the impact of the luminosity uncertainty [52].

DØ has performed a measurement of differential $t\bar{t}$ cross sections in 9.7 fb^{-1} of lepton+jets data as a function of the transverse momentum, and absolute value of the rapidity of the top quarks as well as of the invariant mass of the $t\bar{t}$ pair [53]. Observed differential cross sections are consistent with SM predictions.

The LHC experiments ATLAS and CMS use similar techniques to measure the $t\bar{t}$ cross section in pp collisions. The most precise measurements typically come from the dilepton channel, and in particular the $e\mu$ channel. In order to test consistency of the cross-section measurements with some systematic uncertainties cancelling out while testing pQCD and PDFs, cross-section ratios between measurements at 7 TeV and at 8 TeV are performed and quoted in several cases. In other cases, the cross-section ratio between $t\bar{t}$- and Z-production is determined as that is independent of luminosity uncertainties, but keeps its sensitivity to the ratio of gluon versus quark PDFs. These experimental results should be compared to the theoretical calculations at NNLO+NNLL that yield $7.16^{+0.20}_{-0.23}$ pb for top-quark mass of 173.3 GeV/c^2 at $\sqrt{s} = 1.96$ TeV‘ [27], for top-quark mass of 172.5 GeV/c^2 $\sigma_{t\bar{t}} = 68.2^{+5.2}_{-15.4}$ pb at $\sqrt{s} = 5$ TeV [54], $\sigma_{t\bar{t}} = 158^{+23}_{-24}$ pb at $\sqrt{s} = 7$ TeV [55, 56], $\sigma_{t\bar{t}} = 253^{+13}_{-15}$ pb at $\sqrt{s} = 8$ TeV [27, 54, 57–60], $\sigma_{t\bar{t}} = 832.0^{+46}_{-51}$ pb at $\sqrt{s} = 13$ TeV [27, 54, 58–60], $\sigma_{t\bar{t}} = 924^{+32}_{-40}$ pb at $\sqrt{s} = 13.6$ TeV [27, 57–61]. Unless noted otherwise, the theoretical prediction is in agreement with the measurements. Both are aiming for further improvements in precision. The exact details of the measurements such as the top-quark mass assumption at which the cross section values are quoted can be found in the original publications.

$\sqrt{s} = 5.02$ TeV measurements: In a special run, ATLAS recorded 257 pb^{-1}. The $t\bar{t}$ cross-section is measured in both the dilepton and single-lepton final states of the $t\bar{t}$ system and then combined. The combination of the two measurements yields $\sigma_{t\bar{t}} = 67.5 \pm 0.9(stat.) \pm 2.3(syst.) \pm 1.1(lumi.) \pm 0.2(beam)$ pb [62], giving a total uncertainty of 3.9%. The result is in agreement with theoretical QCD calculations at NLO in the strong coupling constant, including the resummation of NNLL soft-gluon terms, and constrains the parton distribution functions of the proton at large Bjorken-x. CMS has measured the $t\bar{t}$ production cross section, accumulating 27.4 pb^{-1} of data. The measurement is performed by analyzing events with at least one charged lepton. The measured cross section is $\sigma_{t\bar{t}} = 69.5 \pm 8.4$ pb [63], with a relative precision of 12%, in agreement with the expectation from the Standard Model. The impact of the presented measurement on the determination of the gluon distribution function is also investigated. In addition, they performed a measurement in opposite-sign $e\mu$-dilepton events with at least two jets using 302 pb^{-1}. They obtain a Drell-Yan scale factor under the Z-boson mass to estimate the background and extract a cross section using a counting technique of $\sigma_{t\bar{t}} = 60.7 \pm 5.0(stat) \pm 2.8(syst) \pm 1.1(lumi)$ pb. A combination with the result in the single lepton + jets channel is performed, yielding $\sigma_{t\bar{t}} = 63.0 \pm 4.1(stat) \pm 3.0(syst + lumi)$ pb [64].

$\sqrt{s} = 7$ TeV measurements: At $\sqrt{s} = 7$ TeV, ATLAS uses the full dataset of 4.6 fb^{-1} of $e\mu$ events, yielding $\sigma_{t\bar{t}} = 182.9 \pm 7.1$ pb, corresponding to 3.9% precision [65]. Other measurements by ATLAS include a measurement in 0.7 fb^{-1} in the lepton+jets channel [66], in the dilepton channel [67], and in 1.02 fb^{-1} in the all-hadronic channel [68], which together yield a combined value of $\sigma_{t\bar{t}} = 177 \pm 3(stat.)^{+8}_{-7}(syst.) \pm 7(lumi.)$ pb (6.2%) [69]. Further analyses in the hadronic τ plus jets channel in 1.67 fb^{-1} [70] and the hadronic τ + lepton channel in 2.05 fb^{-1} [71], and the all-hadronic channel in 4.7 fb^{-1} [72] yield consistent albeit less precise results. Recently, ATLAS performed a cross section measurement in the lepton+jets channel using 4.6 fb^{-1} using a three-class, multidimensional event classifier based on support vector machines to differentiate $t\bar{t}$ events from $W/Z + b\bar{b}$ and other background processes, yielding $\sigma_{t\bar{t}} = 168.5 \pm 0.7(stat.)^{+6.2}_{-5.9}(syst.)^{+3.4}_{-3.2}(lumi.)$ pb [73].

CMS measures the $t\bar{t}$ cross section in the dilepton channel us-

ing 2.3 fb^{-1} to $\sigma_{t\bar{t}} = 161.9 \pm 2.5(stat.)^{+5.1}_{-5.0}(syst.) \pm 3.6(lumi.)$ pb, corresponding to a 4.2% precision [74]. The most precise measurement from CMS is also obtained in the dilepton channel using 5 fb^{-1}, where they measure $\sigma_{t\bar{t}} = 173.6 \pm 2.1(stat.)^{+4.5}_{-4.0}(syst.) \pm 3.8(lumi.)$ pb, corresponding to a 3.6% precision [75]. Other measurements use 2.3 fb^{-1} in the e/μ+jets channel [76], with 3.5 fb^{-1} in the all-hadronic channel [77], with 2.2 fb^{-1} in the lepton+τ channel [78], and with 3.9 fb^{-1} in the τ+jets channel [79]. ATLAS and CMS also provide a legacy combined cross section of $\sigma_{t\bar{t}} = 178.5 \pm 4.7$ pb using 5 fb^{-1}, yielding a precision of 2.6% [80].

$\sqrt{s}$ = 8 TeV measurements: At $\sqrt{s}$ = 8 TeV, ATLAS measures the $t\bar{t}$ cross section with 20.3 fb^{-1} using $e\mu$ dilepton events, with a simultaneous measurement of the b−tagging efficiency, yielding $\sigma_{t\bar{t}} = 242.9 \pm 1.7(stat.) \pm 5.5(syst.) \pm 5.1(lumi.) \pm 4.2(beam\,energy)$ pb [81] (3.6% precision). In the $\ell + jets$ channel, they measure $\sigma_{t\bar{t}} = 260 \pm 1(stat.)^{+20}_{-23}(syst.) \pm 8(lumi.) \pm 4(beam\,energy)$ pb [82] in 20.3 fb^{-1} using a likelihood discriminant fit and b-jet identification. Subsequently, ATLAS performed a new analysis in 20.2 fb^{-1} using $\ell + jets$ events. They model the W+jets background using Z+jets data and employ neural networks in three jet-multiplicity and b-jet multiplicity regions for the signal and background separation, yielding $\sigma_{t\bar{t}} = 248.3 \pm 0.7(stat.) \pm 13.4(syst.) \pm 4.7(lumi.)$ pb [83]. ATLAS also performed a cross section measurement in the hadronic τ+jets channel yielding consistent, albeit less precise results [84].

CMS performs a template fit to the M_{lb} mass distribution using 19.6 fb^{-1} in the lepton+jets channel yielding $\sigma_{t\bar{t}} = 228.5 \pm 3.8(stat.) \pm 13.7(syst.) \pm 6.0(lumi.)$ pb [85] (6.7% precision). In the $e\mu$ channel, initially using 5.3 fb^{-1} [86] the cross sections are extracted using a binned likelihood fit to multi-differential final state distributions related to identified b quark and other jets in the event, yielding $\sigma_{t\bar{t}} = 239 \pm 2(stat.) \pm 11(sys.) \pm 6(lumi.)$ pb (5.3% precision). Later, they also use the full dataset of 19.7 fb^{-1}, yielding $\sigma_{t\bar{t}} = 244.9 \pm 1.4(stat)^{+6.3}_{-5.5}(syst) \pm 6.4(lumi)$ pb (3.7% precision) [75]. This most precise CMS measurement at 8 TeV is also used to determine the top pole mass and set SUSY limits. The cross section is also measured in the hadronic τ+jets channel, yielding $\sigma_{t\bar{t}} = 257 \pm 3(stat.) \pm 24(syst.) \pm 7(lumi.)$ pb [87] and in the all-hadronic final state giving $\sigma_{t\bar{t}} = 275.6 \pm 6.1(stat.) \pm 37.8(syst.) \pm 7.2(lumi.)$ pb [88]. In combination of the most precise $e\mu$ measurements in $5.3 - 20.3$ fb^{-1}, ATLAS and CMS together yield $\sigma_{t\bar{t}} = 241.5 \pm 1.4(stat.) \pm 5.7(syst.) \pm 6.2(lumi.)$ pb [89] (3.5% precision), challenging the precision of the corresponding theoretical predictions. ATLAS and CMS also provide a legacy combined cross section of $\sigma_{t\bar{t}} = 243.3^{+6.0}_{-5.9}$ pb using 20 fb^{-1} (2.5% precision) [80]. The combinations also provide the ratio between cross sections at 8 and 7 TeV, the top quark pole mass, and the strong coupling.

The LHCb collaboration presented the first observation of top-quark production in the forward region in pp-collisions in the e+jets or μ+jets channel. The results are based on data corresponding to integrated luminosities of 1.0 and 2.0 fb^{-1} collected at center-of-mass energies of 7 and 8 TeV by LHCb. The inclusive top quark production cross sections in the fiducial region are $\sigma_{t\bar{t}} = 239 \pm 53(stat.) \pm 38(syst.)$ pb at 7 TeV, and $\sigma_{t\bar{t}} = 289 \pm 43(stat.) \pm 46(syst.)$ pb at 8 TeV [90].

$\sqrt{s}$ = 13 TeV measurements: In 36.1 fb^{-1} of $e\mu$ data with one or two b-tags, ATLAS measures $\sigma_{t\bar{t}} = 826.4 \pm 3.6(stat.) \pm 11.5(syst.) \pm 15.7(lumi.) \pm 1.9(beam)$ pb (2.4% precision). This measurement is also used to determine the top quark pole mass and to derive ratios and double ratios of $t\bar{t}$ and Z cross-sections at different energies as well as absolute and normalised differential cross-sections as functions of single lepton and dilepton kinematic variables [91]. In the $\ell + jets$ channel, using 85 pb^{-1}, the cross-section is extracted by counting the number of events with exactly one e or μ and at least four jets, at least one of which is identified as originating from a b-quark, yielding $\sigma_{t\bar{t}} = 817 \pm 13(stat.) \pm 103(syst.) \pm 88(lumi.)$ pb [92]. Later, ATLAS measures the inclusive $t\bar{t}$ cross section in 139 fb^{-1} in the $\ell + jets$ through a profile-likelihood fit to be $\sigma_{t\bar{t}} = 830.4 \pm 0.4(stat.) \pm 36(syst.) \pm 14(lumi)$ pb (4.6% precision) [93].

Recently, using the complete Run-2 dataset of 140 fb^{-1} in events containing an oppositely charged $e\mu$ pair and b-tagged jets, ATLAS has presented their legacy measurement of $\sigma_{t\bar{t}} = 829 \pm 1(stat) \pm 13(syst) \pm 8(lumi) \pm 2(beam)$ pb [94], corresponding to a precision of 1.8%. They also measure differential and double-differential distributions of kinematic variables of leptons from decays of top-quark pairs. The results are compared with predictions from several Monte Carlo generators. While no prediction is found to be consistent with all distributions, a better agreement with measurements of the lepton p_T distributions is obtained by reweighting the $t\bar{t}$ sample so as to reproduce the top-quark p_T distribution from an NNLO calculation.

Using 35.9 fb^{-1} of dilepton data, they use a likelihood fit and yield $\sigma_{t\bar{t}} = 803 \pm 2(stat.) \pm 25(syst.) \pm 20(lumi.)$ pb (4.0%). This result is also used to extract the top quark mass in both the pole and the $\overline{\rm MS}$ schemes at NNLO and the strong coupling constant [95]. Using the same dataset in the dilepton channel with a hadronically decaying τ, they measure $\sigma_{t\bar{t}} = 781 \pm 7(stat.) \pm 62(syst.) \pm 20(lumi.)$ pb (8.3%) [96]. A first measurement of the total inclusive and the normalized differential cross section in the $\ell + jets$ channel is made in 42 pb^{-1} yielding $\sigma_{t\bar{t}} = 836 \pm 27(stat.) \pm 88(syst.) \pm 100(lumi.)$ pb [97]. Using 2.2 fb^{-1} of data, $\ell + jets$ events are categorized according to the accompanying jet multiplicity. From a likelihood fit to the invariant mass distribution of the isolated lepton and a b-jet, the cross section is measured to be $\sigma_{t\bar{t}} = 888 \pm 2(stat.)^{+26}_{-28}(syst.) \pm 20(lumi)$ pb [98]. This result is also used to extract the top-quark mass. Using the full Run-2 dataset of 137 pb^{-1}, CMS measures the $t\bar{t}$ cross section in four regions determined by top p_T and b-tag score in the $\ell + jets$ channel. They employ a combined χ^2 fit considering the migration matrices. Most of the measured differential cross sections are well described by standard model predictions with the exception of some double-differential distributions. They obtain $\sigma_{t\bar{t}} = 791 \pm 1(stat.) \pm 21(syst.) \pm 14(lumi)$ pb (3.2%) [99]. In the all-hadronic channel, CMS uses 2.53 fb^{-1} of data, yielding a cross section of $\sigma_{t\bar{t}} = 834 \pm 25(stat.)^{+118}_{-104}(syst.) \pm 23(lumi.)$ pb [100]. Also differential cross sections as a function of the leading top quark transverse momentum are measured. Very recently, CMS presents a first search for the central exclusive production of $t\bar{t}$ pairs using proton-tagged events, using 29.4 fb^{-1}. The $t\bar{t}$ decay products are reconstructed using the central CMS detector, while forward protons are measured in the CMS-TOTEM precision proton spectrometer. An observed (expected) upper bound on the production cross section of 0.59 (1.14) pb [101] is set at 95% confidence level, for collisions of protons with fractional momentum losses between 2 and 20%.

Using 1.93 fb^{-1}, LHCb studies forward top quark pair production in pp collisions in the μeb final state. The cross-section is measured in a fiducial region defined by both leptons transverse momenta and pseudorapidities as well as their angular separation, the b-jet transverse momentum and its angular separation from the leptons, yielding $\sigma_{t\bar{t}} = 126 \pm 19(stat.) \pm 16(syst.) \pm 5(lumi)$ fb [102].

$\sqrt{s}$ = 13.6 TeV measurements: Being one year into the Run-3 data taking at $\sqrt{s}$ = 13.6 TeV with an expected increase in the $t\bar{t}$ cross section by approximately 10%, both experiments, ATLAS and CMS, present the first $t\bar{t}$ cross section measurements already.

ATLAS uses 29 fb^{-1} of data in events with an opposite-charge $e\mu$ pair and b-tagged jets to obtain $\sigma_{t\bar{t}} = 850 \pm 3(stat.) \pm 18(syst.) \pm 20(lumi.)$ pb. Simultaneously, the Z-boson cross section is determined for inclusive e^+e^- and $\mu^+\mu^-$ events in a fiducial phase space, taking cancellation of several systematic uncertainties into account yielding for the ratio $R_{t\bar{t}/Z} = 1.145 \pm 0.003(stat.) \pm 0.021(syst.) \pm 0.002(lumi.)$ [103].

CMS presents the first measurement at this energy using 1.21 fb^{-1} in events with one or two charged leptons (e or μ) and additional jets. A maximum likelihood fit is performed in event categories defined by the number and flavors of the leptons, the number of jets, and the number of jets identified as originating from b quarks. An inclusive $t\bar{t}$ production cross section of $881 \pm 23(stat + syst) \pm 20(lumi)$ pb is measured [104].

proton-lead *pPb* and lead-lead *PbPb* heavy ion collision measurements: CMS establishes first evidence for the production of top-quark pairs in $PbPb$ collision data at a nucleon-nucleon

center-of-mass energy of 5.02 TeV using evens with charged leptons (electrons or muons) and bottom quarks. They obtain $\sigma_{t\bar{t}} = 2.54^{+0.84}_{-0.74}$ μb [105]. CMS also performed a measurement of top-quark pair production in proton-lead pPb heavy ion collisions at $\sqrt{s} = 8.16$ TeV in 174 nb^{-1} of lepton+jets events. They measure a cross section of $\sigma_{t\bar{t}} = 45 \pm 8$ nb [106]. Recently, also ATLAS presents a $t\bar{t}$ cross section measurement in 165 nb^{-1} of pPb collisions at $\sqrt{s} = 8.16$ TeV in the lepton+jets and the dilepton channels, with a significance well over 5 standard deviations in both channels separately, yielding a combination of $\sigma_{t\bar{t}} = 57.9 \pm 2.0(stat.)^{+4.9}_{-4.5}(syst.)$ nb (9%) [107]. Both measurements are consistent with pQCD calculations and with the scaled pp data.

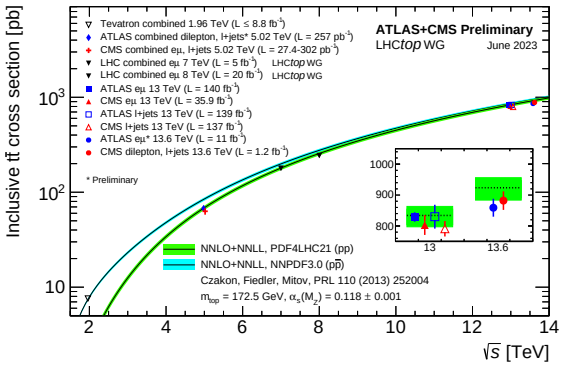

Figure 61.1: Measured and predicted $t\bar{t}$ production cross sections from Tevatron energies in $p\bar{p}$ collisions to LHC energies in pp collisions. The plot is kindly provided by the LHCtopWG working group, status as of June 2023, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

In Fig. 61.1, one sees the importance of $p\bar{p}$ at Tevatron energies where the valence antiquarks in the antiprotons contribute to the dominant $q\bar{q}$ production mechanism. At LHC energies, the dominant production mode is gluon-gluon fusion and the pp-$p\bar{p}$ difference nearly disappears. The excellent agreement of these measurements with the theory calculations is a strong validation of QCD and the soft-gluon resummation techniques employed in the calculations. The measurements reach high precision and provide stringent tests of pQCD calculations at NNLO+NNLL level including their respective PDF uncertainties.

Most of these measurements assume a $t \to Wb$ branching ratio of 100%. CDF and DØ have made direct measurements of the $t \to Wb$ branching ratio [108,109]. Comparing the number of events with 0, 1 and 2 tagged b jets in the lepton+jets channel, and also in the dilepton channel, using the known b-tagging efficiency, the ratio $R = B(t \to Wb)/\sum_{q=d,s,b} B(t \to Wq)$ can be extracted. In 5.4 fb^{-1} of data, DØ measures $R = 0.90 \pm 0.04$, which is 2.5 standard deviations from unity. The currently most precise measurement was made by CMS in 19.7 fb^{-1} at $\sqrt{s} = 8$ TeV. They find $R = 1.014 \pm 0.003(stat.) \pm 0.032(syst.)$ and $R > 0.955$ at 95% C.L. [110]. A significant deviation of R from unity would imply either non-SM top-quark decay (for example a flavor-changing neutral-current decay), or a fourth generation of quarks. The latter is excluded by other measurements.

61.2.1.2 *Differential $t\bar{t}$ cross sections*

Thanks to the large available event samples, the Tevatron and the LHC experiments also performed single-, double- or recently even triple-differential cross-section measurements in $t\bar{t}$ production. Such measurements are crucial, as they allow even more stringent tests of perturbative QCD as description of the production mechanism, and allow along with other data the extraction of PDFs in PDF fits. In addition, they enhance the sensitivity to possible new physics contributions, especially now that NNLO predictions for the main differential observables in $t\bar{t}$ prediction have become available [111] and later confirmed [28]. Furthermore, such measurements reduce the uncertainty in the description of $t\bar{t}$ production as background in Higgs physics and searches for rare processes or beyond Standard Model physics.

Differential cross sections are typically measured by a selection of candidate events, their kinematic reconstruction and subsequent unfolding of the obtained event counts in bins of kinematic distributions in order to correct for detector resolution effects, acceptance and migration effects. In some cases a bin-by-bin unfolding is used, while other analyses use more sophisticated techniques. Most commonly used unfolding techniques are the iterative Bayesian unfolding (IBU) [112] as implemented in the `RooUnfold` package [113] and the profile-likelihood unfolding [114] [115], but also a singular value composition approach [116] or maximum likelihood fit methods [117] are used. As general feature across channels, it is found that the measured top quark p_T spectrum is significantly softer than the NLO+PS theory predictions considered in the corresponding publications.

$\sqrt{s} = 7$ TeV measurements: At $\sqrt{s} = 7$ TeV, ATLAS and CMS measure single-differential $t\bar{t}$ cross sections with respect to jet multiplicity, the top-quark transverse momentum, and of the mass, transverse momentum and rapidity of the top quark, the antitop quark as well as the $t\bar{t}$ system or kinematic properties of the final-state charged leptons and jets associated to b-quarks. While CMS finds in general good agreement with the pQCD calculations [118–120], ATLAS finds the data to be softer, in particular in the $t\bar{t}$ mass and the top-quark p_T than the `Alpgen`+`Herwig` generator. Also some disagreement in the rapidity spectrum is observed indicating a preference for the HERAPDF1.5 pdf set over CT10 [121–123].

$\sqrt{s} = 8$ TeV measurements: At $\sqrt{s} = 8$ TeV, ATLAS measures single-differential cross sections in the dilepton and lepton+jets channel with respect to the mass, the transverse momentum and the rapidity of the $t\bar{t}$ system and event-level kinematic observables [124] [125]. The results are consistent or in fair agreement with the predictions over a wide kinematic range. Predictions beyond NLO accuracy improve the agreement with data at high top-quark transverse momenta. Using the current settings in the Monte Carlo programs and parton distribution functions, improve the agreement with the rapidity distributions. ATLAS also performs a dedicated differential $t\bar{t}$ cross-section measurement of highly boosted top quarks in the lepton+jets channel, where the hadronically decaying top quark has a transverse momentum above 300 GeV [126]. Jet substructure techniques are employed to identify top quarks, which are reconstructed with an anti-k_t jet with a radius parameters $R = 1.0$. The predictions of NLO and LO matrix element plus parton shower Monte Carlo generators are found to generally overestimate the measured cross sections.

CMS measures normalized differential cross sections for $t\bar{t}$ production in lepton+jets events with respect to four kinematic event variables: the missing transverse energy; the scalar sum of the jet transverse momentum (p_T); the scalar sum of the p_T of all objects in the event; and the p_T of leptonically decaying W bosons from top quark decays [119]. Using 19.7 fb^{-1}, they measure the normalized differential cross section in the lepton+jets (e/μ+jets) and in the dilepton (e^+e^-, $\mu^+\mu^-$, and $e^\pm\mu^\pm$) decay channels as a function of the kinematic properties of the charged leptons, the jets associated to b quarks, the top quarks, and the $t\bar{t}$ system. The data are compared with several predictions from perturbative QCD up to approximate next-to-next-to-leading-order precision [127]. Using the same dataset, in the dilepton $e\mu$ channel, they measure normalized double-differential cross sections for $t\bar{t}$ production as a function of various pairs of observables characterizing the kinematics of the top quark and $t\bar{t}$ system [128]. This result has a significant impact on the gluon distribution when included in PDF fits. Overall agreement is observed with the predictions, which is improved when the latest parton distribution functions are used [128]. They also perform a dedicated boosted-top analysis in the e or μ+jets channel where the hadronically decaying top quark is reconstructed as a single large-radius jet and identified as a top candidate using jet substructure techniques [129].

$\sqrt{s} = 13$ TeV measurements: At $\sqrt{s} = 13$ TeV, ATLAS measures the differential $t\bar{t}$ cross section in the lepton+jets and the dilepton channel as a function of the transverse momentum

and absolute rapidity of the top quark, and of the transverse momentum, absolute rapidity and invariant mass of the $t\bar{t}$ system [130] [131] [91]. They find in general good agreement with the theory models with the exception of the `Powheg-Box+ Herwig++` predictions, which differ significantly from the data in both the transverse momentum of the top quark and the mass of the $t\bar{t}$ system. ATLAS measures the single- and double-differential $t\bar{t}$ cross-section in the lepton + jets channel at particle and parton level. Two topologies, resolved and boosted, are considered [132]. In the all-hadronic channel, measurements are presented in the boosted regime [133] as well as in the resolved regime with six separately resolved jets [134].

Using the full Run-2 datset of 140 fb^{-1}, ATLAS measures differential cross sections in the $\ell + jets$ channel and fully hadronic channels in a boosted topology with at least one large-R "top-jet" from a hadronic decay with high-p_T, also as a function of variables that characterise the additional radiation in the events [135]. The measured distribution of the top-quark p_T is used to set limits on the Wilson coefficients describing physics beyond the standard model. The modelling of the additional radiation events show some mild disagreements to the data. Further differential cross-section measurements were made that are specifically useful for MC generator tuning. This includes the ATLAS measurement of the one- and two-dimensional differential cross-sections for eight substructure variables, defined using only the charged components of the jets, in a particle-level phase space by correcting for the smearing and acceptance effects induced by the detector [136] [94]. The QCD predictions for measures of energy-flow are found to be in good agreement with the measurements while variables sensitive to the three-body structure of the top-quark jets exhibit some tensions with the measured distributions. In another example, a measurement of observables sensitive to effects of color reconnection in top-quark pair-production events is presented, in particular for the charged-particle multiplicity, the scalar sum of the transverse momenta of the charged particles, and the same scalar sum in bins of charged-particle multiplicity. These observables are unfolded to the stable-particle level. The particle-level measurements are compared with different color reconnection models in Monte Carlo generators. These measurements disfavour some of the color reconnection models and provide inputs to future optimisation of the parameters in Monte Carlo generators [137]. Furthermore, several observables sensitive to the fragmentation of b-quarks into b-hadrons are measured. Jets containing b-hadrons are used to construct observables that characterize the longitudinal and transverse momentum distributions of the b-hadron within the jet. The measurements have been corrected for detector effects and provide a test of heavy-quark-fragmentation modeling at the LHC in a system where the top-quark decay products are color-connected to the proton beam remnants. The unfolded distributions are compared with the predictions of several modern Monte Carlo parton-shower generators and generator tunes, and a wide range of agreement with the data is observed. These measurements complement similar measurements from e^+e^- collider experiments in which the b-quarks originate from a color-singlet Z/γ^* [138].

CMS measures single- and double-differential $t\bar{t}$ cross sections in the dilepton and the lepton+jets channel as a function of the kinematic properties of the leptons, jets from bottom quark hadronization, top quarks, and top quark pairs and jet multiplicity [139–144]. While in general good agreement is observed, in a dilepton analysis, significant disagreement is observed between data and all predictions for several observables. The measurements are used to constrain the top quark chromomagnetic dipole moment in an effective field theory framework at NLO in QCD and to extract $t\bar{t}$ and leptonic charge asymmetries [145]. In a later dilepton channel analysis, even a triple-differential measurement is performed as a function of the invariant mass and rapidity of the $t\bar{t}$ system and the multiplicity of additional jets at particle level. The measurement is used to extract the strong coupling constant and the top-quark pole mass and parton distribution functions [146]. In the all-hadronic and $\ell + jets$ events in a boosted topology with at least two large-R jets with a b-tag inside and $p_T > 400$ GeV or one large-R jet, respectively, CMS measures the differential cross section as a function of kinematic variables of individual top quarks or of the $t\bar{t}$ system [147]. The observed absolute cross sections are significantly lower than the predictions from theory. Using the full Run-2 dataset of 137 fb^{-1} in $\ell + jets$ data, arranged in four regions according to the top p_T, boosted vs. resolved, and the b-tagging score, CMS measures the single- and double-differential $t\bar{t}$ cross sections [99]. Here also the longitudinal momentum is measured well into the TeV range in one measurement starting in the resolved regime.

61.2.1.3 *$t\bar{t}$ plus heavy flavor production processes*

Further cross-section measurements are performed by ATLAS and CMS for $t\bar{t}$+heavy flavor. The measurement of the cross section for $t\bar{t}$+heavy flavour [148] and $t\bar{t}$+jets production as well as the differential measurement of the jet multiplicity in $t\bar{t}$ events is presented by ATLAS [149] and by CMS [120]. In addition, both experiments measure the production cross section of the $t\bar{t}b\bar{b}$ process as it is an interesting test of QCD due to the different mass scales involved. Furthermore, this process is of high relevance for top quark production as background to searches, for example for measurements of $t\bar{t}h$ production and measurements of 4-top quark production. At $\sqrt{s} = 8$ TeV, CMS measured the cross-section ratio $\sigma_{t\bar{t}b\bar{b}}/\sigma_{t\bar{t}jj}$ using 19.6 fb^{-1} [150]. ATLAS also measured the $t\bar{t}$ production cross section along with the branching ratios into channels with leptons and quarks using 4.6 fb^{-1} of 7 TeV data [151]. They find agreement with the standard model at the level of a few percent.

Using 19.7 fb^{-1} of data recorded at 8 TeV, CMS measures the absolute and normalized differential cross section with respect to the jet multiplicity in $t\bar{t}$+jets events in the dilepton channel. The differential $t\bar{t}b$ and $t\bar{t}b\bar{b}$ cross sections are presented for the first time as a function of the kinematic properties of the leading additional b jets [152].

Using 139 fb^{-1} of $t\bar{t} \to$ dilepton events, ATLAS distinguishes in a dedicated analysis muons originating from $W \to \mu\nu$ decays and those from $W \to \tau\nu \to \mu\nu\nu\nu$ decays via their transverse momentum spectrum and the impact parameter of the muon track, that reflects the tau lifetime, yielding high sensitivity. The measured ratio of $R(\tau/\mu) = 0.992 \pm 0.013$ is in agreement with the hypothesis of universal lepton couplings [153].

Using 36 fb^{-1} of dilepton events at 13 TeV, ATLAS also measures differential cross sections with respect to high-resolution variables, constructed to characterize the longitudinal and transverse momentum distributions of the b-hadron within the b-jets [138]. They are used to test the heavy-quark-fragmentation modelling.

Using 137 fb^{-1} of dilepton events at 13 TeV, CMS measures differential cross sections with respect to the mass of the $t\bar{t}$ system and the rapidity difference of the top-quark and antiquark [154]. Exploiting their sensitivity to the top-quark Yukawa coupling yields a best fit value of $Y_t = 1.16^{+0.24}_{-0.35}$, bounding $Y_t < 1.54$ at a 95% confidence level.

At $\sqrt{s} = 13$ TeV, ATLAS measures the $t\bar{t}b\bar{b}$ cross section and cross section ratios in the dilepton and the $\ell + jets$ channels as inclusive and differential cross sections [155]. The measured inclusive fiducial cross-sections generally exceed the $t\bar{t}b\bar{b}$ predictions from various NLO matrix element calculations matched to a parton shower. CMS measures the $t\bar{t}b\bar{b}$ cross section and cross section ratios in the dilepton channel [156], in the dilepton and the lepton+jets channel [157], in the all-jet channel by selecting events containing at least eight jets, of which at least two are identified as b-jets [158]. In the latter, a combination of multivariate analysis techniques is used to reduce the large background from multijet events not containing a top quark pair, and to help discriminate between jets originating from top quark decays and other additional jets. In the all-hadronic channel, they later measured the $t\bar{t} + b\bar{b}$ cross section to $\approx 25\%$ precision employing a multivariate analysis technique and a 2-dimensional likelihood fit [159]. Using the full Run-2 dataset of 138 fb^{-1}, they measure the inclusive and normalized differential $t\bar{t}b\bar{b}$ cross sections in the lepton+jets decay channel of the top quark [160]. Measurements are made in four fiducial phase space regions, targeting different aspects of the process. Distributions are unfolded to the particle level through

maximum likelihood fits, and compared with predictions from several event generators. In most cases, the measured inclusive cross sections exceed the predictions with the chosen generator settings. The differential cross sections show varying degrees of compatibility with the theoretical predictions.

CMS also measured the $t\bar{t}+c\bar{c}$ cross section using 41.5 fb^{-1} of events with dileptonic final states [161]. A multi-class neural network is employed to separate $t\bar{t}+b\bar{b}$, $t\bar{t}+c\bar{c}$ and $t\bar{t}+ll$. The results are compatible with the prediction within $1-2\,\sigma$.

The production of four top-quarks is an interesting test of QCD in a very rare process and at the same time sensitive to the top quark Yukawa coupling and to production mechanisms with new mediators with strong couplings to top quarks. The latest cross section calculation yields $\sigma_{t\bar{t}t\bar{t}} = 13.32^{+1.04}_{-1.78}$ fb [44]. Using the full Run-II data set of 139 fb^{-1}, ATLAS measures the four-tops cross section in the two-lepton same sign or three-lepton channel with 13% branching ratio and dominant $t\bar{t}V$ background as $\sigma_{t\bar{t}t\bar{t}} = 24^{+7}_{-6}$ fb [162]. Using the same data set in the one-lepton or two-lepton opposite-sign channel with 57% branching ratio and dominant $t\bar{t}$ + heavy flavor background, they measure $\sigma_{t\bar{t}t\bar{t}} = 26^{+17}_{-15}$ fb [163]. The combination yields $\sigma_{t\bar{t}t\bar{t}} = 24^{+7}_{-6}$ fb [163], corresponding to an observed (expected) significance of 4.7 (2.6) σ significance. Using the full Run-2 dataset of 140 fb^{-1}, ATLAS presents the observation of the $t\bar{t}t\bar{t}$ production process in events containing two leptons with the same electric charge or at least three leptons (e or μ). Event kinematics are used to separate signal from background through a multivariate discriminant based on graph neural networks, and dedicated control regions are used to constrain the dominant backgrounds. The cross section is measured to be $\sigma(t\bar{t}t\bar{t}) = 22.5^{+6.6}_{-5.5}$ fb [164], almost twice the Standard Model prediction and compatible with it within 2 standard deviations. The observed (expected) significance of the measured signal with respect to the standard model (SM) background-only hypothesis is 6.1 (4.3) standard deviations. Data are also used to constrain the top-Higgs Yukawa coupling and effective field theory operator coefficients.

After a search for four-top production in 35.8 fb^{-1}, in the one-lepton or two-lepton opposite-sign channel [165], CMS uses the full Run-2 dataset of 137 fb^{-1} to measure the four-top cross section in the two-lepton same sign or three-lepton channel, yielding $\sigma_{t\bar{t}t\bar{t}} = 12.6^{+5.8}_{-5.2}$ fb [166], corresponding to an observed (expected) significance of 2.6 (2.7) σ significance. In the full Run-2 dataset, they manage to achieve evidence for the four-top production in events that have no leptons (all-hadronic), one lepton, or two opposite-sign leptons, yielding $\sigma(t\bar{t}t\bar{t}) = 36^{+12}_{-11}$ fb [167], corresponding to an observed significance of 3.9 standard deviations (1.5 expected). The combination with earlier CMS results in other final states yields $\sigma(t\bar{t}t\bar{t}) = 17 \pm 4(stat.) \pm 3(syst.)$ fb, corresponding to a significance of 4.0 standard deviations (3.2 expected).

Finally, CMS reports the observation of the four-tops production process based on events with two same-sign, three, or four charged leptons (e and μ) and additional jets. Updated identification techniques for charged leptons and jets originating from the hadronization of b quarks, as well as a revised multivariate analysis strategy via a multi-class boosted decision tree to distinguish the signal process from the main backgrounds, lead to an improved signal detection, yielding $\sigma(t\bar{t}t\bar{t}) = 17.7^{+3.7}_{-3.5}(stat.)^{+2.3}_{-1.9}(syst.)$ fb, corresponding to an observed significance of 5.6 standard deviations (4.9 expected) [168].

61.2.1.4 *Single-top production*

Top-quarks cannot only be produced in pairs via the strong interaction, but also individually via the electroweak interaction. This interaction is sensitive to the tWb coupling as well as to the CKM-Matrix Element V_{tb}. The single-top quark production process was first observed in 2009 by DØ [169] and CDF [170,171] at the Tevatron. The production cross section at the Tevatron is roughly half that of the $t\bar{t}$ cross section, but the final state with a single W-boson and typically two jets, which tend to be emitted more in the forward direction, is less distinct than that for $t\bar{t}$ and much more difficult to distinguish from the background of W+jets and other sources. A comprehensive review of the first observation and the techniques used to extract the signal from the backgrounds can be found in [172]. A more recent one can be found in [173].

The dominant production at the Tevatron is through s-channel and t-channel W-boson exchange. Associated production with a W-boson (tW production) has a cross section that is too small to observe at the Tevatron. The t-channel process is $qb \to q't$, while the s-channel process is $q\overline{q'} \to t\bar{b}$. The s- and t-channel productions can be separated kinematically. This is of particular interest because potential physics beyond the Standard Model, such as fourth-generation quarks, heavy W and Z bosons, flavor-changing-neutral-currents [37], or a charged Higgs boson, would affect the s- and t-channels differently. However, the separation is difficult and initial observations and measurements at the Tevatron by both experiments were of combined $s+t$-channel production. The two experiments combined their measurements for maximum precision with a resulting $s+t$-channel production cross section of $2.76^{+0.58}_{-0.47}$ pb [174], which agrees well with the theoretical calculation at $m_t = 173$ GeV/c^2 of $\sigma_{s+t} = 3.12^{+0.00}_{-0.04}(scale) \pm 0.18(pdf)$ pb (including both top and anti-top production) [35,175].

Using the full Run-II data set of up to 9.7 fb^{-1}, CDF and DØ have measured the t-channel single-top quark production to be $\sigma_{t+\bar{t}} = 2.25^{+0.29}_{-0.31}$ pb [176,177]. In the same publication, they also present the simultaneously measured $s-$ and $t-$channel cross sections and the $s+t$ combined cross section measurement resulting in $\sigma_{s+t} = 3.30^{+0.52}_{-0.40}$ pb, without assuming the SM ratio of σ_s/σ_t. The modulus of the CKM matrix element obtained from the $s+t$-channel measurement is $|V_{tb}| = 1.02^{+0.06}_{-0.05}$ and its value is used to set a lower limit of $|V_{tb}| > 0.92$ at 95% C.L. Those results are in good agreement with the theoretical value at the mass 172.5 GeV/c^2 of $\sigma_t = 2.08 \pm 0.13$ pb [175]. It should be noted that the theory citations here list cross sections for t or $\bar{t}$ alone, whereas the experiments measure the sum. At the Tevatron, these cross sections are equal. The theory values quoted here already include this factor of two.

Using datasets of 9.7 fb^{-1} each, CDF and DØ combine their analyses and report the first observation of single-top-quark production in the s-channel, yielding $\sigma_s = 1.29^{+0.26}_{-0.24}$ pb [178]. The probability of observing a statistical fluctuation of the background of the given size is 1.8×10^{-10}, corresponding to a significance of 6.3 standard deviations.

t-channel at the LHC:
At the LHC, the t-channel cross section is expected to be more than three times as large as s-channel and tW production, combined.

At $\sqrt{s} = 5.02$ TeV, very recently, ATLAS measures the t-channel single-top quark production in a dedicated run using 255 pb^{-1}, yielding $\sigma(tq + \bar{t}q) = 27.1^{+4.4}_{-4.1}(stat.)^{+4.4}_{-3.7}(syst.)$ pb and a cross section ratio between top an antitop production $R_t = 2.73^{+1.43}_{-0.82}(stat.)^{+1.01}_{-0.29}(syst.)$ [179]. This result implies for the CKM-matrix element $f_{LV} \cdot |V_{tb}| = 0.94^{+0.11}_{-0.10}$ with f_{LV} being a left-handed form factor.

At $\sqrt{s} = 7$ TeV, using 4.59 fb^{-1} of data, ATLAS measures the t-channel single-top quark cross section in the lepton plus 2 or 3 jets channel with one b-tag by fitting the distribution of a multivariate discriminant constructed with a neural network, yielding $\sigma_t = 46 \pm 6$ pb, $\sigma_{\bar{t}} = 23 \pm 4$ pb with a ratio $R_t = \sigma_t/\sigma_{\bar{t}} = 2.04 \pm 0.18$ and $\sigma_{t+\bar{t}} = 68 \pm 8$ pb, consistent with SM expectations [180,181]. CMS follows two approaches in 1.6 fb^{-1} of lepton plus jets events. The first approach exploits the distributions of the pseudorapidity of the recoil jet and reconstructed top-quark mass using background estimates determined from control samples in data. The second approach is based on multivariate analysis techniques that probe the compatibility of the candidate events with the signal. They find $\sigma^{t-chan.}_{t+\bar{t}} = 67.2 \pm 6.1$ pb, and $|V_{tb}| = 1.020 \pm 0.046(exp.) \pm 0.017(th.)$ [182]. All combined measurements are consistent with their corresponding SM predictions and yield 67.5 ± 5.7 pb [183].

At $\sqrt{s} = 8$ TeV, both experiments repeat and refine their measurements. ATLAS uses 20.2 fb^{-1} of data. Total, fiducial and differential cross-sections are measured for both top-quark and top-antiquark production [184]. An artificial neural network is

employed to separate signal from background. The fiducial cross-section is measured with a precision of 5.8% (top quark) and 7.8% (top antiquark), respectively. The total cross-sections are measured to be $\sigma_t^{t-chan.}(tq) = 56.7^{+4.3}_{-3.8}$ pb for top-quark production and $\sigma_{\bar{t}}^{t-chan.}(\bar{t}q) = 32.9^{+3.0}_{-2.7}$ pb for top-antiquark production, in agreement with the SM prediction. In addition, the ratio of top-quark to top-antiquark production cross-sections is determined to be $R_t = 1.72 \pm 0.09$. The total cross-section is used to extract the Wtb coupling: $f_{LV} \cdot |V_{tb}| = 1.029 \pm 0.048$, which corresponds to $|V_{tb}| > 0.92$ at the 95% confidence level, when assuming $f_{LV} = 1$ and restricting the range of $|V_{tb}|$ to the interval $[0, 1]$. The differential cross-sections as a function of the transverse momentum and rapidity of both, top and antitop, are measured at both the parton and particle levels. The transverse momentum and rapidity differential cross-sections of the accompanying jet from the t-channel scattering are measured at particle level. All measurements are compared to various Monte Carlo predictions as well as to fixed-order QCD calculations where available. The SM predictions provide good descriptions of the data. Using the same dataset, ATLAS probes the Wtb vertex structure from polarization observables in t-channel single-top quark events. The observables are extracted from asymmetries in angular distributions measured with respect to spin quantisation axes appropriately chosen for the top quark and the W-boson and found to be in agreement with the Standard Model predictions [185]. CMS uses 19.7 fb^{-1} in the e or μ plus jets channel, exploiting the pseudorapidity distribution of the recoil jet. They find $\sigma_t = 53.8 \pm 1.5(stat.) \pm 4.4(syst.)$ pb and $\sigma_{\bar{t}} = 27.6 \pm 1.3(stat.) \pm 3.7(syst.)$ pb, resulting in an inclusive t-channel cross section of $\sigma_{t+\bar{t}} = 83.6 \pm 2.3(stat.) \pm 7.4(syst.)$ [186]. They measure a cross section ratio of $R_t = \sigma_t/\sigma_{\bar{t}} = 1.95 \pm 0.10(stat.) \pm 0.19(syst.)$, in agreement with the SM. The CKM matrix element V_{tb} is extracted to be $|V_{tb}| = 0.998 \pm 0.038(exp.) \pm 0.016(th.)$. Later, CMS also provided a fiducial cross section measurement for t-channel single top in the same dataset in events with exactly one μ or e and two jets, one of which is associated with a b-hadron [187]. The total fiducial cross section is measured using different generators at NLO plus parton-shower accuracy. Using as reference the `aMC@NLO` MC predictions in the four-flavor scheme, $\sigma_t^{\text{fid}} = 3.38 \pm 0.25(exp.) \pm 0.20(th.)$ pb is obtained, in good agreement with the theory predictions. All combined measurements are consistent with their corresponding SM predictions and yield 87.7 ± 5.8 pb [183].

At $\sqrt{s} = 13$ TeV, ATLAS uses 3.2 fb^{-1} to measure the t-channel cross section. Using a binned maximum-likelihood fit to the discriminant distribution of a neural network, the cross-sections are determined to be $\sigma_t(tq) = 156 \pm 5(stat.) \pm 27(syst.) \pm 3(lumi.)$ pb and $\sigma(\bar{t}q) = 91 \pm 4(stat.) \pm 18(syst.) \pm 2(lumi.)$ pb [188]. The cross-section ratio is measured to be $R_t = \sigma_t/\sigma_{\bar{t}} = 1.72 \pm 0.09(stat.) \pm 0.18(syst.)$. All results are in agreement with SM predictions. Using the full Run-2 dataset of 140 fb^{-1}, ATLAS measures the t-channel cross sections to be $\sigma(tq) = 137 \pm 8$ pb and $\sigma(\bar{t}q) = 84^{+6}_{-5}$ pb for top-quark and top-antiquark production, respectively [189]. The combined cross-section is found to be $\sigma(tq + \bar{t}q) = 221 \pm 13$ pb and the cross-section ratio is $R_t = \sigma(tq)/\sigma(\bar{t}q) = 1.636^{+0.036}_{-0.034}$, in good agreement with predictions made at NNLO in perturbation theory. The results are also used to demonstrate the potential to constrain parton distributions functions and interpreted in terms of effective field theory operators $-0.25 < C_{qQ}^{(1,3)} < 0.12$, and to derive the constraint $|V_{tb}| > 0.95$ at the 95% confidence level CMS uses 2.2 fb^{-1} for a first measurement. Fits to the transverse W-mass and the output of an artificial neural network allow the determination of the background and the signal contribution. The measured cross-section is $\sigma_t = 238 \pm 13(stat.) \pm 29(syst.)$ pb [190]. The CKM matrix element is determined to $|V_{tb}| = 1.05 \pm 0.07(exp.) \pm 0.02(th.)$. Using 35.9 fb^{-1} of data, CMS refines their measurement. Events with one μ or e are selected, and different categories of jet and b-jet multiplicity and multivariate discriminators are applied to separate the signal from the background, resulting in $\sigma_t(tq) = 130 \pm 1(stat) \pm 19(syst)$ pb and $\sigma_t(\bar{t}q) = 77 \pm 1(stat) \pm 12(syst)$ pb, respectively, and their ratio is $1.68 \pm 0.02(stat) \pm 0.05(syst)$ [191]. The results are in agreement with the predictions from the Standard Model. This dataset is also used to measure differential cross sections in this channel [192]. CMS used the same dataset to measure the CKM matrix elements from their t-channel single-top quark production cross section. In the standard model hypothesis of CKM unitarity, a lower limit of $|V_{tb}| > 0.970$ is measured at the 95% confidence level. Several theories beyond the standard model are considered, and by releasing all constraints among the involved parameters, the values $|V_{tb}| = 0.988 \pm 0.024$, and $|V_{td}|^2 + |V_{ts}|^2 = 0.06 \pm 0.06$ are measured [193].

tW-channel at the LHC:

The predicted cross section for the associated tW process at the LHC at $\sqrt{s} = 7$ TeV is 15.6 ± 1.2 pb [36]. This is of interest because it probes the Wtb vertex in a different kinematic region than s- and t-channel production, and because of its similarity to the associated production of a charged-Higgs boson and a top quark. The signal is difficult to extract because of its similarity to the $t\bar{t}$ signature. Furthermore, it is difficult to uniquely define because at NLO a subset of diagrams has the same final state as $t\bar{t}$ and the two interfere [194]. The cross section is calculated using the *diagram removal* technique [195] to define the signal process. In the diagram removal technique the interfering diagrams are removed, at the amplitude level, from the signal definition (an alternative technique, *diagram subtraction* removes these diagrams at the cross-section level and yields similar results [195]). These techniques work provided the selection cuts are defined such that the interference effects are small, which is usually the case.

At $\sqrt{s} = 7$ TeV, both, ATLAS and CMS, provide evidence for the associated tW production [196, 197]. ATLAS uses 2.05 fb^{-1} in the dilepton plus missing E_T plus jets channel, where a template fit to the final classifier distributions resulting from boosted decision trees as signal to background separation is performed. The result is incompatible with the background-only hypothesis at the 3.3σ (3.4σ expected) level, yielding $\sigma_{tW} = 16.8 \pm 2.9(stat.) \pm 4.9(syst.)$ pb and $|V_{tb}| = 1.03^{+0.16}_{-0.19}$ [196]. CMS uses 4.9 fb^{-1} in the dilepton plus jets channel with at least one b-tag. A multivariate analysis based on kinematic properties is utilized to separate the $t\bar{t}$ background from the signal. The observed signal has a significance of 4.0σ and corresponds to a cross section of $\sigma_{tW} = 16^{+5}_{-4}$ pb [197]. All combined measurements are consistent with their corresponding SM predictions and yield 16.3 ± 4.1 pb [183].

At $\sqrt{s} = 8$ TeV, both experiments repeated their tW-analyses. ATLAS uses 20.3 fb^{-1} to select events with two leptons and one central b-jet. The tW signal is separated from the backgrounds using boosted decision trees, each of which combines a number of discriminating variables into one classifier. Production of tW events is observed with a significance of 7.7σ. The cross section is extracted in a profile likelihood fit to the classifier output distributions. The tW cross section, inclusive of decay modes, is measured to be $\sigma_{tW} = 23.0 \pm 1.3(stat.)^{+3.2}_{-3.5}(syst.) \pm 1.1(lumi.)$ pb, yielding a value for the CKM matrix element $|V_{tb}| = 1.01 \pm 0.10$ and a lower limit of 0.80 at the 95% C.L. [198]. A fiducial cross section is also measured. ATLAS and CMS also combine their early measurements and obtain $\sigma_{tW} = 16.3 \pm 4.1$ pb [199], in agreement with the NLO+NNLL expectation. Later, ATLAS used 20.2 fb^{-1} in the single-lepton channel with at least three jets to measure the Wt production cross section. A neural network is trained to separate the tW signal from the dominant $t\bar{t}$ background. The cross-section is extracted from a binned profile maximum-likelihood fit to a two-dimensional discriminant built from the neural-network output and the invariant mass of the hadronically decaying W boson. The measured cross section is $\sigma_{tW} = 26 \pm 7$ pb [200], in good agreement with the Standard Model expectation. CMS uses 12.2 fb^{-1} in events with two leptons and a jet originating from a b-quark. A multivariate analysis based on kinematic properties is utilized to separate the signal and background. The tW associate production signal is observed at the level of 6.1σ, yielding $\sigma_{tW} = 23.4 \pm 5.4$ pb and $|V_{tb}| = 1.03 \pm 0.12(exp.) \pm 0.04(th.)$ [201].

ATLAS and CMS also combine their early measurements and obtain $\sigma_{tW} = 23.1 \pm 3.6$ pb [183], in agreement with the NLO+NNLL expectation. The product of a form factor with the CKM matrix element V_{tb} is determined to be $|V_{tb}| = 1.02 \pm$

$0.04(meas.) \pm 0.02(theo.) > 0.79$.

At $\sqrt{s} = 13$ TeV, ATLAS uses 3.2 fb^{-1} of events with two opposite sign isolated leptons and at least one jet. They are separated into signal and control regions based on their jet multiplicity and the number of jets with b-tags. Signal is separated from background in two regions using boosted decision trees. The cross section is extracted by fitting templates to the data distributions, and is measured to be $\sigma_{tW} = 94 \pm 10(stat.)^{+28}_{-22}(syst.) \pm 2(lumi.)$ pb [202]. The measurement is in agreement with the SM prediction. CMS uses 36 fb^{-1} of events with two opposite sign isolated leptons, one tight and one loose jet and one b-tag. Signal and background is separated in categories depending on the number of jets and the subset of b-tagged jets using a boosted decision tree. A maximum likelihood fit yields $\sigma_{tW} = 63.1 \pm 1.8(stat.) \pm 6.4(syst.) \pm 2.1(lumi.)$ pb [203]. In this dataset, CMS also analyses the single-lepton channel, where a boosted decision tree is used to separate the tW signal from the dominant $t\bar{t}$ background, whilst the subleading W+jets and multi-jet backgrounds are constrained using data-driven estimates. This result is the first observation of the tW process in final states containing a single μ or single e and several jets, with a significance exceeding 5 standard deviations. The cross section is determined to be $\sigma_{tW} = 89 \pm 4(stat) \pm 12(syst)$ pb [204], consistent with the Standard Model. Using the full Run-2 datset of 138 fb^{-1}, CMS measures the inclusive and normalised differential cross sections. Events containing one e and one μ in the final state are analysed. For the inclusive measurement, a multivariate discriminant, exploiting the kinematic properties of the events is used to separate the signal from the dominant $t\bar{t}$ background. A cross section of $79.2 \pm 0.9(stat)^{+7.7}_{-8.0}(syst) \pm 1.2(lumi)$ pb [205] is obtained, consistent with the predictions of the standard model. For the differential measurements, a fiducial region is defined according to the detector acceptance, and the requirement of exactly one jet coming from the fragmentation of a bottom quark. The resulting distributions are unfolded to particle level and agree with the predictions at NLO in perturbative QCD.

s-channel at the LHC:
At $\sqrt{s} = 7$ TeV, the s-channel production cross section is expected to be 4.6 ± 0.3 pb for $m_t = 173$ GeV/c^2 [35]. At ATLAS, a search for s-channel single top quark production is performed in 0.7 fb^{-1} using events containing one lepton, missing transverse energy and two b-jets. Using a cut-based analysis, an observed (expected) upper limit at 95% C.L. on the s-channel cross-section of $\sigma_s < 26.5$ (20.5) pb is obtained [206].

At $\sqrt{s} = 8$ TeV, ATLAS uses 20.3 fb^{-1} of data with one lepton, large missing transverse momentum and exactly two b-tagged jets. They perform a maximum-likelihood fit of a discriminant based on a Matrix Element Method and optimized in order to separate single top-quark s-channel events from the main background contributions which are $t\bar{t}$ and W+jets production. They find $\sigma_s = 4.8 \pm 0.8(stat.)^{+1.6}_{-1.3}(syst.)$ pb with a signal significance of 3.2 standard deviations [207], which provides first evidence for s-channel single-top production. The signal is extracted through a maximum-likelihood fit to the distribution of a multivariate discriminant defined using boosted decision trees to separate the expected signal contribution from background processes. At 7 TeV and 8 TeV, CMS uses 5.1 fb^{-1} and 19.3 fb^{-1}, respectively, and analyses leptonic decay modes by performing a maximum likelihood fit to a multivariate discriminant defined using a Boosted Decision Tree, yielding cross sections of $\sigma_s = 7.1 \pm 8.1$ pb and $\sigma_s = 13.4 \pm 7.3$ pb, respectively, and a best fit value of 2.0 ± 0.9 for the combined ratio of the measured σ_s values and the ones expected in the Standard Model [208]. The signal significance is 2.5 standard deviations.

ATLAS and CMS present the combinations of their single-top-quark production cross-section measurements, using Run-I data. For the s-channel cross-section, the combination yields 4.9 ± 1.4 pb at $\sqrt{s} = 8$ TeV. All combined measurements are consistent with their corresponding SM predictions [183].

At $\sqrt{s} = 13$ TeV, ATLAS uses 139 fb^{-1} to measure the s-channel cross section on events with an e or μ, missing transverse momentum and exactly two b-tagged jets in the final state. A discriminant based on matrix element calculations is used to separate single-top-quark s-channel events from the main background contributions, which are top-quark pair production and W-boson production in association with jets. The observed (expected) signal significance over the background-only hypothesis is 3.3 (3.9) standard deviations, and the measured cross-section is $\sigma = 8.2^{+3.5}_{-2.9}$ pb, consistent with the Standard Model prediction of $\sigma_{SM} = 10.32^{+0.40}_{-0.36}$ pb [209].

Both, ATLAS and CMS, also measured the electroweak production of single top-quarks in association with a Z-boson, see section 61.2.5.4 of this review.

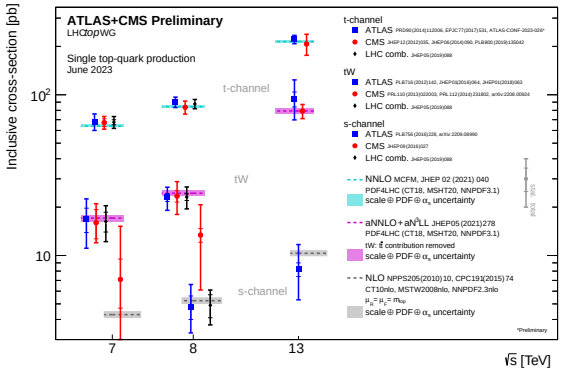

Figure 61.2: Measured and predicted single top production cross sections at LHC energies in pp collisions. The plot is kindly provided by the LHCtopWG working group, status as of June 2023, see `https://twiki.cern.ch/twiki/bin/view/LHCPhysics/LHCTopWGSummaryPlots`.

Fig. 61.2 provides a summary of all single top cross-section measurements at the LHC as a function of the center-of-mass energy. All cross-section measurements are very well described by the theory calculation within their uncertainty.

Thanks to the large statistics now available at the LHC, both CMS and ATLAS experiments also performed differential cross-section measurements in single-top t-channel production [180], [210]. Such measurements are extremely useful as they test our understanding of both QCD and EW top-quark interactions. Using the full Run-2 dataset of 139 fb^{-1}, ATLAS measures the three components of the top-quark and top-antiquark polarisation vectors in t-channel single-top-quark production simultaneously from the distributions of the direction cosines of the charged-lepton momentum in the top-quark rest frame in single-lepton plus jets events. The three components of the polarisation vector for the selected top-quark event sample are $P_{x'} = 0.01 \pm 0.18$, $P_{y'} = -0.029 \pm 0.027$, $P_{z'} = 0.91 \pm 0.10$ and for the top-antiquark event sample they are $P_{x'} = -0.02 \pm 0.20$, $P_{y'} = -0.007 \pm 0.051$, $P_{z'} = -0.79 \pm 0.16$ [211]. They also present normalised differential cross-sections corrected to a fiducial region at the stable-particle level as a function of the charged-lepton angles for top-quark and top-antiquark events inclusively and separately, which are also used to derive bounds on the complex Wilson coefficient of the dimension-six O_{tW} operator.

The CMS collaboration has measured differential single top quark t-channel production cross sections as functions of the transverse momentum and the absolute value of the rapidity of the top quark. The analysis is performed in the leptonic decay channels of the top quark, with either a muon or an electron in the final state, using data collected with the CMS experiment at the LHC at $\sqrt{s} = 8$ TeV and corresponding to an integrated luminosity of 19.7 fb^{-1}. Neural networks are used to discriminate the signal process from the various background contributions. The results are found to agree with predictions from Monte Carlo generators [210]. Using the same data set and under the assumption that the spin analyzing power of a charged lepton is 100% as predicted in the SM, they are also able to measure the spin asymmetry, sensitive to the top quark polarization of the top quark $A_\mu = 0.26 \pm 0.03(stat) \pm 0.10(syst)$ [212], which is compatible with a p-value of 4.6%, equivalent to 2.0 standard deviation. At 13 TeV, using 35.9 fb^{-1}, CMS measures the differential t-channel cross

sections, for the first time in single-top production, and charge ratios for t-channel single top quark production [192]. The results are found to be in agreement with SM predictions using various NLO event generators and sets of parton distribution functions. Additionally, the spin asymmetry, sensitive to the top quark polarization, is determined from the differential distribution of the polarization angle at parton level to be 0.440 ± 0.070, in agreement with the SM prediction. This disfavours the results obtained at 8 TeV. ATLAS has measured the differential tW cross section in 36.1 fb^{-1} at 13 TeV with respect to the energy of the b-jet, the energy of the system of the two leptons and b-jet, and the transverse mass or mass of combinations of leptons, the b-jet and neutrinos [213]. Using 35.9 fb^{-1} of $e\mu$ events, CMS measures the differential tW cross section. A fiducial region is defined according to the detector acceptance, and the requirement of exactly one b-tagged jet. The resulting distributions are unfolded to particle-level and compared with predictions calculated at next-to-leading order in perturbative QCD. Within current uncertainties, all the predictions agree with the data [214].

Further measurements of electroweak single-top quark production in association with addition electroweak gauge bosons such as tZq or $t\gamma q$ production are covered in the section `Top-Quark Electroweak Charges and Couplings`, Sec 61.2.5.4.

61.2.2 *Top-Quark Asymmetries*

A forward-backward asymmetry in $t\bar{t}$ production at a $p\bar{p}$ collider arises starting at order α_S^3 in QCD from the interference between the Born amplitude $q\bar{q} \to t\bar{t}$ with 1-loop box production diagrams and between diagrams with initial- and final-state gluon radiation. The asymmetry, A_{FB}, is defined by

$$A_{FB} = \frac{N(\Delta y > 0) - N(\Delta y < 0)}{N(\Delta y > 0) + N(\Delta y < 0)}, \tag{61.5}$$

where $\Delta y = y_t - y_{\bar{t}}$ is the rapidity difference between the top- and the anti-top quark. Calculations at α_S^3 predict a measurable A_{FB} at the Tevatron. The most recent calculations up to order α_S^4, including electromagnetic and electroweak corrections, yield a predicted asymmetry of $\approx(9.5 \pm 0.7)\%$ [215]. This is about 10% higher than the previous calculation at NLO [216, 217], and improves the agreement with experiment.

Contrary to most measurements in the top sector, many measurements in this section are statistically limited. This is true - by construction - in the measurements in extreme corners of phase space (i.e. boosted measurements) and in rare production processes like ttW and $tt\gamma$. The progress in these measurements is expected to be achieved quite rapidly, as Run-3 athe the LHC and subsequent runs deliver more data.

Both CDF and DØ measured asymmetry values in excess of the SM prediction, fueling speculation about exotic production mechanisms (see, for example, [218] and references therein). The first measurement of this asymmetry by DØ in 0.9 fb^{-1} [219] found an asymmetry at the detector level of $(12 \pm 8)\%$. The first CDF measurement in 1.9 fb^{-1} [220] yielded $(24 \pm 14)\%$ at parton level. Both values were higher, though statistically consistent with the SM expectation. With the addition of more data, the uncertainties have been reduced, and the central values, if somewhat smaller, have remained consistent with the first measurements. At the same time, the improved calculations from theory have increased the predicted asymmetry values, improving the agreement between theory and experiment.

CDF and DØ have combined results using the full Tevatron dataset at $\sqrt{s} = 1.96$ TeV [221]. Three combined asymmetries are reported: $A_{FB}^{t\bar{t}}$ as defined in Eq. 61.5 for fully-reconstructed $t\bar{t}$ events, a single-lepton asymmetry, A_{FB}^{ℓ} defined as in Eq. 61.5 but with Δy replaced by the product of the lepton charge and pseudo-rapidity, and a dilepton asymmetry, $A_{FB}^{\ell\ell}$, defined as in Eq. 61.5 but with Δy replaced by $\Delta\eta$ between the two leptons. The combined results are $A_{FB}^{t\bar{t}} = 0.128 \pm 0.021 \pm 0.014$, $A_{FB}^{\ell} = 0.073 \pm 0.016 \pm 0.012$, and $A_{FB}^{\ell\ell} = 0.108 \pm 0.043 \pm 0.016$, where the first uncertainty is statistical and the second systematic. These are to be compared to SM predictions at NNLO QCD and NLO electroweak of $A_{FB}^{t\bar{t}} = 0.095 \pm 0.007$ [215], $A_{FB}^{\ell} = 0.038 \pm 0.003$, and $A_{FB}^{\ell\ell} = 0.048 \pm 0.004$ [217], respectively. Both experiments have also measured differential asymmetries, in bins of $M_{t\bar{t}}$, Δy, $q_\ell \times \eta_\ell$, and $\Delta\eta_{\ell\ell}$, with consistent results, though the growth of $A_{FB}^{t\bar{t}}$ with increasing $M_{t\bar{t}}$ and Δy appears somewhat more rapid than the SM prediction [221].

At the LHC, where the dominant $t\bar{t}$ production mechanism is the charge-symmetric gluon-gluon fusion, the measurement is more difficult. For the sub-dominant $q\bar{q}$ production mechanism, the symmetric pp collision does not define a forward and backward direction. Instead, the charge asymmetry, A_C, is defined in terms of a positive versus a negative $t - \bar{t}$ rapidity difference, Δy

$$A_C^{t\bar{t}} = \frac{N(\Delta|y| > 0) - N(\Delta|y| < 0)}{N(\Delta|y| > 0) + N(\Delta|y| < 0)}. \tag{61.6}$$

Both CMS and ATLAS have measured A_C in the LHC dataset. Using lepton+jets events in 4.7 fb^{-1} of data at $\sqrt{s} = 7$ TeV, ATLAS measures $A_C^{t\bar{t}} = (0.6 \pm 1.0)\%$ [222]. ATLAS has reported on the same measurement performed at $\sqrt{s} = 8$ TeV with 20.3 fb^{-1} of data, with a result of $A_C^{t\bar{t}} = (0.9 \pm 0.5)\%$ [223]. In the dilepton channel at $\sqrt{s} = 8$ TeV, ATLAS measures [224] $A_C^{t\bar{t}} = (2.1 \pm 1.6)\%$, and $A_C^{\ell\ell} = (0.8 \pm 0.6)\%$ (defined in terms of the $\Delta\eta$ of the two leptons) in agreement with the SM predictions of $(1.11 \pm 0.04)\%$ and $(0.64 \pm 0.03)\%$, respectively [217]. Using lepton+jets events CMS has measured A_C at both $\sqrt{s} = 7$ and 8 TeV. They measure $A_C^{t\bar{t}} = (0.4 \pm 1.5)\%$ and $A_C^{t\bar{t}} = (0.33 \pm 0.26(stat.) \pm 0.33(syst.))\%$ in 5.0 fb^{-1} at $\sqrt{s} = 7$ TeV and in 19.7 fb^{-1} at $\sqrt{s} = 8$ TeV, respectively [225, 226]. Both measurements are consistent with the SM expectations of $A_C^{t\bar{t}} = (1.23 \pm 0.05)\%$ at $\sqrt{s} = 7$ TeV and $(1.11 \pm 0.04)\%$ at $\sqrt{s} = 8$ TeV [217], although the uncertainties are still too large for a precision test. In 19.5 fb^{-1} of dilepton events at $\sqrt{s} = 8$ TeV, CMS measures $A_C^{t\bar{t}} = (1.1 \pm 1.3)\%$ and $A_C^{\ell\ell} = (0.3 \pm 0.7)\%$ [227], consistent with SM expectations [228].

In their 7 and 8 TeV analyses, ATLAS and CMS also provide differential measurements as a function of $M_{t\bar{t}}$ and the transverse momentum p_T and rapidity y of the $t\bar{t}$ system. To reduce model-dependence, the CMS collaboration has performed a measurement in a reduced fiducial phase space [229], with a result of $A_C = (-0.35 \pm 0.72(stat.) \pm 0.31(syst.))\%$, in agreement with SM expectations.

To specifically address the dependence of the asymmetry on $M_{t\bar{t}}$, ATLAS has performed a measurement in boosted $t\bar{t}$ events [230]. In 20.3 fb^{-1} of data at $\sqrt{s} = 8$ TeV, in events with $M_{t\bar{t}} > 0.75$ TeV, and $|(\Delta|y|)| < 2$, ATLAS measures $A_C^{t\bar{t}} = (4.2 \pm 3.2)\%$ compared to a NLO SM prediction of $(1.60 \pm 0.04)\%$. The measurement is also presented in three bins of $M_{t\bar{t}}$, each in agreement, though with large uncertainties, with the SM expectations.

Both ATLAS and CMS have measured asymmetries in the distribution of leptons from $t\bar{t}$ decays. ATLAS, in 4.6 fb^{-1} of $\sqrt{s} = 7$ TeV data, has measured $A^{\ell\ell} = (2.4 \pm 1.5(\text{stat.}) \pm 0.9(\text{sys.}))\%$ in dilepton events [231]. Using a neutrino weighting technique in the same dataset to reconstruct the top quarks, ATLAS measures $A_C = (2.1 \pm 2.5\ (\text{stat.}) \pm 1.7\ (\text{sys.}))\%$. CMS, in 5.0 fb^{-1} of $\sqrt{s} = 7$ TeV data, uses dilepton events to measure $A_C = (1.0 \pm 1.5\ (\text{stat.}) \pm 0.6\ (\text{sys.}))\%$, where a matrix weighting technique is used to reconstruct the top quarks, and $A^{\ell\ell} = (0.9 \pm 1.0\ (\text{stat.}) \pm 0.6\ (\text{sys.}))\%$ [232]. An earlier result using lepton+jets events from the same CMS dataset found $A_C = (0.4 \pm 1.0 \pm 1.1)\%$ [225]. Combined results from ATLAS and CMS have now been released [233]. At $\sqrt{s} = 7$ TeV the combined result is $A_C = (0.5 \pm 0.7\ (\text{stat.}) \pm 0.6\ (\text{sys.}))\%$, and at $\sqrt{s} = 8$ TeV it is $A_C = (0.55 \pm 0.23 \pm 0.25)\%$. These results are all consistent, within their large uncertainties, with the SM expectations of $A^{\ell\ell} = (0.70 \pm 0.03)\%$ and $A_C = (1.23 \pm 0.05)\%$ [217].

ATLAS has released a charge asymmetry measurement at $\sqrt{s} = 13$ TeV using the full 139 fb^{-1} dataset, which combines data in the single-lepton and dilepton channels, and employs reconstruction techniques adapted to both the resolved and boosted topologies. A Bayesian unfolding procedure is performed to correct for detector resolution and acceptance effects. The combined inclusive $t\bar{t}$ charge asymmetry is measured to be $A_{t\bar{t}}^C = 0.0068 \pm 0.0015$,

which differs from zero by 4.7 standard deviations. Differential measurements are performed as a function of the invariant mass, transverse momentum and longitudinal boost of the $t\bar{t}$ system. Both the inclusive and differential measurements are found to be compatible with the Standard Model predictions, at NLO in QCD with NLO electroweak corrections [234]. The measurements are interpreted in the framework of the Standard Model effective field theory, placing competitive bounds on several Wilson coefficients.

A model-independent comparison of the Tevatron and LHC results is made difficult by the differing $t\bar{t}$ production mechanisms at work at the two accelerators and by the symmetric nature of the pp collisions at the LHC. A recent result from the CMS Collaboration [235] in 35.9 fb^{-1} of lepton plus jets events at $\sqrt{s} = 13$ TeV, uses a likelihood analysis to separate the $q\bar{q}$ process from production via gluon-gluon and gluon-quark interactions and extract $A_{FB} = (4.8^{+8.8}_{-8.4}\ (\text{stat.}) \pm 2.8\ (\text{sys.}))\%$. In addition, given a particular model of BSM physics, a comparison can be obtained through the resulting asymmetry predicted by the model at the two machines, see for example [230].

Using 139 fb^{-1} of data at 13 TeV in the lepton plus jets channel, ATLAS presents a measurement of the charge asymmetry in $t\bar{t}$ production in association with a photon. While the $t\bar{t}$ asymmetry is diluted in inclusive measurements at the LHC owing to the large fraction of gluon–gluon-initiated $t\bar{t}$ events, it is enhanced in other topologies such as $t\bar{t}\gamma$ due to an increased fraction of the quark initiated production mode. The charge asymmetry is obtained from the distribution of the difference of the absolute rapidities of the top quark and antiquark using a profile likelihood unfolding approach. It is measured to be $A_C = -0.003 \pm 0.029$ in agreement with the Standard Model expectation [236], where the precision is limited by the presently available statistics.

In a similar fashion and using the same dataset, ATLAS also searches for the leptonic charge asymmetry (A_C^{ℓ}) of $t\bar{t}$ pair production in association with a W boson ($t\bar{t}W$) in event final states with exactly three charged light leptons (electrons or muons). Here, the events are also enhanced in quark-initiated production processes. Additionally, the W boson in the initial state causes polarisation of the $t\bar{t}$ pair, which further leads to a sizeable asymmetry. A profile-likelihood fit to the event yields in multiple regions corresponding to positive and negative differences between the pseudorapidities of the charged leptons from top-quark and top-antiquark decays is used to extract the charge asymmetry. At reconstruction level, the asymmetry is found to be $-0.12 \pm 0.14(stat.) \pm 0.05(syst.)$. An unfolding procedure is applied to convert the result at reconstruction level into a charge-asymmetry value in a fiducial volume at particle level with the result of $-0.11 \pm 0.17(stat.) \pm 0.05(syst.)$. The Standard Model expectations for these two observables are calculated using Monte Carlo simulations with NLO plus parton shower precision in QCD and including NLO electroweak corrections. They are $0.084^{+0.005}_{-0.003}(scale) \pm 0.006(MCstat.)$ and $0.063^{+0.007}_{-0.004}(scale) \pm 0.004(MCstat.)$, respectively, and in agreement with the measurements [237].

ATLAS explores a so-called 'energy asymmetry' in $t\bar{t}$ production in association with a high-p_T jet ($t\bar{t}j$ production). The energy asymmetry is defined as a difference between the top and anti-top quarks' energies, and is measured in ATLAS in three bins of the associated high-p_T jet angle, θ_j. Both, the energies and jet angle, are measured in the $t\bar{t}j$ rest frame. A Bayesian unfolding method corrects for resolution and acceptance effects. The measurement is in agreement with the Standard Model at NLO accuracy [238].

In an early analysis of the Run-2 data, CMS analyzed 35.9 fb^{-1} of 13 TeV data, in particular using $t\bar{t}$ events decaying to muon or electron and jets in final states with low and high Lorentz boosts. Events are reconstructed using a fit of the kinematic distributions of the decay products to those expected for $t\bar{t}$ final states. The values found for the asymmetry parameters are $A_{FB} = 0.048^{+0.095}_{-0.087}(stat)^{+0.020}_{-0.029}(syst)$, for the anomalous chromomagnetic dipole moment $\mu^t = -0.024^{+0.013}_{-0.009}(stat)^{+0.016}_{-0.011}(syst)$, and a limit is placed on the magnitude of a possible anomalous chromoelectric dipole moment $|d^t| < 0.03$ at 95% confidence level [239].

The measurement of the charge asymmetry in $t\bar{t}$ events with highly Lorentz-boosted top quarks decaying to a single, nonisolated lepton and overlapping jets is presented by CMS using the complete Run-2 dataset of 138 fb^{-1} of 13 TeV data. The top quark charge asymmetry is measured for events with a $t\bar{t}$ invariant mass larger than 750 GeV, most relevant for BSM searches, and corrected for detector and acceptance effects using a binned maximum likelihood fit. The measured top quark charge asymmetry of $(0.69^{+0.65}_{-0.69})\%$ is in good agreement with the standard model prediction at NNLO in QCD with NLO electroweak corrections. The result is also presented for two invariant mass ranges, 750 – 900 and $>$ 900 GeV [240].

61.2.3 *Top Quark Spin Correlations, Polarization, and Entanglement*

One of the unique features of the top quark is that it decays before its spin can be flipped by chromomagnetic interactions. Thus the top quark polarization is directly observable via the angular distribution of its decay products and it is possible to define and measure observables sensitive to the top quark spin and its production mechanism. Although the top- and antitop-quarks produced by strong interactions in hadron collisions are essentially unpolarized, the spins of t and $\bar{t}$ are correlated. For QCD production at threshold, the $t\bar{t}$ system is produced in a $^3S_1$ state with parallel spins for $q\bar{q}$ annihilation or in a $^1S_0$ state with antiparallel spins for gluon-gluon fusion. The situations at the Tevatron, where the production is primarily from $q\bar{q}$ annihilation, and at the LHC, where the production is primarily from gluon-gluon fusion, are therefore somewhat complementary. However, at the LHC production of $t\bar{t}$ pairs at large invariant mass occurs primarily via fusion of gluons with opposite helicities, and the $t\bar{t}$ pairs so produced have parallel spins as in production at the Tevatron via $q\bar{q}$ annihilation. The direction of the top quark spin is 100% correlated to the angular distributions of the down-type fermion (charged leptons or d-type quarks) in the decay. The joint angular distribution [241–243]

$$\frac{1}{\sigma}\frac{d^2\sigma}{d(\cos\theta_+)d(\cos\theta_-)} = \frac{1}{4}(1 + B_+\cos\theta_+ + B_-\cos\theta_- + \kappa\cdot\cos\theta_+\cdot\cos\theta_-), \tag{61.7}$$

where θ_+ and θ_- are the angles of the daughters in the top-quark rest frame with respect to a particular spin quantization axis (assumed here to be the same for θ_+ and θ_-), is a very sensitive observable. The maximum value for κ, 0.782 at NLO at the Tevatron [244], is found in the off-diagonal basis [241], while at the LHC the value at NLO is 0.326 in the helicity basis [244]. The coefficients B_+ and B_- are near zero in the SM because the top quarks are unpolarized in $t\bar{t}$ production. In place of κ, $A\alpha_+\alpha_-$ is often used, where α_i is the spin analyzing power, and A is the spin correlation coefficient, defined as

$$A = \frac{N(\uparrow\uparrow) + N(\downarrow\downarrow) - N(\uparrow\downarrow) - N(\downarrow\uparrow)}{N(\uparrow\uparrow) + N(\downarrow\downarrow) + N(\uparrow\downarrow) + N(\downarrow\uparrow)}, \tag{61.8}$$

where the first arrow represents the direction of the top quark spin along a chosen quantization axis, and the second arrow represents the same for the antitop-quark. The spin analyzing power α_i is +0.998 for positively charged leptons, -0.966 for down-type quarks from W decays, and -0.393 for bottom quarks [245]. The sign of α flips for the respective antiparticles. The spin correlation could be modified by a new $t\bar{t}$ production mechanism such as through a Z' boson, Kaluza-Klein gluons, a dark-matter mediator, or a Higgs boson.

The experiments typically use a Monte Carlo to provide templates for the measured distributions, or alternatively a matrix-element technique, and fit a parameter f, representing the fraction of events with the expected Standard Model correlation, with $(1-f)$ the fraction with no correlation. The correlation coefficient is extracted via $A_{\text{meas}} = f \cdot A_{\text{SM}}$. A 'fraction' $f > 1$ means that the measured correlation coefficient is larger than the Standard Model expectation.

For a more complete introduction and discussion of the spin density matrix, see reference [246].

CDF and DØ have studied spin correlations in $t\bar{t}$ production in the dilepton and lepton+jets channel with limited sensitivity, showing first evidence (see the PDG listings for details).

Spin correlations have been conclusively measured at the LHC by both the ATLAS and CMS collaborations. In the dominant gluon fusion production mode for $t\bar{t}$ pairs at the LHC, the angular distribution between the two leptons in $t\bar{t}$ decays to dileptons is sensitive to the degree of spin correlation [247].

Measurements have been made at 7, 8, and now 13 TeV. While there is some interest in the $\sqrt{s}$ dependence of the correlations as a test of the production mechanism ($q\bar{q}$ vs gluon-gluon and possible sensitivity to new physics) the earlier measurements at 7 and 8 TeV [248–253] had relatively large uncertainties and have now been overtaken by the high-statistics 13 TeV measurements, which we review here.

In an ATLAS measurement at $\sqrt{s} = 8$ TeV [254], the spin-correlation coefficient κ is measured in the helicity basis to be $\kappa = 0.296 \pm 0.093$ in good agreement with the SM expectation of 0.318 (corresponding to a central value of f of 0.931). The polarization coefficients, B, in Eq. 61.7 are measured, also in the helicity basis, to be $B_+ = -0.044 \pm 0.038$ and $B_- = -0.064 \pm 0.040$, consistent with the SM predictions of 0.0030 ± 0.0010 and 0.0034 ± 0.00104, respectively.

The most recent result from ATLAS, in 36.1 fb^{-1} at $\sqrt{s} = 13$ TeV, uses $\Delta\phi$, the azimuthal angle between the two charged leptons in $e\mu$ events in an analysis that also measures the differential cross sections in $\Delta\phi$ and $\Delta\eta$ between the two leptons [255]. The result, measured by comparison with NLO Monte Carlo generators, is $f = 1.249 \pm 0.024 \pm 0.061^{+0.067}_{-0.090}$, where the uncertainties are statistical, systematic, and theoretical, is again greater than 1.0. Whereas the previous results were statistically consistent with the Standard Model expectation of 1.0, this result is slightly higher than the expectation and hence inconsistent at the level of 2.2σ. The NLO generators are NLO in QCD only (and only at the production level). Including electroweak couplings produces an expected Standard Model distribution consistent with the data, but results in a large scale uncertainty, giving $f = 1.03 \pm 0.13$.

In 35.9 fb^{-1} of data at $\sqrt{s} = 13$ TeV, CMS has studied spin correlations in dilepton events via the measurement of parton-level normalized differential cross sections, sensitive to each of the independent coefficients of the spin-dependent parts of the $t\bar{t}$ production density matrix. The measured distributions and extracted coefficients are compared with standard model predictions from simulations at NLO accuracy in QCD, and from NLO QCD calculations including electroweak corrections. The normalized differential cross sections are used in fits to constrain the anomalous chromomagnetic and chromoelectric dipole moments of the top $-0.24 < C_{tG}/\Lambda^2 < 0.07$ TeV^{-2} and $-0.33 < C^I_{tG}/\Lambda^2 < 0.20$ TeV^{-2}, respectively, at 95% confidence level [256]. These results are part of a complete study of the top quark spin density matrix at $\sqrt{s} = 13$ TeV, through the measurement of the coefficients of Eq. 61.7.

Entanglement is a striking feature of quantum mechanics [257–259]. If two particles are entangled, the state of one particle cannot be described independently from the other. More precisely, an entangled state is one that cannot be written as a convex combination of product states of density matrices [260, 261]. It has been observed in a wide variety of systems, ranging from the microscopic to the macroscopic scale. However, up to now entanglement has remained largely unexplored at high-energy colliders, except for flavor entanglement in $\Upsilon(4S) \to B_0\bar{B}_0$ decays [262] and a study of Bell inequality violation in $B_0 \to J/\Psi K^*(892)^0$ decays [263]. Entanglement in top quark pairs has now been proposed to be studied for the first time via their spin correlation [264–271].

At the LHC, $t\bar{t}$ pairs are produced mainly via gluon-gluon fusion. When they are produced close to their production threshold, that is, when their invariant mass ($m_{t\bar{t}}$) is close to twice the mass of the top quark ($m_{t\bar{t}} \approx 2 \cdot m_t \approx 350$ GeV), they exist nearly in a spin singlet state, which is therefore expected to be maximally entangled. After averaging over all possible top-quark directions, entanglement only survives at threshold because there the $t\bar{t}$ pairs are produced in a spin singlet, which is rotationally invariant. The rotational invariance of a spin singlet implies that the trace of the spin correlation matrix C is a good entanglement witness. It is an observable that can signal the presence of entanglement without any assumption on the particular form of the quantum state, with $tr[C] + 1 < 0$ as a sufficient condition for entanglement. It is more convenient to define an entanglement witness using

$$D = tr[C]/3, \tag{61.9}$$

which can be experimentally measured as:

$$D = -3 \cdot \langle \cos\phi \rangle, \tag{61.10}$$

where $\langle \cos\phi \rangle$ is the average of the angle between the charged lepton directions in each one of the parent top quark and antitop quark rest frames which can be experimentally measured from an ensemble dataset. The existence of an entangled state is demonstrated if the measurement satisfies $D < -1/3$.

Using 139 fb^{-1} of Run-2 data, recorded at 13 TeV, ATLAS reports the highest-energy observation of entanglement so far in top–antitop quark events produced at the Large Hadron Collider. Spin entanglement is now detected from the measurement of a single observable D, inferred by the angle between the charged leptons in their parent top- and antitop-quark rest frames. The observable is measured on a narrow interval around the $t\bar{t}$ production threshold, where the entanglement detection is expected to be significant. The entanglement observable is measured in a fiducial phase-space with stable particles. The entanglement witness is measured to be $D = -0.547 \pm 0.002(stat.) \pm 0.021(syst.)$ for $340 < m_{t\bar{t}} < 380$ GeV [272]. The large spread in predictions from several mainstream event generators indicates that modelling this property is challenging. The predictions depend in particular on the parton-shower algorithm used. The observed result is more than five standard deviations from a scenario without entanglement and hence constitutes the first observation of entanglement in a pair of quarks, and the observation of entanglement at the highest energy to date.

61.2.4 *W-Boson Helicity in Top-Quark Decay*

The Standard Model dictates that the top quark has the same vector-minus-axial-vector ($V - A$) charged-current weak interactions $\left(-i\frac{g}{\sqrt{2}}V_{tb}\gamma^\mu\frac{1}{2}(1-\gamma_5)\right)$ as all the other fermions. In the SM, the fraction of top-quark decays to longitudinally polarized W bosons is proportional to its Yukawa coupling and hence enhanced with respect to the weak coupling. It is expected to be [273] $\mathcal{F}_0^{\rm SM} \approx x/(1+x)$, $x = m_t^2/2M_W^2$ ($\mathcal{F}_0^{\rm SM} \sim 70\%$ for $m_t = 173$ GeV/c^2). Fractions of left-handed, right-handed, or longitudinal W bosons are denoted as $\mathcal{F}_-$, $\mathcal{F}_+$, and $\mathcal{F}_0$ respectively. In the SM, $\mathcal{F}_-$ is expected to be $\approx 30\%$ and $\mathcal{F}_+ \approx 0\%$. Predictions for the W polarization fractions at NNLO in QCD are available [274].

The Tevatron and the LHC experiments use various techniques to measure the helicity of the W boson in top-quark decays, in both the lepton+jets and in dilepton channels in $t\bar{t}$ production.

The first method uses a kinematic fit, similar to that used in the lepton+jets mass analyses, but with the top-quark mass constrained to a fixed value, to improve the reconstruction of final-state observables, and render the under-constrained dilepton channel solvable. Alternatively, in the dilepton channel the final-state momenta can also be obtained through an algebraic solution of the kinematics. The distribution of the helicity angle ($\cos\theta^*$) between the lepton and the b quark in the W rest frame provides the most direct measure of the W helicity. In a simplified version of this approach, the $\cos\theta^*$ distribution is reduced to a forward-backward asymmetry.

The second method (p_T^ℓ) uses the different lepton p_T spectra from longitudinally or transversely polarized W-decays to determine the relative contributions.

A third method uses the invariant mass of the lepton and the b-quark in top-quark decays ($M^2_{\ell b}$) as an observable, which is directly related to $\cos\theta^*$.

At the LHC, top-quark pairs in the dilepton channels are reconstructed using the neutrino weighting technique, see section 61.2.5.1.

Finally, the Matrix Element Method (MEM) has also been used [275], in which a likelihood is formed from a product of event probabilities calculated from the MEM for a given set of measured kinematic variables and assumed W-helicity fractions.

The results of recent CDF, DØ, ATLAS, and CMS analyses are summarized in Table 61.2. The datasets are now large enough to allow for a simultaneous fit of $\mathcal{F}_0$, $\mathcal{F}_-$ and $\mathcal{F}_+$, which we denote by '3-param' or $\mathcal{F}_0$ and $\mathcal{F}_+$, which we denote by '2-param' in the table. Results with either $\mathcal{F}_0$ or $\mathcal{F}_+$ fixed at its SM value are denoted '1-param'. For the simultaneous fits, the correlation coefficient between the two values is about -0.8. A complete set of published results can be found in the Listings. All results are in agreement with the SM expectation.

CDF and DØ combined their results based on $2.7 - 5.4$ fb^{-1} [276] for a top-quark mass of 172.5 GeV/c^2. ATLAS presents results from 1.04 fb^{-1} of $\sqrt{s} = 7$ TeV data using a template method for the $\cos\theta^*$ distribution and angular asymmetries from the unfolded $\cos\theta^*$ distribution in the lepton+jets and the dilepton channel [277]. CMS performs a similar measurement based on template fits to the $\cos\theta^*$ distribution with 5.0 fb^{-1} of 7 TeV data in the lepton+jets final state [278]. As the polarization of the W bosons in top-quark decays is sensitive to the Wtb vertex Lorentz structure and anomalous couplings, both experiments also derive limits on anomalous contributions to the Wtb couplings. CMS and ATLAS collaborations have also combined their results from 7 TeV data to obtain values on the helicity fractions as well as limits on anomalous couplings [279].

At 8 TeV, ATLAS came out with a measurement of the W-helicity fractions in 20.2 fb^{-1} in lepton+jets events with at least one b-tag [280]. Using 19.8 fb^{-1} of 8 TeV data, CMS measured the W-helicity in lepton + 4 jet events with two b-tags [281] as well as in events with two opposite-sign leptons (electron or muon) in the final state, applying six kinematic constraints on the kinematics of the produced particles [282]. Also, using the same dataset, a first measurement of the W-boson helicity in top-quark decays was made in electroweak single top production [283], yielding similarly precise and consistent results. The 8 TeV results obtained in $t\bar{t}$ and single-top events by ATLAS and CMS have also been combined recently [284]. These results are in agreement with the standard model predictions at next-to-next-to-leading order in perturbative QCD and represent an improvement in precision of 25 (29)% for F_0 (F_L) with respect to the most precise single measurement. A limit on anomalous right-handed vector (V_R), and left- and right-handed tensor (g_L, g_R) tWb couplings and on corresponding Wilson coefficients is set.

Recently, ATLAS used 139 fb^{-1} of data recorded at 13 TeV in dilepton events with at least two b-tags to measure the normalised differential $t\bar{t}$ cross section with respect to $\cos\theta^*$ at parton level and from that, based on template fits, extract the helicity fractions. The results are complementary to previous results and compatible with Standard Model expectations [285].

61.2.5 *Top-Quark Properties*

61.2.5.1 *Top-Quark Mass Measurements*

The most precisely studied property of the top quark is its mass. The top-quark mass has been measured in the lepton+jets, the dilepton, and the all-jets channel by all four Tevatron and LHC experiments, and now in single-top events at the LHC. The latest and/or most precise results are summarized in Table 61.3. The lepton+jets channel yields the most precise single measurements because of good signal to background ratio (in particular after b-tagging) and the presence of only a single neutrino in the final state. The momentum of a single neutrino can be reconstructed (up to a quadratic ambiguity) via the missing E_T measurement and the constraint that the lepton and neutrino momenta reconstruct to the known W boson mass. In the large data samples available at the LHC, measurements in the dilepton channel can be competitive and certainly complementary to those in the lepton+jets final state.

A large number of techniques have now been applied to measuring the top-quark mass. The original 'template method' [286], in which Monte Carlo templates of reconstructed mass distributions are fit to data, has evolved into a precision tool in the lepton+jets channel, where the systematic uncertainty due to the jet energy scale (JES) uncertainty is controlled by a simultaneous, *in situ* fit to the $W \to jj$ hypothesis [287]. All the latest measurements in the lepton+jets and the all-jets channels use this technique in one way or another. In 20.2 fb^{-1} of data at $\sqrt{s} = 8$ TeV in the lepton+jets channel, ATLAS achieves a total uncertainty of 0.53% with a statistical component of 0.23% [288]. The measurement is based on a 3-dimensional template fit, determining the top-quark mass, the global jet energy scale and a b-to-light jet energy scale factor. The most precise CMS result in the lepton+jets channel uses an ideogram method and comes from a so-called 'hybrid' approach in which the prior knowledge about the jet energy scale is incorporated as a Gaussian constraint, with a width determined by the uncertainty on the jet energy corrections. In 19.7 fb^{-1} of $\sqrt{s} = 8$ TeV data, CMS achieves a total uncertainty of 0.30% with a statistical component of 0.09% with the hybrid approach [289]. Using this same method, CMS has released a top-mass measurement from $\sqrt{s} = 13$ TeV data. Using 35.9 fb^{-1} of lepton+jets events they measure the top mass with a precision of 0.36%, with a statistical component of 0.05% [290]. The measurements at $\sqrt{s} = 13$ TeV include, for the first time, an uncertainty due to 'color reconnection' [291, 292]. In this same dataset, CMS has extracted a top mass from highly boosted top-quark decays by selecting events in which the hadronic-side top decay is reconstructed as a single jet with $P_T > 400$ GeV. The cross section as a function of jet mass is unfolded at the particle level to extract a top mass with a precision of 1.4% [293].

The template method is complemented by the 'matrix element' method. This method was first applied by the DØ Collaboration [294], and is similar to a technique originally suggested by Kondo *et al.* [275] and Dalitz and Goldstein [295]. In the matrix element method a probability for each event is calculated as a function of the top-quark mass, using a LO matrix element for the production and decay of $t\bar{t}$ pairs. The *in situ* calibration of dijet pairs to the $W \to jj$ hypothesis is now also used with the matrix element technique to constrain the jet energy scale uncertainty. In the lepton+jets channel, DØ uses the full Tevatron dataset of 9.7 fb^{-1} and yields an uncertainty of about 0.43% [296].

In the dilepton channel, the signal to background is typically very good, but reconstruction of the mass is non-trivial because there are two neutrinos in the final state, yielding a kinematically unconstrained system. A variety of techniques have been developed to handle this. An analytic solution to the problem has been proposed [297], but this has not yet been used in the mass measurement. One of the most precise measurements in the dilepton channel comes from using the invariant mass of the charged lepton and b-quark system ($M_{\ell b}$), which is sensitive to the top-quark mass and avoids the kinematic difficulties of the two-neutrino final state. In 4.6 fb^{-1} of $\sqrt{s} = 7$ TeV data, ATLAS has measured the top-quark mass in the dilepton channel to a precision of 0.53% using a template fit to the $M_{\ell b}$ distribution [298]. Using 19.7 fb^{-1} of data at $\sqrt{s} = 8$ TeV, CMS has released [299] a mass measurement in the dilepton channel based on a simultaneous fit to $M_{\ell b}$ and a transverse-mass-like variable M_{T2} [300]. The most precise result in this analysis, which comes from a linear combination of fits with the jet energy scale fixed at its nominal value and one that simultaneously determines the top mass and jet energy scale, has a total uncertainty of 0.54%. At the LHC, because of their precision, these techniques have largely displaced a number of earlier techniques in the dilepton channel, though these techniques are still included, and described, in the combined results from CMS, reported in Ref. [289].

In the neutrino weighting technique, used by CDF to analyze the full Run 2 dilepton dataset of 9.1 fb^{-1}, a weight is assigned by assuming a top-quark mass value and applying energy-momentum conservation to the top-quark decay, resulting in up to four possible pairs of solutions for the neutrino and anti-neutrino momenta. The missing E_T calculated in this way is then compared to the observed missing E_T to assign a weight [305]. The CDF result achieves a precision of 1.8% using a combination of neutrino weighting and an "alternative mass", which is insensitive to the jet energy scale [306]. The alternative mass depends on the angles between the leptons and the leading jets and the lepton four-momenta.

Table 61.2: Measurement and 95% C.L. upper limits of the W helicity in top-quark decays. The table includes both preliminary, as of September 2023, and published results. A full set of published results, including the results obtained at the Tevaton, is given in the Listings.

W Helicity	Source	$\int \mathcal{L}$dt (fb^{-1})	Ref.	Method

In the all-jets channel there is no ambiguity due to neutrino momenta, but the signal to background is significantly poorer due to the severe QCD multijets background. The emphasis therefore has been on background modeling, and reduction through event selection. The most recent measurement in the all-jets channel, by CMS in 35.9 fb^{-1} of $\sqrt{s} = 13$ TeV data [301], uses an ideogram method and a 2-dimensional simultaneous fit for m_t and the jet energy scale to extract the top-quark mass and achieves a precision of 0.36%. A measurement from ATLAS [302] uses a template fit to the ratio of three-jet (m_t) to two-jet (M_W) mass in the all-hadronic channel, the two-jet denominator provides an *in situ*, fit to the $W \to jj$ hypothesis. In 20.2 fb^{-1} of data at $\sqrt{s} = 8$ TeV, the result has a precision of 0.65%. A measurement from CDF in 9.3 fb^{-1} uses a two-dimensional template fit and achieves a precision of 1.1% [307].

The CMS Collaboration extracted a top-quark mass measurement from single-top events, something not previously done because of the poor signal to background ratio. The mass is extracted from the invariant mass of the muon, bottom quark, and missing transverse energy. The first measurement with 19.7 fb^{-1} of data at $\sqrt{s} = 8$ TeV, achieved a precision of 0.71% [308]. A more recent measurement in 35.9 fb^{-1} of data at $\sqrt{s} = 13$ TeV achieves 0.44% precision [303].

A dominant systematic uncertainty in these methods is the understanding of the jet energy scale, and so several techniques have been developed that have little sensitivity to the jet energy scale uncertainty. In addition to Reference [306] mentioned above, these include the measurement of the top-quark mass using the following techniques: Fitting of the lepton p_T spectrum of candidate events [309]; fitting of the transverse decay length of the b-jet (L_{xy}) [310]; fitting the invariant mass of a lepton from the W-decay and a muon from the semileptonic b decay [311, 312], kinematic properties of secondary vertices from b-quark fragmentation [313], the invariant mass of the $J/\psi + \ell$ system in events in which a b-quark fragments to a J/ψ particle [314], fitting the b-jet energy peak [315], and dilepton kinematics in $e\mu$ events [316].

Several measurements have now been made in which the top-quark mass is extracted from the measured $t\bar{t}$ cross section using the theoretical relationship between the mass and the production cross section. These determinations make use of predictions calculated at higher orders, where the top mass enters as an input parameter defined in a given scheme. At variance with the usual methods, which involve the kinematic properties of the final states and therefore the pole mass, this approach can also directly determine a short-distance mass, such as the $\overline{\text{MS}}$ mass [317]. With an alternative method ATLAS extracted the top-quark pole mass using $t\bar{t}$ events with at least one additional jet, basing the measurement on the relationship between the differential rate of gluon radiation and the mass of the quark [318]. A similar analysis by CMS used the differential cross section as a function of the invariant mass of the $t\bar{t}$ system and the leading jet not associated with the top decays [319].

Each of the experiments has produced a measurement combining its various results. The combined measurement from CMS with up to 19.7 fb^{-1} of data achieves statistical and systematic uncertainties of 0.08% and 0.27%, respectively [289]. The combined measurement from ATLAS, with up to 20.3 fb^{-1} yields statistical and systematic uncertainties of 0.14% and 0.24%, re-

spectively [288]. CDF has combined measurements with up to 9.3 fb^{-1} [320] and achieves a statistical precision of 0.33% and a systematic uncertainty of 0.43%. DØ achieves a 0.33% statistical+JES and a 0.28% systematic uncertainty by combining results in 9.7 fb^{-1} [321].

Combined measurements from the Tevatron experiments and from the LHC experiments take into account the correlations between different measurements from a single experiment and between measurements from different experiments. The Tevatron average [304], using up to 9.7 fb^{-1} of data, now has a precision of 0.37%. The LHC combination, using up to 4.9 fb^{-1} of data, has a precision of 0.56% [322], where more work on systematic uncertainties is required. A Tevatron-LHC combination has been released, combining the results of all four experiments, using the full Tevatron dataset and the $\sqrt{s} = 7$ TeV LHC data, with a resulting precision of 0.44% [29]. Recently, ATLAS and CMS have released a combinations of fifteen individual top quark mass measurements in semi-leptonic and hadronic decays of the top quark, and a measurement using events enriched in single top quark production via the electroweak t-channel. The data sets used correspond to an integrated luminosity of up to 5 and 20 fb^{-1}, recorded at 7 and 8 TeV, respectively, yielding a precision of 0.33 GeV (0.2%) [1].

The direct measurements of the top-quark mass, such as those shown in Table 61.3, correspond to the parameter used in the Monte Carlo generators, which is closely related to the pole mass [8]. The relation between the pole mass and short-distance masses, such as $\overline{\rm MS}$, is affected by non-perturbative effects. Recent calculations evaluate the size of this ambiguity to be below 250 MeV and therefore still smaller than the current measurement uncertainty [323, 324]. ATLAS has recently performed a 'calibration' of the top mass parameter in POWHEG + PYTHIA 8 with respect to the so-called 'MSR' mass scheme [325]. Using simulated lepton+jets events and the mass distribution of large-radius jets containing the three quarks from the hadronically decaying top quark, they find a mass difference between the Monte Carlo mass and the MSR mass of 80 MeV with large uncertainties [326].

As a result of renormalization at higher-orders in perturbation theory, the top quark mass depends on the scale at which it is evaluated. The CMS collaboration has made the first measurement of the so-called running of the top-quark mass in the $\overline{\rm MS}$ scheme [327]. The running mass is extracted from a measurement of the differential cross section as a function of the $t\bar{t}$ invariant mass, unfolded back to the parton level, in $e\mu$ final states. The running mass varies by about 15% from $M_{t\bar{t}} = 400$ GeV to $M_{t\bar{t}} \approx 1$ TeV, in good agreement with the renormalization group calculation at one-loop level. Compared to the hypothesis of no running, the significance of the measured running is 2.6σ. However, caveats of such an interpretation have been raised as a result of the large theoretical uncertainties [328].

With the discovery of a Higgs boson at the LHC with a mass of about 125 GeV/c^2 [329, 330], the precision measurement of the top-quark mass takes a central role in the question of the stability of the electroweak vacuum because top-quark radiative corrections tend to drive the Higgs quartic coupling, λ, negative, potentially leading to an unstable vacuum. A calculation at NNLO [2] leads to the conclusion of vacuum stability for a Higgs mass satisfying $M_H \geq 129.4 \pm 5.6$ GeV/c^2 [331]. Given the uncertainty, a Higgs mass of 125 GeV/c^2 satisfies the limit, but the central values of the Higgs and top-quark masses put the electroweak vacuum squarely in the metastable region. The uncertainty is dominated by the precision of the top-quark mass measurement and its interpretation as the pole mass. For more details, see the Higgs boson review in this volume.

As a test of the CPT-symmetry, the mass difference of top- and antitop-quarks $\Delta m_t = m_t - m_{\bar{t}}$, which is expected to be zero, can be measured. CDF measures the mass difference in 8.7 fb^{-1} of 1.96 TeV data in the lepton+jets channel using a template methode to find $\Delta m_t = -1.95 \pm 1.11(stat.) \pm 0.59(syst.)$ GeV/c^2 [332] while DØ uses 3.6 fb^{-1} of lepton+jets events and the matrix element method with at least one b-tag. They find $\Delta m_t = 0.8 \pm 1.8(stat.) \pm 0.5(syst.)$ GeV/c^2 [333]. In 4.7 fb^{-1} of 7 TeV data, ATLAS measures the mass difference in lepton+jets events with a double b-tag requirement and hence very low background to find $\Delta m_t = 0.67 \pm 0.61(stat.) \pm 0.41(syst.)$ GeV/c^2 [334]. CMS measures the top-quark mass difference in 5 fb^{-1} of 7 TeV data in the lepton+jets channel and finds $\Delta m_t = -0.44 \pm 0.46(stat.) \pm 0.27(syst.)$ GeV/c^2 [335]. They repeat this measurement with 19.6 fb^{-1} of 8 TeV data to find $\Delta m_t = -0.15 \pm 0.19(stat.) \pm 0.09(syst.)$ GeV/c^2 [336]. Now that the top mass has been measured in single-top events, the mass difference can be measured by tagging the top- or anti-top quark with the lepton charge. In 35.9 fb^{-1} of 13 TeV single-top candidate events CMS measures the mass ratio and difference to be $0.995^{+0.005}_{-0.006}$ and $0.83^{+0.77}_{-1.01}$ GeV, respectively [303]. All measurements are consistent with the SM expectation.

61.2.5.2 *Width*

Observation of top-quark spin correlations requires a top-quark lifetime less than the spin decorrelation timescale [337]. The top-quark width, inversely proportional to its lifetime, is expected to be of order 1 GeV/c^2 (Eq. 1). Early measurements made at CDF [338] and CMS [339] established confidence-level intervals for the width, but did not have the sensitivity to make a direct measurement.

The first direct measurement comes from an ATLAS analysis that directly fits reconstructed lepton+jets events in 20.2 fb^{-1} of data at $\sqrt{s} = 8$ TeV. They find $\Gamma_t = 1.76 \pm 0.33^{+0.79}_{-0.68}$ GeV/c^2 [340]. A more recent measurement from ATLAS with 139 fb^{-1} of data at $\sqrt{s} = 13$ TeV [341], uses a template fit to the lepton-b-quark invariant mass in dilepton final states. The result, $\Gamma_t = (1.9 \pm 0.5)$ GeV/c^2, is the most precise measurement to date.

The total width of the top-quark can also be determined from the partial decay width $\Gamma(t \to Wb)$ and the branching fraction $B(t \to Wb)$. DØ obtains $\Gamma(t \to Wb)$ from the measured t-channel cross section for single top-quark production in 5.4 fb^{-1}, and $B(t \to Wb)$ is extracted from a measurement of the ratio $R = B(t \to Wb)/B(t \to Wq)$ in $t\bar{t}$ events in lepton+jets channels with 0, 1 and 2 b-tags. Assuming $B(t \to Wq) = 1$, where q includes any kinematically accessible quark, the result is: $\Gamma_t = 2.00^{+0.47}_{-0.43}$ GeV/c^2 which translates to a top-quark lifetime of $\tau_t = (3.29^{+0.90}_{-0.63}) \times 10^{-25}$ s. Assuming a high mass fourth generation b' quark and unitarity of the four-generation quark-mixing matrix, they set the first upper limit on $|V_{tb'}| < 0.59$ at 95% C.L. [342]. A similar analysis has performed by CMS in 19.7 fb^{-1} of $\sqrt{s} = 8$ TeV data. It provides a better determination of the total width with respect to the measurement by DØ giving $\Gamma_t = 1.36 \pm 0.02(stat.)^{+0.14}_{-0.11}(syst.)$ GeV/c^2 [110].

61.2.5.3 *Yukawa coupling*

The top-Higgs Yukawa coupling is expected to be the largest among all Yukawa couplings. It can be accessed directly by measurements of the $t\bar{t}$ cross section in association with a Higgs boson, $t\bar{t}h$, or indirectly via loop processes in $h \to \gamma\gamma$ or $h \to WW$ decays or in the rare process of $t\bar{t}t\bar{t}$ production. A discussion of the former can be found in this review, See Sec. 11.3.3 of "Status of Higgs Boson Physics", in this Review. Searches for and recently the observation of $t\bar{t}t\bar{t}$ production is discussed in 61.2.1.3.

61.2.5.4 *Top-Quark Electroweak Charges and Couplings*

The top quark is the only quark whose electric charge has not been measured through production at threshold in e^+e^- collisions. Furthermore, it is the only quark whose electromagnetic coupling has not been observed and studied until recently. Since the CDF and DØ analyses on top-quark production did not associate the b, $\bar{b}$, and $W^{\pm}$ uniquely to the top or antitop, decays such as $t \to W^+\bar{b}, \bar{t} \to W^-b$ were not excluded. A charge 4/3 quark of this kind is consistent with current electroweak precision data. The $Z \to \ell^+\ell^-$ and $Z \to b\bar{b}$ data, in particular the discrepancy between A_{LR} from SLC at SLAC and $A_{FB}^{0,b}$ of b-quarks and $A_{FB}^{0,\ell}$ of leptons from LEP at CERN, can be fitted with a top quark of mass $m_t = 270$ GeV/c^2, provided that the right-handed b quark mixes with the isospin +1/2 component of an exotic doublet of charge −1/3 and −4/3 quarks, $(Q_1, Q_4)_R$ [343, 344]. Also the third component of the top quark's weak isospin has not been measured so far.

DØ studied the top-quark charge in double-tagged lepton+jets

events, CDF did it in single tagged lepton+jets and dilepton events. Assuming the top- and antitop-quarks have equal but opposite electric charge, then reconstructing the charge of the b-quark through jet charge discrimination techniques, the $|Q_{top}| = 4/3$ and $|Q_{top}| = 2/3$ scenarios can be differentiated. For the exotic model of Chang *et al.* [344] with a top-quark charge $|Q_{top}| = 4/3$, CDF excluded the model at 99% C.L. [345] in 5.6 fb^{-1}, while DØ excluded the model at a significance greater than 5 standard deviations using 5.3 fb^{-1} and set an upper limit of 0.46 on the fraction of such quarks in the selected sample [346]. These results indicate that the observed particle is indeed consistent with being a SM $|Q| = 2/3$ quark.

In 2.05 fb^{-1} at $\sqrt{s} = 7$ TeV, ATLAS performed a similar analysis, reconstructing the b-quark charge either via a jet-charge technique or via the lepton charge in soft muon decays in combination with a kinematic likelihood fit. They measure the top-quark charge to be $0.64 \pm 0.02(stat.) \pm 0.08(syst.)$ from the charges of the top-quark decay products in single lepton $t\bar{t}$ events, and hence exclude the exotic scenario with charge $-4/3$ at more than 8σ [347].

In 4.6 fb^{-1} at $\sqrt{s} = 7$ TeV, CMS discriminates between the SM and the exotic top-quark charge scenario in the muon+jets final states in $t\bar{t}$ events. They exploit the charge correlation between high-p_t muons from W-boson decays and soft muons from B-hadron decays in b-jets. Using an asymmetry technique, where $A = -1$ represents the exotic $Q = -4/3$ scenario and $A = +1$ the SM $Q = +2/3$ scenario, they find $A_{meas} = 0.97 \pm 0.12(stat.) \pm 0.31(sys.)$, which agrees with the Standard Model expectation and excludes the exotic scenario at 99.9% C.L. [348].

$t\bar{t}\gamma$ production:
The electromagnetic or the weak coupling of the top quark can be probed directly by investigating $t\bar{t}$ events with an additional gauge boson, such as $t\bar{t}\gamma$, $t\bar{t}W$, and $t\bar{t}Z$ events. The corresponding coupling can be extracted from the corresponding cross section, cross section ratios with respect to the $t\bar{t}$ cross section or extracted from effective field theory (EFT) fits to various measured distributions and differential cross sections.

CDF performed a first search for $t\bar{t}\gamma$ producton in events containing a lepton, a photon, significant missing transverse momentum, and a jet identified as containing a b-quark and at least three jets and large total transverse energy in 6.0 fb^{-1}. They reported evidence for the observation of $t\bar{t}\gamma$ production with a cross section $\sigma_{t\bar{t}\gamma} = 0.18 \pm 0.08$ pb and a ratio of $\sigma_{t\bar{t}\gamma}/\sigma_{t\bar{t}} = 0.024 \pm 0.009$ [349].

ATLAS performed a first measurement of the $t\bar{t}\gamma$ cross section in pp collisions at $\sqrt{s} = 7$ TeV using 4.6 fb^{-1} of data. Events are selected that contain a large transverse momentum electron or muon and a large transverse momentum photon. The production of $t\bar{t}\gamma$ events was observed with a significance of 5.3 standard deviations. The resulting cross section times branching ratio into the single lepton channel for $t\bar{t}\gamma$ production with a photon with transverse momentum above 20 GeV is $\sigma^{fid.}(t\bar{t}\gamma) \times BR = 63 \pm 8(stat.)^{+17}_{-13}(syst.) \pm 1(lumi.)$ pb per lepton flavor [350], which is consistent with leading-order theoretical calculations.

At 8 TeV, ATLAS has used 20.2 fb^{-1} of data to measure the $t\bar{t}\gamma$ cross section with a photon above 15 GeV and $|\eta| < 2.37$. The fiducial cross section is measured to be 139 ± 18 fb [351], in good agreement with the NLO prediction [352]. Using 19.7 fb^{-1} of data at 8 TeV, CMS performed a similar measurement of the $t\bar{t}\gamma$ production cross section in the lepton+jets decay mode with a photon transverse momentum above 25 GeV and $|\eta| < 1.44$. They obtain a normalized cross section $\mathcal{R} = \sigma_{t\bar{t}+\gamma}/\sigma_{t\bar{t}} = (5.7 \pm 1.8) \times 10^{-4}$ in e+jets and $(4.7 \pm 1.3) \times 10^{-4}$ in μ+jets. The fiducial $t\bar{t}\gamma$ cross section is obtained by multiplying by the measured $t\bar{t}$ fiducial cross section of $244.9 \pm 1.4(stat.)^{+6.3}_{-5.5}(sys.) \pm 6.4(lumi.)$ pb. Extrapolating to the full phase space, the result is $\sigma_{t\bar{t}\gamma} \times \mathrm{BR} = (515 \pm 108)$ fb, per lepton+jets final state [353], in good agreement with the theoretical prediction.

At $\sqrt{s} = 13$ TeV, using 36.1 fb^{-1} of single-lepton and dilepton events with exactly one photon, ATLAS measures the $t\bar{t}\gamma$ cross section. They employ neural network algorithms to separate the signal from the backgrounds. The fiducial cross-sections are measured to be $521 \pm 9(stat.) \pm 41(sys.)$ fb and $69 \pm 3(stat.) \pm 4(sys.)$ fb for the single-lepton and dilepton channels, respectively. The differential cross-sections are measured as a function of photon transverse momentum, photon absolute pseudorapidity, and angular distance between the photon and its closest lepton in both channels, as well as azimuthal opening angle and absolute pseudorapidity difference between the two leptons in the dilepton channel. All measurements are in agreement with the theoretical predictions [354].

ATLAS uses 139 fb^{-1} of $\sqrt{s} = 13$ TeV $e\mu + \gamma$ events with at least two jets, out of which at least one is b-tagged, to measure the inclusive and differential cross-sections for the production of a top-quark pair in association with a photon. This analysis is sensitive to both processes, $t\bar{t}\gamma + tW\gamma$. The fiducial cross-section is measured to be $39.6^{+2.7}_{-2.3}$ fb in good agreement with the dedicated theoretical calculation provided by the authors of refs. [355, 356], which predicts a value of $\sigma_{fid} = 38.50^{+0.56}_{-2.18}$ (scale)$^{+1.04}_{-1.18}$ (PDF) fb for the chosen fiducial phase space. Differential cross-sections as functions of several observables are compared to state-of-the-art Monte Carlo simulations and NLO theoretical calculations. These include cross-sections as functions of the photon transverse momentum and absolute pseudorapidity and angular variables related to the photon and the leptons and between the two leptons in the event. All measurements are in agreement with the predictions [357].

Recently, CMS used 137 fb^{-1} of data to measure the $t\bar{t}\gamma$ cross section. In the lepton-plus-jets channel, they perform measurements in a fiducial volume defined at the particle level. Events with an isolated, highly energetic lepton, at least three jets from the hadronization of quarks, among which at least one is b-tagged, and one isolated photon are selected. The inclusive fiducial $t\bar{t}\gamma$ cross section, for a photon with transverse momentum greater than 20 GeV and pseudorapidity $|\eta| < 1.4442$, is measured to be $\sigma_{t\bar{t}\gamma} = 798 \pm 7(stat) \pm 48(syst)$ fb, in good agreement with the prediction from the standard model at NLO in QCD [358]. The differential cross sections are also measured as a function of several kinematic observables such as the transverse momentum of the photon, its rapidity, or the opening angle between the photon and the lepton. The measurements on detector-level are also interpreted in terms of limits on the Wilson coefficients in the context of the standard model effective field theory. The confidence intervals for the Wilson coefficients c_{tZ} and c^I_{tZ} are the most stringent to date. Using the same dataset, in the dilepton channel, an inclusive cross section of $174.4 \pm 2.5(stat) \pm 6.1(syst)$ fb is measured in a signal region with at least one b-tagged jet and exactly one photon with transverse momentum above 20 GeV [359]. In the same analysis, differential cross sections are measured as a function of several kinematic observables of the photon, leptons, and jet, and compared to standard model predictions. Combinations of the measurements in the l+jets and the dilepton channels are also interpreted in the standard model effective field theory framework, yielding the most stringent limits for the Wilson coefficients c_{tZ} and c^I_{tZ} to date.

$tq\gamma$ production:
Using the full Run-2 data set of 139 fb^{-1} at 13 TeV, ATLAS observes the production of single top quark together with a photon. The analysis uses the presence of a forward jet, characteristic of t-channel production, and separates the signal from the background with neural networks. Requiring a photon with transverse momentum larger than 20 GeV and within the detector acceptance, the fiducial cross section is measured to be $688 \pm 23(stat.)^{+75}_{-71}(syst.)$ fb, to be compared with the Standard Model prediction of 515^{+36}_{-42} fb at NLO in QCD [360]. In 35.9 fb^{-1} of lepton-plus-photon-plus-jets events, CMS manages to establish the first evidence for the associated production of a single-top quark and a photon at $\sqrt{s} = 13$ TeV. They employ a multivariate discriminant based on topological and kinematic event properties to separate signal from background processes. An excess above the background-only hypothesis is observed, with a significance of 4.4 standard deviations. A fiducial cross section is measured for isolated photons with transverse momentum greater than 25 GeV in the central region of the detector. The measured product of the cross section and branching fraction is $\sigma(pp \to t\gamma j)B(t \to \mu\gamma b) = 115 \pm 17(stat) \pm 30(syst)$ fb, which is consistent with the SM prediction [361]. A precision test of the vector and axial vector couplings in $t\bar{t}\gamma$ events or searches for

possible tensor couplings of top-quarks to photons will only be feasible with an integrated luminosity of several hundred fb^{-1} in the future [362].

$t\bar{t}Z$ and $t\bar{t}W$ production:
ATLAS and CMS have also studied the associate production of top-antitop quark pairs along with an electroweak gauge boson, $t\bar{t}W$ or $t\bar{t}Z$, where in the Standard Model the W-boson is expected to be produced via initial state radiation, while the Z-boson can also be radiated from a final-state top-quark and hence provides sensitivity to the top-quark neutral current weak gauge coupling, which implies a sensitivity to the third component of the top-quark's weak isospin, which has not been measured so far.

CMS performed measurements of the $t\bar{t}W$ and $t\bar{t}Z$ cross section at $\sqrt{s} = 7$ TeV with 5 fb^{-1}, yielding $\sigma_{t\bar{t}V} = 0.43^{+0.17}_{-0.15}(stat.)^{+0.09}_{-0.07}(syst.)$ pb ($V = Z, W$) and $\sigma_{t\bar{t}Z} = 0.28^{+0.14}_{-0.11}(stat.)^{+0.06}_{-0.03}(syst.)$ fb, at about 3 standard deviations significance [363] and compatible with the SM expectations of $0.306^{+0.031}_{-0.053}$ pb and $0.137^{+0.012}_{-0.016}$ pb, respectively [364, 365]. ATLAS performed a similar analysis with 4.7 fb^{-1} in the three-lepton channel and set an upper limit of 0.71 pb at 95% C.L. [366].

Using 20.3 fb^{-1} of 8 TeV data, ATLAS performs a simultaneous measurement of the $t\bar{t}W$ and $t\bar{t}Z$ cross section. They observe the $t\bar{t}W$ and $t\bar{t}Z$ production at the 5.0σ and 4.2σ level, respectively, yielding $\sigma_{t\bar{t}W} = 369^{+100}_{-91}$ fb and $\sigma_{t\bar{t}Z} = 176^{+58}_{-52}$ fb [367]. CMS performs an analysis where signal events are identified by matching reconstructed objects in the detector to specific final state particles from $t\bar{t}W$ and $t\bar{t}Z$ decays using 19.5 fb^{-1} of 8 TeV data. They obtain $\sigma_{t\bar{t}W} = 382^{+117}_{-102}$ fb and $\sigma_{t\bar{t}Z} = 242^{+65}_{-55}$ fb, yielding a significance of 4.8 and 6.4 standard deviation, respectively [368]. These measurements are used to set bounds on five anomalous dimension-six operators that would affect the $t\bar{t}W$ and $t\bar{t}Z$ cross sections.

The most recent measurements in these channels are made at 13 TeV from ATLAS and CMS in multilepton final states. ATLAS made a measurement using 36.1 fb^{-1} of events with two, three or four leptons. In multiple regions, the $t\bar{t}Z$ and $t\bar{t}W$ cross sections are simultaneously measured using a combined fit to all regions, yielding $\sigma_{t\bar{t}Z} = 0.95 \pm 0.08(stat) \pm 0.10(syst)$ pb and $\sigma_{t\bar{t}W} = 0.87 \pm 0.13(stat) \pm 0.14(syst)$ pb [369] to be compared with the NLO+NLL (QCD) and NLO (EW) SM predictions, $\sigma_{t\bar{t}W} = 579^{+14\%}_{-9\%}$ fb and $\sigma_{t\bar{t}Z} = 811^{+11\%}_{-10\%}$ fb [43]. Recently, ATLAS uses 139 fb^{-1} in three and four lepton events to measure the inclusive and differential $t\bar{t}Z$ cross section. The inclusive cross section is measured to be $\sigma_{t\bar{t}Z} = 0.99 \pm 0.05(stat.) \pm 0.08(syst.)$ pb [370], in agreement with the most precise theoretical predictions. The differential measurements are presented as a function of a number of kinematic variables which probe the kinematics of the $t\bar{t}Z$ system. Overall, good agreement is observed between the unfolded data and the predictions. Using the same dataset of 140 fb^{-1}, ATLAS performs an improved measurement in both, the inclusive and differential $t\bar{t}Z$ production cross sections. Final states with two, three and four isolated leptons (electrons or muons) are targeted. The inclusive cross section is measured to be $\sigma_{t\bar{t}Z} = 0.86 \pm 0.04(stat.) \pm 0.04(syst.)$ pb and found to be in agreement with the most advanced Standard Model predictions [371]. The improvement with respect to the previous measurement using the same dataset is mainly in a better machine learning-based separation of signal and background, the addition of a 2-lepton signal region, and better modelling. The differential measurements are presented as a function of a number of observables that probe the kinematics of the $t\bar{t}Z$ system. Both absolute and normalised differential cross section measurements are performed at particle- and parton-level for specific fiducial volumes, and are compared with theoretical predictions at NLO+NNLL. The results are interpreted in the framework of the Standard Model Effective Field Theory and used to set limits on a large number of dimension-6 operators involving the top quark. CMS uses 35.9 fb^{-1} of $\sqrt{s} =$ 13 TeV data to measure $\sigma_{t\bar{t}W} = 0.77^{+0.12}_{-0.11}(stat.)^{+0.13}_{-0.12}(syst.)$ pb and $\sigma_{t\bar{t}Z} = 0.99^{+0.09}_{-0.08}(stat.)^{+0.12}_{-0.10}(syst.)$ pb production cross sections, and significances over the background-only hypotheses of 5.5σ and 9.5σ, respectively [372], firmly establishing the observation of these processes. CMS measured the inclusive $t\bar{t}Z$ cross section in 77.5 fb^{-1} of events with three or four charged leptons, and the Z boson is detected through its decay to an oppositely charged lepton pair. The production cross section is measured to be $\sigma(t\bar{t}Z) = 0.95 \pm 0.05(stat) \pm 0.06(syst)$ pb. This measurement includes differential cross sections as functions of the transverse momentum of the Z boson and the angular distribution of the negatively charged lepton from the Z boson decay, which characterise the $t\bar{t}Z$ process in detail for the first time, as well as stringent direct limits on the anomalous tZ couplings [373]. Very recently, using the complete Run-2 dataset of 138 fb^{-1}, CMS searches for signs of new physics, interpreted in effective field theory, in $t\bar{t}$ events produced in association with a Lorentz-boosted Z or Higgs boson [374]. Selected events contain a single lepton and hadronic jets, including two identified with the decay of bottom quarks, plus an additional large-radius jet with high transverse momentum identified as a Z or Higgs boson decaying to a bottom quark pair. Machine learning techniques are employed to discriminate between $t\bar{t}Z$ or $t\bar{t}H$ events and events from background processes, which are dominated by $t\bar{t}$+jets production. No indications of new physics are observed. The signal strengths of boosted $t\bar{t}Z$ and $t\bar{t}H$ production are measured, and upper limits are placed on the $t\bar{t}Z$ and $t\bar{t}H$ differential cross sections as functions of the Z or Higgs boson transverse momentum, expressed as limits on eight possible dimension-six operators.

Recently, CMS measured the $t\bar{t}W$ cross section in 138 fb^{-1} at 13 TeV in events with two or three leptons (electrons and muons) and additional jets. In events with two leptons, a multiclass neural network is used to distinguish between the signal and background processes. Events with three leptons are categorized based on the number of jets and of jets originating from b quark hadronization, and the lepton charges. The inclusive $t\bar{t}W$ production cross section in the full phase space is measured to be $868 \pm 40(stat) \pm 51(syst)$ fb. The $t\bar{t}W^+$ and $t\bar{t}W^-$ cross sections are also measured as $553 \pm 30(stat) \pm 30(syst)$ fb and $343 \pm 26(stat) \pm 25(syst)$ fb, respectively, and the corresponding ratio of the two cross sections is found to be $1.61 \pm 0.15(stat)^{+0.07}_{-0.05}(syst)$ [375]. The measured cross sections are larger than but consistent with the standard model predictions within two standard deviations. Also ATLAS presents both, the inclusive and differential cross-sections of $t\bar{t}W$ production in 140 fb^{-1} of 13 TeV data using final states with two same-sign or three isolated leptons (electrons or muons). The inclusive production cross-section is measured to be 890 ± 80 fb, which turns out a bit high compared to the new reference theoretical prediction at NNLO in QCD of $745.3 \pm 49.9(scale) \pm 13.4(PDF)$ fb [46]. Differential cross-section measurements characterise this process in detail for the first time. Several particle-level observables are compared to a variety of theoretical predictions which are generally in good agreement with the normalised differential cross-section results [376]. They also measure the $t\bar{t}W^+$ and $t\bar{t}W^-$ cross section individually, yielding a ratio of $R = 1.95^{+0.21}_{-0.18}(stat.)^{+0.16}_{-0.13}(syst.)$.

single-top + W/Z production:
The electroweak couplings can also be probed in single-top production in association with a Z boson. The $pp \to tZq$ process at the LHC probes both the WWZ coupling in the case where the Z emerges from the t-channel W in single-top production and, in the case where the Z is radiated from the top quark, the tZ coupling. A CMS search at 8 TeV using 19.7 fb^{-1} produced a hint of a tZq signal in tri-lepton events, with a significance compared to the background-only hypothesis of 2.4σ [377]. Very recently, CMS and ATLAS collaborations used 139 fb^{-1} at 13 TeV in three-lepton events to measure $tZ(\to \ell^+\ell^-)q$. CMS obtains $\sigma_{tZq} = 87.9^{+7.5}_{-7.3}(stat)^{+7.3}_{-6.0}(syst)$ fb for $m(\ell\ell) > 30$ GeV [378], following the evidence [361] of the observation of the process [379]. The ratio between the cross sections for the top quark and the top antiquark production in association with a Z boson is measured as $2.37^{+0.56}_{-0.42}(stat)^{+0.27}_{-0.13}(syst)$. Differential measurements at parton and particle levels are performed for the first time. Additionally, the spin asymmetry, which is sensitive to the top quark polarization, is determined from the differential distribution of the polarization angle at parton level to be $0.58^{+0.15}_{-0.16}$ (stat) $\pm$ 0.06 (syst), in agreement with SM predictions at next-to-leading order. Using neural networks, ATLAS improves the background rejection and extracts the signal. The measured cross-section for

$m(\ell\ell) > 30$ GeV is $97 \pm 13(stat.) \pm 7(syst.)$ fb, consistent with the Standard Model prediction [380].

tWZ production:
Using 138 fb^{-1} at 13 TeV, CMS presents the first evidence for the standard model production of a top quark in association with a W and a Z boson in multilepton final states. The Z boson is reconstructed via its decays to electron or muon pairs. The measured cross section amounts to $0.37 \pm 0.05(stat) \pm 0.10(syst)$ pb, and corresponds to an observed (expected) significance of 3.5 (1.4) standard deviations [381].

Searches for and now also measurements of the associate production of a top-antitop quark pair along with a Higgs boson, $t\bar{t}h$, with various subsequent decays provide sensitivity to the top-Higgs Yukawa coupling. For further details, see the review on "Status of Higgs boson physics".

61.2.6 *New Physics*

The top quark plays a special role in the SM. Being the only quark with a coupling to the Higgs boson of order one, it provides the most important contributions to the quadratic radiative corrections to the Higgs mass exposing the issue of the naturalness of the SM. It is therefore very common for models where the naturalness problem is addressed to have new physics associated with the top quark. In SUSY, for instance, naturalness predicts the scalar top partners to be the lightest among the squarks and to be accessible at the LHC energies (see the review "Supersymmetry: Theory"). In models where the Higgs is a pseudo-Goldstone boson, such as Little Higgs models, naturalness predicts the existence of partners of the top quarks with the same spin and color, but with different electroweak couplings, the so-called vectorial t'. Stops and t''s are expected to have sizeable branching ratios to top quarks. Another intriguing prediction of SUSY models with universal couplings at the unification scale is that for a top-quark mass close to the measured value, the running of the Yukawa coupling down to 1 TeV naturally leads to the radiative breaking of the electroweak symmetry [382]. In fact, the top quark plays a role in the dynamics of electroweak symmetry breaking in many models [383]. One example is topcolor [384], where a large top-quark mass can be generated through the formation of a dynamic $t\bar{t}$ condensate, X, which is formed by a new strong gauge force coupling preferentially to the third generation. Another example is topcolor-assisted technicolor [385], predicting the existence of a heavy Z' boson that couples preferentially to the third generation of quarks. If light enough such a state might be directly accessible at the present hadron collider energies, or if too heavy, lead to four-top interactions possibly visible in the $t\bar{t}t\bar{t}$ final state. This final state has been observed by CMS [168] and by ATLAS [164].

61.2.6.1 *Direct Searches for Physics Beyond the Standard Model*

In this section we review the latest direct searches for Physics Beyond the Standard Model (PBSM) in top-quark production and decay. These direct search come in two categories: $t\bar{t}$ resonance searches and searches for rare non-SM interactions involving top quarks, including Flavor-Changing-Neutral-Current (FCNC) searches. Top-sector resonance searches come in two categories, $t\bar{t}$ resonances in which a presumed heavy particle X decays into a $t\bar{t}$ pair, and searches in which a non-SM decay product of the top quark is observed via its resonant decay. The most recent results are of the latter category. We refer the reader to Refs. [393–395] for $X \to t\bar{t}$ searches. Searches for rare non-SM interactions and FCNC final states are interpreted using the EFT approach described in Section 61.1.1.2. In this section we focus on the branching-ratio limits from these searches, while the EFT interpretations are cited in Section 61.2.6.4.

61.2.6.2 *FCNC and Rare non-SM Interaction Searches*

The most recent FCNC searches target a $t \to qH$ decay in $t\bar{t}$ production, or an FCNC vertex in single-top production together with a Higgs boson. The ATLAS search in Ref. [386] looks for $H \to \tau\tau$ in both cases. A small, 2.3σ excess of events is observed and limits on $t \to qH$ branching ratios are set. The most recent CMS result uses Higgs decays to vector bosons in addition to $\tau\tau$. That result is combined with results from Refs. [396] and [397] that use the $b\bar{b}$ and $\gamma\gamma$ decay channels of the Higgs [387]. Table 61.4 shows the most recent independent limits for $q = u$ or $q = c$ and assume the other branching ratio is zero. Other results can be found in the Listings.

Searches targeting tZq couplings use leptonic decays of the Z-boson and a trilepton final state. In $t\bar{t}$ events, the signal occurs through the FCNC decay $t \to Zq$, in single-top the signal occurs through the associated production of a top quark and a Z-boson. The branching-ratio limits shown in Table 61.4 are for tZu and tZc left-handed couplings and assume, for tZu, that the tZc coupling is zero and vice versa. Reference [388] also presents limits for right-handed couplings, which are close to the values quoted in Table 61.4 for left-handed couplings

Searches targeting $t\gamma q$ couplings focus on a high-P_T photon in the final state. As with tZq couplings, signal events occur through top-quark decay in $t\bar{t}$ and through associated production of a top quark and a photon in single-top events. In Ref. [389] limits are found for the EFT couplings shown in Table 61.7, and the limits shown in Table 61.4 are derived from the limits on the WCs. The table shows the limits assuming a left-handed coupling. Limits on right-handed couplings are also give in Ref. [389] and are only slightly weaker than those determined for left-handed couplings.

tion. The couplings increase the single-top production cross section and, in the case of the tgc coupling, also affect the rapidity distribution of the produced top quark because of the different PDFs for valence and sea quarks.

CMS searches for charged-lepton-flavor-violating interactions in both production, $q \to e\mu t$, and decay, $t \to e\mu q$, with $q = u$ or c [391]. The branching ratio limits set are included in Table 61.4 and the Wilson coefficients constrained are listed in Table 61.6.

ATLAS has searched for charged-lepton-flavor-violating $\mu\tau\ qt$ interactions which are sensitive to the two-quark-two-lepton operators of Table 61.1 [392]. The branching ratio limit set is included in Table 61.4 and the Wilson coefficients constrained are listed in Table 61.6.

61.2.6.3 *Resonance Searches*

While technically an FCNC search, a decay of the type $t \to qX$ where $q = u$ or c, could be missed when X is not the expected quark or boson. ATLAS has searched for $t \to qX$ where X is a light scalar with a mass below the top quark that decays to $b\bar{b}$ [402]. Such phenomena exist in composite Higgs models [403]. The ATLAS search used $t\bar{t}$ events and separated signal from background by categorizing events according to the number of jets and the number of jets tagged as originating from b-quarks. The observed limits correspond to the product of the BR $t \to qX$ and $X \to b\bar{b}$. The limit in the $t \to uX(t \to cX)$ channel is 0.019%(0.018%) for $M_X = 20$ GeV and 0.062%(0.078%) for $M_X = 160$ GeV.

61.2.6.4 *Effective Field Theory Results*

As described in Section 61.1.1.2, EFTs have become a primary tool for evaluating the outcome of top PBSM searches. EFT provides both model-independent limits, a straightforward way to compare and contrast search results from different processes and different experiments, and a guide to the full space of possible top-quark-related PBSM. In a nice pedagogical paper [404], Zhang and Willenbrock elucidate the advantages of the EFT approach compared to the vertex-function approach for searching for PBSM in top-quark interactions, including the fact that the EFT approach incorporates the SM gauge symmetry and contact interactions that are neglected in the vertex-function approach. As a result of these advantages, EFTs have become the dominant technique for evaluating search limits, and we review the most recent results in this section.

As ATLAS and CMS do, we categorize the top-EFT operators as follows: four-fermion operators, vector-boson operators and scalar-boson operators. Operators can change the overall rate of top-quark production, modify the kinematics of production and/or decay, or produce new interactions, such as flavor-changing neutral currents (FCNC). To date, all results are consistent with the SM expectation of zero for each Wilson coefficient. The numerical values of the limits are not intuitively meaningful, especially given that they correspond to an arbitrarily chosen mass scale of $\Lambda = 1$ TeV. Therefore, rather than providing a table of confidence intervals, we refer the interested reader to the LHC Top Working Group page of summary plots where the limits on the Wilson coefficients are presented graphically [405], and to the references given below. Instead, the tables below provide the most recent relevant references (i.e. those using the full LHC dataset of 139 fb^{-1}) for limits on each coefficient wherein measurement, fitting, and limit derivation techniques can be found. Additional limits and references can be found in the listings and in references [359, 374, 391, 398, 399, 406–408].

61.3 Outlook

Top quark physics at hadron colliders has developed into precision physics. Various properties of the top quark have been measured with high precision, where the LHC has by now surpassed the Tevatron precision and reach in the majority of relevant observables. Several $\sqrt{s}$-dependent physics quantities, such as the production cross-section, have been measured at several energies

at the Tevatron and the LHC. Up to now, all measurements are consistent with the SM predictions and allow stringent tests of the underlying production mechanisms by strong and weak interactions. Given the very large event samples available at the LHC, top-quark properties will be further determined in $t\bar{t}$ as well as in electroweak single top-quark production. At the Tevatron, the $t-$ and $s-$channels for electroweak single top-quark production have been estblished separately. At the LHC, quick progress has been achieved in the last years yielding more than 3 sigma significance of the s-channel and more than 5 sigma significance for the t-chnnel and Wt-production. Furthermore, $t\bar{t}\gamma$, $t\bar{t}Z$, and $t\bar{t}W$ together with $t\bar{t}H$ associated production have started to provide key information on the top-quark electroweak couplings. Corresponding effective field theory (EFT) fits for the coupling extraction are being developed. At the same time various models of physics beyond the SM involving top-quark production are being constrained. While a majority of the Run-II data recorded at 13 TeV has been analysed or is in an advanced stage, the beginning of the Run-III at $\sqrt{s} = 13.6$ to 14 TeV and an expected integrated luminosity of $160-200$ fb^{-1}, doubling the Run-I plus Run-II data set, is immanent. With the first results being released, top-quark physics has the potential to shed light on open questions and new aspects of physics at the TeV scale.

62. Form Factors for Semileptonic Kaon ($K_{\ell 3}$), Radiative Pion ($\pi_{\ell 2\gamma}$) and Kaon ($K_{\ell 2\gamma}$) Decays

Revised August 2023 by M.A. Bychkov (Virginia U.) and G. D'Ambrosio (INFN, Napoli).

62.1 $\pi^{\pm}_{\ell 2\gamma}$ and $K^{\pm}_{\ell 2\gamma}$ Form Factors

The radiative decays, $\pi^{\pm} \to l^{\pm}\nu\gamma$ and $K^{\pm} \to l^{\pm}\nu\gamma$, with l standing for an e or a μ, and γ for a real or virtual photon (e^+e^- pair), provide a powerful tool to investigate the hadronic structure of pions and kaons. The structure-dependent part SD_i of the amplitude describes the emission of photons from virtual hadronic states, and is parametrized in terms of form factors V, A, (vector, axial vector), in the standard description [1–4]. Note that in the Listings and some literature, equivalent nomenclature F_V and F_A for the vector and axial form factors is often used. Exotic, non-standard contributions like $i = T, S$ (tensor, scalar) have also been considered. Apart from the SD terms, there is also the Inner Bremsstrahlung amplitude, IB, corresponding to photon radiation from external charged particles and described by Low theorem in terms of the physical decay $\pi^{\pm}(K^{\pm}) \to l^{\pm}\nu$. Experiments try to optimize their kinematics so as to minimize the IB part of the amplitude.

The SD amplitude in its standard form is given as

$$M(\mathrm{SD}_V) = \frac{-eG_F U_{qq'}}{\sqrt{2}m_P}\epsilon^\mu l^\nu V^P \epsilon_{\mu\nu\sigma\tau}k^\sigma q^\tau \tag{62.1}$$

$$M(\mathrm{SD}_A) = \frac{-ieG_F U_{qq'}}{\sqrt{2}m_P}\epsilon^\mu l^\nu \{A^P[(qk-k^2)g_{\mu\nu} - q_\mu k_\nu] + R^P k^2 g_{\mu\nu}\}\ , \tag{62.2}$$

which contains an additional axial form factor R^P which only can be accessed if the photon remains virtual. $U_{qq'}$ is the Cabibbo-Kobayashi-Maskawa mixing-matrix element; ϵ^μ is the polarization vector of the photon (or the effective vertex, $\epsilon^\mu = (e/k^2)\overline{u}(p_-)\gamma^\mu v(p_+)$, of the e^+e^- pair); $\ell^\nu = \overline{u}(p_\nu)\gamma^\nu(1-\gamma_5)v(p_\ell)$ is the lepton-neutrino current; q and k are the meson and photon four-momenta ($k = p_+ + p_-$ for virtual photons); and P stands for π or K.

For decay processes where the photon is real, the partial decay width can be written in analytical form as a sum of IB, SD, and IB/SD interference terms INT [1, 4]:

$$\begin{aligned}\frac{d^2\Gamma_{P\to\ell\nu\gamma}}{dxdy} &= \frac{d^2\left(\Gamma_{\mathrm{IB}} + \Gamma_{\mathrm{SD}} + \Gamma_{\mathrm{INT}}\right)}{dxdy} \\ &= \frac{\alpha}{2\pi}\Gamma_{P\to\ell\nu}\frac{1}{(1-r)^2}\Bigg\{\mathrm{IB}(x,y) \\ &+ \frac{1}{r}\left(\frac{m_P}{2f_P}\right)^2\Big[(V+A)^2\mathrm{SD}^+(x,y) + (V-A)^2\mathrm{SD}^-(x,y)\Big] \\ &+ \epsilon_P\frac{m_P}{f_P}\Big[(V+A)\mathrm{S}^+_{\mathrm{INT}}(x,y) + (V-A)\mathrm{S}^-_{\mathrm{INT}}(x,y)\Big]\Bigg\}.\end{aligned} \tag{62.3}$$

Here

$$\begin{aligned}\mathrm{IB}(x,y) &= \left[\frac{1-y+r}{x^2(x+y-1-r)}\right] \\ &\quad \left[x^2 + 2(1-x)(1-r) - \frac{2xr(1-r)}{x+y-1-r}\right] \\ \mathrm{SD}^+(x,y) &= (x+y-1-r)\Big[(x+y-1)(1-x) - r\Big] \\ \mathrm{SD}^-(x,y) &= (1-y+r)\Big[(1-x)(1-y) + r\Big] \\ \mathrm{S}^+_{\mathrm{INT}}(x,y) &= \left[\frac{1-y+r}{x(x+y-1-r)}\right]\Big[(1-x)(1-x-y) + r\Big] \\ \mathrm{S}^-_{\mathrm{INT}}(x,y) &= \left[\frac{1-y+r}{x(x+y-1-r)}\right]\Big[x^2 - (1-x)(1-x-y) - r\Big]\end{aligned} \tag{62.4}$$

where $x = 2E_\gamma/m_P$, $y = 2E_\ell/m_P$, $r = (m_\ell/m_P)^2$, f_P is the meson decay constant, and ϵ_P is +1 for pions and -1 for kaons. The structure dependent terms SD^+ and SD^- are shown in Fig. 1. The SD^- term is maximized in the same kinematic region where overwhelming IB term dominates (along $x + y = 1$ diagonal). Thus experimental yields with less background are dominated by SD^+ contribution and proportional to $A^P + V^P$ making simultaneous precise determination of the form factors difficult.

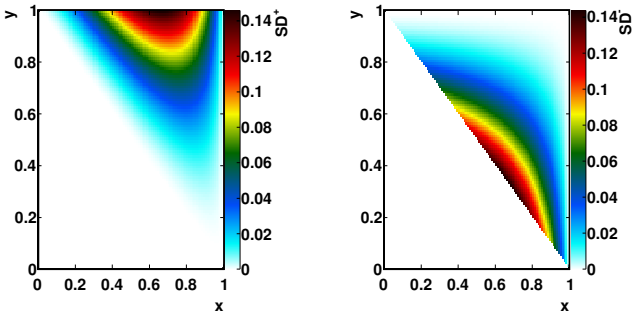

Figure 62.1: Components of the structure dependent terms of the decay width. Left: SD^+, right: SD^-

Recently, formulas 62.3 and 62.4 have been extended to describe polarized distributions in radiative meson and muon decays [5].

The "helicity" factor r is responsible for the enhancement of the SD over the IB amplitude in the decays $\pi^{\pm} \to e^{\pm}\nu\gamma$, while $\pi^{\pm} \to \mu^{\pm}\nu\gamma$ is dominated by IB. Interference terms are important for the decay $K^{\pm} \to \mu^{\pm}\nu\gamma$ [6], but contribute only a few percent correction to pion decays. However, they provide the basis for determining the signs of V and A. Radiative corrections to the decay $\pi^+ \to e^+\nu\gamma$ have to be taken into account in the analysis of the precision experiments. They make up to 4% corrections in the total decay rate [7]. In $\pi^{\pm} \to e^{\pm}\nu e^+e^-$ and $K^{\pm} \to \ell^{\pm}\nu e^+e^-$ decays, all three form factors, V^P, A^P, and R^P, can be determined [8, 9].

Theoretically, the first non-trivial χPT contributions to A^P and V^P appear at $\mathcal{O}(p^4)$ [4], respectively from Gasser-Leutwyler coefficients, L_i's, and the anomalous lagrangian:

$$A^P = \frac{4\sqrt{2}M_P}{F_\pi}(L^r_9 + L^r_{10}), \quad V^P = \frac{\sqrt{2}M_P}{8\pi^2 F_\pi}. \tag{62.5}$$

In case of the kaon $A^K = 0.042$ and $V^K = 0.096$. $\mathcal{O}(p^6)$ contributions to A^K can be predicted accurately: they are flat in the momentum dependence and shift the $\mathcal{O}(p^4)$ value to 0.034. $\mathcal{O}(p^6)$ contributions to V^K are model dependent and can be approximated by a form factor linearly dependent on momentum. For example, when looking at the spread of results obtained within two different models, the constant piece of this linear form factor is shifted to 0.078 ± 0.005 [1, 2, 4].

We give the experimental $\pi^{\pm}$ form factors V^π, A^π, and R^π in the Listings. In the $K^{\pm}$ Listings, we give the extracted sum $A^K + V^K$ and difference $A^K - V^K$, as well as V^K, A^K and R^K. In particular KLOE has measured for the constant piece of the form factor $A^K + V^K = 0.125 \pm 0.007 \pm 0.001$ [10] while ISTRA+, $V^K - A^K = 0.21 \pm 0.04 \pm 0.04$ [11].

The pion vector form factor, V^π, is related via CVC (Conserved Vector Current) to the $\pi^0 \to \gamma\gamma$ decay width. The constant term is given by $|V^\pi(0)| = (1/\alpha)\sqrt{2\Gamma_{\pi^0\to\gamma\gamma}/\pi m_{\pi^0}}$ [3]. The resulting value, $V^\pi(0) = 0.0259(9)$, has been confirmed by calculations based on chiral perturbation theory (χPT) [4], and by two experiments given in the Listings.

A recent experiment by the PIBETA collaboration [12] obtained a $V^\pi(0)$ that is in excellent agreement with the CVC hypothesis. It also measured the slope parameter a in $V^\pi(s) = V^\pi(0)(1 + a\cdot s)$, where $s = (1 - 2E_\gamma/m_\pi)$, and E_γ is the gamma energy in the pion rest frame: $a = 0.095 \pm 0.058$. A functional dependence on s is expected for all form factors. It becomes non-negligible in the

case of $V^\pi(s)$ when a wide range of photon momenta is recorded; proper treatment in the analysis of K decays is mandatory.

The form factor, R^P, can be related to the electromagnetic radius, r_P, of the meson [2]: $R^P = \frac{1}{3} m_P f_P \langle r_P^2 \rangle$ using PCAC (Partial Conserved Axial vector Current).

In lowest order χPT, the ratio A^π/V^π is related to the pion electric polarizability $\alpha_E = [\alpha/(8\pi^2 m_\pi f_\pi^2)] \times A^\pi/V^\pi$ [13]. Direct experimental and theoretical status of pion polarizability studies currently is not settled. Most recent theoretical predictions from χPT at $\mathcal{O}(p^6)$ [14] and experimental results from COMPASS collaboration [15] favor a small value of pion polarizability $\alpha_\pi \sim (2 \div 3) \times 10^{-4}\,\mathrm{fm}^3$. Dispersive analysis of $\gamma\gamma \to \pi^+\pi^-$ crossection [16] and experimental results from MAMI collaboration [17] report a much larger value of $\alpha_\pi \sim 6 \times 10^{-4}\,\mathrm{fm}^3$. Precise measurement of the pion form factors by PIBETA collaboration favors smaller values of polarizability $\alpha_\pi = 2.7^{+0.6}_{-0.5} \times 10^{-4}\,\mathrm{fm}^3$.

Several searches for the exotic form factors F_T^π, F_T^K (tensor), and F_S^K (scalar) have been pursued in the past. In particular, F_T^π has been brought into focus by experimental as well as theoretical work [18]. New high-statistics data from the PIBETA collaboration have been re-analyzed together with an additional data set optimized for low backgrounds in the radiative pion decay. In particular, lower beam rates have been used in order to reduce the accidental background, thereby making the treatment of systematic uncertainties easier and more reliable. The PIBETA analysis now restricts F_T^π to the range $-5.2 \times 10^{-4} < F_T^\pi < 4.0 \times 10^{-4}$ at a 90% confidence limit [12]. This result is in excellent agreement with the most recent theoretical work [4].

Precision measurements of radiative pion and kaon decays are effective tools to study QCD in the non-perturbative region and are of interest beyond the scope of radiative decays. Meanwhile other processes such as $\pi^+ \to e^+\nu$ that seem to be better suited to search for new physics at the precision frontier are currently studied. The advantages of such process are the very accurate and reliable theoretical predictions and the more straightforward experimental analysis.

62.2 $K^\pm_{\ell 3}$ and $K^0_{\ell 3}$ Form Factors

Assuming that only the vector current contributes to $K \to \pi\ell\nu$ decays, we write the matrix element as

$$M \propto f_+(t)\left[(P_K + P_\pi)_\mu \bar{\ell}\gamma_\mu(1+\gamma_5)\nu\right] + f_-(t)\left[m_\ell \bar{\ell}(1+\gamma_5)\nu\right] \ , \qquad (62.6)$$

where P_K and P_π are the four-momenta of the K and π mesons, m_ℓ is the lepton mass, and f_+ and f_- are dimensionless form factors which can depend only on $t = (P_K - P_\pi)^2$, the square of the four-momentum transfer to the leptons. If time-reversal invariance holds, f_+ and f_- are relatively real. $K_{\mu 3}$ experiments, discussed immediately below, measure f_+ and f_-, while K_{e3} experiments, discussed further below, are sensitive only to f_+ because the small electron mass makes the f_- term negligible.

62.2.1 $K_{\mu 3}$ *Decays*

Analyses of $K_{\mu 3}$ data frequently assume a linear dependence of f_+ and f_- on t, *i.e.*,

$$f_\pm(t) = f_\pm(0)\left[1 + \lambda_\pm(t/m^2_{\pi^+})\right] \ . \qquad (62.7)$$

Most $K_{\mu 3}$ data are adequately described by formula 62.7 for f_+ and a constant f_- (*i.e.*, $\lambda_- = 0$).

There are two equivalent parametrizations commonly used in these analyses: $\lambda_+, \xi(0)$ parametrization and λ_+, λ_0 parametrization.

Older analyses of $K_{\mu 3}$ data often introduce the ratio of the two form factors

$$\xi(t) = f_-(t)/f_+(t) \ . \qquad (62.8)$$

The $K_{\mu 3}$ decay distribution is then described by the two parameters λ_+ and $\xi(0)$ (assuming time reversal invariance and $\lambda_- = 0$).

More recent $K_{\mu 3}$ analyses have parametrized in terms of the form factors f_+ and f_0, which are associated with vector and scalar exchange, respectively, to the lepton pair. f_0 is related to f_+ and f_- by

$$f_0(t) = f_+(t) + \left[t/(m_K^2 - m_\pi^2)\right] f_-(t) \ . \qquad (62.9)$$

Here $f_0(0)$ must equal $f_+(0)$. The earlier assumption that f_+ is linear in t and f_- is constant leads to f_0 linear in t:

$$f_0(t) = f_0(0)\left[1 + \lambda_0(t/m^2_{\pi^+})\right] \ . \qquad (62.10)$$

With the assumption that $f_0(0) = f_+(0)$, the two parametrizations, $(\lambda_+, \xi(0))$ and (λ_+, λ_0) are equivalent as long as correlation information is retained. (λ_+, λ_0) correlations tend to be less strong than $(\lambda_+, \xi(0))$ correlations.

Since the 2006 edition of the *Review* [19], we no longer quote results in the $(\lambda_+, \xi(0))$ parametrization. We have removed many older low statistics results from the Listings. See the 2004 version of this note [20] for these older results, and the 1982 version [21] for additional discussion of the $K^0_{\mu 3}$ parameters, correlations, and conversion between parametrizations.

More recent high-statistics experiments have included a quadratic term in the expansion of $f_+(t)$,

$$f_+(t) = f_+(0)\left[1 + \lambda_+'(t/m^2_{\pi^+}) + \frac{\lambda_+''}{2}(t/m^2_{\pi^+})^2\right] \ . \qquad (62.11)$$

If there is a non-vanishing quadratic term, then λ_+ of formula 62.7 represents the average slope, which is then different from λ_+'. Our convention is to include the factor $\frac{1}{2}$ in the quadratic term, and to use m_{π^+} even for K^+_{e3} and $K^+_{\mu 3}$ decays. We have converted other's parametrizations to match our conventions, as noted in the beginning of the "$K^\pm_{\ell 3}$ and $K^0_{\ell 3}$ Form Factors" sections of the Listings.

There are two alternatives to the Taylor parametrization: The Pole Parametrization and Dispersive Parametrization.

The pole model describes the t-dependence of $f_+(t)$ and $f_0(t)$ in terms of the exchange of the lightest vector and scalar K^* mesons with masses M_V and M_S, respectively:

$$f_+(t) = f_+(0)\left[\frac{M_V^2}{M_V^2 - t}\right] \ , \quad f_0(t) = f_0(0)\left[\frac{M_S^2}{M_S^2 - t}\right] \ . \qquad (62.12)$$

The Dispersive Parametrization approach, valid in a much wider kinematic range and able to describe at the same time τ-decay data, [22] uses dispersive techniques and the known low-energy K-π phases to parametrize the vector and scalar form factors:

$$f_+(t) = f_+(0)\exp\left[\frac{t}{m_\pi^2}(\Lambda_+ + H(t))\right]; \qquad (62.13)$$

$$f_0(t) = f_+(0)\exp\left[\frac{t}{(m_K^2 - m_\pi^2)}\,(ln[C] - G(t))\right], \qquad (62.14)$$

where Λ_+ is the slope of the vector form factor, and $\ln C = \ln[f_0(m_K^2 - m_\pi^2)]$ is the logarithm of the scalar form factor at the Callan-Treiman point. The functions $H(t)$ and $G(t)$ are dispersive integrals.

62.2.2 K_{e3} *Decays*

Analysis of K_{e3} data is simpler than that of $K_{\mu 3}$ because the second term of the matrix element assuming a pure vector current [formula 62.6 above] can be neglected. Here f_+ can be assumed to be linear in t, in which case the linear coefficient λ_+ of formula 62.7 is determined, or quadratic, in which case the linear coefficient λ_+' and quadratic coefficient λ_+'' of formula 62.11 are determined.

If we remove the assumption of a pure vector current, then the matrix element for the decay, in addition to the terms in formula 62.6, would contain

$$+2m_K\, f_S\, \bar{\ell}(1+\gamma_5)\nu + (2f_T/m_K)(P_K)_\lambda (P_\pi)_\mu\, \bar{\ell}\,\sigma_{\lambda\mu}(1+\gamma_5)\nu \ , \qquad (62.15)$$

where f_S is the scalar form factor, and f_T is the tensor form factor. In the case of the K_{e3} decays where the f_- term can be neglected, experiments have yielded limits on $|f_S/f_+|$ and $|f_T/f_+|$.

For K_{e3} data, we determine best values for the three parametrizations: linear (λ_+), quadratic ($\lambda_+^{'}$, $\lambda_+^{''}$) and pole (M_V). For $K_{\mu 3}$ data, we determine best values for the three parametrizations: linear (λ_+, λ_0), quadratic ($\lambda_+^{'}$, $\lambda_+^{''}$, λ_0) and pole (M_V, M_S). We then assume $\mu-e$ universality so that we can combine K_{e3} and $K_{\mu 3}$ data, and again determine best values for the three parametrizations: linear (λ_+, λ_0), quadratic ($\lambda_+^{'}$, $\lambda_+^{''}$, λ_0), and pole (M_V, M_S). When there is more than one parameter, fits are done including input correlations. Simple averages suffice in the two K_{e3} cases where there is only one parameter: linear (λ_+) and pole (M_V).

A comprehensive global analysis of the semileptonic kaon decay data and its effect on the CKM unitarity debate can be found in [23, 24]. An update on experimental data including NA48/2 newest results can be found in [25].

Both KTeV and KLOE see an improvement in the quality of their fits relative to linear fits when a quadratic term is introduced, as well as when the pole parametrization is used. The quadratic parametrization has the disadvantage that the quadratic parameter $\lambda_+^{''}$ is highly correlated with the linear parameter $\lambda_+^{'}$, in the neighborhood of 95%, and that neither parameter is very well determined. The pole fit has the same number of parameters as the linear fit, but yields slightly better fit probabilities, so that it would be advisable for all experiments to include the pole parametrization as one of their choices.

The "Kaon Particle Listings" show the results with and without assuming μ-e universality. The "Meson Summary Tables" show all of the results assuming μ-e universality, but most results not assuming μ-e universality are given only in the Listings.

63. Spectroscopy of Light Meson Resonances

Revised March 2024 by C. Amsler (Stefan Meyer Inst.), A. Masoni (INFN, Cagliari) and G. Venanzoni (Liverpool U.; INFN, Pisa).

63.1 Introduction

According to the constituent quark model, a light meson consists of a color singlet quark-antiquark pair made of the u, d, or s quarks and the $\overline{u}$, $\overline{d}$, or $\overline{s}$ antiquarks, grouped into a flavor multiplet of SU(3). However, additional mesons made of bound gluons (glueballs) could exist in the same mass range, suggested by the self coupling of gluons in QCD. Multiquark structures are also possible, such as quark-antiquark pairs with an excited gluon (hybrid mesons). Tetraquarks are compact color singlets of diquark-antidiquark pairs ($qq\overline{q}\overline{q}$) or 'molecular' bound states of two mesons ($q\overline{q}q\overline{q}$). More complex systems such as $qqq\overline{q}\overline{q}\overline{q}$ (baryonia) are also predicted.

Fundamentals on the constituent quark model on light and heavy mesons and baryons (including hadrons with charm and bottom quarks), and on predictions from lattice gauge theories, are described in 'Quark Model' in this issue of the *Review of Particle Physics*, henceforth called the *Review*. In the present text we describe the experimental spectrum of light mesons and their classifications within the constituent quark model, with emphasis on states exhibiting properties incompatible with $q\bar{q}$ structures. The discussion is driven by the results entered in the database of the *Review*. The spectrum of kaon excitations is much less clear cut and therefore deferred to a future edition, when further data might become available. More detailed discussions on exotic mesons – including those involving the c and b quarks – can be found in Refs. [1–7] and in 'Heavy Non-$q\bar{q}$ Mesons' of the *Review*. For more information on the meson (and baryon) spectrum of light (and heavy) quarks we refer to one of the textbooks [8].

Figure 63.1 shows the mass spectrum of $q\bar{q}$ mesons. The mass (vertical axis) increases with orbital excitations ℓ (horizontal axis) and radial excitation n. In the quark model one uses the notation nS, nP, nD... for the radial excitations ($n = 1$ for the ground states), in contrast to the usual $1s$, $2p$, $3d$... notation in atomic physics. Each box represents an SU(3) nonet containing multiplets of the isospin i, three isovectors, two strange isodoublets, and two isosinglets (one SU(3) singlet and one SU(3) octet). The spin, parity [$P = -(-1)^{\ell}$] and C-parity [$C = (-1)^{\ell+s}$] take the possible values $J^{PC} = 0^{++}$ (scalar), 0^{-+} (pseudoscalar), 1^{--} (vector), $1^{+\pm}$ (axial- or pseudovector), 2^{++} (tensor), etc. Therefore mesons with the *exotic* quantum numbers 0^{--}, 0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, etc. cannot be $q\bar{q}$ states. Note that the C-parity is defined only for the electrically neutral non-strange nonet members.

The two isosinglets in each nonet mix with an angle θ close to the *ideal* value of 35.3° for the 1^{--}, $1^{+\pm}$, 2^{++} and 3^{--} nonets, in which case the isosinglets decouple to $u\overline{u}+d\overline{d}$ and $s\overline{s}$. The orbital excitations $\ell \geq 1$ consist of four nonets for each value of n, since $j = \ell$ for antiparallel quark spins and $j = \ell-1, \ell$ or $\ell+1$ for parallel spins. Since the C-parity is not defined for strange mesons, the K_{1A} and K_{1B} in the axial vector 1^{++} and 1^{+-} nonets of fig. 63.1 are mathematical constructs which mix to give the observed $K_1(1270)$ and $K_1(1400)$ mesons. A similar scenario occurs for the observed 2^{-+} $K_2(1770)$ and 2^{--} $K_2(1820)$ mesons.

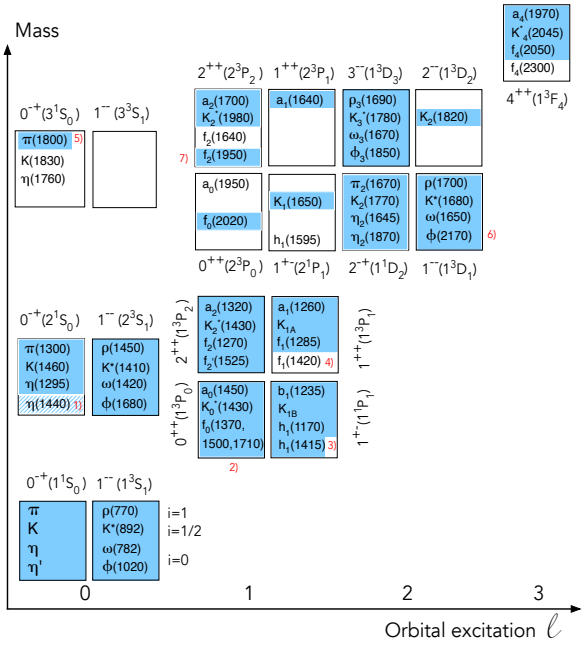

Figure 63.1: The mesons made of the u, d, and s light quarks are organised in $J^{PC}(n^{2s+1}\ell_j)$ nonets with isospin i. The established mesons (which appear in the *Summary Table* of the *Review*) are shown in the dark (blue) areas. The white areas contain those omitted in the *Summary Table* but reported in the *Listings*. States with the same J^{PC} mix, such as the 2^3S_1 and 1^3D_1 mesons. The states become broad and overlap with increasing masses, which complicates the determination of the resonance parameters *e.g.* mass, width and spin. For a complete list of mesons see the *Listings*.
[1] The $\eta(1440)$ stands for the $\eta(1405)$ and the $\eta(1475)$, section 63.4.
[2] The classification of the scalar nonet is controversial. In alternative schemes the 1^3P_0 nonet contains the light scalars below 1 GeV, section 63.2.
[3] Considered established, but more data would be desirable.
[4] An alternative to the $f_1(1420)$ is the $f_1(1510)$, section 63.6.
[5] The $\pi(1800)$ has also been proposed as a hybrid meson, section 63.7.
[6] The $\phi(2170)$ has also been proposed as a tetraquark state, section 63.8.
[7] The $f_2(1950)$ has also been proposed as a tensor glueball, section 63.3.2.

As described in more detail below (section 63.2), it is hard to accommodate all the known scalar mesons in the lower $q\bar{q}$ nonets: The light scalar mesons $a_0(980)$, $K_0^*(700)$ (also known as κ), the $f_0(500)$ (also known as σ), and the $f_0(980)$, not shown in the figure, could build the lightest nonet, but could also be two-meson resonances or tetraquarks (section 63.8). Three isoscalars are known in the 1500 MeV region, the $f_0(1500)$ or $f_0(1710)$ being proposed as gluonic states mixing with the $f_0(1370)$ (section 63.3.1). The pseudoscalar labeled $\eta(1440)$ may consist of two states (section 63.4). The status of vector meson excitations is described in section 63.5. The axial-vector meson $f_1(1420)$ could be replaced in the 1^{++} nonet by the $f_1(1510)$ which, however, needs confirmation (see the *Listings* and section 63.6). Mesons with exotic quantum numbers are discussed in section 63.7.

63.2 Scalar mesons

Scalar mesons decay dominantly into pairs of pseudoscalar mesons ($\pi\pi$, $K\overline{K}$, $\pi\eta$, $\eta\eta$ or $\eta\eta'$). The widths tend to be large for those decaying into $\pi\pi$, due to the absence of angular momentum barrier and the large available phase space. Broad overlapping

states decaying into the same final state interfere, which complicates the determination of their masses and widths. Furthermore, the ground state glueball, a 0^{++} expected below 2 GeV, will mix with the isoscalar 0^{++} $q\bar{q}$ states. The onset of the $K\overline{K}$, $\eta\eta$ or $\eta\eta'$ thresholds also distorts the line shapes and produces cusps. This requires high statistics data and the use of coupled channel analyses taking into account unitarity and analyticity (see 'Resonances' in the *Review*).

Two isovector scalars are established, the $a_0(980)$ and the $a_0(1450)$, together with five isoscalars: the very broad $f_0(500)$, the $f_0(980)$, the broad $f_0(1370)$, and the comparatively narrow $f_0(1500)$ and $f_0(1710)$. The strange partners are the $K_0^*(700)$ and the $K_0^*(1430)$. The $f_0(500)$ and $K_0^*(700)$ deserve a separate treatment and can be found in 'Scalar Mesons below 1 GeV', which contains more details on the $a_0(980)$ and $f_0(980)$, briefly reviewed in section 63.8.

The $a_0(1450)$ was first reported by the Crystal Barrel experiment in $\bar{p}p$ annihilation with stopped antiprotons [9, 10] (see [11] for a review of Crystal Barrel results). An isovector scalar, possibly the $a_0(1450)$ (albeit at a lower mass of 1317 MeV) is observed by Belle in $\gamma\gamma$ collisions leading to $\eta\pi^0$ [12]. The state interferes destructively with the non-resonant background. Its $\gamma\gamma$ coupling is comparable to that of the $a_2(1320)$, in accord with simple predictions (see *e.g.* [13]). A contribution from $a_0(1450) \to K\bar{K}$ is also found in the CLEO-c analysis of $D^{\pm} \to K^+K^-\pi^{\pm}$ [14] and $D^0 \to K_S^0 K^{\pm}\pi^{\mp}$ from LHCb [15]. The $a_0(1450)$ is reported at a lower mass in $\bar{p}p$ annihilation in flight, overlapping with the $a_2(1320)$ [16, 17].

The $f_0(1370)$ and $f_0(1500)$ were observed by Crystal Barrel [18–20] and by WA102 in central production with 450 GeV protons [21,22]. They decay mostly into 2π and 4π. The $f_0(1500)$ was also observed to decay into $\eta\eta$ [23–25] and $\eta\eta'$ [26]. All data agree that the 4π decay mode represents about half of the $f_0(1500)$ decay width, but is dominant for $f_0(1370)$.

The determination of the $\pi\pi$ coupling of the very broad $f_0(1370)$ is complicated by its interference with the $f_0(500)$. The existence of the $f_0(1370)$ was questioned by COMPASS from $\pi^-p \to \pi^-\pi^-\pi^+p$ data [27] and by LHCb in $\overline{B}_s^0 \to J/\psi(1S)\pi^+\pi^-$ [28]. In $\overline{B}^0 \to J/\psi(1S)\pi^+\pi^-$ the $\pi\pi$ mass spectrum does not show any significant scalar component above ∼1.2 GeV [29] (an analysis that is challenged in [30]). The existence of the $f_0(1370)$ has been disputed by a reassessment of various production modes [31] (the $K_0^*(700)$ is also not needed in $K\pi$ scattering). This contrasts with its $\pi\pi$ decay analyzed in Ref. [32]). However, data from CLEO-c in $D^0 \to \pi^+\pi^-\pi^+\pi^-$ require a contribution from $f_0(500)f_0(1370) \to 4\pi$ [33]. A broad 2π signal is also observed by BaBar around 1400 MeV in the decay $B^{\pm} \to \pi^{\pm}\pi^{\pm}\pi^{\mp}$ [34] which is attributed to the $f_0(1370)$ (but could also be due to the $f_0(1500)$). The existence of the $f_0(1370)$ is confirmed by a recent dispersive analysis of $\pi\pi$ scattering data, which leads to a complex pole around 1245 MeV with a very large width of about 600 MeV [35].

In Refs. [36, 37] the $f_0(1370)$ and $f_0(1710)$ (together with the $f_2(1270)$ and $f_2'(1525)$) are interpreted as bound systems of two vector mesons. This view is challenged in Ref. [38] where in a covariant formalism, e.g. the $f_2(1270)$ does not appear as a $\rho\rho$ bound state. Photoproduction data of the $f_2(1270)$ in $\gamma p \to \pi^0\pi^0 p$ from CLAS [39], as a function of momentum transfer, also disagree with predictions [40] for the $f_2(1270)$ to be a $\rho\rho$ bound state.

While the $K\bar{K}$ decay branching ratio of the $f_0(1500)$ is small [21] [41], the $f_0(1710)$ decays dominantly into $K\overline{K}$. The $f_0(1710)$ is not observed in $p\overline{p}$ annihilation at rest [41] and only weakly produced in $p\overline{p}$ annihilation in flight [42], with a rate strongly suppressed compared to that of the $f_0(1500)$ (∼7%). For comparison, the rate for the $(s\bar{s})$ $f_2'(1525)$ production is about 9% that of the $(u\bar{u}+d\bar{d})$ $f_2(1270)$, as expected from the OZI rule [42]. On the other hand the $f_0(1370)$ does not couple strongly to $K\bar{K}$ [21]. This suggests an $n\bar{n}$ structure $(u\bar{u}+d\bar{d})$ for the $f_0(1370)$ and $s\bar{s}$ for the $f_0(1710)$. The $f_0(1500)$ would also qualify as an $n\bar{n}$ state, although it is very narrow compared to the other states. Occam's razor principle therefore suggests that the $f_0(1370)$, $a_0(1450)$, and the $f_0(1710)$ are in the 1^3P_0 $q\bar{q}$ SU(3) flavor nonet, the $f_0(1370)$ and $a_0(1450)$ being the two (mostly) $n\bar{n}$ states, and the $f_0(1710)$ the (dominantly) $s\bar{s}$ one. The nature of the $f_0(1500)$ is discussed along this scheme in section 63.3.1.

There is long-time evidence for the existence of two scalar nonets and one glueball below 2 GeV [43]. The ground state 1^3P_0 $q\bar{q}$ nonet and a lighter one made of four-quark states which recombine at large distances to become meson-meson resonances, the $a_0(980)$, $a_0(980)$, $f_0(500)$ and $K_0^*(700)$, see section 63.8. For a review see Ref. [1] and for the $f_0(500)$ Ref. [44].

Other schemes have been proposed, for example a tetraquark for the $f_0(1500)$ [45] or flavor octets for the $f_0(1500)$ and $f_0(1710)$ [3]. In Ref. [46] the $a_0(1450)$, $f_0(1370)$, $f_0(1500)$ and $K_0^*(1430)$ are radial excitations of the scalar nonet below 1 GeV. In Ref. [47] the light and 1^3P_0 scalar nonets are interpreted as mixing of two tetraquark nonets. In the unitarized quark model with coupled $q\bar{q}$ and meson-meson channels, the scalars below 1 GeV are manifestations of bare $q\bar{q}$ confinement states, mass shifted from the 1.4 GeV region and distorted by the strong $^3P_0$ coupling to S-wave two-meson decay channels [48, 49]. Thus, in these models the light scalar nonet comprising the light and 1^3P_0 scalar nonets are manifestations of the same bare input states (see also [50]). Surprisingly for a state decaying strongly into 2π and 4π, the $f_0(1370)$ is assumed to be an $s\bar{s}$ state in Ref. [51]. The $f_0(1500)$ is then a radial excitation.

There is evidence for the existence of two further 0^{++} mesons in the 1700 – 1800 MeV range, one isoscalar ($f_0(1770)$) and one isovector ($a_0(1710)$), which could be the isovector partner of the $f_0(1710)$. The $f_0(1770)$, claimed by BESII/III [52–54], and also observed in $\pi^-p \to n\omega\phi$ [55], has been interpreted as a radial excitation [56]. Two isoscalars are also reported by a re-analysis of BESIII radiative $J/\psi(1S)$ decay data [57, 58]. Evidence for the $a_0(1710)$ is inferred from the interference of the K^+K^- and $K_S^0K_S^0$ decays of the $f_0(1710)$ in $D_s^+ \to f_0(1710)\pi^+$, leading to a relative branching ratio an order of magnitude larger than expected from isospin symmetry [59, 60]. A signal for $a_0(1710) \to K_S^0K^+$ is indeed reported by BESIII [61], albeit at 1817 MeV, in contrast to the state observed by BaBar in $\eta\pi$ at 1704 MeV [62].

From a study of the vector-vector interaction the authors of Ref. [63], predict an isovector pole at 1780 MeV, while the $f_0(1710)$ is a $K^*\bar{K}^*$ molecule, a view also supported by Refs. [64–67]. Thus the $f_0(1710)$ and $a_0(1710)$ might be $K^*\bar{K}^*$ molecules, similar to the $f_0(980)$ and $a_0(980)$ which have been interpreted as $K\bar{K}$ molecules. Scalar resonances near the D_0 mass such as the $f_0(1710)$ and the $f_0(1770)$ are also suggested to produce CP violation enhancements in the charm system [68]. Unfortunately, the spectrum of scalar mesons above the $f_0(1710)$ is not well established experimentally and more data are needed to confirm the $f_0(1770)$ and $a_0(1710)$.

63.3 Glueballs

Lattice calculations, QCD sum rules, flux tube, and constituent glue models agree that the lightest glueball has quantum numbers $J^{PC} = 0^{++}$ and the first excited state 2^{++}. Lattice calculations predict for the ground state (0^{++}) a mass around 1600 – 1700 MeV [69–72], while the 2^{++} state lies around 2300 MeV. For more information on lattice calculations see 'Quark Model' in the *Review* and fig. 15.3 therein for an example of mass spectrum. These predictions were made in the quenched approximation, neglecting $q\bar{q}$ loops. However quenched predictions and full QCD calculations lead to small mass shifts (see 'Quark Model' and fig. 15.15 therein).

Heavier glueballs with quantum numbers 0^{-+}, 2^{-+}, 1^{+-}, etc. are predicted above 2500 MeV and the lowest exotic ones (with exotic quantum numbers such as 0^{+-} and 2^{+-}) are expected above 4000 MeV [72]. In holographic QCD the 0^{-+} is predicted to be very broad [73] and the 1^{+-} is at least as broad as its width [74]. Calculations of the three lowest scalar and pseudoscalar glueballs masses in pure Yang-Mills theory are in quantitative agreement with lattice results [75]. The lightest glueballs lie in the same mass region as ordinary isoscalar $q\bar{q}$ states, in the mass range of the $1^3P_0(0^{++})$, $2^3P_2(2^{++})$, $3^3P_2(2^{++})$, and $1^3F_2(2^{++})$ $q\bar{q}$ states. Therefore, mixing of glueballs with nearby $q\bar{q}$ states of the same quantum numbers leads to supernumerary isoscalar state in the $q\bar{q}$ nonets (however, see Ref. [57] discussed in section

63.3.1).

Among the signatures naively expected for glueballs are (i) isoscalar states that do not fit into $q\bar{q}$ nonets, (ii) enhanced production in gluon-rich channels such as central production and radiative $J/\psi(1S)$ decay, (iii) decay branching fractions incompatible with SU(3) predictions for $q\bar{q}$ states, and (iv) reduced $\gamma\gamma$ couplings (see however [76, 77]). Mixing effects with isoscalar $q\bar{q}$ mesons [31, 69, 76, 78–84] and decay form factors [85] can also obscure these simple signatures.

According to SU(3) the decay branching ratios for $q\bar{q}$ mesons and pure glueballs are different, and therefore useful to determine the internal structures of mesons. For pure glueballs with flavor symmetric couplings the decay ratios are $\pi\pi : K\bar{K} : \eta\eta : \eta\eta' = 3 : 4 : 1 : 0$, apart from phase space factors. The partial widths for the decay of a scalar (or a tensor) meson into a pair of pseudoscalar mesons are given in fig. 63.2 (for a derivation see e.g. [8]). The decay of a $q\bar{q}$ meson into a pair of mesons involves the creation of a $q\bar{q}$ pair, and SU(3) symmetry assumes that the matrix elements for the creation of $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ pairs are equal. (The generalization to unequal $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ couplings is given in Ref. [78].) An excellent fit to the tensor meson decay widths is obtained with $\beta \simeq 0.5$ GeV/c, $\theta_V \simeq 26\,^\circ$ and $\theta_P \simeq -17\,^\circ$ [78].

Note that the assumption of flavor symmetric couplings may not apply in models describing the scalar glueball by a dilaton field, which lead to mass dependent couplings [86, 87] (see Ref. [88] which predicts that a scalar glueball above 1 GeV would be unobservably wide).

Another way to determine the flavor contents of neutral mesons is the decay $B \to J/\psi(1S)X$ which filters out the $d\bar{d}$ content of X, while $B_s^0 \to J/\psi(1S)X$ selects its $s\bar{s}$ component [89]. More precise data on $B^0_{(s)} \to J/\psi(1S)[f_0(1370), f_0(1500), f_0(1710)]$ would help to pin down the nature of these scalar mesons [90].

63.3.1 *Scalar glueballs*

One of the three isoscalars, the $f_0(1370)$, $f_0(1500)$ or $f_0(1710)$, appears to be supernumerary. The branching ratios in fig. 63.2 can be used to deduce the structures of these states, assuming that they are $q\bar{q}$. The comparison of decay branching ratios from Crystal Barrel annihilation and WA102 central collision data shows that the $f_0(1500)$ is compatible with an $n\bar{n}$ structure, while the $f_0(1710)$ is mostly $s\bar{s}$ [13]. However, the close vicinity of the very broad $n\bar{n}$ $f_0(1370)$, its narrow width, enhanced production at low transverse momentum transfer in central collisions [91–93] favor the $f_0(1500)$ to be the supernumerary non-$q\bar{q}$ state. According to [78, 83] the $f_0(1370)$ and $f_0(1710)$ would be dominantly $\bar{q}q$ states mixing with glue, while the $f_0(1500)$ would be dominantly a glueball mixing with $q\bar{q}$ states. Its suppressed $K\bar{K}$ decay would be due to interferences with the $f_0(1370)$ and $f_0(1710)$. In the analogous mixing scheme of Ref. [56], which uses central production data from WA102 and the hadronic $J/\psi(1S)$ decay data from BES [94, 95], glue is shared between the $f_0(1370)$ (mainly $n\bar{n}$), $f_0(1500)$(mainly glue) and $f_0(1710)$ (dominantly $s\bar{s}$). This agrees with the analyses [78, 83]. In the mixing scheme of Ref. [96] the QCD spectral sum rule also leads to a large gluonic component in the $f_0(1500)$ (satisfying the observed strong $\pi\pi$ and $f_0(500)f_0(500) \to 4\pi$ decays).

However, not everybody agrees that the strong $K\bar{K}$ signal is indicative of an $s\bar{s}$ structure for the $f_0(1710)$. The $f_0(1710)$ could still be the glueball, since the two-gluon coupling to $n\bar{n}$ appears to be suppressed by chiral symmetry [97], thus $K\bar{K}$ would be enhanced compared to $\pi\pi$. It was argued that chiral symmetry constraints in a multichannel analysis imply that the $f_0(1710)$ is an unmixed scalar glueball [98]. However, this view is challenged in [63].

The $K\bar{K}$ decay is also naturally enhanced in the extended linear sigma model with a dilaton as glueball [86] and in the holographic model of [87, 99] which both prefer the $f_0(1710)$ as the glueball. For a scalar glueball Ref. [87] finds a strong enhancement of the decays into $K\bar{K}$ and $\eta\eta$, in fairly close agreement with the measured branching ratios of the $f_0(1710)$, while Ref. [99] predicts the (so far not measured) rate into $\eta\eta'$ to be very small.

In $\gamma\gamma$ collisions leading to K_SK_S [100] and K^+K^- [101] a spin-0 signal is observed at the $f_0(1710)$ mass (together with a dominant spin-2 component), while the $f_0(1500)$ is not observed in $\gamma\gamma \to K\bar{K}$ nor $\pi^+\pi^-$ [102]. The $f_0(1500)$ is also not observed by Belle in $\gamma\gamma \to \pi^0\pi^0$, although a shoulder is seen which could also be due to the $f_0(1370)$ [103]. The absence of $f_0(1500)$ signal in the $\pi\pi$ channel in $\gamma\gamma$ collisions does not favor an $\overline{n}n$ interpretation for the $f_0(1500)$. The upper limit for $\Gamma_{2\gamma}$ (< 1.4 keV) in $\pi^+\pi^-$ [13]) excludes a large $n\overline{n}$ content, and hence points to a mainly $s\overline{s}$ content [13], which contradicts the small $K\overline{K}$ decay branching ratio of the $f_0(1500)$ [10, 21, 41]. Belle finds that in $\gamma\gamma \to K_SK_S$ collisions the 1500 MeV region is dominated by the $f_2'(1525)$. The $f_0(1710)$ is also observed with a production rate × branching ratio compatible with an $s\bar{s}$ state [104]. Note, however, that the $\gamma\gamma$ couplings of glueballs are sensitive to glue mixing with $q\bar{q}$ [56]. Ref. [76] predict the glueball $\gamma\gamma$ partial width in the few keV range (comparable to that of $q\bar{q}$ mesons) due to couplings of vector mesons to γ via VDM, in agreement with holographic models [77].

Alternative assignments for the scalar glueball have been proposed: In Ref. [80] the gluonic signal is distributed over $f_0(1370)$, $f_0(1500)$ and another broad isoscalar around 1530 MeV, while the gluonic contribution to the $f_0(1710)$ is small. As mentioned already, in Ref. [69, 86, 87] the $f_0(1710)$ is the glueball state, as in Ref. [84], where the $f_0(1500)$ is the $q\bar{q}$ octet state degenerate with the $a_0(1450)$. In the generalized linear sigma model [105] the $a_0(980)$ is dominantly a tetraquark and $a_0(1450)$ a $q\bar{q}$ state. The $f_0(980)$, $f_0(1370)$ and $f_0(1500)$ (or $f_0(1710)$) are dominantly tetraquark, $q\bar{q}$ and glue.

In Ref. [82] the $f_0(500)$ and $f_0(1370)$ are signals from a single broad resonance proposed as the scalar glueball. The ground state scalar nonet then consists of the $f_0(980)$, $a_0(980)$, $K_0^*(1430)$, $f_0(1500)$ and $f_0(1710)$ [31]. The $f_0(980)$ and $f_0(1500)$ mix (similarly to the η and η' in the pseudoscalar nonet), while the $f_0(1500)$ mixes with a glueball in the 500 – 1000 MeV mass range, which is identified as the $f_0(500)$.

In Ref. [106], a large K^+K^- scalar signal reported by Belle in B decays into $KK\bar{K}$ [107], compatible with the $f_0(1500)$, is explained as due to constructive interference of a flavor octet with a broad glueball background. However, the Belle data are inconsistent with the BaBar measurements which show instead a broad scalar at this mass for B decays into both $K^\pm K^\pm K^\mp$ [108] and $K^+K^-\pi^0$ [109].

The $f_0(1500)$ is observed by BESII in $J/\psi(1S) \to \gamma\pi\pi$ [110] and by BESIII in $J/\psi(1S) \to \gamma\eta\eta$ [111] with a much smaller rate than for the $f_0(1710)$, which would speak against a glueball interpretation of the former, although the systematic errors are large. Also, the $f_0(1500)$ appears at a lower mass and the $f_0(1710)$ at a higher mass than the accepted values. However, the coupled channel analysis of more data on radiative $J/\psi(1S)$ decay from BESIII [57] (described in the next paragraph) finds comparable contributions from $f_0(1500)$ and $f_0(1710)$ with a preference for $\pi\pi$ decay over $K\bar{K}$ for the former and $K\bar{K}$ over $\pi\pi$ for the latter.

The authors of Ref. [57] have analyzed the high statistics data from $J/\psi(1S)$ radiative decays into $\pi^0\pi^0$, $K_S^0K_S^0$, $\eta\eta$ and $\omega\phi$ from BESIII, including data on $\pi\pi$, $\eta\eta$ and $\eta\eta'$ from the CERN SPS, BNL data on $\pi\pi \to K_S^0K_S^0$ and $\bar{p}p$ annihilation data from LEAR into various final states. The coupled channel analysis requires ten scalar mesons, the established ones in the *Review* and the $f_0(2020$, as well as the isoscalars $f_0(2100, 2200, 2330)$ so far omitted from the *Summary Table*. As a new feature, the $f_0(1710)$ splits into two states, one at about 1700 MeV, the former $f_0(1710)$, and the new $f_0(1770$ discussed above, being mandatory to obtain a good fit. A broad (∼370 MeV) enhancement is observed in $J/\psi(1S)$ radiative decays around 1865 MeV, attributed to the contribution of glue distributed among the scalar mesons, with a very strong contribution from the 1770 MeV state [58]. In this model there are no supplementary states as the glue 'fragments' between the various isoscalars.

Ref. [112] reports on a very recent re-analysis of the BESIII $J/\psi(1S)$ radiative decay data into $\pi^0\pi^0$ and $K_S^0K_S^0$. A good fit is obtained with only two scalar resonances below 2 GeV, the $f_0(1500)$ and $f_0(1710)$. The latter is more strongly produced, which points to a sizeable glueball component.

Isospin	Decay channel	γ^2
0	$\pi\pi$	$3\cos^2\alpha$
	$K\overline{K}$	$(\cos\alpha - \sqrt{2}\sin\alpha)^2$
	$\eta\eta$	$(\cos\alpha\cos^2\phi - \sqrt{2}\sin\alpha\sin^2\phi)^2$
	$\eta\eta'$	$\frac{1}{2}\sin^2 2\phi\ (\cos\alpha + \sqrt{2}\sin\alpha)^2$
1	$\eta\pi$	$2\ \cos^2\phi$
	$\eta'\pi$	$2\ \sin^2\phi$
	$K\overline{K}$	1
$\frac{1}{2}$	$K\pi$	$\frac{3}{2}$
	$K\eta$	$(\sin\phi - \frac{\cos\phi}{\sqrt{2}})^2$
	$K\eta'$	$(\cos\phi + \frac{\sin\phi}{\sqrt{2}})^2$

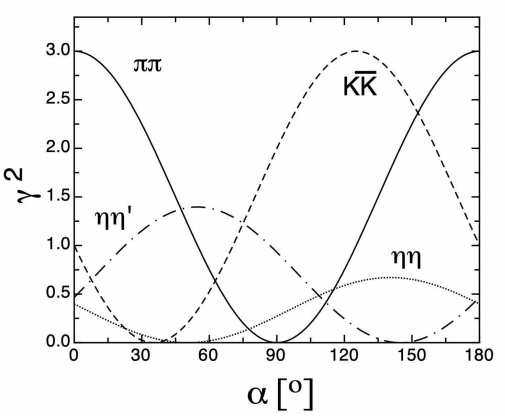

Figure 63.2: Left: SU(3) couplings γ^2 for scalar (or tensor) $q\bar{q}$ meson decays. The angles α and ϕ are defined as $\alpha = 54.7^\circ + \theta$ and $\phi = 54.7^\circ + \theta_P$, where θ is the mixing angle of the decaying isoscalars and θ_P the mixing angle in the 0^{-+} nonet. The partial decay width is given by $\Gamma = C \times \gamma^2 \times |F(q)|^2 \times q$, where C is a nonet constant, q the momentum of the decay products and $F(q)$ a form factor which may be taken as $|F(q)|^2 = q^{2\ell} \times \exp(-q^2/8\beta^2)$ with β= 0.5 GeV/c, and where ℓ is the relative angular momentum between the decay products ($\ell = 0$ for scalars and $\ell = 2$ for tensors). Right: SU(3) couplings as a function of mixing angle α for isoscalar decays for $\theta_P = -17.3^\circ$ (from [78]).

63.3.2 *Tensor glueballs*

Above the well known $f_2(1270)$ and $f_2'(1525)$ $q\bar{q}$ mesons, the $f_2(1640)$ and $f_2(1950)$ are tentatively assigned to the 2^3P_2 nonet (see fig. 63.1). The broad $f_2(1950)$ has been observed by several experiments, *e.g.* in central production [22] and in $\overline{p}p$ annihilation in flight [17] and is often identified as a glueball [113], the ground state of the pomeron [114,115]. Three further isoscalar tensors are established, the $f_2(2010)$, $f_2(2300)$ and $f_2(2340)$, which are in the range of the 1^3F_2 and 3^3P_2 nonets. The large $\phi\phi$ cross section in $\overline{p}p$ just above threshold [116] could be due to the production of the 2^{++} glueball, in accord with earlier observations in $\pi^- N \to \phi\phi n$ reactions [117,118] and in central collisions [119].

The $f_2(2010)$, $f_2(2300)$ and $f_2(2340)$ have been observed by BESIII in $J/\psi(1S) \to \gamma\phi\phi$ [120]. The production rate of a tensor glueball in $J/\psi(1S)$ radiative decay has been calculated in quenched lattice QCD to be large (around 1%) [121] and is claimed by BESIII [120] to be compatible with their rates measured in $J/\psi(1S) \to f_2(2340)$, $f_2(2340) \to \eta\eta$ [111], and $f_2(2340) \to \phi\phi$ [120]. The authors of Ref. [122] have re-analyzed the $J/\psi(1S)$ radiative decay into $\pi^0\pi^0$ and $K_S K_S$ from BESIII and found an enhancement described by a 360 MeV broad pole around 2210 MeV, possibly composed of the resonances observed earlier in $\phi\phi$.

The relatively narrow $f_2(2300)$ with a measured width of 149 MeV [118] is preferred by the holographic QCD model of Ref. [123]. However, the tensor glueball is predicted to be much broader (600-900 MeV) by the holographic model of Ref. [124].

There is no evidence for a narrow meson, $f_J(2220)$ (a tensor candidate) in $\overline{p}p$ annihilation (see the note under the $f_J(2220)$ in the 2004 issue of the *Review*). The measured partial width to $\overline{p}p$ in radiative $J/\psi(1S)$ decay [125] is too large and inconsistent with the upper limit from $\overline{p}p$ annihilation into $\pi\pi$ [126].

63.4 Pseudoscalar mesons

We now deal with the first radial excitations of the 0^{-+} nonet (fig. 63.1). The $\pi(1300)$ is a very broad resonance (200–600 MeV) decaying into 3π. The $K(1460)$ was recently confirmed with high statistics data from LHCb in $D^0 \to K3\pi$ decays [127] and has become an established kaon excitation. The first observation of an isoscalar resonance around 1425 MeV – the E-meson – was made in $p\overline{p}$ annihilation at rest into $E\,\pi^+\pi^-$, $E \to K\overline{K}\pi$ [128]. This state was reported to decay into $a_0(980)\pi$ and $K^*(892)\overline{K}$ with roughly equal contributions. An isoscalar state, the ι meson, was observed in radiative $J/\psi(1S)$ decay into $K\overline{K}\pi$ [129–131] and $\gamma\rho$ [132], and was considered at that time as a glueball candidate, owing to its strong signal in radiative $J/\psi(1S)$ decay. The E and ι were later assumed to be the same state, called $\eta(1440)$.

The $\eta(1295)$ has been observed in various production mechanisms, in $\pi^- p$ experiments [133–136], and possibly in $\overline{p}p$ annihilation [137, 138]. In $J/\psi(1S)$ radiative decay, the $\eta(1295)$ signal is also evident in the 0^{-+} $\eta\pi\pi$ wave of the DM2 data [139]. Also BaBar reports a signal around 1295 MeV in B decays into $\eta\pi\pi K$ [140]. We therefore assume that the $\eta(1295)$ is one of the isoscalars in this nonet.

However, two isoscalars were later observed in this mass region, the $\eta(1405)$ and $\eta(1475)$. The former decays mainly into $a_0(980)\pi$ (or direct $K\overline{K}\pi$) and the latter mainly into $K^*(892)\overline{K}$. The simultaneous observation of two pseudoscalars is reported in three production mechanisms: $\pi^- p$ [133, 141], radiative $J/\psi(1S)$ decay [139,142], and $\overline{p}p$ annihilation at rest [143–146]. All of them give values for the masses, widths, and decay modes that are in reasonable agreement. (However, Ref. [139] favors a state decaying into $K^*(892)\overline{K}$ at a lower mass than the state decaying into $a_0(980)\pi$.) In $J/\psi(1S)$ radiative decay, the $\eta(1405)$ decays into $K\overline{K}\pi$ through $a_0(980)\pi$, and hence a signal is also expected in the $\eta\pi\pi$ mass spectrum. This was indeed observed by MARK III in $\eta\pi^+\pi^-$ [147], which reported a mass of 1400 MeV, in line with the existence of the $\eta(1405)$ decaying into $a_0(980)\pi$. The $\eta(1405)$ decaying into $\eta\pi\pi$ is also observed by Crystal Barrel [138]. Two states were also reported by BES: Around 1452 MeV BESII observed a $K\bar{K}\pi$ enhancement in $J/\psi(1S) \to \omega K\bar{K}\pi$ but not in $J/\psi(1S) \to \phi K\bar{K}\pi$ [148], while BESIII reported a 52 MeV broad state in $\psi(2S) \to \omega K^* K$ [149], both left without J^{PC} determination.

The $K\overline{K}\pi$ and $\eta\pi\pi$ channels were studied in $\gamma\gamma$ collisions by L3 [150]. (For the 2γ couplings of glueballs and $q\bar{q}$ mesons see [76, 77, 151, 152].) The analysis led to a clear $\eta(1475)$ signal in $K\overline{K}\pi$, decaying into $K^*\overline{K}$, well identified in the untagged data sample, where spin 1 resonances are not allowed. At the same time, L3 did not observe the $\eta(1405)$, neither in $K\overline{K}\pi$ nor in $\eta\pi\pi$ [150]. On the other hand, CLEO-II did not observe any pseudoscalar signal with tagged γ's in $\gamma\gamma \to \eta(1475) \to K_S^0 K^\pm\pi^\mp$ [153], with an upper limit slightly smaller than the signal observed by L3. After the CLEO-II result, L3 performed a further analysis with full statistics [154], confirming their previous evidence for the $\eta(1475)$. The CLEO upper limit [153] for $\Gamma_{\gamma\gamma}$, and the L3 results [154], are consistent with the world average for the $\eta(1475)$ width. BaBar [140] also reported the $\eta(1475)$ in B decays into $K\bar{K}^*$ recoiling against a K, while upper limits only were given for the $\eta(1405)$.

Hence, in radiative $J/\psi(1S)$ decay, $\pi^- p$ and $\overline{p}p$ annihilation at rest two isoscalar signals are observed in the 1400 – 1500 MeV mass region, while the $\eta(1405)$ is not seen in $\gamma\gamma$ interactions nor in B decays. The $\eta(1475)$ could be the first radial excitation of the η', with the $\eta(1295)$ being the first radial excitation of the η. Ideal mixing, suggested by the $\eta(1295)$ and $\pi(1300)$ mass degeneracy, would then imply that the second isoscalar in the nonet is mainly

$s\bar{s}$, and hence couples to $K^*\overline{K}$, in agreement with properties of the $\eta(1475)$. Also, its width agrees with the expected one for the radially excited $s\bar{s}$ state [85, 91]. A study of radial excitations of pseudoscalar mesons [155] also favors the $s\bar{s}$ interpretation of the $\eta(1475)$. However, due to the strong kinematical suppression in $\eta(1405) \to K^*\overline{K}$ the data are not sufficient to exclude a sizeable $s\bar{s}$ admixture also in the $\eta(1405)$.

The supernumerary isoscalar $\eta(1405)$ would be a candidate for the 0^{-+} glueball in the fluxtube model [156], in which the 0^{++} glueball is also naturally related to a 0^{-+} glueball with mass degeneracy broken in QCD. However, this scenario is not favored by lattice gauge theories which predict the 0^{-+} state above 2 GeV [70, 157] (see 'Quark model' in this issue of the *Review*). Nevertheless, the pseudoscalar glueball could lie at a lower mass than predicted from lattice calculation [158], see also Refs. [159–161]. The holographic model of Ref. [77] predicts the pseudoscalar glueball below 2600 MeV, decaying dominantly into two vector mesons. A detailed review of the experimental situation on the pseudoscalar glueball is available in Ref. [162].

Here also, there are alternative explanations. The mere existence of the $\eta(1295)$ is questioned in Refs. [3, 163], in which the authors also propose a single pseudoscalar meson at 1440 MeV, the first radial excitation of the η. According to Ref. [3] the splitting of the 1440 MeV state into $\eta(1405)$ and $\eta(1475)$ is due to nodes in the decay amplitudes, which differ in $\eta\pi\pi$ and $K^*(892)\overline{K}$. The splitting could also be due to a triangle singularity, hence the manifestation of one state only (fig. 63.3) [164–166]. The importance of the triangle singularity for the $\eta(1295)$ and $\eta(1405/1475)$ in the $\eta\pi\pi$ and $K\bar{K}\pi$ channels is stressed in Ref. [167].

In Ref. [168], using the triangle singularity approach of [164], the authors conclude that the BESIII results can be reproduced either with the $\eta(1405)$ or the $\eta(1475)$, or by a mixture of these two states. From a high statistics data sample in $J/\psi(1S) \to \gamma K_S K_S \pi^0$ BESIII reports the observation of both $\eta(1405)$ and $\eta(1475)$ [169]. A one resonance parametrization is ruled out and triangle singularity models do not describe the data satisfactorily. This radiative decay channel has been studied in a three-body unitary coupled-channel analysis and compared to the BESIII data, including ratios of radiative branching ratios into $\eta\pi^+\pi^-$ and $K\bar{K}\pi$ through the $\eta(1405/1475)$ intermediate states [170]. Two poles emerge for $K^*\overline{K}$ in different Riemann sheets around 1400 MeV and only one pole around 1500 MeV.

To summarise this section, the experimental data on the 1400 — 1500 MeV region span several decades, various production mechanisms and decay modes, with models for data analysis evolving with time. A comprehensive coherent picture of all available data is therefore difficult. We believe that there is sufficient evidence to consider the 0^{-+} nonet with the $\eta(1440)$ in fig. 63.1 as established. Whether one or two different states – $\eta(1405)$ and $\eta(1475)$ – exist is an open question, in which case the $\eta(1405)$ would be supernumerary. The most recent high statistics data and their theoretical interpretation seem to favor the two-resonance scenario.

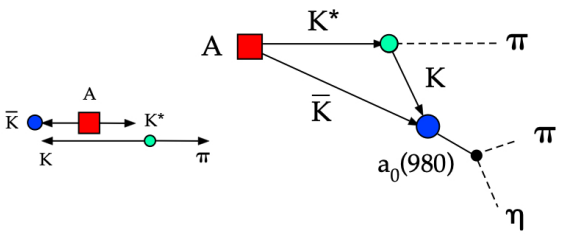

Figure 63.3: Triangle singularity: a state A decays into $K^*\overline{K}$. The K from K^* decay catches up with the $\overline{K}$ and excites the $a_0(980)$ resonance which in turn decays into $\eta\pi$. This mechanism can lead to two distinct peaks (depending on the width of A), one in $K^*\overline{K}$ and the other via rescattering in $\eta\pi\pi$. Similarly, the virtual $K^*\overline{K}$ loop can couple to $f_0(980)$ which, decaying into $\pi\pi$, leads to a peak in the 3π final state.

63.5 Vector mesons

In this section we restrict ourselves to the more interesting isovector spectrum which contains broad and overlapping states.

63.5.1 *The* $\rho(770)$ *meson*

The determination of the parameters of the $\rho(770)$ is beset with many difficulties because of its large width. The line shape depends on the production process and is not described by a relativistic Breit-Wigner function with a P-wave width, but requires some additional shape parameter. This dependence on parameterization was demonstrated long ago [171]. Bose-Einstein correlations are another source of shifts in the $\rho(770)$ line shape, particularly in multiparticle final-state systems [172].

The same model dependence afflicts any other source of resonance parameters, such as the energy dependence of the phase shift δ_1^1, or the pole position. It is, therefore, not surprising that a study of $\rho(770)$ dominance in the decays of the η and η' reveals the need for specific dynamical effects, in addition to the $\rho(770)$ pole [173, 174].

The cleanest determination of the $\rho(770)$ mass and width comes from e^+e^- annihilation and τ-lepton decays. ALEPH data [175] showed that the charged $\rho(770)$ parameters measured from τ-lepton decays are consistent with those of the neutral one determined from e^+e^- data [176]. This conclusion is qualitatively supported by the later studies of CLEO [177] and Belle [178]. However, a comparison of the two-pion mass spectrum in τ decays from OPAL [179], CLEO [177], and ALEPH [180, 181], and the $e^+e^- \to \pi^+\pi^-$ cross section from CMD-2 [182, 183], showed significant discrepancies between the two shapes which can be as high as 10% above the ρ meson mass [184, 185]. This discrepancy remains after measurements of the two-pion cross section in e^+e^- annihilation at KLOE [186–189], SND [190, 191], BaBar [192] and, more recently BESIII [193]. The effect is not accounted for by isospin breaking [194–197], but the accuracy of its calculation may be overestimated [198, 199].

Two recent measurements of the $e^+e^- \to \pi^+\pi^-$ cross section by SND [200] and CMD-3 [201, 202] show discrepancies in the ρ region: while SND is consistent with previous e^+e^- experiments, CMD-3 finds differences as high as 5% around the ρ meson mass. In addition, in the fit of the $e^+e^- \to \pi^+\pi^-$ cross section CMD-3 reports values for the mass of the ω and the mass and width of the ϕ, which differ slightly from the PDG values, showing for the first time the effect of the $\phi \to \pi^+\pi^-$ interference.

The problem of the difference in the $\pi^+\pi^-$ shapes between e^+e^- and τ decays seems to be solved after a recent analysis by [203], which showed that, after correcting the τ data for the missing $\rho-\gamma$ mixing contribution, besides the other known isospin symmetry violating corrections, the $\pi\pi$ isospin 1 part of the hadronic vacuum polarization contribution to the muon $g-2$ is fully compatible between τ-based and e^+e^--based evaluations. The global fit of the whole set of the ρ, ω, and ϕ decays, taking into account mixing effects in the hidden local symmetry model, also showed consistency of the two-pion data in τ decay and e^+e^- annihilation [204, 205]. However, because of the progress in e^+e^- data, the τ input is now less precise and less reliable due to additional theoretical uncertainties [206] decreasing the importance of τ decay for the determination of the $\rho(770)$ parameters.

63.5.2 *The* $\rho(770)$ *excitations*

In our 1988 edition, we replaced the $\rho(1600)$ entry with two new ones, the $\rho(1450)$ and the $\rho(1700)$, because there was emerging evidence that the 1600-MeV region actually contains two ρ-like resonances. This possibility was pointed out by a theoretical analysis [207] on the consistency of the 2π and 4π electromagnetic form factors and the $\pi\pi$ scattering length. A consistent picture of $e^+e^- \to 2\pi, 4\pi$ and diffractive photoproduction is obtained with two resonances [208]. The existence of the $\rho(1450)$ was supported by the analysis of $\eta\rho^0$ mass spectra obtained in photoproduction and e^+e^- annihilation [209], as well as that of $e^+e^- \to \omega\pi$ [210].

The analysis of [208] was further extended by [211, 212] to include new data on 4π-systems produced in e^+e^- annihilation, and in τ decays ($\tau \to 4\pi$ and $e^+e^- \to 4\pi$ are related by the Conserved Vector Current hypthesis). These systems were successfully analyzed using interfering contributions from two ρ-like

states, and from the tail of the $\rho(770)$ two-body decay. While specific conclusions on $\rho(1450) \to 4\pi$ were obtained, little could be said about the $\rho(1700)$. Independent evidence for two 1^- states is provided by [213] in 4π electroproduction at $\langle Q^2 \rangle = 1$ (GeV/c)^2, and by [214] in a high-statistics sample of the $\eta\pi\pi$ system in $\pi^- p$ charge exchange.

This scenario with two overlapping resonances is supported by other data. DM2 [215] measured the pion form factor in the interval 1.35–2.4 GeV, and observed a deep minimum around 1.6 GeV. The best fit was obtained with the hypothesis of ρ-like resonances at 1420 and 1770 MeV, with widths of about 250 MeV. DM2 [216] found that the $e^+e^- \to \eta\,\pi^+\,\pi^-$ cross section is better fitted with two fully interfering Breit-Wigners, with parameters in fair agreement with those of [208] and [215]. These results can be considered as a confirmation of the $\rho(1450)$.

Decisive evidence for the $\pi\pi$ decay mode of both $\rho(1450)$ and $\rho(1700)$ comes from $\overline{p}p$ annihilation at rest [217]. It has been shown that these resonances possess a $K\overline{K}$ decay mode [10, 218, 219]. This decay mode has also been studied in three-body hadronic B decays [220]. High-statistics studies of the decays $\tau \to \pi\pi\nu_\tau$ [175, 177], and $\tau \to 4\pi\nu_\tau$ [221] also require the $\rho(1450)$, but are not sensitive to the $\rho(1700)$, being too close to the τ mass. A recent very-high-statistics study of the $\tau \to \pi\pi\nu_\tau$ from Belle [178] reports the first observation of both $\rho(1450)$ and $\rho(1700)$ in τ decays. A clear picture of the two $\pi^+\pi^-$ resonances interfering with the $\rho(770)$ in e^+e^- annihilation was also reported by BaBar using the ISR (Initial State Radiation) method [222], and more recently by CMD-3 [201].

The structure of these ρ states is not yet completely clear. The authors of Refs. [85,223] claim that $\rho(1450)$ has a mass consistent with radial $2S$, but its decays show characteristics of hybrids, and suggest that this state may be a $2S$-hybrid mixture. Hybrid states could have a 4π decay mode dominated by the $a_1\pi$ [224]. Such behavior has been observed by [225] in $e^+e^- \to 4\pi$ in the energy range 1.05–1.38 GeV, and by [221] in $\tau \to 4\pi$ decays. CLEO [226] and Belle [227] observe the $\rho(1450) \to \omega\pi$ decay mode in B-meson decays, however, do not find $\rho(1700) \to \omega\pi^0$. A similar conclusion is made in Refs. [228,229], which studied the process $e^+e^- \to \omega\pi^0$ and do not observe a statistically significant signal of the $\rho(1700)$. Various decay modes of the $\rho(1450)$ and $\rho(1700)$ are observed in $\overline{p}n$ and $\overline{p}p$ annihilation [230, 231], but no definite conclusions can be drawn. More data should be collected to clarify the nature of the ρ states, particularly in the energy range above 1.6 GeV.

We now list under a separate entry the $\rho(1570)$, the $\phi\pi$ state with $J^{PC} = 1^{--}$ earlier observed in [232] – referred to as $C(1480)$ – also reported in [233] and possibly seen in [234]. While this may be due to a threshold effect [235], Refs. [211] and [236] suggest two independent vector states with this decay mode. The $C(1480)$ has not been seen in $\overline{p}p$ [237] nor in other e^+e^- [238,239] experiments. However, the sensitivity of the two latter is an order of magnitude lower than that of Ref. [234] which cannot exclude that the observation is due to an OZI-suppressed decay mode of the $\rho(1700)$.

Several observations on the $\omega\pi$ system in the 1200 MeV region [240–246] may be interpreted in terms of either $J^P = 1^-$ $\rho(770) \to \omega\pi$ production [247], or $J^P = 1^+$ $b_1(1235)$ production [245, 246]. The LASS amplitude analysis [248] showing evidence for $\rho(1270)$ is preliminary and needs confirmation. Evidence for a $\rho(1250)$ from a reanalysis of elastic scattering data is claimed in Ref. [249].

Ref. [250] reported a very broad 1^{--} resonance-like K^+K^- state in $J/\psi \to K^+K^-\pi^0$ decays. Its pole position corresponds to mass of 1576 MeV and width of 818 MeV. Its exotic structure (molecular or multiquark) is suggested [251–253], while in Refs. [254] and [255] this is explained by the interference between the $\rho(1450)$ and $\rho(1700)$. The latter statement is qualitatively supported by BaBar [256] and SND [257]. We quote the state reported by [250] as $X(1575)$ in the section "Further States." Another state observed in $J/\psi \to K^+K^-\pi^0$ is the $\phi(2170)$ [258] which has been interpreted as exotic, e.g. as tetraquark, see section 63.8.

Evidence for ρ-like mesons decaying into 6π was first noted by [259] in the analysis of $e^+e^- \to 6\pi$ [260, 261] and diffractive photoproduction [262]. The authors of Ref. [259] argued that two states at about 2.1 and 1.8 GeV exist: while the former is a candidate for the $\rho(2150)$, the latter could be a manifestation of the $\rho(1700)$ distorted by threshold effects. BaBar reported observations of the new decay modes of the $\rho(2150)$ in the channels $\eta'(958)\pi^+\pi^-$, $f_1(1285)\pi^+\pi^-$ [263] and $\pi^+\pi^-$ [264]. The decay of the $\rho(2150)$ into K^+K^- has been observed by BESIII [265] and confirmed by BaBar [266]. The relativistic quark model [267] predicts the 2^3D_1 state with $J^{PC} = 1^{--}$ at 2.15 GeV which can be identified with the $\rho(2150)$.

Under $\rho(1900)$ we list various observations of irregular behavior of the cross sections near the $N\bar{N}$ threshold. Dips of various width around 1.9 GeV were reported by the E687 Collaboration (a narrow one in the $3\pi^+3\pi^-$ diffractive photoproduction [268, 269]), by the FENICE experiment reporting a narrow dip [270], by BaBar in ISR (a narrow structure in $e^+e^- \to \phi\pi$ final state [234], but much broader in $e^+e^- \to 3\pi^+3\pi^-$ and $e^+e^- \to 2(\pi^+\pi^-\pi^0)$ [271]), by CMD-3 (also a rather broad dip in $e^+e^- \to 3\pi^+3\pi^-$ [272]). A dedicated scan of the $N\bar{N}$-threshold region by CMD-3 confirms this effect in the $e^+e^- \to 3\pi^+3\pi^-$ and $e^+e^- \to K^+K^-\pi^+\pi^-$ final states, but does not see it in the cross section of $e^+e^- \to 2\pi^+2\pi^-$ [273]. Most probably, these structures emerge as a threshold effect due to the opening of the $N\bar{N}$ channel [274–276]. A similar enhancement is observed by BESIII in $e^+e^- \to \Lambda\bar{\Lambda}$ near the $\Lambda\bar{\Lambda}$ threshold [277, 278] which can be described as $\Lambda\bar{\Lambda}$ final state interaction [279].

63.6 Axial-vector mesons

The $J^{PC} = 1^{++}$ nonet consists of the isovector $a_1(1260)$, the isoscalars $f_1(1285)$ and $f_1(1420)$, and the K_{1A}, which is a superposition of the physical states $K_1(1270)$ and $K_1(1400)$ with a mixing angle of about 35° [280]. The nonet mixing angle $\theta_{1^{++}}$ is around 23°. The orthogonal combination – the K_{1B} – belongs to the 1^{+-} nonet with a mixing angle $\theta_{1^{+-}}$ of about 28° [280]. $f_1(1510)$. However, a two-pole structure for the $K_1(1270)$ emerges when using the unitary extension of chiral perturbation theory [281].

The mass region above 1400 MeV is rather complex [282–284]. The $f_1(1420)$ was first reported in $\pi^- p$ reactions at 4 GeV/c, decaying into $K^*\overline{K}$ [285]. The $f_1(1420) \to K\overline{K}\pi$ was also observed in a reanalysis of the MARK III data [142], and a C=+1 state seen in tagged $\gamma\gamma$ collisions [286]. Axial-vector mesons are not observed in $\overline{p}p$ annihilation at rest in liquid hydrogen, which proceeds dominantly through S-wave annihilation. However, in gaseous hydrogen, P-wave annihilation is enhanced and the $f_1(1420)$ is indeed observed, decaying into $K^*\overline{K}$ [144]. The $f_1(1420)$, decaying into $K\overline{K}\pi$, is also seen in pp central production, together with the $f_1(1285)$. The latter decays via $a_0(980)\pi$, and the former only via $K^*\overline{K}$. The $K^0_S K^0_S \pi^0$ decay mode of the $f_1(1420)$ establishes unambiguously C=+1. Neither central production [287] nor $\pi^- p$ interactions at 100 GeV [135] find any evidence for a $\eta\pi\pi$ decay mode of the $f_1(1420)$.

The $f_1(1285)$ has been suggested to be a $K^*\overline{K}$ molecule [288]. However, LHCb has determined the 1^{++} nonet mixing angle to be consistent with a mostly $n\bar{n}$ structure for the $f_1(1285)$ from $\overline{B}^0/\overline{B}^0 \to J/\psi(1S)f_1(1285)$, independent of the identity of its isoscalar partner [289]. The mixing angle $\theta_{1^{++}} = 24°$ agrees with that of Ref. [280] quoted above. The ratio of $\overline{B}^0/\overline{B}^0_s$ decay rates also excludes the tetraquark interpretation of the $f_1(1285)$ [289]. This is consistent with earlier determinations assuming that the $f_1(1420)$ is the other isoscalar in the nonet [290].

The resonance candidate $a_1(1420)$ decaying into 3π, reported earlier by COMPASS at 1420 MeV in $\pi^- p \to \pi^-\pi^-\pi^+ p$ [291,292], appears to originate from a triangle singularity: the decay of the $a_1(1260)$ into $K^*(\to K\pi)\bar{K}$ is followed by rescattering into the $f_0(980)\pi$ channel, $f_0(980) \to \pi\pi$ [293] (see the caption of fig. 63.3). A similar triangle singularity is proposed for the $f_1(1420)$, resulting from the $K^*\overline{K}$ and $a_0(980)\pi$ decay modes of the $f_1(1285)$ [294]. The $f_1(1420)$ was also suggested to be a hybrid $q\bar{q}g$ meson [295] or a $K^*\overline{K}$ molecule, due to the proximity of the $K^*\overline{K}$ threshold [296]. The $f_1(1420)$ is not seen in the $K^- p$ data [297], which would argue against this state being the $s\bar{s}$ member of the 1^{++} nonet. Note, however, that Ref. [298] reports a signal from $f_1(1420)$ in $K^- p$, but not in $\pi^- p$.

The $s\bar{s}$ partner of the $f_1(1285)$ could also be the (not well

established) $f_1(1510)$ [299]. This state was seen to decay into $K\bar{K}\pi$ in K^-p interactions at 4 and 11 GeV/c, recoiling against a Λ [297, 300], which indeed points to an $s\bar{s}$ state. Evidence was reported in π^-p interactions, based on the phase motion of the 1^{++} $K^*\overline{K}$ wave [284]. The $f_1(1510)$ is also needed by CMD-3 in $e^+e^- \to f_1\rho(770)$, together with the $f_1(1285)$ and $f_1(1420)$ peaks, to describe the shoulder in the $K_SK^\pm\pi^\mp$ mass around 1500 MeV [301]. A somewhat broader 1^{++} signal is observed in $J/\psi(1S) \to \gamma\eta\pi^+\pi^-$ [302] and a small signal in $J/\psi(1S) \to \gamma\eta'\pi^+\pi^-$ [303].

However, there is no evidence for the $f_1(1510)$ in other K^-p experiments [298, 304]. The $f_1(1510)$ is not seen in central collisions [305], nor in $\gamma\gamma$ collisions [306], although surprisingly for an assumed $s\bar{s}$ meson, a signal is reported in 4π decays [307]. Given this confusing experimental situation, the meson classification in the 1^{++} nonet is not entirely settled.

63.7 Hybrid mesons

Hybrids may be viewed as $q\bar{q}$ mesons with a vibrating gluon flux tube. In contrast to glueballs, they can have isospin 0 or 1 and be electrically charged. The mass spectrum of hybrids with exotic (non-$q\bar{q}$) quantum numbers was predicted in Ref. [308], while Ref. [309] also deals with non-exotic quantum numbers. The ground-state hybrids with quantum numbers (0^{-+}, 1^{-+}, 1^{--}, and 2^{-+}) are expected around 1.7 to 1.9 GeV. Lattice calculations predict that the hybrid with exotic quantum numbers 1^{-+} lies at a mass of 1.9 ± 0.2 GeV [310,311]. Most hybrids are expected to be rather broad, but some can be as narrow as 100 MeV [312]. They prefer to decay into a pair of S- and P-wave mesons. The lattice study in [313, 314], based on full QCD with pion masses around 400 MeV, finds that several of the high-lying states observed in their spectrum show significant overlap with gluon rich source terms interpreted as hybrid states. A very broad 1^{-+} structure is predicted by a recent lattice calculation [315]. The main decay mode is $b_1(1235)\pi$ (a pair of S- and P-wave mesons), while other modes, such as $\rho\pi$, $\eta\pi$ and $\eta'\pi$, are suppressed by at least an order of magnitude. For an experimental and theoretical review on hybrid mesons see [4, 316].

Two isovector 1^{-+} candidates have been reported, one around 1400 MeV (the $\pi_1(1400)$ in previous versions on this *Review*) and the $\pi_1(1600)$. The ∼350–400 MeV broad $\pi_1(1400)$, was reported in $\pi^-p \to \eta\pi^-p$ [317, 318] and in $\pi^-p \to \eta\pi^0n$ [319]. It was observed as an interference between the angular momentum $L = 1$ and $L = 2$ $\eta\pi$ amplitudes, leading to a forward/backward asymmetry in the $\eta\pi$ angular distribution. This state had been reported earlier in π^-p reactions [320], but ambiguous solutions in the partial wave analysis were pointed out [321, 322]. A resonating 1^{-+} contribution to the $\eta\pi$ P-wave is also required in the Dalitz plot analysis of $\bar{p}n$ annihilation into $\pi^-\pi^0\eta$ [323], and in $\bar{p}p$ annihilation into $\pi^0\pi^0\eta$ [324]. Mass and width are consistent with the results of Ref. [317]. A coupled channel re-analysis of the $\pi^0\pi^0\eta$, $\pi^0\eta\eta$ and $K^+K^-\pi^0$ Crystal Barrel data at 900 MeV/c, supplemented with data from other collaboration in $\pi\pi \to \pi\pi, K\bar{K}, \eta\eta$ and $\eta\eta'$, leads to a single 1^{-+} ∼600 MeV broad state with a pole around 1400 MeV, decaying into $\eta\pi^0$ [16]. Ref. [325] suggested for the production in π^-p that a Deck-generated $\eta\pi$ background from final state rescattering in $\pi_1(1600)$ decay could mimic $\pi_1(1400)$, a mechanism that is, however, absent in $\bar{p}p$ annihilation.

The $\pi_1(1600)$, decaying into $\rho\pi$, was reported by COMPASS with 190 GeV pions hitting a lead target [326, 327]. It had already been observed in π^-p interactions in the decay modes $\eta'\pi$ [328], $f_1(1285)\pi$ [329], and $\omega\pi\pi$ [330], $b_1(1235)\pi$, but not $\eta\pi$ [331]. A strong enhancement in the 1^{-+} $\eta'\pi$ wave, compared to $\eta\pi$, was reported at this mass in [332]. The enhancement is also observed by COMPASS in $\pi^-p \to \eta'\pi$ but in $\eta\pi$ a peak appears at 1400 MeV and in $\eta'\pi$ at 1600 MeV [333]. A coupled channel analysis of the $\eta\pi$ and $\eta'\pi$ COMPASS data leads to a single pole at 1564 ± 89 MeV, with a width of 492 ± 115 MeV [334]. The predicted width from the lattice calculation [315] is compatible with the COMPASS result. Furthermore, a combined analysis of the COMPASS and Crystal Barrel data at 900 MeV/c leads to similar results, a single pole around 1623 MeV, with a width of about 455 MeV, although a two-pole scenario cannot be completely excluded [335]. Accordingly, in the current review we have moved the former $\pi_1(1400)$ data into the $\pi_1(1600)$ section.

Very recently, BESIII reported a 188 MeV broad enhancement at 1855 MeV in $J/\psi(1S)$ radiative decay into the $\eta\eta'$ P-wave [336], hence with exotic quantum numbers 1^{-+}. This isoscalar resonance is needed with very high significance, albeit the contribution to $\gamma\eta\eta'$ is weak and several other isoscalars expected to contribute are absent [337]. Hence this state needs confirmation. In the past there had been claims for such a state decaying into $\eta\eta'$ in this mass range, which we have listed under the $f_2(1910)$ (see e.g. Ref. [26] from WA102 central production, suggesting 1^{-+} as an alternative to 2^{++}). If confirmed, the $\eta(1855)$ could be one of the isospin 0 partners of the $\pi_1(1600)$, a member of the 1^{-+} hybrid nonet [338–340] or a $K\bar{K}_1(1400)$ molecule [341].

Hybrid candidates with the non-exotic quantum numbers 0^{-+}, 1^{--}, and 2^{-+} have also been reported: the $\pi(1800)$ is somewhat narrow if interpreted as the second radial excitation of the pion. It decays mostly into a pair of S- and P-wave mesons [342,343], in line with expectations for 0^{-+} hybrid mesons. The evidence for 1^{--} hybrids in e^+e^- annihilation and in τ decays has been discussed in [224]. The near degeneracy of the $\eta_2(1645)$ and $\pi_2(1670)$ suggests ideal mixing in the 2^{-+} $q\bar{q}$ nonet, and hence, the second isoscalar, presumably the $\eta_2(1870)$, should be mainly $s\bar{s}$ (fig. 63.1). However, the $\eta_2(1870)$ is also observed in $\bar{p}p$ annihilation and decays mainly into $a_2(1320)\pi$ and $f_2(1270)\pi$ [344], with a relative rate compatible with a hybrid state [309].

Evidence for another exotic $\pi_1(2015)$ has been claimed in π^-p interactions [329, 330]. A flavor multiplet of vector hybrids between 2200 and 2300 MeV is predicted by the constituent gluon model [340].

Summarizing, there is evidence for a very broad 1^{-+} enhancement in the 1400–1600 MeV region, which consists in one (or pssibly two) exotic states, the lowest mass one favored by $\bar{p}p$ annihilation data, the highest one by high energy π^-p data. As isovectors, these states cannot be glueballs. The coupling to $\eta\pi$ of the lighter one points to a four-quark state [345], while the $\eta'\pi$ coupling of the heavier one is favored for hybrid states [346, 347]. The mass of the latter, the $\pi_1(1600)$, is not far below the lattice and flux tube model predictions. The $\eta_1(1855)$ is an isoscalar candidate for the ground state 1^{-+} hybrid nonet.

63.8 Tetraquark states

The existence of multiquark states was suggested a long time ago, based on duality arguments [348, 349]. The most prominent light tetraquark candidates are the $a_0(980)$ and $f_0(980)$ [350–352]. A remarkable prediction for the existence of low-lying four quarks states is based on color hyperfine splitting. The lowest ground state ($L = 0$) tetraquark multiplet is predicted to be a scalar nonet. The scalar nonet lies just below 1 GeV when one assumes as mass scale the hyperfine color splitting between the ρ and the π (for a simple derivation see [8]). One then gets the nonet structures

$$
\begin{aligned}
|a_0(980)\rangle &= |us\bar{d}\bar{s}\rangle, \frac{1}{\sqrt{2}}|(u\bar{u} - d\bar{d})s\bar{s}\rangle, |\bar{u}\bar{s}ds\rangle,\\
|f_0(980)\rangle &= \frac{1}{\sqrt{2}}|(u\bar{u} + d\bar{d})s\bar{s}\rangle,\\
|f_0(500)\rangle &= |\bar{u}\bar{d}ud\rangle,\\
|K_0^*(700)\rangle &= |\bar{s}\bar{d}ud\rangle, |\bar{s}\bar{u}ud\rangle \quad \text{and} \quad |\bar{u}\bar{d}us\rangle, |\bar{u}\bar{d}ds\rangle. \qquad (63.1)
\end{aligned}
$$

The two isoscalars are expected to mix with the angle φ:

$$
\begin{aligned}
|f_0(980)\rangle &= \cos\varphi|s\bar{s}\rangle + \sin\varphi|n\bar{n}\rangle,\\
|f_0(500)\rangle &= -\sin\varphi|s\bar{s}\rangle + \cos\varphi|n\bar{n}\rangle. \qquad (63.2)
\end{aligned}
$$

Whether these mesons are really tetraquark states or $q\bar{q}$ mesons, is still an open issue. The $f_0(980)$ is strongly produced in D_s^+ decay [354], which suggests a large $s\bar{s}$ component, due to the Cabibbo-favored $c \to s$ coupling. However, the mainly $n\bar{n}$ $f_0(1370)$ is also strongly produced in D_s^+ decay, hence additional graphs must contribute [355].

The relative branching ratios for $\bar{B}^0$ and $\bar{B}_s^0 \to J/\psi(1S)f_0(500)$ and $J/\psi(1S)f_0(980)$ can be used to probe the $q\bar{q}$ or tetraquark natures of the $f_0(500)$ and $f_0(980)$, as proposed in Refs. [353,356].

Table 63.1: Coupling amplitudes for $\bar{B}^0$ and $\bar{B}^0_s$ decays into $J/\psi(1S)f_0(500)/f_0(980)$, depending on the $q\bar{q}$ or tetraquark structures of the $f_0(500)$ and $f_0(980)$ (from [353] where illustrative decay diagrams can be found). The angle φ is defined in Eq. 63.2.

	$\bar{B}^0$		$\bar{B}^0_s$	
	$f_0(980)$	$f_0(500)$	$f_0(980)$	$f_0(500)$
$q\bar{q}$	$\sin\varphi/\sqrt{2}$	$\cos\varphi/\sqrt{2}$	$\cos\varphi$	$\sin\varphi$
$qq\bar{q}\bar{q}$	$1/\sqrt{2}$	1	$\sqrt{2}$	0

LHCb observes the $f_0(980)$ in $\bar{B}^0_s$ decays, but not the $f_0(500)$ [28], as would be expected for tetraquarks (see Table 63.1). In contrast, LHCb also observes the $f_0(500)$ in $\bar{B}^0$ decays, but not the $f_0(980)$ with an upper limit eight standard deviations below the predicted value for a tetraquark state [29]. However, these contradicting findings have been challenged by a dispersive analysis [357], using a model independent inclusion of hadronic final state interactions, in which a substantial $f_0(980)$ contribution is nevertheless found in $\bar{B}^0$-decays, thus still leaving the tetraquark structure as an open possibility. The ALICE collaboration reports a much stronger K_SK_S femtoscopic correlation than for $K_SK^\pm$ in high energy pp collisions, indicative of the $a_0(980)$ being a tetraquark state [358].

The $f_0(980)$ and $a_0(980)$ could also be $K\overline{K}$ molecular states [359–361], being close to the $K\overline{K}$ threshold and decaying strongly into $K\overline{K}$. For $q\bar{q}$ states, the expected $\gamma\gamma$ widths [362, 363] are not significantly larger than for molecular states [362, 364] and both predictions are consistent with data. Radiative decay of the $\phi(1020)$ into $a_0(980)$ and $f_0(980)$ were proposed to disentangle compact (tetraquark) structures from hadronic molecules. Following Refs. [365, 366] the data from KLOE [367, 368], CMD-2 [369] and SND [370] seem to favor these mesons to be tetraquark states. This is also supported by a BESIII analysis of $J/\psi(1S) \to \gamma\pi^0\pi^0$ data [371] and by a measurement of $a_0(980) - f_0(980)$ mixing at BESIII [372]. In Ref. [43] these states are made of four-quark cores and virtual $K\bar{K}$ clouds at the periphery, a view that is challenged in Ref. [373] showing that radiative ϕ decay data are consistent with molecular structures of light scalars.

As mentioned already, the $f_0(1500)$ [45] and the $f_1(1285)$ [353] have been proposed as tetraquarks, the latter also as $K^*\overline{K}$ molecule [288], together with the $f_1(1420)$ [296].

Another potential candidate for a tetraquark is the $\phi(2170)$. As an excited $q\bar{q}$ state of the $\phi(1020)$, this meson should decay strongly into K^+K^- and $K^0_SK^0_L$, and also $K^*\bar{K}^*$. However, these decays are not observed. Hence, based on its observed decay into $f_0(980)\phi(1020)$ this meson could be $ss\bar{s}\bar{s}$ [374], where relative decay rates into various channels are predicted for both $q\bar{q}$ and tetraquark structures of the $f_0(980)$. However Refs. [375,376] claim that the $\phi(2170)$ may not be a good candidate for the $ss\bar{s}\bar{s}$ state, but could qualify as an $su\bar{s}\bar{u}$ tetraquark [376].

More information on the $a_0(980)$, $f_0(980)$, $f_0(500)$ and $K^*_0(700)$ is provided by 'Scalar Mesons below 1 GeV' in the *Review*.

63.9 Baryonia

Nucleon-antinucleon ($N\bar{N}$) bound states and resonances (baryonium) were predicted a long time ago [377, 378], based on the strongly attractive $N\bar{N}$ meson exchange potential, which is obtained from the NN one by multiplying with the G-parity of the exchanged meson. Several candidates had been reported in the seventies by experiments at CERN, BNL and KEK, some of them being indisputably statistically significant (for details on the model and on experiments, see [379, 380] and references therein). Most potential models predict a sequence of deeply bound isoscalar baryonia with quantum numbers $J^{PC} = 2^{++}$, 1^{--} and 0^{++}, the latter being the mostly bound [381, 382]. The $f_2(1565)$ which is observed in $\bar{p}p$ annihilation only [383, 384], is a good candidate for the 2^{++} $\bar{p}p$ bound state.

Enhancements close to the $\bar{p}p$ threshold have also been reported in B decays [385–387]. The strong signal in $J/\psi(1S) \to \gamma\bar{p}p$ [388–390] could be due to a 0^{-+} baryonium [391], but could also be generated by the $N\bar{N}$ final state interaction [392–395]. The strong energy dependence of the cross section in $e^+e^- \to \bar{p}p$ [396, 397] and $\bar{p}p \to e^+e^-$ [398] is attributed to the $N\bar{N}$ final state interaction [399] (see also our comments on the $\rho(1900)$ at the end of section 63.5.2). Alternative explanations to baryonia have been proposed for the signals in $B \to \bar{p}pK$, such as the dynamics of the fragmentation mechanism [386].

63.10 Conclusions

The ground state nonets 1^1S_0, 1^3S_1, 1^1P_1, 1^3P_2, 1^1D_2 and 1^3D_3 (see fig. 63.1) are established (although more data are desirable for the $h_1(1415)$ in the 1^1P_1 nonet). There are uncertainties and ambiguities in all other nonets. In the pseudoscalar sector the $\eta(1440)$ consists of two states, one at 1405 MeV, the other at 1475 MeV, which could also be the manifestation of a single resonance decaying into two different final states. In this case the 1475 one could be the radial excitation of the η' and the 1405 the pseudoscalar ground state glueball predicted a long time ago by the bag model, although the lattice puts it above 2 GeV. In the 1^{++} nonet two isoscalars – the $f_1(1420)$ and $f_1(1510)$ – compete for the $s\bar{s}$ slot. The first radial excitation 2^3S_1 is complete, but questions have been raised as to the nature of the $\rho(1450)$ and its relation to the $\rho(1700)$. The classification of scalar mesons is not settled, with the ones below 1 GeV being tetraquark states or building the ground state nonet. The nature of the scalars in the 1.5 – 1.8 GeV region is unclear, obscured by the interference with the ground state scalar glueball predicted in this mass region. For example, the $f_0(1500)$ and the $f_0(1710)$ could be $q\bar{q}$ states ($n\bar{n}$ and $s\bar{s}$, respectively) or made of gluons mixed with $q\bar{q}$. The $f_0(1500)$, or alternatively the $f_0(1710)$, have been proposed as mostly gluonic. Scalar mesons above the $f_0(1710)$ need experimental confirmation. Another pair of scalars, $a_0(1710)$ and $f_0(1770)$, has been reported. An isovector meson with exotic (1^{-+}) quantum numbers, $\pi_1(1600)$, is observed around 1.6 GeV with mass not far below theoretical predictions, although a further 1^{-+} state, decaying into $\eta\pi$, cannot be entirely excluded around 1.4 GeV. An isoscalar partner, the $\eta_1(1855)$, has been reported. Above 1.8 GeV mesons are broad and overlap, which complicates the data analyses. This makes the classification difficult, in particular the identification of the 2^{++} glueball, expected in 2200 – 2300 MeV mass range.

64. Scalar Mesons below 1 GeV

Revised August 2023 by T. Gutsche (Tübingen U.), C. Hanhart (FZ Jülich), R.E. Mitchell (Indiana U.) and S. Spanier (Tennessee U.).

64.1 Introduction

The identification of the light scalar mesons is a long-standing puzzle. Scalar resonances are difficult to resolve experimentally as they can have large decay widths, which cause a strong overlap between neighboring resonances and with background. In addition, in some cases, several decay channels open up within a short mass interval (*e.g.* at the $K\bar{K}$ and $\eta\eta$ thresholds), producing cusps in the line shapes of the nearby resonances. Furthermore, one expects non-$q\bar{q}$ scalar objects, such as hadronic molecules and multiquark states, in the mass range of interest (for reviews see, *e.g.*, Refs. [1–6]).

Light scalars are produced, for example, in πN scattering on polarized/unpolarized targets, $p\bar{p}$ annihilation, central hadronic production, $J/\psi(1S)$, B-, D- and K-meson decays, $\gamma\gamma$ formation, and ϕ radiative decays. Especially for the lightest scalar mesons simple parameterizations like Breit-Wigner functions and variants thereof fail — this is demonstrated explicitly on the example of the $f_0(500)$ or σ, e.g., in Ref. [7]. Accordingly, more advanced theory tools are necessary to extract the resonance parameters from data. In the analyses available in the literature, fundamental properties of the amplitudes such as unitarity, analyticity, Lorentz invariance, and chiral and flavor symmetry are implemented at different levels of rigor. Especially, chiral symmetry implies the appearance of zeros, the so-called Adler zeros, close to the threshold in elastic S-wave scattering amplitudes involving soft (pseudo) Goldstone bosons [8, 9], which may be shifted or removed in associated production processes [10]. Moreover, especially for the lightest non-strange and strange scalar resonance precision extractions of pole parameters get complicated by the presence of both left-hand cuts as well as circular cuts (for a recent review on the subject see Ref. [5]). The methods employed are the K-matrix formalism, the N/D-method, the Dalitz-Tuan ansatz, the inverse amplitude method, unitarized quark models with coupled channels, effective chiral field theories and the linear sigma model, *etc.* Dynamics near the lowest two-body thresholds in some analyses are described by crossed channel (t, u) meson exchange or with an effective range parameterization instead of, or in addition to, resonant features in the s-channel. Dispersion theoretical approaches are applied to pin down the location of resonance poles for the low mass states [11–16] unambigously — in particular the existence of a nonet of light scalar is not questioned anymore.

In parallel to the developments sketched above also lattice QCD entered the field of precision spectroscopy, since it was acknowledged that a study of resonances calls for a proper treatment of the scattering process employing e.g. the Lüscher method [17], later extended to coupled channels in Refs. [18–23]. This allowed for determinations of the poles of the $I = 1/2$ [24], the $I = 1$ [25] as well as the $I = 0$ [26, 27] light scalar mesons. Besides and additional firm confirmation of the existence of a nonet of light scalar mesons, via the quark mass dependence of the pole locations (here the most sophisticated analysis is reported in Ref. [28]) these studies allow for an alternative look on their nature [29–31].

The mass and width of a resonance are found from the position of the nearest pole in the process amplitude (S- or T-matrix) at an unphysical sheet of the complex energy plane, traditionally labeled as

$$\sqrt{s_{\rm Pole}} = M - i\,\Gamma/2\ . \qquad (64.1)$$

It is important to note that in general the pole of a Breit-Wigner parameterization does not agree with the S- or T-matrix pole. For a detailed discussion of this issue we refer to the review on *Resonances* in this Review of Particle Physics (RPP).

In this review we present proposed values for the mass parameters of the scalar resonances below 1 GeV. Note that those are labeled as 'our estimate' — it is not an average over the quoted analyses, but is chosen to include the bulk of the analyses. An averaging procedure is not justified, since the analyses use overlapping or sometimes even identical data sets so that they are not statistically independent.

In this note, we discuss the light scalars below 1 GeV organized in the *Listings* under the entries $K_0^*(700)$ (or κ) with isospin $I = 1/2$, $a_0(980)$ with $I = 1$, as well as $f_0(500)$ (or σ) and $f_0(980)$ both with $I = 0$. The $I = 2$ $\pi\pi$ and $I = 3/2$ $K\pi$ partial waves do not exhibit resonant behaviour.

64.2 The $K_0^*(700)$, also known as κ ($I = 1/2$)

The $K_0^*(700)$ shows up as a pole in the low energy πK scattering, although its presence and properties are difficult to establish, since it appears to have a very large width ($\Gamma \approx 500$ MeV) and resides close to the $K\pi$ threshold. Hadronic D- and B-meson decays provide additional data points in the vicinity of the $K\pi$ threshold and are discussed in detail in the *Review on Multibody Charm Analyses* in this RPP. With a few exceptions discussed there, the three- or more-hadron final states are usually treated as non-interacting two-body systems. Precise information from semileptonic D decays, where the strongly interacting two-particle final states could be treated without approximation, is not available. BES II [32] (re-analyzed in [33]) finds a $K_0^*(700)$-like structure in $J/\psi(1S)$ decays to $\bar{K}^{*0}(892)K^+\pi^-$ where $K_0^*(700)$ recoils against the $K^*(892)$. The decay $\tau^- \to K_S^0\pi^-\nu_\tau$ can be considered clean with respect to final-state interactions and is studied by Belle [34], with $K_0^*(700)$ parameters fixed to those of Ref. [32].

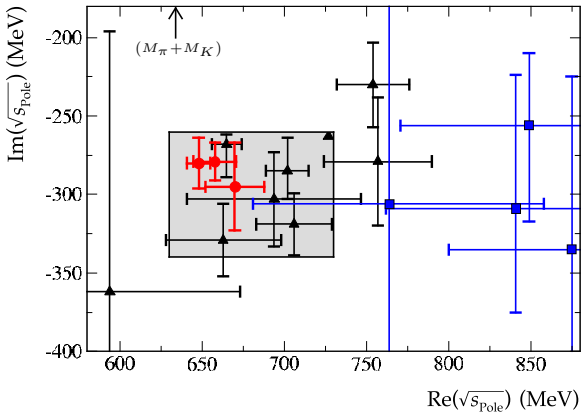

Figure 64.1: Location of the $K_0^*(700)$ (or κ) poles in the complex energy plane. Red circles denote the results of the most sophisticated analyses based on dispersion relations (see text for details), poles extracted from Breit-Wigner fits are shown as blue squares, while all other analyses quoted in the *Listings* are denoted by black triangles. The corresponding references are given in the listing. The arrow shows the location of the πK thresholds. The grey box indicates the range of pole locations classified as 'our estimate' .

Some authors find a $K_0^*(700)$ pole in their phenomenological analysis (see, *e.g.*, [35–44]), while others do not need to include it in their fits (see, *e.g.*, [45–48]; note that in Ref. [49] only a K_0^* meson above 825 MeV was discarded using scattering data fits and analyticity, which is not in conflict with the properties quoted below). All works including constraints from chiral symmetry at low energies naturally find a light $K_0^*(700)$ below 800 MeV, see, *e.g.*, [50–56]. The analyses of Ref. [15, 16] are based on the Roy-Steiner equations, which include analyticity and crossing symmetry constraints. Ref. [57] uses the Padé method to extract pole parameters after refitting scattering data constrained to satisfy forward dispersion relations. All three arrive at compatible pole positions for the $K_0^*(700)$ that are also consistent with the pole parameters deduced from other theoretical methods. Due to their large uncertainties, the pole locations deduced from the Breit-Wigner fits appear to be just about consistent with the other determinations, but the real parts of all those analyses lie systematically higher. Moreover, phase shifts extracted from the Breit-Wigner functions for the $K_0^*(700)$ are very different from the known scalar πK phase shifts. The various poles are shown

in in Fig. 64.1. The compilation in this figure motivates the pole parameters of the $K_0^*(700)$, which we quote as 'our estimate', namely,

$$\sqrt{s^{\kappa}_{\rm Pole}} = (630-730) - i(260-340)\ \text{MeV}\ . \qquad (64.2)$$

For an extensive discussion about the πK system in general and the κ meson in particular, see Ref. [58].

64.3 The $a_0(980)$ ($I = 1$)

The $a_0(980)$ couples strongly to the channels $\pi\eta$ and $K\bar{K}$. Independent of any model, the $K\bar{K}$ component must be large in the $a_0(980)$ wave function, since the mass of the $a_0(980)$ lies very close to the opening of the $K\bar{K}$ channel, to which it strongly couples [59,60]. This generates a pronounced cusp-like behavior in the resonant amplitude and to reveal its true coupling constants the presence of the $K\bar{K}$ channel cannot be ignored. All listed $a_0(980)$ measurements agree on a mass position value near 980 MeV, but the width deduced from the imaginary part of the pole location has values between 50 and 100 MeV, mostly due to the different models. For example, the analysis of the $p\bar{p}$ annihilation data [59] using a unitary K-matrix description finds a width determined from the T-matrix pole of 92 ± 8 MeV. Note that the width of the $a_0(980)$ line shape is typically smaller than what could be expected from the pole location.

The relative coupling $K\bar{K}/\pi\eta$ is determined indirectly from $f_1(1285)$ [61–63] or $\eta(1410)$ decays [64–66], from the line shape observed in the $\pi\eta$ decay mode [67–70], or from the coupled-channel analysis of the $\pi\pi\eta$ and $K\bar{K}\pi$ final states of $p\bar{p}$ annihilation at rest [59].

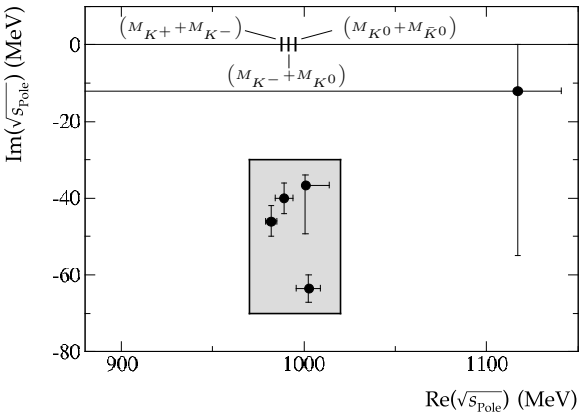

Figure 64.2: Location of the $a_0(980)$ poles from different extractions in the complex energy plane. The corresponding references are given in the *Listings*. Also shown are the thresholds for the K^+K^- and $K^0\bar{K}^0$ channels, relevant for $a_0(980)^0$, and for the K^-K^0 channel, relevant for the $a_0(980)^-$. The grey box indicates the range of pole locations classified as 'our estimate'. Note that by default we take the pole located closest to the physical axis; thus the poles shown are not all on the same sheet.

For the extraction of the $a_0(980)$ pole locations, Refs. [52, 53, 55, 71] use unitarized chiral perturbation theory. Ref. [72] uses a similar formalism to extract the pole of the $a_0(980)$, employing the amplitude fixed in Ref. [73]. A dispersion theoretical approach to the isovector scalar $\pi\eta - K\bar{K}$ system is presented in Ref. [74] that may be refined further from studies of heavy meson decays [75]. Those efforts lead to a rather precise determination of the $a_0(980)$ pole location [76]. A value consistent for the mass parameter, but with a larger width, is found in the analysis of $\bar{p}p$ annihilation in flight data employing a K-matrix [77]. The poles presented in Refs. [55, 59, 70, 76, 77] are shown in Fig. 64.2 together with the range of pole parameters estimated by us from this compilation, namely,

$$\sqrt{s^{a_0(980)}_{\rm Pole}} = (970-1020) - i(30-70)\ \text{MeV} \qquad (64.3)$$

indicated by the box.

64.4 The $f_0(500)$, also known as σ-meson ($I = 0$)

For discussions of the $\pi\pi$ S wave below the $K\bar{K}$ threshold and on the long history of the $f_0(500)$, which was suggested in linear sigma models more than 50 years ago, see the review [5]. Information on the $\pi\pi$ S-wave phase shift $\delta^I_J = \delta^0_0$ was already extracted many years ago from πN scattering [78–80], and near the $\pi\pi$ threshold from K_{e4} decays [81]. The kaon decays were later revisited leading to consistent data with very much improved statistics [82, 83]. The reported $\pi\pi \to K\bar{K}$ cross sections [84–87] have large uncertainties. The πN data have been analyzed in combination with high-statistics data (see entries labeled as RVUE for reanalyses of the data). The $2\pi^0$ invariant mass spectra, extracted from $p\bar{p}$ annihilation at rest into $3\pi^0$ [88,89] and into $5\pi^0$ [90] and from central pp collision [91] do not show a distinct resonance structure below 900 MeV, but these data sets are consistently described with the standard solution for the $\pi\pi$ scalar isoscalar S-wave extracted from high energy $\pi N \to \pi\pi N$ data [79, 92], which allows for the existence of the broad $f_0(500)$. An enhancement is observed in the $\pi^+\pi^-$ invariant mass near threshold in the decays $D^+ \to \pi^+\pi^-\pi^+$ [93–95] and $J/\psi(1S) \to \omega\pi^+\pi^-$ [96, 97], and in $\psi(2S) \to J/\psi(1S)\pi^+\pi^-$ with very limited phase space [98, 99].

The precise $f_0(500)$ (or σ) pole is difficult to establish because of its large width. The $\pi\pi$ scattering amplitude shows an unusual energy dependence due to the presence of the Adler zero in the unphysical regime close to the threshold [8, 9], required by chiral symmetry. However, most of the analyses listed under $f_0(500)$ agree on a pole position near $(500 - i\,250)$ MeV). In particular, analyses of $\pi\pi$ data that include unitarity, are consistent with the near threshold $\pi\pi$ data from K_{e4} decays, and the chiral symmetry constraints from Adler zeroes and/or scattering lengths find a light $f_0(500)$, see, *e.g.*, [100, 101].

Precise pole positions with an uncertainty of less than 20 MeV (see our table for the T-matrix pole in the *Listings*) are extracted using the Roy equations, which are twice subtracted dispersion relations derived from crossing symmetry and analyticity. In Ref. [12] the subtraction constants are fixed to the S-wave scattering lengths a^0_0 and a^2_0 derived from matching the Roy equations and two-loop chiral perturbation theory [11]. The only additional relevant input to fix the $f_0(500)$ pole is the $\pi\pi$-wave phase shift at some higher energy point, chosen as 800 MeV. The analysis is improved further in Ref. [14]. Alternatively, in Ref. [13] Roy equations are used as constraints for a fit to data. In that reference also once-subtracted Roy–like equations, called GKPY equations, are used, since the extrapolation into the complex plane based on the twice-subtracted equations leads to larger uncertainties, mainly due to the limited experimental information on the isospin 2 $\pi\pi$ scattering length. Ref. [102] uses Padé approximants for the analytic continuation. All these extractions find consistent results. Using only analyticity and unitarity to describe data from $K_{2\pi}$ and K_{e4} decays, Ref. [103] finds consistent values for the pole position and the scattering length a^0_0. The importance of the $\pi\pi$ scattering data for fixing the $f_0(500)$ pole is nicely illustrated by comparing analyses of $\bar{p}p \to 3\pi^0$ omitting [88, 104] or including [89, 105] information on $\pi\pi$ scattering: while the former analyses find an extremely broad structure above 1 GeV, the latter find $f_0(500)$ masses of the order of 400 MeV.

From Fig. 64.3 we estimate the range of pole positions for the $f_0(500)$, namely,

$$\sqrt{s^{\sigma}_{\rm Pole}} = (400-550) - i(200-350)\ \text{MeV}\ . \qquad (64.4)$$

The plot contains the poles from Refs. [40, 51, 53, 55, 56, 69, 71, 78, 89, 95, 98–101, 103, 105–124] as well as the advanced dispersion analyses [11–14, 102]. The extracted $f_0(500)$ pole position is very sensitive to the high accuracy low energy $\pi\pi$ scattering data [82, 83]. In fact, all analyses consistent with this data find poles within the accepted range indicated in the figure. As in case of the $K_0^*(700)$, poles extracted from Breit-Wigner analyses are shown as blue squares. Again we see that those poles have the tendency to appear at higher masses, although here the effect is not as pronounced as in case of the $K_0^*(700)$. One should not take this as an indication that using Breit-Wigners is justified in case of the $f_0(500)$, since $\pi\pi$ phase shifts extracted from Breit-Wigners

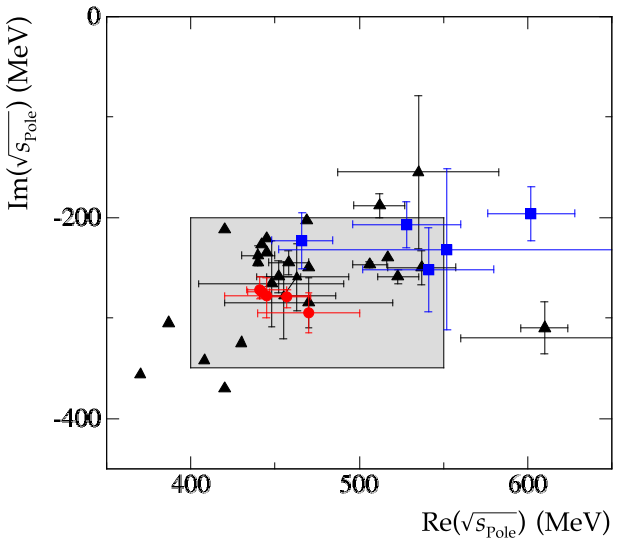

Figure 64.3: Location of the $f_0(500)$ (or σ) poles in the complex energy plane. Circles denote the recent analyses based on Roy(-like) dispersion relations, poles extracted from Breit-Wigner fits are shown as blue squares, while all other analyses are denoted by triangles. The corresponding references are given in the *Listings*. The grey box indicates the range of pole locations classified as 'our estimate' .

are in strong discrepancy with the scattering phase shifts.

If one uses just the most advanced dispersive analyses of Refs. [11–14], shown as solid dots in Fig. 64.3 to determine the pole location of the $f_0(500)$, the range narrows down to [5]

$$\sqrt{s^{\sigma}_{\rm Pole}} = (449^{+22}_{-16}) - i(275 \pm 12)\ \text{MeV}\ , \qquad (64.5)$$

which is labeled as 'conservative dispersive estimate' in this reference.

Besides $\pi\pi$, the only other decay channel of the $f_0(500)$ is two photons. Due to the large full width of the $f_0(500)$ an extraction of its two-photon width directly from data is not possible. Thus, the values for $\Gamma(\gamma\gamma)$ quoted in the literature as well as the in *Listings* are based on the expression in the narrow width approximation [125] $\Gamma(\gamma\gamma) \simeq \alpha^2|g_\gamma|^2/(4\text{Re}(\sqrt{s^{\sigma}_{\rm Pole}}))$, where g_γ is derived from the residue at the $f_0(500)$ pole to two photons and α denotes the electromagnetic fine-structure constant (see also the review on *Resonances* in this issue of the RPP). The explicit form of the expression may vary between different authors due to different definitions of the coupling constant, however, the expression given for $\Gamma(\gamma\gamma)$ is free of ambiguities. According to Refs. [126–129], $\pi\pi$ and $\gamma\gamma$ scattering data sets are consistently described including $f_0(500)$ via the two step process of $\gamma\gamma \to \pi^+\pi^-$ with pion exchange in the t- and u-channel, followed by a final state interaction $\pi^+\pi^- \to \pi^0\pi^0$. The same conclusion is drawn in Ref. [130], where the $f_0(500) \to \gamma\gamma$ decay width is dominated by re-scattering. Therefore, it might be difficult to learn anything new about the nature of the $f_0(500)$ from its $\gamma\gamma$ coupling. For the most recent work on $\gamma\gamma \to \pi\pi$, see Refs. [56, 71, 103–105, 112–125, 128–133]. There are strong indications (*e.g.*, [134–164]) that the $f_0(500)$ pole cannot be classified as a $q\bar{q}$ state.

64.5 The $f_0(980)$ $(I = 0)$

The $f_0(980)$ couples predominantly to the $\pi\pi$ and $K\bar{K}$ channels and its signal overlaps strongly with the background represented mainly by the $f_0(500)$ and the $f_0(1370)$. This can lead to a dip in the $\pi\pi$ spectrum at the $K\bar{K}$ threshold. It changes from a dip into a peak structure in the $\pi^0\pi^0$ invariant mass spectrum of the reaction $\pi^- p \to \pi^0\pi^0 n$ [138], with increasing four momentum transfer to the $\pi^0\pi^0$ system, which means increasing the $a_1(1260)$ exchange contribution in the amplitude, while the π exchange decreases. Also when a $(u\bar{u} + d\bar{d})$ source is switched to a $s\bar{s}$ source, as it appears when moving from $B_d \to J/\psi(1S)\pi\pi$ to $B_s \to J/\psi(1S)\pi\pi$, the f_0 signal switches from a dip to a peak [152]. The $f_0(500)$ and the $f_0(980)$ are also observed in the data for radiative ϕ decays $(\phi \to f_0\gamma)$ from SND [139,140], CMD2 [141], and KLOE [142,143].

Unitarized chiral perturbation theory is employed to extract the pole of the $f_0(980)$ in Refs. [52, 53, 55, 71, 72]. Two different dispersive analyses are used in Ref. [13] to simultaneously pin down the pole parameters of both the $f_0(500)$ and the $f_0(980)$. The poles extracted in Refs. [13, 14, 55, 56, 77, 108, 165, 166] are shown in Fig. 64.4, together with the range of pole parameters estimated by us from this compilation, namely,

$$\sqrt{s^{f_0(980)}_{\rm Pole}} = (980 - 1010) - i(20 - 35)\ \text{MeV} \qquad (64.6)$$

indicated by the box. A disclaimer is important here: Both the poles of $a_0(980)$ and of $f_0(980)$ are located very close to the kaon thresholds, with the charged and neutral thresholds being 8 MeV apart — to illustrate this point the pertinent thresholds are shown explicitly in Figs. 64.2 and 64.4. This observation leads to the prediction of an enhanced $a_0 - f_0$ mixing [167–170]. On the other hand, all analyses employed in the pole determinations quoted above are done assuming isospin symmetry. Future studies need to show the impact of isospin violation on the extraction of the $a_0(980)/f_0(980)$ pole parameters.

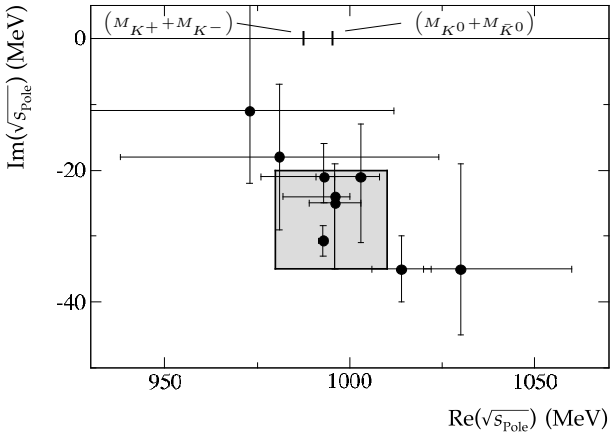

Figure 64.4: Location of the $f_0(980)$ poles from different extractions in the complex energy plane. The corresponding references are given in the *Listings*. Also shown are the thresholds for the K^+K^- and $K^0\bar{K}^0$ channels. The grey box indicates the range of pole locations classified as 'our estimate' .

Analyses of $\gamma\gamma \to \pi\pi$ data [144–146] underline the importance of the $K\bar{K}$ coupling of the $f_0(980)$, while the resulting two-photon width of the $f_0(980)$ cannot be determined precisely [147]. The prominent appearance of the $f_0(980)$ in the semileptonic D_s decays and decays of B and B_s mesons implies a dominant $(\bar{s}s)$ component: those decays occur via weak transitions that alternatively result in $\phi(1020)$ production. Ratios of decay rates of B and/or B_s mesons into $J/\psi(1S)$ plus $f_0(980)$ or $f_0(500)$ are proposed to extract the flavor mixing angle and to probe the tetraquark nature of those mesons within a certain model [148, 149]. The resulting phenomenological fits of the LHCb collaboration [150, 151] lead the authors to conclude that their data are incompatible with a model where $f_0(500)$ and $f_0(980)$ are formed from two quarks and two antiquarks (tetraquarks). However, a dispersive analysis of the same data that allows for a model independent inclusion of the hadronic final state interactions in Ref. [152] puts into question the conclusions of Ref. [150]. Moreover, the assumption underlying Ref. [150] that the production dynamics of $f_0(500)$ and $f_0(980)$ are equal such that they cancel in ratios appears to be not justified [5].

64.6 Interpretation of the scalars below 1 GeV

In the literature, many structures are discussed for the light scalar mesons, such as conventional $q\bar{q}$ mesons, compact $(qq)(\bar{q}\bar{q})$ structures (tetraquarks), or meson-meson bound states (hadronic

molecules). In reality, there can be superpositions of these components, and one often depends on models to determine the dominant one. Although we have seen progress in recent years, this question remains open. Here, we mention some of the present conclusions.

The $f_0(980)$ and $a_0(980)$ are often interpreted as compact tetraquark states [161–164, 171] or $K\bar{K}$ bound states [172]. The insight into their internal structure using two-photon widths [140, 173–179] is not conclusive. The $f_0(980)$ appears as a peak structure in D_s decays without $f_0(500)$ background. Based on that observation it is suggested that $f_0(980)$ has a large $s\bar{s}$ component, which according to Ref. [180] is surrounded by a virtual $K\bar{K}$ cloud (see also Ref. [181]). The inclusive production property of the $f_0(980)$ in Z^0 decays is consistent with mesons of other nonets [182]. However, as stated by the authors, the results should be taken as model-dependent measurements while presently no reliable predictions for production rates of non-$q\bar{q}$ states in Z^0 decay are available. Data sets on radiative decays ($\phi \to f_0\gamma$ and $\phi \to a_0\gamma$) from SND, CMD2, and KLOE (see above) are consistent with a prominent role of kaon loops. This observation is interpreted as evidence for a compact four-quark structure of the light scalars in Ref. [183], while it is claimed to point at a molecular nature in Ref. [184, 185]. Details of this controversy are given in the comments [186, 187]; see also Ref. [188]. There is now a rather broad consensus that the states $f_0(980)$ and $a_0(980)$, together with the $f_0(500)$ and the $K_0^*(700)$, form a nonet of predominantly four-quark states, where at larger distances the quarks recombine into a pair of pseudoscalar mesons creating a meson cloud (see, *e.g.,* Ref. [189]). Different QCD sum rule studies [190–195] do not agree on a tetraquark configuration for the same particle group.

Models that start directly from chiral Lagrangians, either in non-linear [52, 55, 100, 184] or in linear [196–202] realization, predict the existence of the $f_0(500)$ meson near 500 MeV. Here the $f_0(500)$, $a_0(980)$, $f_0(980)$, and $K_0^*(700)$ (in some models the $K_0^*(1430)$) would form a nonet (not necessarily $q\bar{q}$). In the linear sigma models the lightest pseudoscalars appear as their chiral partners.

In the non-linear approaches of Refs. [52] and [100] the above resonances together with the low mass vector states are generated starting from chiral perturbation theory predictions near the first open channel, and then by shifting the states to the resonance locations, using unitarity and analyticity.

Ref. [196] uses a framework with explicit resonances that are unitarized and coupled to the light pseudoscalars in a chirally invariant way. Evidence for a dominant non-$\bar{q}q$ nature of the lightest scalar resonances is derived from their mixing scheme. In Ref. [197] the scheme is extended and applied to the decay $\eta' \to \eta\pi\pi$, which leads to the same conclusions. In Ref. [203] the large N_c behavior of the poles is studied to identify the nature of the resonances generated from scattering equations. This leads to the observation that, while the light vector states behave consistent with what is predicted for $\bar{q}q$ states, the light scalars behave very differently. This finding provides strong support for a dominant non-$\bar{q}q$ nature of the light scalar resonances. Note, the more refined study of Ref. [134] which finds, in the case of the $f_0(500)$, indications for a subdominant $\bar{q}q$ component located around 1 GeV in addition to a dominant non-$\bar{q}q$ nature. Additional support for the dominant non-$q\bar{q}$ nature of the $f_0(500)$ is given in Ref. [204], where the connection between the pole of resonances and their Regge trajectories is analyzed. All works including constraints from chiral symmetry at low energies naturally find a light $K_0^*(700)$ below 800 MeV and a $f_0(500)$ below 600 MeV, see, *e.g.*, [50–55]. In these works the $K_0^*(700)$, $f_0(500)$, $f_0(980)$, and $a_0(980)$ appear to form a nonet [51, 54]. Additional evidence for this assignment is presented in Ref. [14], where the couplings of the nine states to $\bar{q}q$ sources are compared. Similar conclusions are reached in Ref. [205] where in the analyzed data the $f_0(980)$ for example appears as a peak structure in $J/\psi(1S) \to \phi\pi^+\pi^-$ while in $J/\psi(1S) \to \omega\pi^+\pi^-$ the signal is suppressed. The same low mass scalar nonet is also found earlier in the unitarized quark model of Ref. [111]. A recent phenomenological study based on a $q\bar{q}$ flavor scheme for the light scalars concludes that their glueball content is ruled out because of low production rates in radiative $J/\psi(1S)$ decays [206].

There are, however, alternative interpretations of the light scalars. For example Ref. [207] (for a more recent, condensed discussion of the idea see Ref. [208]), also builds on chiral symmetry, but expands around an infrared fixed point such that the $f_0(500)$ appears as a QCD dilaton with a mass driven by the QCD scale anomaly. The phenomenology studied in that work appears consistent with this proposal. In Ref. [108, 130, 209, 210] data sets on $\pi\pi - \bar{K}K$ scattering, as well as $\gamma\gamma \to \pi\pi$, are analysed and the authors conclude that especially the $f_0(500)$ should have a significant gluon content. An extensive analysis on mass, width and decay couplings of the light scalars in a QCD spectral sum rule study [211] leads to ambiguous results for their internal structure. The $f_0(500)$ can equally well have tetraquark, molecular or gluonic content, while the states $f_0(980)$ and $a_0(980)$ can be of molecular or tetraquark nature. A scenario where the $f_0(500)$ and $f_0(980)$ result from quarkonia-glueball mixing is also possible. Note, however, that the large similarities of the features of the κ and the σ meson put into question both a dilaton and a glueball contribution to the latter, since neither of them can be present in the former.

A model independent method to identify hadronic molecules goes back to a proposal by Weinberg [212] (an extension of the formalism to virtual states is provided in Ref. [31]), which is shown to be equivalent to the pole counting arguments of [167–170, 213–218] in Ref. [216]. The formalism allows one to extract the amount of molecular component in the wave function from the effective coupling constant of a physical state to a nearby continuum channel. It can be applied to near threshold states only and provides strong evidence that the $f_0(980)$ is predominantly a $\bar{K}K$ molecule, while the situation turns out to be less clear for the $a_0(980)$ (see also Refs. [177,179]). This is in line with the findings of Ref. [72], which reports an important role of the $\pi\eta$ channel to the formation of the $a_0(980)$ in addition to the $\bar{K}K$ channel, while the $f_0(980)$ also in this work appears to be predominantly a $\bar{K}K$ molecule. The relevance of both the $\bar{K}K$ and the $\pi\eta$ channels in a dynamically generated $a_0(980)$ is also pointed out in the description of the $\chi_{c1} \to \eta\pi^+\pi^-$ and $D_s^+ \to \pi^+\pi^0\eta$ reactions [219, 220]. A recent analysis on the compositeness of the $\pi\pi - K\bar{K}$ and $\pi\eta - K\bar{K}$ channels for the $f_0(980)$ and $a_0(980)$ resonances based on pole values and decay branchings is performed in Ref. [221]. While the $K\bar{K}$ configuration dominates in the $f_0(980)$, the meson-meson components are subdominant in $a_0(980)$. Further insights into $a_0(980)$ and $f_0(980)$ are expected from their mixing [167–170]. A corresponding signal predicted in Refs. [168, 169] is reported by BES III [222]. The importance of the molecular structure of $a_0(980)$, $f_0(980)$ and of their mixing in the reactions $\bar{B}_s^0 \to J/\psi(1S)\pi^+\pi^-$ and $\bar{B}_s^0 \to J/\psi(1S)\pi^0\eta$ is pointed out in Ref. [223].

In the unitarized quark model with coupled $q\bar{q}$ and meson-meson channels, the light scalars are interpreted as additional manifestations of bare $q\bar{q}$ confinement states, strongly mass shifted from the 1.3 - 1.5 GeV region and very distorted due to the strong $^3P_0$ coupling to S-wave two-meson decay channels [218,224]. Thus, in these models the light scalar nonet comprising the $f_0(500)$, $f_0(980)$, $K_0^*(700)$, and $a_0(980)$, as well as the nonet consisting of the $f_0(1370)$, $f_0(1500)$ (or $f_0(1710)$), $K_0^*(1430)$, and $a_0(1450)$, respectively, are seen as two manifestations of the same bare input states (see also Ref. [225]). It should not remain unmentioned, however, that the heavier nonet lies rather close to the input nonet and that the light scalar one emerges only once the coupling to the two-meson channels is switched on, again highlighting that the meson-meson interaction is indispensable for the light scalars.

Acknowledgement

The authors would like to thank Eberhard Klempt, and Jose Ramon Pelaez for helpful input and discussions in the preparation of the review.

65. Rare Kaon Decays

Revised August 2023 by L. Littenberg (BNL) and G. Valencia (Monash U.).

65.1 Introduction

There are several useful reviews on rare kaon decays and related topics [1–13]. Activity in rare kaon decays can be divided roughly into four categories:

1. Searches for explicit violations of the Standard Model (SM)
2. The golden modes: $K \to \pi\nu\bar{\nu}$
3. Other constraints on SM parameters
4. Studies of strong interactions at low energy.

The paradigm of Category 1 is the lepton flavor violating decay $K_L \to \mu e$. Category 2 includes the two modes that can be calculated with negligible theoretical uncertainty, $K^+ \to \pi^+\nu\bar{\nu}$ and $K_L \to \pi^0\nu\bar{\nu}$. These modes can lead to precision determinations of CKM parameters or, in combination with other measurements of these parameters, they can constrain new interactions. They constitute the main focus of the current experimental kaon program. The search for new light particles through the reaction $K \to \pi X^0$ is a byproduct of these measurements. Category 3 is focused on decays with charged leptons, such as $K_L \to \pi^0\ell^+\ell^-$ or $K_L \to \ell^+\ell^-$ where $\ell \equiv e, \mu$. These modes are sensitive to CKM parameters, but they suffer from multiple hadronic uncertainties that can be addressed, at least in part, through a systematic study of the peripheral modes indicated in Fig. 65.1.

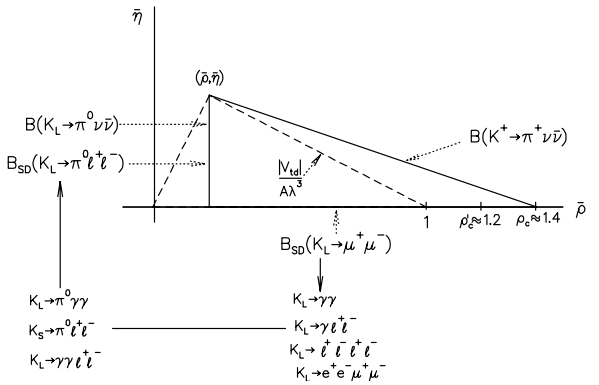

Figure 65.1: Role of rare kaon decays in determining the unitarity triangle. The solid arrows point to auxiliary modes needed to interpret the main results, or potential backgrounds to them.

The interplay between Categories 3-4 and their complementarity to Category 2 is illustrated in the figure. Category 4 includes reactions like $K^+ \to \pi^+\ell^+\ell^-$ where long distance contributions are dominant and which constitute a testing ground for the ideas of chiral perturbation theory. Other decays in this category are $K_L \to \pi^0\gamma\gamma$ and $K_L \to \ell^+\ell^-\gamma$. The former is important in understanding a CP-conserving contribution to $K_L \to \pi^0\ell^+\ell^-$, whereas the latter could shed light on long distance contributions to $K_L \to \mu^+\mu^-$.

65.2 Explicit violations of the Standard Model

Much activity has focussed on searches for lepton flavor violation (LFV). This is motivated by the fact that many extensions of the minimal Standard Model violate lepton flavor and by the potential to access very high energy scales. For example, the tree-level exchange of a LFV vector boson of mass M_X that couples to left-handed fermions with electroweak strength and without mixing angles yields $\mathrm{B}(K_L \to \mu e) = 4.7 \times 10^{-12}(148\ \mathrm{TeV}/M_X)^4$ [2]. This simple dimensional analysis may be used to read from Table 65.1 that the reaction $K_L \to \mu e$ is already probing scales of over 100 TeV. Table 65.1 summarizes the present experimental situation vis-à-vis LFV. The decays $K_L \to \mu^\pm e^\mp$ and $K^+ \to \pi^+ e^\mp \mu^\pm$ (or $K_L \to \pi^0 e^\mp \mu^\pm$) provide complementary information on potential family number violating interactions, since the former is sensitive to parity-odd couplings and the latter is sensitive to parity-even couplings.

Limits on certain lepton-number violating (LNV) kaon decays also have been obtained, with special interest arising from their role in constraining possible extensions of the neutrino sector [14, 15], and we list those in the table as well. Related searches in μ and τ processes are discussed in our section "Tests of Conservation Laws."

Table 65.1: Searches for lepton flavor and lepton number violation in K decay

LFV mode	90% CL upper limit	Experiment	Yr./Ref.	Type
$K^+ \to \pi^+ e^- \mu^+$	1.3×10^{-11}	BNL-865	2005/ [16]	LFV
$K^+ \to \pi^+ e^+ \mu^-$	6.6×10^{-11}	NA62	2021/ [17]	LFV
$K_L \to \mu e$	4.7×10^{-12}	BNL-871	1998/ [18]	LFV
$K_L \to \pi^0 e\mu$	7.6×10^{-11}	KTeV	2008/ [19]	LFV
$K_L \to \pi^0\pi^0 e\mu$	1.7×10^{-10}	KTeV	2008/ [19]	LFV
$K^+ \to \pi^- e^+ e^+$	5.3×10^{-11}	NA62	2022/ [20]	LNV
$K^+ \to \pi^- \pi^0 e^+ e^+$	8.5×10^{-10}	NA62	2022/ [20]	LNV
$K^+ \to \pi^- \mu^+ \mu^+$	4.2×10^{-11}	NA62	2019/ [21]	LNV
$K_L \to e^\pm e^\pm \mu^\mp \mu^\mp$	4.12×10^{-11}	KTeV	2003/ [22]	LNV
$K^+ \to \pi^- \mu^+ e^+$	4.2×10^{-11}	NA62	2021/ [17]	LNFV
$K^+ \to \mu^- \nu e^+ e^+$	8.1×10^{-11}	NA62	2023/ [23]	LNV/LFV

65.3 The golden modes: $K \to \pi\nu\bar{\nu}$

In the SM, the decay $K^+ \to \pi^+\nu\bar{\nu}$ is dominated by one-loop diagrams with top-quark intermediate states while long-distance contributions are known to be quite small [24–26]. This permits a precise calculation of this rate in terms of SM parameters. Studies of this process are thus motivated by the possibility of detecting non-SM physics when comparing with the results of global fits [27, 28].

The branching ratio can be written in a compact form that exhibits the different ingredients that go into the calculation [29],

$$\mathrm{B}\left(K^+ \to \pi^+\nu\bar{\nu}(\gamma)\right) = \kappa_+(1+\Delta_{\mathrm{EM}})\left[\left(\frac{\mathrm{Im}(V_{ts}^\star V_{td})}{\lambda^5}X_t\right)^2 + \left(\frac{\mathrm{Re}(V_{cs}^\star V_{cd})}{\lambda}P_c + \frac{\mathrm{Re}(V_{ts}^\star V_{td})}{\lambda^5}X_t\right)^2\right]. \quad (65.1)$$

The parameters in Eq. 65.1 incorporate the *a priori* unknown hadronic matrix element in terms of the very well-measured K_{e3} rate [24] in κ_+; long distance QED corrections in Δ_{EM} [30]; the Inami-Lim function for the short distance top-quark contribution [31] including NLO QCD corrections [32,33] and the two-loop electroweak correction [29], all in X_t; and the charm-quark contributions due to short distance effects including NNLO QCD corrections [34, 35] and NLO electroweak corrections via P_c [36], which also includes certain long distance terms dubbed $\delta P_{c,u}$ [26, 37].

An interesting approximate way to cast this result in terms of the CKM parameters λ, V_{cb}, $\bar{\rho}$ and $\bar{\eta}$ (see our Section on "The Cabibbo-Kobayashi-Maskawa mixing matrix") [9] is:

$$\mathrm{B}(K^+ \to \pi^+\nu\bar{\nu}) \approx 1.6 \times 10^{-5}|V_{cb}|^4[(\sigma\bar{\eta})^2 + (\rho_c - \bar{\rho})^2] \quad (65.2)$$

where $\rho_c \approx 1.45$ and $\sigma \equiv \frac{1}{(1-\frac{1}{2}\lambda^2)^2}$. Thus, $\mathrm{B}(K^+ \to \pi^+\nu\bar{\nu})$ determines an ellipse in the $\bar{\rho}$, $\bar{\eta}$ plane with center $(\rho_c, 0)$ and semiaxes $\approx \frac{1}{|V_{cb}|^2}\sqrt{\frac{\mathrm{B}(K^+\to\pi^+\nu\bar{\nu})}{1.6\times10^{-5}}}$ and $\frac{1}{\sigma|V_{cb}|^2}\sqrt{\frac{\mathrm{B}(K^+\to\pi^+\nu\bar{\nu})}{1.6\times10^{-5}}}$.

BNL-787 observed two candidate events [38, 39] in the clean high π^+ momentum and one event [40] in the low-momentum region. The successor experiment BNL-949 observed one more in the high-momentum region [41] and three more in the low-momentum region [42], yielding a branching ratio of $(1.73^{+1.15}_{-1.05})\times 10^{-10}$ [43].

NA62 was commissioned in 2015 and took data in 2016, 2017 and 2018 and published results from those runs [44]. Twenty candidate events were observed, including an estimated background of 7.03, yielding $\mathrm{B}(\mathrm{K}^+ \to \pi^+\nu\overline{\nu}) = (10.6^{+4.0}_{-3.4}|_{\mathrm{stat}} \pm 0.9_{\mathrm{sys}}) \times 10^{-11}$. They resumed data taking in 2023 after some upgrades to the detector with the goal of achieving a 20% measurement of the branching ratio by the next long shutdown of the accelerator.

Using the latest CKMfitter input (Jan. 2022) [27], we estimate $\mathrm{B}(K^+ \to \pi^+\nu\overline{\nu})_{SM} = (8.1 \pm 0.4) \times 10^{-11}$, near the lower end of the measurements of BNL-787/949 and NA62. Current parametric uncertainty in the CKM angles can result in numbers with central values differing from this one by up to 10% [45].

The second golden mode is the neutral counterpart to our preceeding discussion: $K_L \to \pi^0\nu\overline{\nu}$. It is dominantly CP-violating and free of hadronic uncertainties [24, 46, 47]. In the Standard Model, this mode is dominated by an intermediate top-quark state and does not suffer from the small uncertainty associated with the charm-quark intermediate state that affects $K^+ \to \pi^+\nu\overline{\nu}$. The branching ratio is given by [9]:

$$\mathrm{B}(K_L \to \pi^0\nu\overline{\nu}) = \kappa_L \left(\frac{\mathrm{Im}(V_{ts}^\star V_{td})}{\lambda^5} X_t\right)^2 \approx 7.6\times 10^{-5}|V_{cb}|^4\overline{\eta}^2 \ . \tag{65.3}$$

As with the charged mode, the hadronic matrix element can be related to that measured in $K_{\ell 3}$ decay and is parameterized in κ_L.

Our estimate for the branching ratio within the SM, using the latest CKMfitter input (Jan. 2022) [27], is $(2.8 \pm 0.2) \times 10^{-11}$. Similarly to the charged kaon case, parametric uncertainty in the CKM angles can result in a central value that differs from this one by up to almost 20% [45].

Grossman and Nir (GN) [48] pointed out that, in a nearly model-independent manner, the two golden modes satisfy the relation $\mathrm{B}(K_L \to \pi^0\nu\overline{\nu}) \lesssim 4.3\ \mathrm{B}(K^+ \to \pi^+\nu\overline{\nu})$. Using the BNL 787/949 90% CL bound on $K^+ \to \pi^+\nu\overline{\nu}$, GN then predict $B(K_L \to \pi^0\nu\overline{\nu}) < 1.46\times 10^{-9}$. Using instead the latest NA62 result, the GN upper bound becomes $B(K_L \to \pi^0\nu\overline{\nu}) < 8.14\times 10^{-10}$ [13].

The KOTO experiment at J-PARC, whose goal is to make an initial observation of this decay, has been in operation since 2013. It has made a series of data collection runs and has reported on three data sets thus far. In 2018 it published a 90% CL upper limit of 3.0×10^{-9} [49], based on 2015 data. They have run almost every year since, making incremental improvements to the experimental configuration between runs. In 2021 they published a result on the data taken between 2016 and 2018 in which three events were observed in the signal region [50], whereas the expected background was 1.22 events, mainly from charged kaons produced by K_L interactions in the downstream collimator. Conservatively assuming the three events were due to background, they extracted a 90% CL upper limit of 4.9×10^{-9}. Subsequent hardware and analysis improvements reduced the expected background to 0.26 in a sample of similar sensitivity taken in 2021. No events were observed in the signal region and a 90% CL upper limit of 2.0×10^{-9} was established [51]. An increase of 3-5 in sensitivity is anticipated from runs planned in the next three years.

The current theoretical and experimental situation for the golden modes is summarized in Fig. 65.2. The red area corresponds to the 1σ SM prediction we obtain with the latest input available from CKMfitter (January 2022) [27]. The yellow region shows the result established by the combined BNL-787 and BNL-949 results, whereas the green region marks the new NA62 result for $K^+ \to \pi^+\nu\overline{\nu}$. The black shaded region marks the GN exclusion, which lies significantly above the SM expectation leaving a large window for discovery of new physics contributions by experiments seeking to measure $\mathrm{B}(K_L \to \pi^0\nu\overline{\nu})$. The 90% CL upper bound on this mode from the KOTO result published in 2018 [49] is shown as a dashed orange line, and is seen to still lie in the GN excluded zone.

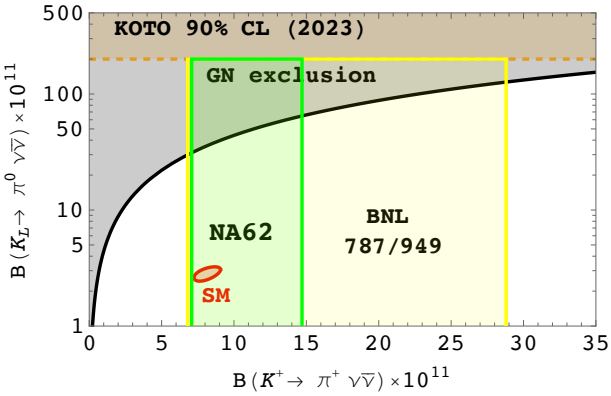

Figure 65.2: Summary of current situation for the golden modes $K \to \pi\nu\overline{\nu}$. The red ellipse shows the 1σ SM prediction with input from CKMfitter; the green (yellow) region corresponds to the NA62 (BNL787/949) 1σ measurement; and the dashed orange line marks the 90% CL KOTO upper bound. The black shaded region shows the GN exclusion.

Much theoretical work has explored beyond the SM scenarios that can populate this window as well as their correlations with other rare processes outside kaon physics. Although it would be relatively straightforward to establish the existence of new physics by observing deviations from their SM values in the $K \to \pi\nu\overline{\nu}$ modes, it would take much more extensive global fits to pinpoint the origin of any such deviation. Partial summaries with references focusing on quark flavor physics can be found in Refs. [9, 52–56]. Different possibilities emphasizing an interpretation of these modes as $K \to \pi + E_{\mathrm{miss}}$ can be found in Refs. [57–59].

There is a subtlety in converting the GN bound extracted from measurements of $K^+ \to \pi^+\nu\overline{\nu}$ into an upper bound for $K_L \to \pi^0\nu\overline{\nu}$ as applied to KOTO [60]. This is due to a lack of sensitivity of the charged kaon experiments to a kinematic window near the pion mass. New physics appearing through a two body mode $K^+ \to \pi^+X^0$, for an invisible X^0 with mass near the pion mass, has a much weaker constraint. The situation is illustrated in Fig. 65.3 which shows the BNL787/949 [43] and NA62 [61] 90% c.l. limits on $K^+ \to \pi^+X^0$ as a function of m_{X^0} assuming X^0 is stable. The implied GN bound for $K_L \to \pi^0X^0$, $B(K_L \to \pi^0X^0) \lesssim 4.3B(K^+ \to \pi^+X^0)$ is shown as a blue line and can be compared with the actual KOTO [49] constraint on $K_L \to \pi^0X^0$ in red. Notice that the upper bound derived from NA62 is lower than that derived from BNL787/949 except for a small mass window. For $120 \lesssim m_{X^0} \lesssim 150$ MeV, KOTO already has better sensitivity than that implied by the GN bound in this case. The possibility of new physics in this scenario has generated much theoretical speculation [62–72].

The search for a new light particle X^0 in $K^+ \to \pi^+X^0$ has a long tradition covering both long-lived particles (*e.g.*, hyperphoton, axion, familon, *etc.*), and short-lived ones that decay to muon, electron, photon or neutrino pairs. The longstanding 90% CL upper limit on $K^+ \to \pi^+X^0$ from BNL787/949 7.3×10^{-11} [41] for the case of massless X^0 has been slightly improved by NA62 to 5×10^{-11} as can be read from Fig. 65.3. These limits can also be reinterpreted in connection with a dark photon [73] or dark Z [74], and in this context NA48/2 also constrained the mode $B(K^\pm \to \pi^\pm A' \to \pi^\pm e^+e^-)$ [75]. Complementary searches for new light particles in kaon experiments use modes with two pions and include the KTeV bound $B(K_L \to \pi^0\pi^0X^0 \to \pi^0\pi^0\mu^+\mu^-) < 1\times 10^{-10}$ [76] and the E391a bound $B(K_L \to \pi^0\pi^0X^0 \to \pi^0\pi^0\gamma\gamma) < 2.4\times 10^{-7}$ [77].

Neutrino pair modes with one extra pion, $K \to \pi\pi\nu\overline{\nu}$, are similarly dominated by short distance contributions in the SM [78–80]. Even though they are theoretically clean, they occur with very

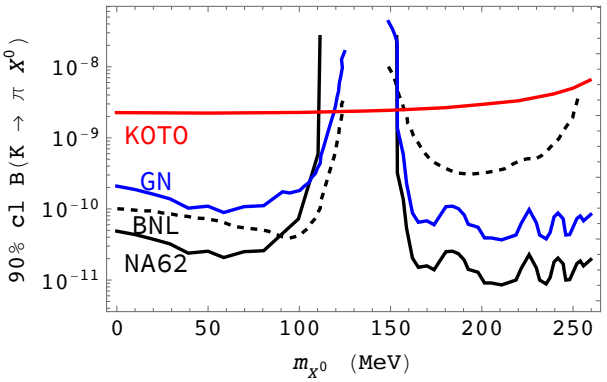

Figure 65.3: Summary of current situation for $K \to \pi X^0$. The solid (dashed) black line shows the exclusion limit for $K^+ \to \pi^+ X^0$ from NA62 (BNL787/949) assuming X^0 is stable. The blue line marks the constraint implied for $K_L \to \pi^0 X^0$ by the Grossman-Nir relation and the red line marks the current KOTO limit on $K^+ \to \pi^+ X^0$.

low rates with branching ratios of order 10^{-13}. The current best bound comes from KEK-391a, $B(K_L \to \pi^0\pi^0\nu\bar{\nu}) < 8.1 \times 10^{-7}$ at 90% CL [81]. There is also a bound for the charged kaon mode $B(K^+ \to \pi^+\pi^0\nu\bar{\nu}) < 4.3 \times 10^{-5}$ at 90% CL [82] from BNL-787. New physics contributions to these modes are discussed in [83].

65.4 Other constraints on Standard Model parameters

The decay $K_L \to \mu^+\mu^-$ has a short distance contribution sensitive to the CKM parameter $\bar{\rho}$, given by [5]:

$$\mathrm{B_{SD}}(K_L \to \mu^+\mu^-) \approx 2.7 \times 10^{-4} |V_{cb}|^4 (\rho_c' - \bar{\rho})^2 \qquad (65.4)$$

where ρ_c' depends on the charm quark mass and is approximately 1.2. This decay, however, is dominated by a long-distance contribution from a two-photon intermediate state. The absorptive (imaginary) part of the long-distance component is determined by the measured rate for $K_L \to \gamma\gamma$ to be $\mathrm{B_{abs}}(K_L \to \mu^+\mu^-) = (6.64 \pm 0.07) \times 10^{-9}$; and it almost completely saturates the observed rate $\mathrm{B}(K_L \to \mu^+\mu^-) = (6.84 \pm 0.11) \times 10^{-9}$ [84]. The difference between the observed rate and the absorptive component can be attributed to the (coherent) sum of the short-distance amplitude and the real part of the long-distance amplitude. The latter cannot be derived directly from experiment [85], but can be estimated with certain assumptions [86,87].

By contrast, the decay $K_L \to e^+e^-$ is completely dominated by long distance physics and is easier to estimate. The result, $B(K_L \to e^+e^-) \sim 9 \times 10^{-12}$ [85,88], is in good agreement with the BNL-871 measurement, $(8.7^{+5.7}_{-4.1}) \times 10^{-12}$ [89].

The mode $K_S \to \mu^+\mu^-$ has a short distance contribution proportional to the square of the CKM parameter $\bar{\eta}$ entering at the 10^{-13} level [10]. It also has long distance contributions arising from the two photon intermediate state which result in a rate $B(K_S \to \mu^+\mu^-)_{LD} = 5.1 \times 10^{-12}$ [10]. There is a 90% CL limit $B(K_S \to \mu^+\mu^-) < 2.1 \times 10^{-10}$ from LHCb [90,91]. The interplay between $K_L \to \mu^+\mu^-$ and $K_S \to \mu^+\mu^-$ has been the subject of [92,93], and it has been pointed out that a measurement of time-dependent interference effects could be used to extract information on CKM angles from $K \to \mu^+\mu^-$ measurements [94,95].

The decay $K_L \to \pi^0 e^+e^-$ is sensitive to the CKM parameter η through its CP-violating component. There are both direct and indirect CP-violating amplitudes that can interfere. The direct CP-violating amplitude is short distance dominated and has been calculated in detail within the SM [5]. The indirect CP-violating amplitude can be inferred from a measurement of $K_S \to \pi^0 e^+e^-$. The complete CP-violating contribution to the rate can be written as [96–98]:

$$\mathrm{B_{CPV}} \approx \left[15.7|a_S|^2 \pm 1.4 \left(\frac{|V_{cb}|^2\bar{\eta}}{10^{-4}} \right) |a_S| + 0.12 \left(\frac{|V_{cb}|^2\bar{\eta}}{10^{-4}} \right)^2 \right] \times 10^{-12} \qquad (65.5)$$

where the three terms correspond to the indirect CP violation, the interference, and the direct CP violation, respectively. The parameter a_S has been extracted by NA48/1 from a measurement of $K_S \to \pi^0 e^+e^-$ with the result $|a_S| = 1.06^{+0.26}_{-0.21} \pm 0.07$ [99], as well as from a measurement of $K_S \to \pi^0\mu^+\mu^-$ with the result $|a_S| = 1.54^{+0.40}_{-0.32} \pm 0.06$ [100]. With current constraints on the CKM parameters, and assuming a positive sign for the interference term [98,101], this implies that $\mathrm{B_{CPV}}(K_L \to \pi^0 e^+e^-) \approx (3.1 \pm 0.9) \times 10^{-11}$, where the three contributions to the central value from indirect, interference and direct CP violation are $(1.76, 0.9, 0.45) \times 10^{-11}$ respectively. It should be noted that more recent studies suggest a much larger uncertainty in the value of a_S [102].

$K_L \to \pi^0 e^+e^-$ also has a CP-conserving component dominated by a two-photon intermediate state. This component can be decomposed into an absorptive and a dispersive part. The absorptive part can be extracted from the measurement of the low $m_{\gamma\gamma}$ region of the $K_L \to \pi^0\gamma\gamma$ spectrum. The rate and the shape of the distribution $d\Gamma/dm_{\gamma\gamma}$ in $K_L \to \pi^0\gamma\gamma$ are well described in chiral perturbation theory in terms of three (*a priori*) unknown parameters [103–106].

Both KTeV and NA48 have studied the mode $K_L \to \pi^0\gamma\gamma$, reporting similar results. KTeV finds $B(K_L \to \pi^0\gamma\gamma) = (1.29 \pm 0.03_{\mathrm{stat}} \pm 0.05_{\mathrm{sys}}) \times 10^{-6}$ [107], while NA48 finds $B(K_L \to \pi^0\gamma\gamma) = (1.36 \pm 0.03_{\mathrm{stat}} \pm 0.03_{\mathrm{sys}} \pm 0.03_{\mathrm{norm}}) \times 10^{-6}$ [108]. Both experiments are consistent with a negligible rate in the low $m_{\gamma\gamma}$ region, suggesting a very small CP-conserving component $B_{\mathrm{CP}}(K_L \to \pi^0 e^+e^-) \sim \mathcal{O}(10^{-13})$ [98,106,108]. There remains some model dependence in the estimate of the dispersive part of the CP-conserving $K_L \to \pi^0 e^+e^-$ [98].

The related process, $K_L \to \pi^0\gamma e^+e^-$, is potentially an additional background to $K_L \to \pi^0 e^+e^-$ in some region of phase space [109]. This process has been observed with a branching ratio of $(1.62 \pm 0.14_{\mathrm{stat}} \pm 0.09_{\mathrm{sys}}) \times 10^{-8}$ [110].

The decay $K_L \to \gamma\gamma e^+e^-$ constitutes the dominant background to $K_L \to \pi^0 e^+e^-$. It was first observed by BNL-845 [111], and subsequently confirmed with a much larger sample by KTeV [112]. It has been estimated that this background will enter at about the 10^{-10} level [113,114], comparable to or larger than the signal level. Because of this, the observation of $K_L \to \pi^0 e^+e^-$ at the SM level will depend on background subtraction with good statistics. Possible alternative strategies are discussed in [98] and references cited therein.

The 90% CL upper bound for the process $K_L \to \pi^0 e^+e^-$ is 2.8×10^{-10} [114]. For the closely related muonic process, the published upper bound is $\mathrm{B}(K_L \to \pi^0\mu^+\mu^-) \leq 3.8 \times 10^{-10}$ [115], compared with the SM prediction of $(1.9 \pm 0.5) \times 10^{-11}$. The latter assumes positive interference between the direct- and indirect-CP violating components and includes a CP-conserving component which contributes about 30% of the total [10,116].

A study of $K_L \to \pi^0\mu^+\mu^-$ has indicated that it might be possible to extract the direct CP-violating contribution by a joint study of the Dalitz plot variables and the components of the μ^+ polarization [117]. The latter tends to be quite substantial so that large statistics may not be necessary.

Combined information from $K_L \to \pi^0\ell^+\ell^-$ as well as $K_L \to \mu^+\mu^-$ complements the $K \to \pi\nu\bar{\nu}$ measurements in constraining physics beyond the SM [118].

65.5 Other long distance dominated modes

The rates and spectra for the decays $K^+ \to \pi^+\ell^+\ell^-$ (ℓ = e or μ) have been measured [119–124] and are successfully described with a parameterization inspired by chiral perturbation theory but with large corrections beyond leading order [96, 97] (see [102, 125] for a review). The most recent NA62 result shows good agreement between the electron and muon mode form factors [126]. NA62 has also obtained a first measurement of the forward-backward asymmetry in the muon mode [126].

The mode $K^+ \to \pi^+\pi^0 e^+e^-$, analyzed by NA48/2 [127], is also dominated by long distance physics but it has been argued that measuring asymmetries can provide information on the short distance components [128]. The current status of these modes is discussed in [129]. Contributions to $K^+ \to \pi^+e^+e^-e^+e^-$ beyond the double Dalitz decay in $K^+ \to \pi^+\pi^0$ are considered in [130], and have been measured by NA62 [131].

The decay $K^+ \to \pi^+\gamma\gamma$ can be predicted in terms of one unknown parameter to leading order in χPT, dubbed $\hat{c}$, resulting in a correlation between the rate and the diphoton mass spectrum [132]. Certain important corrections at the next order are also known [133]. The rate and spectrum were first measured by E787 [134], followed by NA48/2 [135] and NA62 [136]. The most recent measurement from NA62 [137], based on a sample of over 4000 events, finds $B(K^+ \to \pi^+\gamma\gamma) = (9.73 \pm 0.17 \pm 0.08) \times 10^{-7}$ and a precise value for $\hat{c}$.

Much information has been recorded by KTeV and NA48 on the rates and spectrum for the Dalitz pair conversion modes $K_L \to \ell^+\ell^-\gamma$ [138, 139], and $K_L \to \ell^+\ell^-\ell'^+\ell'^-$ for $\ell, \ell' =$ e or μ [22, 140]. LHCb has recently placed limits on $K_{L,S} \to \mu^+\mu^-\mu^+\mu^-$ [141]. All these results are used to test hadronic models and should eventually help unravel the underlying physics in $K_L \to \mu^+\mu^-$ [87, 92, 142].

66. *CPT* Invariance Tests in Neutral Kaon Decay

Revised August 2023 by M. Antonelli (INFN, Frascati), G. D'Ambrosio (INFN, Napoli) and M.S. Sozzi (Pisa U.).

CPT theorem is based on three assumptions: quantum field theory, locality, and Lorentz invariance, and thus it is a fundamental probe of our basic understanding of particle physics. Strangeness oscillation in $K^0-\overline{K}^0$ system, described by the equation

$$i\frac{d}{dt}\begin{bmatrix}K^0\\ \overline{K}^0\end{bmatrix}=[M-i\Gamma/2]\begin{bmatrix}K^0\\ \overline{K}^0\end{bmatrix}\ ,$$

where M and Γ are hermitian matrices (see PDG review [1], references [2,3], and KLOE paper [4] for notations and previous literature), allows a very accurate test of CPT symmetry; indeed since CPT requires $M_{11}=M_{22}$ and $\Gamma_{11}=\Gamma_{22}$, the mass and width eigenstates, $K_{S,L}$, have a CPT-violating piece, δ, in addition to the usual CPT-conserving parameter ϵ:

$$K_{S,L}=\frac{1}{\sqrt{2\left(1+|\epsilon_{S,L}|^2\right)}}\left[\left(1+\epsilon_{S,L}\right)K^0\pm\left(1-\epsilon_{S,L}\right)\overline{K}^0\right]$$

$$\epsilon_{S,L}=\frac{-i\Im\left(M_{12}\right)-\frac{1}{2}\Im\left(\Gamma_{12}\right)\mp\frac{1}{2}\left[M_{11}-M_{22}-\frac{i}{2}\left(\Gamma_{11}-\Gamma_{22}\right)\right]}{m_L-m_S+i(\Gamma_S-\Gamma_L)/2}$$

$$\equiv\epsilon\pm\delta. \tag{66.1}$$

Using the phase convention $\Im(\Gamma_{12})=0$, we determine the phase of ϵ to be $\varphi_{SW}\equiv\arctan\frac{2(m_L-m_S)}{\Gamma_S-\Gamma_L}$. Imposing unitarity to an arbitrary combination of K^0 and $\overline{K}^0$ wave functions, we obtain the Bell-Steinberger relation [5] connecting CP and CPT violation in the mass matrix to CP and CPT violation in the decay; in fact, neglecting $\mathcal{O}(\epsilon)$ corrections to the coefficient of the CPT-violating parameter, δ, we can write [4]

$$\left[\frac{\Gamma_S+\Gamma_L}{\Gamma_S-\Gamma_L}+i\tan\phi_{\rm SW}\right]\left[\frac{\Re(\epsilon)}{1+|\epsilon|^2}-i\Im(\delta)\right]=\frac{1}{\Gamma_S-\Gamma_L}\sum_f A_L(f)A_S^*(f), \tag{66.2}$$

where $A_{L,S}(f)\equiv A(K_{L,S}\to f)$. We stress that this relation is phase-convention-independent. The advantage of the neutral kaon system is that only a few decay modes give significant contributions to the r.h.s. in Eq. (66.2); in fact, defining for the hadronic modes

$$\alpha_i\equiv\frac{1}{\Gamma_S}\langle\mathcal{A}_L(i)\mathcal{A}_S^*(i)\rangle=\eta_i\ \mathcal{B}(K_S\to i),$$
$$i=\pi^0\pi^0,\pi^+\pi^-(\gamma),3\pi^0,\pi^0\pi^+\pi^-(\gamma), \tag{66.3}$$

the recent data from CPLEAR, KLOE, KTeV, and NA48 have led to the following determinations (the analysis described in Ref. [4] has been updated by using the recent measurements of K_L branching ratios from KTeV [6, 7], NA48 [8, 9], the results described in the CP violation in K_L decays minireview, and the KLOE result [10])

$$\begin{aligned}\alpha_{\pi^+\pi^-}&=((1.121\pm0.010)+i(1.061\pm0.010))\times10^{-3}\ ,\\ \alpha_{\pi^0\pi^0}&=((0.493\pm0.005)+i(0.471\pm0.005))\times10^{-3}\ ,\\ \alpha_{\pi^+\pi^-\pi^0}&=((0\pm2)+i(0\pm2))\times10^{-6},\\ |\alpha_{\pi^0\pi^0\pi^0}|&<1.5\times10^{-6}\ \text{ at 95\% CL}\ .\end{aligned} \tag{66.4}$$

The semileptonic contribution to the right-handed side of Eq. (66.2) requires the determination of several observables: we define [2,3]

$$\begin{aligned}\mathcal{A}(K^0\to\pi^-l^+\nu)&=\mathcal{A}_0(1-y)\ ,\\ \mathcal{A}(K^0\to\pi^+l^-\nu)&=\mathcal{A}_0^*(1+y^*)(x_+-x_-)^*\ ,\\ \mathcal{A}(\overline{K}^0\to\pi^+l^-\nu)&=\mathcal{A}_0^*(1+y^*)\ ,\\ \mathcal{A}(\overline{K}^0\to\pi^-l^+\nu)&=\mathcal{A}_0(1-y)(x_++x_-)\ ,\end{aligned} \tag{66.5}$$

where x_+ (x_-) describes the violation of the $\Delta S=\Delta Q$ rule in CPT-conserving (violating) decay amplitudes, and y parameterizes CPT violation for $\Delta S=\Delta Q$ transitions. Taking advantage of their tagged $K^0(\overline{K}^0)$ beams, CPLEAR has measured $\Im(x_+)$, $\Re(x_-)$, $\Im(\delta)$, and $\Re(\delta)$ [11]. These determinations have been improved in Ref. [4] by including the information $A_S-A_L=4[\Re(\delta)+\Re(x_-)]$ (valid at first order in the small parameters), where $A_{L,S}$ are the K_L and K_S semileptonic charge asymmetries, respectively, from the PDG [12] and the new KLOE semileptonic measurement [13]. Here we are also including the T-violating asymmetry measurement from CPLEAR [14] with a finer binning than appearing in the published article.

Table 66.1: Values, errors, and correlation coefficients for $\Re(\delta)$, $\Im(\delta)$, $\Re(x_-)$, $\Im(x_+)$, and A_S+A_L obtained from a combined fit, including KLOE [4, 13] and CPLEAR [14].

	value	Correlations coefficients				
$\Re(\delta)$	$(4.3\pm2.7)\ \times10^{-4}$	1				
$\Im(\delta)$	$(-0.9\pm0.6)\times10^{-2}$	−0.40	1			
$\Re(x_-)$	$(-0.22\pm0.10)\times10^{-2}$	−0.14	−0.30	1		
$\Im(x_+)$	$(0.06\pm0.19)\times10^{-2}$	−0.12	−0.02	0.34	1	
A_S+A_L	$(-0.23\pm0.38)\times10^{-2}$	−0.12	−0.29	0.94	0.18	1

The value A_S+A_L in Table 66.1 can be directely included in the semileptonic contributions to the Bell Steinberger relations in Eq. (66.2)

$$\begin{aligned}&\sum_{\pi\ell\nu}\langle\mathcal{A}_L(\pi\ell\nu)\mathcal{A}_S^*(\pi\ell\nu)\rangle\\ &\quad=2\Gamma(K_L\to\pi\ell\nu)(\Re(\epsilon)-\Re(y)-i(\Im(x_+)+\Im(\delta)))\\ &\quad=2\Gamma(K_L\to\pi\ell\nu)((A_S+A_L)/4-i(\Im(x_+)+\Im(\delta)))\ .\end{aligned} \tag{66.6}$$

Defining

$$\alpha_{\pi\ell\nu}\equiv\frac{1}{\Gamma_S}\sum_{\pi\ell\nu}\langle\mathcal{A}_L(\pi\ell\nu)\mathcal{A}_S^*(\pi\ell\nu)\rangle+2i\frac{\tau_{K_S}}{\tau_{K_L}}\mathcal{B}(K_L\to\pi\ell\nu)\Im(\delta)\ , \tag{66.7}$$

we find:

$$\alpha_{\pi\ell\nu}=((-0.1\pm0.2)+i(-0.1\pm0.5))\times10^{-5}\ . \tag{66.8}$$

Table 66.2: Summary of results: values, errors, and correlation coefficients for $\Re(\epsilon)$, $\Im(\delta)$, $\Re(\delta)$, and $\Re(x_-)$.

	value	Correlations coefficients			
$\Re(\epsilon)$	$(161.2\pm0.5)\times10^{-5}$	+1			
$\Im(\delta)$	$(-0.3\pm1.4)\times10^{-5}$	+0.08	1		
$\Re(\delta)$	$(2.6\pm2.5)\times10^{-4}$	+0.00	−0.05	1	
$\Re(x_-)$	$(-2.7\pm1.0)\times10^{-3}$	+0.05	0.13	−0.30	1

The analysis of semileptonic decay asymmetries implicitly assumes Lepton Flavour Universality (LFU) of any effect violating CPT or $\Delta S=\Delta Q$, through the use of a single set of x, y parameters, consistently with the availability of experimental information on A_S for the electron mode only. The explicit LFU assumption in the input BR measurements has been lifted exploiting the measurement of $BR(K_S\to\pi\mu\nu)$ Ref. [15], with no effect on the numerical results.

Inserting the values of the α parameters into Eq. (66.2), we find

$$\Re(\epsilon) = (161.2 \pm 0.5) \times 10^{-5},$$
$$\Im(\delta) = (-0.3 \pm 1.4) \times 10^{-5}. \quad (66.9)$$

The complete information on Eq. (66.9) is given in Table 66.2.

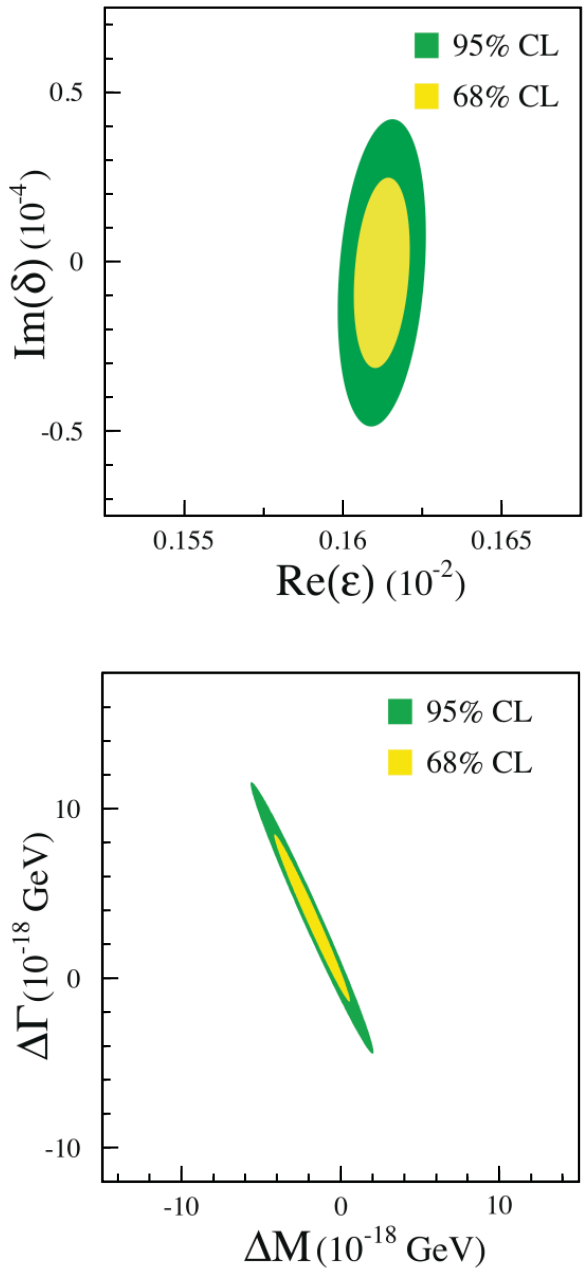

Figure 66.1: Top: allowed region at 68% and 95% C.L. in the $\Re(\epsilon)$, $\Im(\delta)$ plane. Bottom: allowed region at 68% and 95% C.L. in the $\Delta M, \Delta\Gamma$ plane.

Now the agreement with CPT conservation, $\Im(\delta) = \Re(\delta) = \Re(x_-) = 0$, is at 18% C.L.

The allowed region in the $\Re(\epsilon) - \Im(\delta)$ plane at 68% CL and 95% C.L. is shown in the top panel of Fig. 66.1.

The process giving the largest contribution to the size of the allowed region is $K_L \to \pi^+\pi^-$, through the uncertainty on ϕ_{+-}.

The limits on $\Im(\delta)$ and $\Re(\delta)$ can be used to constrain the $K^0 - \overline{K}^0$ mass and width difference

$$\delta = \frac{i(m_{K^0} - m_{\overline{K}^0}) + \frac{1}{2}(\Gamma_{K^0} - \Gamma_{\overline{K}^0})}{\Gamma_S - \Gamma_L} \cos\phi_{SW} e^{i\phi_{SW}} [1 + \mathcal{O}(\epsilon)].$$

The allowed region in the $\Delta M = (m_{K^0} - m_{\overline{K}^0}), \Delta\Gamma = (\Gamma_{K^0} - \Gamma_{\overline{K}^0})$ plane is shown in the bottom panel of Fig. 66.1. As a result, we improve on the previous limits (see for instance, P. Bloch in Ref. [12]) and in the limit $\Gamma_{K^0} - \Gamma_{\overline{K}^0} = 0$ we obtain

$$-4.0\times10^{-19}\ \text{GeV} < m_{K^0} - m_{\overline{K}^0} < 4.0\times10^{-19}\ \text{GeV} \quad \text{at 95 \% C.L.}$$

67. V_{ud}, V_{us} the Cabibbo Angle, and CKM Unitarity

Revised March 2024 by E. Blucher (Chicago U.), G. D'Ambrosio (INFN, Napoli) and W.J. Marciano (BNL).

The Cabibbo-Kobayashi-Maskawa (CKM) [1, 2] three-generation quark mixing matrix written in terms of the Wolfenstein parameters (λ, A, ρ, η) [3] nicely illustrates the orthonormality constraint of unitarity, as well as the central role played by λ.

$$V_{\rm CKM} = \begin{pmatrix} V_{ud} & V_{us} & V_{ub} \\ V_{cd} & V_{cs} & V_{cb} \\ V_{td} & V_{ts} & V_{tb} \end{pmatrix} = \begin{pmatrix} 1-\lambda^2/2 & \lambda & A\lambda^3(\rho - i\eta) \\ -\lambda & 1-\lambda^2/2 & A\lambda^2 \\ A\lambda^3(1-\rho-i\eta) & -A\lambda^2 & 1 \end{pmatrix} + \mathcal{O}(\lambda^4)\ . \tag{67.1}$$

That cornerstone parameter is a carryover from the two-generation Cabibbo angle, $\lambda = \sin(\theta_{\rm Cabibbo}) = V_{us}$. Its value is an important component in tests of CKM unitarity.

Up until 2003, the precise value of λ was controversial, with kaon decays (specifically $K \to \pi e \nu$) branching fractions suggesting [4] $\lambda \simeq 0.220$, while indirect determinations via V_{ud} obtained from nuclear β-decays combined with unitarity preferred a somewhat larger $\lambda \simeq 0.225 - 0.230$. This difference implied a 2 - 2.5 sigma deviation from the first row unitarity requirement

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 1, \tag{67.2}$$

a possible hint [5, 6] of new physics effects. Below, we describe the current status of V_{ud} and V_{us}, and their implication for the unitarity test in Eq. (67.2). (Since $|V_{ub}|^2 \simeq 1.7\times10^{-5}$ is negligibly small, it is ignored in this discussion.) Eq. (67.2) is currently the most stringent test of unitarity in the CKM matrix. As we shall see, it is again showing signs of a possible 2 to 3 sigma inconsistency.

67.1 V_{ud}

Precise values of V_{ud} have been obtained from superallowed nuclear, neutron, and pion beta decays. Currently, the best determination of V_{ud} comes from analysis of a set of 15 precisely measured superallowed nuclear beta-decays [5,6] ($0^+ \to 0^+$ transitions). Measuring their half-lives, t, and Q values gives the decay rate factors, f, which lead to a precise determination of V_{ud} via [7–12]. Based on several decades of dedicated studies, Hardy and Towner recently updated the average of the half-life, $\overline{\mathcal{F}t}$, [6]

$$|V_{ud}|^2 = \frac{K}{2G_F^2(1+\Delta_{\rm R}^{\rm V})\overline{\mathcal{F}t}} = \frac{2912.95 \pm 0.54}{\overline{\mathcal{F}t}} = 0.94815 \pm 0.00060 \quad \text{for } \Delta_R^V = 2.454(19)\%, \tag{67.3}$$

where $K/(\hbar c)^6 = 2\pi^3\hbar \ln 2/(m_e c^2)^5 = 8120.27648(26) \times 10^{-10} GeV^{-4}s$, Δ_R^V denotes the so-called inner or universal electroweak radiative corrections (RC) to superallowed nuclear beta decays. A dispersion relation (DR) calculational approach [13] to quantum loop corrections, specifically the gamma-W box diagram, gives $\Delta_R^V = 0.02467(22)$. Actually the authors of Ref. [14] have combined the different theoretical calculations leading to $\Delta_R^V = 0.02467(27)$ and

$$V_{ud} = 0.97367(11)_{\rm exp}(13)_{\Delta_R^V}(27)_{\rm NS}\ (32)_{\rm total}\ \text{(superallowed)}\ . \tag{67.4}$$

As a result of its small uncertainty and more rigorous theoretical footing, we use this value below. A somewhat different approach [15] found $\Delta_R^V = 0.02426(32)$. These recent values are roughly consistent. Both are larger than the 2018 PDG value of 0.02361(38). Implications and possible nuclear physics modifications of those studies are still under scrutiny [16, 17]. Note that an additional uncertainty $(54)_{\rm NS}$ from nuclear structure (NS) [17] has been recently included [6] in that master formula. This recent determination of V_{ud} has shifted significantly down compared to the 2018 PDG value of 0.97420(21). In addition, NS uncertainties are now the dominant contribution to the overall uncertainty. Taken at face value, along with current V_{us} determinations (see subsection 67.2), the reduced V_{ud} would seem to violate the first row unitarity requirement, and thus suggest the presence of deviations from unitarity or unaccounted uncertainties.

Measurements of the neutron lifetime, τ_n, and the ratio of axial-vector/vector couplings, $g_A \equiv G_A/G_V$, via neutron decay asymmetries combined with the inner radiative corrections can also be used to determine V_{ud} via the precise formula [14, 18]

$$|V_{ud}|^2 = \frac{5024.7\ \text{s}}{\tau_n(1+3g_A)(1+\Delta_R)}, \tag{67.5}$$

where $\Delta_R = 0.03983(27)$ represents radiative corrections [14]. We present the V_{ud} results using either the the current published world averages [19] or the best measured values for λ [20] and for τ_n [21]. The average leads to

$$\tau_n^{\rm ave} = 879.4(6)\ \text{s}\ \ \text{(1.6 PDG scale factor)}$$
$$g_A^{\rm ave} = 1.2756(13),\ \text{(2.6 PDG scale factor)}, \tag{67.6}$$

$$|V_{ud}^{n,PDG}| = 0.97441(28)_{\tau_n}(82)_\lambda(13)_{\Delta_R}(88)_{\rm TOT}, \tag{67.7}$$

while the best values lead to

$$|V_{ud}^{n,best}| = 0.97413(20)_{\tau_n}(35)_\lambda(13)_{\Delta_R}(42)_{\rm TOT}. \tag{67.8}$$

Both central values are similar to the superallowed nuclear beta decay result reported above. Reconciliation with CKM unitarity suggests a shorter neutron lifetime near 878.5 s or a smaller g_A. We note that the most precise recent neutron lifetime update reported [21], $\tau_n = 877.75(34)$ s, has an uncertainty about half as big as the average given in Eq. 67.6. It corresponds to $|V_{ud}| = 0.9746(8)$, a value more in keeping with unitarity expectations; but too large an uncertainty from g_A to be meaningful. Future neutron studies [22] are expected to resolve any current inconsistencies and further reduce the uncertainties in g_A and τ_n making them a potentially better way to determine V_{ud} without the nuclear physics uncertainties.

The PIBETA experiment at PSI measured the very small ($\mathcal{O}(10^{-8})$) branching ratio for $\pi^+ \to \pi^o e^+ \nu_e$ with about $\pm 0.6\%$ precision. Its result gives [23]

$$|V_{ud}| = 0.9739(27)\left[\frac{BR(\pi^+ \to e^+\nu_e(\gamma))}{1.2325\times10^{-4}}\right]^{\frac{1}{2}}, \tag{67.9}$$

which is normalized using the very precisely measured $BR(\pi^+ \to e^+\nu_e(\gamma)) = 1.2325(23) \times 10^{-4}$ [7], rather than the theoretical branching ratio of $1.2350(2)\times10^{-4}$, which if used, would increase $|V_{ud}|$ to 0.9749(27). Theoretical uncertainties in pion beta decay are very small [24], leaving open more than an order of magnitude improvement of its experimental branching ratio before theory uncertainties become a problem. Although challenging, improved measurements of pion beta decay currently under discussion would allow this decay mode to compete with superallowed beta decays and future neutron decay efforts for the most precise direct $|V_{ud}|$ determination.

67.2 V_{us}

$|V_{us}|$ may be directly obtained from kaon decays, hyperon decays, and tau decays. Early determinations most often used $K\ell3$ decays:

$$\Gamma_{K\ell3} = \frac{G_F^2 M_K^5}{192\pi^3} S_{EW}(1+\delta_K^\ell+\delta_{SU2})C^2\,|V_{us}|^2\,f_+^2(0)I_K^\ell. \tag{67.10}$$

Here, ℓ refers to either e or μ, G_F is the Fermi constant, M_K is the kaon mass, S_{EW} is the short-distance radiative correction, δ_K^ℓ is the mode-dependent long-distance radiative correction, $f_+(0)$ is the calculated form factor at zero momentum transfer for the $\ell\nu$ system, and I_K^ℓ is the phase-space integral, which depends on measured semileptonic form factors. For charged kaon decays, δ_{SU2} is the deviation from one of the ratio of $f_+(0)$ for the charged to neutral kaon decay; it is zero for the neutral kaon. C^2 is 1 (1/2) for neutral (charged) kaon decays. Most early determinations of

$|V_{us}|$ were based solely on $K \to \pi e\nu$ decays; $K \to \pi\mu\nu$ decays were not used because of large uncertainties in I_K^μ. The experimental measurements are the semileptonic decay widths (based on the semileptonic branching fractions and lifetime) and form factors (allowing calculation of the phase space integrals). Theory is needed for S_{EW}, δ_K^ℓ, δ_{SU2}, and $f_+(0)$.

Many measurements during the last 20 years have resulted in a shift in $|V_{us}|$. Most importantly, the $K \to \pi e\nu$ branching fractions are significantly different than much earlier PDG averages, probably as a result of inadequate treatment of radiation in older experiments. This effect was first observed by BNL E865 [25] in the charged kaon system and then by KTeV [26,27] in the neutral kaon system; subsequent measurements were made by KLOE [28–31], NA48 [32–34], and ISTRA+ [35]. Current averages (*e.g.*, by the PDG [36] or Flavianet [37]) of the semileptonic branching fractions are based only on recent, high-statistics experiments where the treatment of radiation is clear. In addition to measurements of branching fractions, new measurements of lifetimes [38] and form factors [39–43], have resulted in improved precision for all of the experimental inputs to $|V_{us}|$. Precise measurements of form factors for $K_{\mu 3}$ decay make it possible to use both semileptonic decay modes to extract V_{us}.

Following the analysis of Moulson [18, 44] and the Flavianet group [37, 45, 46], along with recent improvements in the QED radiative corrections [47], one finds [48], after including the isospin violating effect, δ_{SU2} , the values of $|V_{us}|f_+(0)$ in Table 67.1. The average of these measurements, including correlation effects [18, 48–50] gives [14]

$$f_+(0)|V_{us}| = 0.21656(35) \quad \text{FLAVIANET} \tag{67.11}$$

where the errors correspond to kaon experimental parameters and radiative corrections, respectively, leading, as we shall see, to $|V_{us}| = 0.22330(35)_{\rm exp}(39)_{\rm LAT}(8)_{\rm RC+IB}(53)_{TOT}$.

Lattice QCD calculations of $f_+(0)$ have been carried out for 2, 2+1, and 2+1+1 quark flavors and range from about 0.96 to 0.97. Here, we illustrate recent FLAG (2020) updated averages [51] for 2+1 and 2+1+1 flavors:

$$\begin{aligned} f_+(0) &= 0.9677(27) \quad N_f = 2+1 \\ f_+(0) &= 0.9698(17) \quad N_f = 2+1+1 \end{aligned} \tag{67.12}$$

Updating the result for $N_f = 2+1+1$ we obtain for V_{us} from Eq. (67.11) and Eq. (67.12),

$$\begin{aligned} |V_{us}| &= 0.2238(4)_{\rm exp+RC}(6)_{\rm lattice} \ (N_f = 2+1, \ K_{\ell 3} \text{ decays}) \\ &= 0.22330(4)_{\rm exp+RC}(4)_{\rm lattice} \ (N_f = 2+1+1, \ K_{\ell 3} \text{ decays}) \end{aligned} \tag{67.13}$$

based on ref. [18] and ref. [48]

Table 67.1: $|V_{us}|f_+(0)$ from $K\ell 3$, based on ref. [18, 48]

Decay Mode	$\lvert V_{us}\rvert f_+(0)$
$K^\pm e3$	0.2169(6)
$K^\pm \mu 3$	0.2168(10)
$K_L e3$	0.2162(5)
$K_L \mu 3$	0.2165(6)
$K_S e3$	0.2169(8)
$K_S \mu 3$	0.2125(47)
Average (including correlation effects [18, 48])	0.21656(35)

A value of V_{us} can also be obtained from a comparison of the radiative inclusive decay rates for $K \to \mu\nu(\gamma)$ and $\pi \to \mu\nu(\gamma)$ combined with a lattice gauge theory calculation of f_{K^+}/f_{π^+} via

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.23871(20) \left[\frac{\Gamma(K \to \mu\nu(\gamma))}{\Gamma(\pi \to \mu\nu(\gamma))}\right]^{\frac{1}{2}} \tag{67.14}$$

with the small error coming from electroweak radiative corrections [52–54]; these corrections were confirmed by direct lattice calculation of the kaon and pion leptonic decay rates [53, 54].

A recent fit [14, 18] gives

$$\frac{|V_{us}|f_{K^+}}{|V_{ud}|f_{\pi^+}} = 0.27679(28)_{\rm BR}(20)_{\rm corr}. \tag{67.15}$$

Employing the FLAG [51] lattice QCD averages for the isospin broken decay constants

$$\frac{f_{K^+}}{f_{\pi^+}} = 1.1978(22) \quad N_f = 2+1+1 \tag{67.16}$$

leading to

$$\frac{|V_{us}|}{|V_{ud}|} = 0.23108(51) \ (N_f = 2+1+1, \ K_{\mu 2} \text{ decays}). \tag{67.17}$$

Actually we can average the Cabibbo angle determinations from kaons: from $K_{\ell 3}$ decays in eqs. 67.11, 67.12 and from $K_{\mu 2}$ in eqs. 67.15, 67.16 with $N_f = 2+1+1$. Assuming 20% correlation between $(|V_{us}/V_{ud}|f_K/f_\pi)$ and (f_K/f_π) we obtain

$$V_{us} = 0.22431(85) \quad \text{S} = 2.5. \tag{67.18}$$

The result shown in Eq. 67.18 is what we use when we consider the first row test of CKM unitarity. The quoted uncertainty includes a scale factor of 2.5 to account for the discrepancies between the values of V_{us} obtained from $K\ell 3$ and $K\mu 2$ decays.

This is the current status of the Cabibbo Angle determination from the kaon sector, and theoretical and experimental progress is expected to clarify the situation soon.

It should be mentioned that hyperon decay fits suggest [55]

$$|V_{us}| = 0.2250(27) \text{ (Hyperon Decays)} \tag{67.19}$$

modulo SU(3) breaking effects that could shift that value up or down. We note that a representative effort [56] that incorporates SU(3) breaking found $V_{us} = 0.226(5)$. Strangeness changing tau decays, averaging both inclusive and exclusive measurements, give [57, 58]

$$|V_{us}| = 0.2207(14) \text{ (Tau Decays)} \ , \tag{67.20}$$

which differs by about 2 sigma from the kaon determination discussed above, and would, if combined with V_{ud} from super-allowed beta decays, lead to a 4 sigma deviation from unitarity. This discrepancy results mainly from the inclusive tau decay results that rely on Finite Energy Sum Rule techniques and assumptions, as well as experimental uncertainties. Recent investigation of that approach suggests a larger value for V_{us}, which is more in accord with other determinations [59].

Employing the values of V_{ud} and V_{us} with an error scale factor of 2 from Eq. (67.4) and the average obtained after rescaling the errors from mEq. 67.18 leads to the unitarity consistency check

$$|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9983(6)(4), \tag{67.21}$$

where the first error is the uncertainty from $|V_{ud}|^2$ and the second error is the uncertainty from the average $|V_{us}|^2$ in Eq. 67.18 . One finds about an overall 2 sigma deviation from unitarity. (The deviation increases to 3 sigma if nuclear structure uncertainties are ignored.) That deviation could be due a problem with $|V_{ud}|$ theory (RC or NS), the lattice determination of $f_+(0)$ or new physics.

67.3 CKM Unitarity Constraints

The current 2 sigma experimental disagreement with unitarity, $|V_{ud}|^2 + |V_{us}|^2 + |V_{ub}|^2 = 0.9983(7)$, still provides strong confirmation of Standard Model radiative corrections (which range between 3-4% depending on the nucleus used) at a high significance level [60]. In addition, it implies constraints on "New Physics" effects at both the tree and quantum loop levels. Those effects could be in the form of contributions to nuclear beta decays, K decays and/or muon decays, with the last of these providing normalization via the muon lifetime [61], which is used to obtain the Fermi constant, $G_\mu = 1.1663787(6) \times 10^{-5}\text{GeV}^{-2}$.

In the following examples, we illustrate the implications of CKM unitarity for (1) exotic muon decays [62] (beyond ordinary

muon decay $\mu^+ \to e^+\nu_e\bar{\nu}_\mu$) and (2) new heavy quark mixing V_{uD} [63]. Other examples in the literature [64, 65] include Z_χ boson quantum loop effects, supersymmetry, leptoquarks, compositeness etc.

68. CP Violation in K_L^0 Decays

Revised August 2023 by C.-J. Lin (LBNL).

The symmetries C (particle-antiparticle interchange) and P (space inversion) hold for strong and electromagnetic interactions. After the discovery of large C and P violation in the weak interactions, it appeared that the product CP was a good symmetry. In 1964 CP violation was observed in K^0 decays at a level given by the parameter $\epsilon \approx 2.3 \times 10^{-3}$.

A unified treatment of CP violation in K, D, B, and B_s mesons is given in "CP Violation in Meson Decays" by D. Kirkby and Y. Nir in this *Review*. A more detailed review including a thorough discussion of the experimental techniques used to determine CP violation parameters is given in a book by K. Kleinknecht [1]. Here we give a concise summary of the formalism needed to define the parameters of CP violation in K_L decays, and a description of our fits for the best values of these parameters.

68.1 Formalism for CP violation in Kaon decay

CP violation has been observed in the semi-leptonic decays $K_L^0 \to \pi^\mp \ell^\pm \nu$, and in the nonleptonic decay $K_L^0 \to 2\pi$. The experimental numbers that have been measured are

$$A_L = \frac{\Gamma(K_L^0 \to \pi^- \ell^+ \nu) - \Gamma(K_L^0 \to \pi^+ \ell^- \nu)}{\Gamma(K_L^0 \to \pi^- \ell^+ \nu) + \Gamma(K_L^0 \to \pi^+ \ell^- \nu)} \tag{68.1a}$$

$$\eta_{+-} = A(K_L^0 \to \pi^+\pi^-)/A(K_S^0 \to \pi^+\pi^-) = |\eta_{+-}|\, e^{i\phi_{+-}} \tag{68.1b}$$

$$\eta_{00} = A(K_L^0 \to \pi^0\pi^0)/A(K_S^0 \to \pi^0\pi^0) = |\eta_{00}|\, e^{i\phi_{00}} \ . \tag{68.1c}$$

CP violation can occur either in the $K^0 - \overline{K}^0$ mixing or in the decay amplitudes. Assuming CPT invariance, the mass eigenstates of the K^0–$\overline{K}^0$ system can be written

$$|K_S\rangle = p|K^0\rangle + q|\overline{K}^0\rangle \ , \quad |K_L\rangle = p|K^0\rangle - q|\overline{K}^0\rangle \ . \tag{68.2}$$

If CP invariance held, we would have $q = p$ so that K_S would be CP-even and K_L CP-odd. (We define $|\overline{K}^0\rangle$ as CP $|K^0\rangle$). CP violation in K^0–$\overline{K}^0$ mixing is then given by the parameter $\widetilde{\epsilon}$ where

$$\frac{p}{q} = \frac{(1+\widetilde{\epsilon})}{(1-\widetilde{\epsilon})} \ . \tag{68.3}$$

CP violation can also occur in the decay amplitudes

$$A\Big(K^0 \to \pi\pi(I)\Big) = A_I e^{i\delta_I} \ , \quad A\Big(\overline{K}^0 \to \pi\pi(I)\Big) = A_I^* e^{i\delta_I} \ , \tag{68.4}$$

where I is the isospin of $\pi\pi$, δ_I is the final-state phase shift, and A_I would be real if CP invariance held. The CP-violating observables are usually expressed in terms of ϵ and ϵ' defined by

$$\eta_{+-} = \epsilon + \epsilon' \ , \quad \eta_{00} = \epsilon - 2\epsilon' \ . \tag{68.5a}$$

One can then show [2]

$$\epsilon = \widetilde{\epsilon} + i\,\Big(\mathrm{Im}\ A_0/\mathrm{Re}\ A_0\Big) \ , \tag{68.5b}$$

$$\sqrt{2}\epsilon' = ie^{i(\delta_2-\delta_0)}(\mathrm{Re}\, A_2/\mathrm{Re}\, A_0)\,\Big(\mathrm{Im}\, A_2/\mathrm{Re}\, A_2 - \mathrm{Im}\, A_0/\mathrm{Re}\, A_0\Big) \ , \tag{68.5c}$$

$$A_L = 2\mathrm{Re}\ \epsilon/(1+|\epsilon|^2) \approx 2\mathrm{Re}\ \epsilon \ . \tag{68.5d}$$

In Eq. (68.5a), small corrections [3] of order $\epsilon' \times \mathrm{Re}\ (A_2/A_0)$ are neglected, and Eq. (68.5d) assumes the $\Delta S = \Delta Q$ rule.

The quantities Im A_0, Im A_2, and Im $\widetilde{\epsilon}$ depend on the choice of phase convention, since one can change the phases of K^0 and $\overline{K}^0$ by a transformation of the strange quark state $|s\rangle \to |s\rangle\, e^{i\alpha}$; of course, observables are unchanged. It is possible by a choice of phase convention to set Im A_0 or Im A_2 or Im $\widetilde{\epsilon}$ to zero, but none of these is zero with the usual phase conventions in the Standard Model. The choice Im $A_0 = 0$ is called the Wu-Yang phase convention [4], in which case $\epsilon = \widetilde{\epsilon}$. The value of ϵ' is independent of phase convention, and a nonzero value demonstrates CP violation in the decay amplitudes, referred to as direct CP violation. The possibility that direct CP violation is essentially zero, and that CP violation occurs only in the mixing matrix, was referred to as the superweak theory [5].

By applying CPT invariance and unitarity the phase of ϵ is given approximately by

$$\phi_\epsilon \ \approx \ \tan^{-1}\,\frac{2(m_{K_L} - m_{K_S})}{\Gamma_{K_S} - \Gamma_{K_L}} \approx 43.52 \pm 0.05^\circ \ , \tag{68.6a}$$

while Eq. (68.5c) gives the phase of ϵ' to be

$$\phi_{\epsilon'} = \delta_2 - \delta_0 + \frac{\pi}{2} \approx 42.3 \pm 1.5^\circ \ , \tag{68.6b}$$

where the numerical value is based on an analysis of π–π scattering using chiral perturbation theory [6]. The approximation in Eq. (68.6a) depends on the assumption that direct CP violation is very small in all K^0 decays. This is expected to be good to a few tenths of a degree, as indicated by the small value of ϵ' and of η_{+-0} and η_{000}, the CP-violation parameters in the decays $K_S \to \pi^+\pi^-\pi^0$ [7], and $K_S \to \pi^0\pi^0\pi^0$ [8]. The relation in Eq. (68.6a) is exact in the superweak theory, so this is sometimes called the superweak-phase $\phi_{\rm SW}$. An important point for the analysis is that $\cos(\phi_{\epsilon'} - \phi_\epsilon) \simeq 1$. The consequence is that only two real quantities need be measured, the magnitude of ϵ and the value of (ϵ'/ϵ), including its sign. The measured quantity $|\eta_{00}/\eta_{+-}|^2$ is very close to unity so that we can write

$$|\eta_{00}/\eta_{+-}|^2 \approx 1 - 6\mathrm{Re}\ (\epsilon'/\epsilon) \approx 1 - 6\epsilon'/\epsilon \ , \tag{68.7a}$$

$$\mathrm{Re}(\epsilon'/\epsilon) \approx \frac{1}{3}(1 - |\eta_{00}/\eta_{+-}|) \ . \tag{68.7b}$$

From the experimental measurements in this edition of the *Review*, and the fits discussed in the next section, one finds

$$|\epsilon| = (2.228 \pm 0.011) \times 10^{-3}, \tag{68.8a}$$

$$\phi_\epsilon = (43.5 \pm 0.5)^\circ, \tag{68.8b}$$

$$\mathrm{Re}(\epsilon'/\epsilon) \approx \epsilon'/\epsilon = (1.66 \pm 0.23) \times 10^{-3}, \tag{68.8c}$$

$$\phi_{+-} = (43.4 \pm 0.5)^\circ, \tag{68.8d}$$

$$\phi_{00} - \phi_{+-} = (0.34 \pm 0.32)^\circ, \tag{68.8e}$$

$$A_L = (3.32 \pm 0.06) \times 10^{-3}. \tag{68.8f}$$

Direct CP violation, as indicated by ϵ'/ϵ, is expected in the Standard Model. However, the numerical value cannot be reliably predicted because of theoretical uncertainties [9]. The value of A_L agrees with Eq. (68.5d). The values of ϕ_{+-} and $\phi_{00} - \phi_{+-}$ are used to set limits on CPT violation [see "Tests of Conservation Laws"].

68.2 Fits for K_L^0 CP-violation parameters

In recent years, K_L^0 CP-violation experiments have improved our knowledge of CP-violation parameters,

and their consistency with the expectations of CPT invariance and unitarity. To determine the best values of the CP-violation parameters in $K_L^0 \to \pi^+\pi^-$ and $\pi^0\pi^0$ decay, we make two types of fits, one for the phases ϕ_{+-} and ϕ_{00} jointly with Δm and τ_S, and the other for the amplitudes $|\eta_{+-}|$ and $|\eta_{00}|$ jointly with the $K_L^0 \to \pi\pi$ branching fractions.

68.2.1 *Fits to ϕ_{+-}, ϕ_{00}, $\Delta\phi$, Δm, and τ_S data*

These are joint fits to the data on ϕ_{+-}, ϕ_{00}, the phase difference $\Delta\phi = \phi_{00} - \phi_{+-}$, the $K_L^0 - K_S^0$ mass difference Δm, and the K_S^0 mean life τ_S, including the effects of correlations.

Measurements of ϕ_{+-} and ϕ_{00} are highly correlated with Δm and τ_S. Some measurements of τ_S are correlated with Δm. The correlations are given in the footnotes of the ϕ_{+-} and ϕ_{00} sections of the K_L^0 Listings, and the τ_S section of the K_S^0 Listings.

In most cases, the correlations are quoted as 100%, with the value and error of ϕ_{+-} or ϕ_{00} given at a fixed value of Δm and τ_S, with additional terms specifying the dependence of the value on Δm and τ_S. These cases lead to diagonal bands in Figs. 68.1

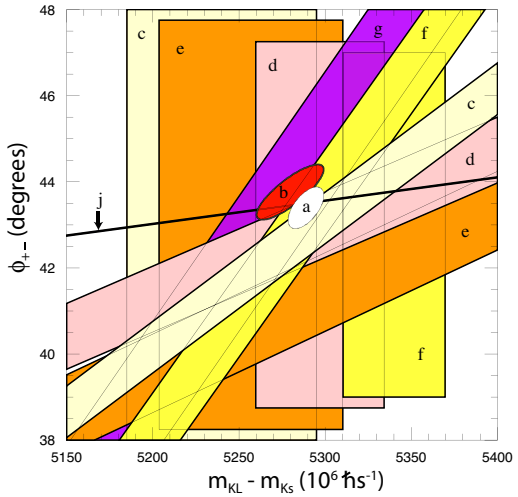

Figure 68.1: ϕ_{+-} vs Δm for experiments which do not assume CPT invariance. Δm measurements appear as vertical bands spanning $\Delta m \pm 1\sigma$, cut near the top and bottom to aid the eye. Most ϕ_{+-} measurements appear as diagonal bands spanning $\phi_{+-} \pm \sigma_\phi$. Data are labeled by letters: "b"–FNAL KTeV, "c"–CERN CPLEAR, "d"–FNAL E773, "e"–FNAL E731, "f"–CERN, "g"–CERN NA31, and are cited in Table 68.1. The narrow band "j" shows ϕ_{SW}. The ellipse "a" shows the $\chi^2 = 1$ contour of the fit result.

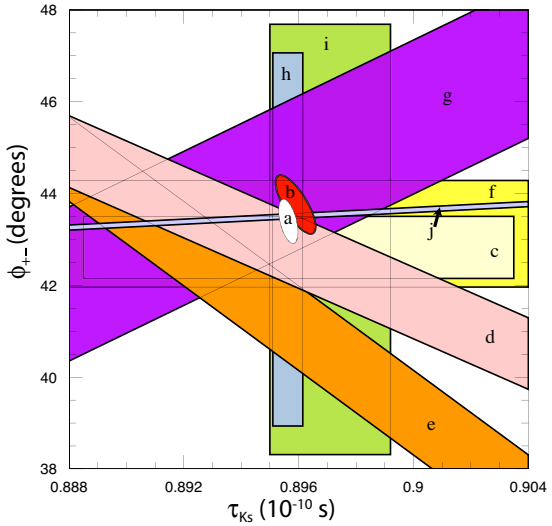

Figure 68.2: ϕ_{+-} vs τ_S. τ_S measurements appear as vertical bands spanning $\tau_S \pm 1\sigma$, some of which are cut near the top and bottom to aid the eye. Most ϕ_{+-} measurements appear as diagonal or horizontal bands spanning $\phi_{+-} \pm \sigma_\phi$. Data are labeled by letters: "b"–FNAL KTeV, "c"–CERN CPLEAR, "d"–FNAL E773, "e"–FNAL E731, "f"–CERN, "g"–CERN NA31, "h"–CERN NA48, "i"–CERN NA31, and are cited in Table 68.1. The narrow band "j" shows ϕ_{SW}. The ellipse "a" shows the fit result's $\chi^2 = 1$ contour.

and 68.2. The KTeV experiment [10] quotes its results as values of Δm, τ_S, ϕ_ϵ, Re(ϵ'/ϵ), and Im(ϵ'/ϵ) with correlations, leading to the ellipses labeled "b." The correlations for the KTeV measurements are given in the Im(ϵ'/ϵ) section of the K^0_L Listings. For small $|\epsilon'/\epsilon|$, $\phi_{+-} \approx \phi_\epsilon + \text{Im}(\epsilon'/\epsilon)$.

Table 68.1: References, Document ID's, and sources corresponding to the letter labels in the figures. The data are given in the ϕ_{+-} and Δm sections of the K_L Listings, and the τ_S section of the K_S Listings.

j	This *Review*	SUPERWEAK 16	

The data on τ_S, Δm, and ϕ_{+-} shown in Figs. 68.1 and 68.2 are combined with data on ϕ_{00} and $\phi_{00} - \phi_{+-}$ in two fits, one without assuming CPT, and the other with this assumption. The results without assuming CPT are shown as ellipses labeled "a." These ellipses are seen to be in good agreement with the superweak phase

$$\phi_{SW} = \tan^{-1}\left(\frac{2\Delta m}{\Delta\Gamma}\right) = \tan^{-1}\left(\frac{2\Delta m \tau_S \tau_L}{\hbar(\tau_L - \tau_S)}\right) . \qquad (68.9)$$

In Figs. 68.1 and 68.2, ϕ_{SW} is shown as narrow bands labeled "j."

Table 68.2 column 2, "Fit w/o CPT," gives the resulting fitted parameters, while Table 68.3 gives the correlation matrix for this fit. The white ellipses labeled "a" in Figure 68.1 and 68.2 are the $\chi^2 = 1$ contours for this fit.

For experiments which have dependencies on unseen fit parameters, that is, parameters other than those shown on the x or y axis of the figure, their band positions are evaluated using the fit results and their band widths include the fitted uncertainty in the unseen parameters. This is also true for the ϕ_{SW} bands.

If CPT invariance and unitarity are assumed, then by Eq. (68.6a), the phase of ϵ is constrained to be approximately equal to

$$\phi_{SW} = (43.50258 \pm 0.00021)^\circ + 54.1(\Delta m - 0.5289)^\circ + 32.0(\tau_S - 0.89564) \qquad (68.10)$$

where we have linearized the Δm and τ_S dependence of Eq. (68.9). The error ± 0.00021 is due to the uncertainty in τ_L. Here Δm has units $10^{10}\,\hbar\,\text{s}^{-1}$ and τ_S has units 10^{-10} s.

If in addition we use the observation that $Re(\epsilon'/\epsilon) \ll 1$ and $cos(\phi_{\epsilon'} - \phi_\epsilon) \simeq 1$, as well as the numerical value of $\phi_{\epsilon'}$ given in Eq. (68.6b), then Eqs. 68.5a, which are sketched in Fig 68.3, lead to the constraint

$$\begin{aligned} \phi_{00} - \phi_{+-} &\approx -3\ \text{Im}\left(\frac{\epsilon'}{\epsilon}\right) \\ &\approx -3\ \text{Re}\left(\frac{\epsilon'}{\epsilon}\right)\tan(\phi_{\epsilon'} - \phi_\epsilon) \\ &\approx 0.006^\circ \pm 0.008^\circ\ , \end{aligned} \qquad (68.11)$$

so that $\phi_{+-} \approx \phi_{00} \approx \phi_\epsilon \approx \phi_{SW}$.

Table 68.2: Fit results for ϕ_{+-}, Δm, τ_S, ϕ_{00}, $\Delta\phi = \phi_{00} - \phi_{+-}$, and ϕ_ϵ without and with the CPT assumption

Quantity(units)	Fit w/o CPT	Fit w/ CPT
$\phi_{+-}(^\circ)$	43.4 ± 0.5 (S=1.2)	43.51 ± 0.05 (S=1.2)
$\Delta m(10^{10}\hbar\,\text{s}^{-1})$	0.5289 ± 0.0010	0.5293 ± 0.0009 (S=1.3)
$\tau_S(10^{-10}\text{s})$	0.89564 ± 0.00033	0.8954 ± 0.0004 (S=1.1)
$\phi_{00}(^\circ)$	43.7 ± 0.6 (S=1.2)	43.52 ± 0.05 (S=1.3)
$\Delta\phi(^\circ)$	0.34 ± 0.32	0.006 ± 0.014 (S=1.7)
$\phi_\epsilon(^\circ)$	43.5 ± 0.5 (S=1.3)	43.52 ± 0.05 (S=1.2)
χ^2	16.4	20.0
# Deg. Free.	14	16

In the fit assuming CPT, we constrain $\phi_\epsilon = \phi_{SW}$ using the linear expression in Eq. (68.10), and constrain $\phi_{00} - \phi_{+-}$ using Eq. (68.11). These constraints are inserted into the Listings with the Document ID of SUPERWEAK 16. Some additional data for which the authors assumed CPT are added to this fit or substitute for other less precise data for which the authors did not make this assumption. See the Listings for details.

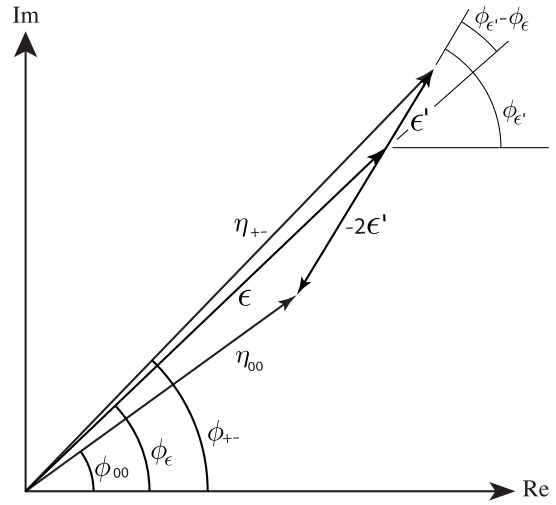

Figure 68.3: Sketch of Eqs. 68.5a. Not to scale

The results of this fit are shown in Table 68.2, column 3, "Fit w/CPT," and the correlation matrix is shown in Table 68.4. The Δm precision is improved by the CPT assumption.

Table 68.3: Correlation matrix for the results of the fit without the CPT assumption

	ϕ_{+-}	Δm	τ_S	ϕ_{00}	$\Delta\phi$	ϕ_ϵ
ϕ_{+-}	1.000	0.596	-0.488	0.827	-0.040	0.976
Δm	0.596	1.000	-0.572	0.487	-0.035	0.580

Table 68.4: Correlation matrix for the results of the fit with the CPT assumption

	ϕ_{+-}	Δm	τ_S	ϕ_{00}	$\Delta\phi$	ϕ_ϵ
ϕ_{+-}	1.000	0.972	-0.311	0.957	-0.105	0.995
Δm	0.972	1.000	-0.509	0.958	-0.007	0.977
τ_S	-0.311	-0.509	1.000	-0.306	0.004	-0.312
ϕ_{00}	0.957	0.958	-0.306	1.000	0.189	0.981
$\Delta\phi$	-0.105	-0.007	0.004	0.189	1.000	-0.006
ϕ_ϵ	0.995	0.977	-0.312	0.981	-0.006	1.000

68.2.2 *Fits for ϵ'/ϵ, $|\eta_{+-}|$, $|\eta_{00}|$, and $B(K_L \to \pi\pi)$*

We list measurements of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ. Independent information on $|\eta_{+-}|$ and $|\eta_{00}|$ can be obtained from measurements of the K_L^0 and K_S^0 lifetimes (τ_L, τ_S), and branching ratios (B) to $\pi\pi$, using the relations

$$|\eta_{+-}| = \left[\frac{\mathrm{B}(K_L^0 \to \pi^+\pi^-)}{\tau_L}\ \frac{\tau_S}{\mathrm{B}(K_S^0 \to \pi^+\pi^-)}\right]^{1/2}, \quad (68.12a)$$

$$|\eta_{00}| = \left[\frac{\mathrm{B}(K_L^0 \to \pi^0\pi^0)}{\tau_L}\ \frac{\tau_S}{\mathrm{B}(K_S^0 \to \pi^0\pi^0)}\right]^{1/2}. \quad (68.12b)$$

For historical reasons, the branching ratio fits and the CP-violation fits are done separately, but we want to include the influence of $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{00}/\eta_{+-}|$, and ϵ'/ϵ measurements on $\mathrm{B}(K_L^0 \to \pi^+\pi^-)$ and $\mathrm{B}(K_L^0 \to \pi^0\pi^0)$ and vice versa. We approximate a global fit to all of these measurements by first performing two independent fits: 1) BRFIT, a fit to the K_L^0 branching ratios, rates, and mean life, and 2) ETAFIT, a fit to the $|\eta_{+-}|$, $|\eta_{00}|$, $|\eta_{+-}/\eta_{00}|$, and ϵ'/ϵ measurements. The results from fit 1, along with the K_S^0 values from this edition, are used to compute values of $|\eta_{+-}|$ and $|\eta_{00}|$, which are included as measurements in the $|\eta_{00}|$ and $|\eta_{+-}|$ sections with a document ID of BRFIT 16. Thus, the fit values of $|\eta_{+-}|$ and $|\eta_{00}|$ given in this edition include both the direct measurements and the results from the branching ratio fit.

The process is reversed in order to include the direct $|\eta|$ measurements in the branching ratio fit. The results from fit 2 above (before including BRFIT 16 values) are used along with the K_L^0 and K_S^0 mean lives and the $K_S^0 \to \pi\pi$ branching fractions to compute the K_L^0 branching ratio $\Gamma(K_L^0 \to \pi^0\pi^0)/\Gamma(K_L^0 \to \pi^+\pi^-)$. This branching ratio value is included as a measurement in the branching ratio section with a document ID of ETAFIT 16. Thus, the K_L^0 branching ratio fit values in this edition include the results of the direct measurement of $|\eta_{00}/\eta_{+-}|$ and ϵ'/ϵ. Most individual measurements of $|\eta_{+-}|$ and $|\eta_{00}|$ enter our fits directly via the corresponding measurements of $\Gamma(K_L^0 \to \pi^+\pi^-)/\Gamma(\text{total})$ and $\Gamma(K_L^0 \to \pi^0\pi^0)/\Gamma(\text{total})$, and those that do not have too large errors to have any influence on the fitted values of these branching ratios. A more detailed discussion of these fits is given in the 1990 edition of this *Review* [20].

69. Review of Multibody Charm Analyses

Revised August 2023 by J. Rademacker (Bristol U.); written with D.M. Asner (BNL)

69.1 Overview

The study of multibody charm decays is a vibrant field, with vast and fast-increasing datasets, new developments in theory and experimental technique, and implications reaching beyond charm. This review is structured as follows: Sec. 69.2 summarizes key aspects of amplitude models that describe multibody charm decays, their application to data, and theory progress; Sec. 69.3 reviews the special role of charm threshold data in model-independent approaches; and Sec. 69.4 describes applications of multi-body charm analyses, focusing on Charge-Parity (*CP*) violation, charm mixing and the role of threshold data in this context. In Sec. 69.5, we conclude.

69.2 Kinematics & Models

The differential decay rate to a point $\mathbf{s} = (s_1, \ldots, s_n)$ in n dimensional phase space can be expressed as

$$d\Gamma = |\mathcal{M}(\mathbf{s})|^2 \left| \frac{\partial^n \phi}{\partial(s_1 \ldots s_n)} \right| d^n s \qquad (69.1)$$

where $|\partial^n \phi / \partial(s_1 \ldots s_n)|$ represents the density of states at $\mathbf{s}$, and $\mathcal{M}$ the matrix element for the decay at that point in phase space, which is $2, 5, 8, \ldots$ dimensional for D decays to $3, 4, 5, \ldots$ spinless particles. Additional parameters are required to fully describe decays involving particles with non-zero spin in the initial or final state.

For the important case of D decays to three pseudoscalars, the decay kinematics can be represented in a two-dimensional Dalitz plot [1]. This is usually parameterized in terms of $s_{12} \equiv (p_1 + p_2)^2$ and $s_{23} \equiv (p_2 + p_3)^2$, where p_1, p_2, and p_3 are the four-momenta of the final-state particles. In terms of these variables, phase-space density is constant across the kinematically allowed region, so that any structure seen in the Dalitz plot is a direct consequence of the dynamics encoded in $|\mathcal{M}|^2$. Note that decays to four or more particles cannot be unambiguously described in terms of analogously-defined variables s_{ij} and s_{ijk}, which are all parity-even. Parity-odd kinematics are absent in three-body decays because the final-state momenta are confined to a plane; the use of parity-odd observables in four body decays is discussed in Sec. 69.4.4.

In the widely-used isobar approach, the matrix element $\mathcal{M}$ is modeled as a sum of interfering decay amplitudes, each proceeding through resonant two-body decays [2–6]. See [2, 7, 8] for a review of resonance phenomenology. In most analyses, each resonance is described by a relativistic Breit-Wigner [9] or Flatté [10] lineshape, and the model includes a non-resonant term with a constant phase and magnitude. This approach has well-known theoretical limitations, such as the violation of unitarity and analyticity, which can break the relationship between magnitude and phase across phase space. This motivates the use of more sophisticated descriptions, especially for broad, overlapping resonances (frequently found in S-wave components) where these limitations are particularly problematic. In charm analyses, these approaches have included the K-matrix [11] which respects two-body unitarity; the use of LASS scattering data [12]; dispersive methods [13–16]; multi-meson models using chiral Lagrangians [17–20]; and methods based on chiral unitarity [21–24]; QCD factorization [25–28]; and quasi model-independent parameterizations that use generic lineshapes, with minimal theory input and many free parameters, for a subset of resonances [29–37].

An important example for a multibody charm decay is $D^0 \to K^0_S \pi^+ \pi^-$, which is a key channel in *CP* violation and charm-mixing analyses. The latest analysis, published jointly by BaBar and Belle [38], describes the Dalitz plot with 1.1M $D^0 \to K^0_S \pi^+ \pi^-$ events with 18 resonant components, including four doubly Cabibbo suppressed ones. The model uses a K-matrix description for the $\pi\pi$ S-wave based on [39] and input from LASS scattering data [12, 40] for the $K\pi$ S-wave, with no need to add a non-resonant component to describe the data. These data were re-analyzed by [25] in a QCD factorization framework, using lineshape parameterizations for the S [41, 42] and P wave [14] contributions that preserve two-body unitarity and analyticity. The analyses give compatible results for the components they share.

The field of charm amplitude analyses remains very active. Publications since the last update of this review two years ago include Dalitz plot analyses of $D^0 \to K^0_L \pi^+ \pi^-$, $D^0 \to K^0_S \pi^+ \pi^-$, $D^+_s \to K^0_S K^+ \pi^0$, $D^+_s \to K^0_S K^0_S \pi^+$, $D^+_s \to K^+ \pi^- \pi^+$, $D^+_s \to \pi^+ \pi^0 \eta'$, and $D^+_s \to \pi^+ \pi^0 \pi^0$ by BESIII [43–48]; $D^+_s \to \pi^+ \pi^- \pi^+$ by LHCb [36] and BESIII [35]; and $D^+ \to \pi^+ \pi^- \pi^+$ by LHCb [37]. LHCb studied the amplitude structure of $\Lambda_c \to p K^- \pi^+$ [49] and BESIII that of $\Lambda_c \to \Lambda \pi^+ \pi^0$ [50]. BESIII continued its series of four-body amplitude analyses with $D^+ \to K^0_S \pi^+ \pi^0 \pi^0$ and $D^+_s \to K^+ \pi^- \pi^+ \pi^0$ [51, 52], and performed a five-body amplitude analysis of $D^+_s \to K^+ K^- \pi^+ \pi^+ \pi^-$ [53]. These analyses provide valuable insight into hadronic dynamics and have wider impact beyond that. The amplitude structure of $\Lambda_c \to p K^- \pi^+$ for example is found to have a high sensitivity to the Λ_c polarization, which can prove valuable in polarization measurements of Λ_b baryons decaying to Λ_c [49, 54]. The importance of charm amplitude analyses for *CP* violation and charm mixing is further discussed below. Comparing the $D^0 \to K^0_L \pi^+ \pi^-$ amplitude structure with that of $D^0 \to K^0_S \pi^+ \pi^-$ reveals U-spin breaking effects [43]. The D^+_s and $D^+ \to \pi^+ \pi^- \pi^+$ analyses mentioned above, as well an earlier one by BaBar [31], analyse the $\pi^+ \pi^-$ S-wave using a quasi-model-independent approach. They observe substantial differences between the $\pi^+ \pi^+$ S-wave components observed in the two decays, and between the associated phase shift seen in either compared to that observed in scattering data [55–57]. These observations suggest that broad scalar meson resonances in these decays might be generated from meson-meson rescattering [37]; more broadly, they emphasize the importance of final state interactions in multibody decays.

Noteworthy is the increasing sophistication of recent amplitude analyses, most of which go substantially beyond the isobar model with Breit Wigner and Flatté lineshapes. However, with the notable exceptions of [15, 16, 23, 24, 58, 59], they remain within the isobar framework which describes the decay as a series of two-body processes, ignores long-range hadronic effects such as rescattering, and does not respect three (or four)-body unitarity and analyticity.

Several groups work on improved models. Dispersive techniques, which respect three-body unitarity and analyticity, have been applied to regions of the $D^+ \to K^- \pi^+ \pi^+$ and $D^+ \to K^0_S \pi^0 \pi^+$ Dalitz plots below the $\eta' K$ threshold [15, 16], where they provide a good description of the data with fewer fit parameters than the isobar approach. Reference [58] uses a unitary coupled channel approach to describe $D^+ \to K^- \pi^+ \pi^+$, which has no restrictions on the kinematic range, but requires additional parameters to describe the Dalitz plot above the $\eta' K$ threshold. Using an effective chiral Lagrangian, the authors of reference [19] provide a description of the annihilation contribution to the decay amplitude which respects three-body unitarity. The approach provides a good description of LHCb's $D^+ \to K^+ K^- K^+$ data, with fewer parameters than an equivalent isobar model [59]. The same channel has more recently been re-analyzed by the authors of [23], who argue that the internal emission diagram should dominate and use a chiral unitarity-based approach to achieve a reasonable description of the data with two free parameters.

Limitations in the theoretical description of interfering resonances are the leading source of systematic uncertainty in many analyses. In some cases, the model uncertainty can be removed through model-independent methods, often relying on input from the charm threshold, as discussed in Sec. 69.3. The authors of [60] expand the scope and applicability of the quasi model-independent approach in amplitude fits. At the same time, increasingly sophisticated models are being developed, and applied to data. The authors of [20] and [61] provide valuable practical frameworks for sophisticated amplitude analyses.

69.3 Model Independent Methods and the Charm Threshold

Precision measurements of the *CP*-violation phase γ/ϕ_3 using $B^- \to DK^-$, $D \to K^0_S\pi^+\pi^-$ and related decay modes, as well as precision measurements of charm-mixing parameters in decay modes such as $D^0 \to K^0_S\pi^+\pi^-$, require input on the relative decay amplitudes of D^0 and $\overline{D}^0$. In the above examples, $K^0_S\pi^+\pi^-$ can be replaced with other final state accessible to both D^0 and $\overline{D}^0$ [62–70]. While the magnitudes of the decay amplitudes can be measured precisely using the vast charm samples at the B factories and LHCb, obtaining the relative phases requires either amplitude models with reliable phase motion, or model-independent approaches. More details on the measurements of γ/ϕ_3 and charm mixing can be found in sections 69.4.1 and 69.4.2.

Model-independent measurements of relative phases between D^0 and $\overline{D}^0$ decay amplitudes rely on interference effects in the decays of well-defined coherent superpositions of D^0 and $\overline{D}^0$. These are accessible at the charm threshold [65,68,70–75], where CLEO–c and BESIII operate. There, quantum-correlated D-meson pairs are produced, which have opposite *CP* and flavour content. For example if one (the tag) is identified as a *CP* eigenstate through its decay (e.g. to K^+K^- or $K_S\pi^0$) the other D meson is an eigenstate state with the opposite *CP* eigenvalue. The decay rate of a *CP* eigenstate $\frac{1}{\sqrt{2}}\left(D^0 \pm \overline{D}^0\right)$ is proportional to $|A_D|^2 + |\overline{A}_D|^2 \pm 2|A_D||\overline{A}_D|\cos(\delta_D)$, where A_D and $\overline{A}_D$ are the D^0 and $\overline{D}^0$ decay amplitudes, and δ_D is their sought-after phase difference. Other quantum correlations give access to $\sin(\delta_D)$. For multibody decays, A_D, $\overline{A}_D$ and δ_D vary across phase space. Model-independent phase information is measured either integrated over the entire phase space of the decay, or in sub-regions/bins. The results can be expressed in terms of one complex parameter $\mathcal{Z} = Re^{-i\delta} = c + is$ per pair of *CP*-conjugate bins; c and s are the average of $\cos(\delta_D)$ and $\sin(\delta_D)$ over that region of phase space. Amplitude models can be used to optimize the binning for sensitivity to γ/ϕ_3, without introducing a model-dependent bias in the result [76]; novel unbinned approaches have the potential to further increase the precision on γ/ϕ_3 in future analyses [77–79].

CLEO–c data have been analyzed to provide binned $\mathcal{Z}$ for the self-conjugate decays $D^0 \to K^0_{S,L}\pi^+\pi^-$, $K^0_{S,L}K^+K^-$, $\pi^+\pi^-\pi^+\pi^-$, and $K^0_S\pi^-\pi^+\pi^0$ and phase space-integrated values for $D^0, \overline{D}^0 \to K^0_SK^+\pi^-$, $K^+\pi^-\pi^0$ and $K^+\pi^-\pi^+\pi^+$ [80–85]. BESIII significantly improved the precision for the $K^0_S\pi^+\pi^-$, $K^0_SK^+K^-$, $K^+\pi^-\pi^0$ and $K^+\pi^-\pi^+\pi^-$ final states [86–89]. CLEO–c and BESIII $K^+\pi^-\pi^+\pi^-$ data were also analysed in four bins of five-dimensional phase space [89,90] with a binning based on [33].

For self-conjugate decays such as $D^0 \to \pi^+\pi^-\pi^0$, one can define the *CP*-even fraction F_+ which is +1 for a *CP*-even eigenstate and 0 for a *CP*-odd one [73]. F_+ is related to $Re(\mathcal{Z}) = c$, defined for a single *CP*-conjugate bin pair. For the purpose of γ/ϕ_3 measurements, this information allows the decay to be treated equivalently to a two-body decay, where γ/ϕ_3 is determined from relative decay rates in multiple decay modes, without the need to resolve the phase-space distribution. In the mathematical expressions for the decay rates, a factor $(2F_+ - 1)$ multiplies the γ/ϕ_3-sensitive term, leading to best sensitivity for $F_+ = 1$ or $F_+ = 0$. $D^0 \to \pi^+\pi^-\pi^0$ is found to be, with $F_+ = (97.3 \pm 1.7)\%$, compatible with being completely *CP*-even (CLEO–c data); a recent BESIII analysis of $D^0 \to K_{L,S}\pi^+\pi^-$ finds $F_+ = (35.3 \pm 0.6 \pm 1.4)\%$ and $(55.6 \pm 0.6 \pm 1.2)\%$, respectively; $D^0 \to \pi^+\pi^-\pi^+\pi^-$ (BESIII, CLEO–c data), $D^0 \to K^+K^-\pi^+\pi^-$ (BESIII), $D^0 \to K^+K^-\pi^0$ (CLEO–c data), are all predominantly *CP* even with F_+ ranging from 73% to 77%; $D^0 \to K^0_S\pi^+\pi^-\pi^0$ (BESIII, CLEO–c data), is predominantly *CP* odd with $F_+ = (23.5 \pm 10)\%$ [43,74,82,83,91–93]. In cases where results from both BESIII and CLEO–c data exist, BESIII's more precise results are quoted.

Comparing measured parameters like F_+ and $\mathcal{Z}$ with those predicted from amplitude models provides a test of the models' phase motion. Model-predicted values for F_+ in $D^0 \to K_{L,S}\pi^+\pi^-$ agree, with $(35.3 \pm 0.6 \pm 1.4)\%$ and $(55.6 \pm 0.6 \pm 1.2)\%$ [38,43] well with the measured values given above; as does the measured F_+ for $D^0 \to \pi^+\pi^-\pi^+\pi^-$, $F_+ = 0.769 \pm 0.023$ [92], with 0.729 ± 0.020 calculated from [32]; and the coherence factor $|\mathcal{Z}| = R$ measured in $D^0 \to K^\pm\pi^\mp\pi^\pm\pi^\mp$, $0.44^{+0.10}_{-0.09}$ [85,94], with 0.459 ± 0.025 predicted by [33]. The latest bin-wise comparisons between model and data for $D^0 \to K_{L,S}\pi^+\pi^-$, $K^\pm\pi^\mp\pi^\pm\pi^\mp$, $K^\pm\pi^\mp\pi^0$, $K^0_SK^+K^-$, and $\pi^+\pi^-\pi^+\pi^-$ can be found in [43, 82, 86–89, 89] and generally show good agreement. These results are a welcome surprise given the preceding discussion on the theoretical shortcomings of amplitude models.

69.4 Applications of multibody charm analyses for *CP* violation and mixing

Amplitude analyses provide sensitivity to both relative magnitudes and phases of the interfering decay amplitudes. It is especially the sensitivity to phases that makes amplitude analyses such a uniquely powerful tool for studying a wide range of phenomena. Here we concentrate on their critical role in *CP* violation and mixing measurements. Properties of light-meson resonances determined in D amplitude analyses are reported in the light-unflavored-meson section of this *Review*.

The closely related topics of multibody charm decays in measurements of *CP* violation in beauty decays to charm and charm mixing will be discussed in turn, followed by a review of searches for time-integrated *CP* violation in multibody charm decays.

69.4.1 *CP violation in decays of Beauty to Charm*

Neutral D mesons originating from $B^- \to DK^-$ (here denoted as D_{B^-}) are a superposition of D^0 and $\overline{D}^0$ with a relative phase that depends on the CKM unitarity triangle parameter γ/ϕ_3,

$$D_{B^-} \propto D^0 + r_B e^{i(\delta_B - \gamma)}\overline{D}^0,$$

where δ_B is a *CP* conserving strong phase, and $r_B \sim 0.1$ is the magnitude of the ratio of the $B^- \to \overline{D}^0K^-$ and $B^- \to D^0K^-$ decay amplitudes. In the corresponding *CP*-conjugate expression, γ/ϕ_3 changes sign. The amplitude analysis of the subsequent $D_{B^\pm}$ decay to a state accessible to both D^0 and $\overline{D}^0$ allows the measurement of γ/ϕ_3 [62–69]. The method generalizes to similar B hadron decays, such as $B^0 \to DK^{*0}$, and, albeit with reduced sensitivity, to decays where the kaon is replaced by a pion.

Measurements based on this technique have been reported by BaBar [95,96], Belle [97–99], Belle II [100], and LHCb [101–114]. Since it relies on $D^0 - \overline{D}^0$ interference, the phase differences between the relevant D^0 and $\overline{D}^0$ decay amplitudes are required in order to extract γ/ϕ_3. Because the theoretical shortcomings of amplitude models discussed above make their phases unreliable, most recent γ/ϕ_3 measurements use amplitude model-independent approaches to obtain this information [98–105, 107–114]. These depend critically on information from the charm threshold described in Sec. 69.3. Charm mixing also results in a (time-dependent) $D^0 - \overline{D}^0$ superposition, that can be used to measure the relevant phase information as input to γ/ϕ_3 measurements. This method is particularly powerful in doubly Cabibbo-suppressed decays such as $D^0 \to K^+\pi^-\pi^+\pi^-$, and when used in combination with threshold data [115, 116]. Under some circumstances, with large data sets, the relevant strong phases and γ/ϕ_3 can be extracted simultaneously without external input, for example in simultaneous analysis of the $B^0 \to DK^+\pi^-$ Dalitz plot and that of the subsequent $D \to K^0_S\pi^+\pi^-$ decay [117]. However, the global effort to measure γ/ϕ_3 to sub-degree precision will continue to rely critically on input from the charm threshold and BESIII's increasing datasets [118].
