- Reactor $\bar{\nu}_e$ disappear over distances of $\sim$ 200 km and $\sim$ 1.5 km with different probabilities. The observed energy spectra show two different mass-induced oscillation wavelengths: at short distances in agreement with the one observed in accelerator ν_μ disappearance, and a long distance compatible with the required parameters for MSW conversion in the Sun.

The minimum scenario to describe these results requires the mixing between the three flavour neutrinos of the standard model in three distinct mass eigenstates. In this case U in Eq. (14.32) is a 3×3 matrix analogous to the CKM matrix for the quarks [21], but due to the possible Majorana nature of the neutrinos it can depend on six independent parameters: three mixing angles and three phases. There are several possible conventions for the ranges of the angles and ordering of the states. The community finally agreed to a parametrization of the leptonic mixing matrix as in Eq. (14.33). The angles θ_{ij} can be taken without loss of generality to lie in the first quadrant, $\theta_{ij} \in [0, \pi/2]$, and the phase $\delta_{\rm CP} \in [0, 2\pi]$. Values of $\delta_{\rm CP}$ different from 0 and π imply CP violation in neutrino oscillations in vacuum [156–158]. The Majorana phases η_1 and η_2 play no role in neutrino oscillations [157, 159]. Hence for the study of neutrino oscillations in the 3ν mixing scenario one can use the parametrization in Eq. (14.34) irrespective of whether neutrinos are Dirac or Majorana particles. Indeed, Majorana phases are very hard to measure since they are only physical if neutrino mass is non-zero, and therefore, the amplitude of any process involving them is suppressed by a factor m_ν/E to some power where E is the energy involved in the process, which is typically much larger than the neutrino mass. The most sensitive experimental probe of Majorana phases is the rate of neutrinoless $\beta\beta$ decay discussed in Secs. 14.9.3 and 14.9.2.

In this convention there are two non-equivalent orderings for the spectrum of neutrino masses:

– Spectrum with Normal Ordering (NO) with $m_1 < m_2 < m_3$
– Spectrum Inverted ordering (IO) with $m_3 < m_1 < m_2$.

Furthermore, the data show a hierarchy between the mass splittings, $\Delta m^2_{21} \ll |\Delta m^2_{31}| \simeq |\Delta m^2_{32}|$ with $\Delta m^2_{ij} \equiv m^2_i - m^2_j$.

In this section, we follow the convention used in the listing section of the PDG and discuss the results for both, NO and IO, using Δm^2_{21}, which is always the smallest mass splitting, and Δm^2_{32}, which up to a sign, is the largest mass splitting for IO, while for NO the largest mass splitting is $\Delta m^2_{31} = \Delta m^2_{32} + \Delta m^2_{21}$.

With what we know of the mass differences (see table 14.7) and the neutrino mass scale (see Sec. 14.9), depending on the value of the lightest neutrino mass, the neutrino mass spectrum can be further classified in:

– Normal Hierarchical Spectrum (NH): $m_1 \ll m_2 < m_3$, $\Rightarrow m_2 \simeq \sqrt{\Delta m^2_{21}} \sim 8.6\times10^{-3}$eV, $m_3 \simeq \sqrt{\Delta m^2_{32} + \Delta m^2_{21}} \sim 0.05$eV,

– Inverted Hierarchical Spectrum (IH): $m_3 \ll m_1 < m_2$, $\Rightarrow m_1 \simeq \sqrt{|\Delta m^2_{32} + \Delta m^2_{21}|} \sim 0.0492\text{eV}, m_2 \simeq \sqrt{|\Delta m^2_{32}|} \sim 0.05\text{eV}$,

– Quasidegenerate Spectrum (QD): $m_1 \simeq m_2 \simeq m_3 \gg \sqrt{|\Delta m^2_{32}|}$.

Sometimes in the literature the determination of the neutrino mass spectrum is referred to as determination of the neutrino hierarchy. However, as described above, with what we know so far of the neutrino mass scale, the neutrino spectrum may or may not be hierarchical. Therefore determination of neutrino mass ordering is a more precise expression, and it is the one used in this review.

In total, the 3-ν oscillation analysis of the existing data involves six parameters: 2 mass differences (one of which can be positive or negative), 3 mixing angles, and the CP phase. The different experiments described in Sec.14.6 provide information on different subsets of these parameters. The precise statistical analysis of the data requires the numerical evaluation of the corresponding oscillation probabilities by solving the evolution equation of the neutrino ensemble from their source to the experiment. Nevertheless, the dominant effects in the different experiments can be qualitatively understood in terms of approximate expressions for the oscillation probabilities which, for convenience, we briefly summarize here.

14.7.1 *3ν Oscillation Probabilities*

The relevant survival probabilities for solar and KamLAND experiments in the framework of three neutrino oscillations can be written as:

$$P^{3\nu}_{ee} = \sin^4\theta_{13} + \cos^4\theta_{13} P^{2\nu}_{ee}(\Delta m^2_{21}, \theta_{12})\,, \tag{14.72}$$

where we have used the fact that $L^{\rm osc}_{0,32} = 4\pi E_\nu/\Delta m^2_{32}$ is much shorter than the distance traveled by both solar and KamLAND neutrinos, so that the oscillations related to $L^{\rm osc}_{0,32}$ are averaged. In the presence of matter effects $P^{2\nu}_{ee}(\Delta m^2_{21}, \theta_{12})$ should be calculated, taking into account the evolution in an effective matter density $n^{\rm eff}_e = n_e \cos^2\theta_{13}$. For $10^{-5} \lesssim \Delta m^2/\text{eV}^2 \lesssim 10^{-4}$, $P^{2\nu}_{ee}(\Delta m^2_{21}, \theta_{12})$ presents the following asymptotic behaviors [160]:

$$P^{2\nu,\rm sun}_{ee} \simeq 1 - \frac{1}{2}\sin^2(2\theta_{12}) \qquad \text{for } E_\nu \lesssim \text{few} \times 100 \text{ keV}\,, \tag{14.73}$$

$$P^{2\nu,\rm sun}_{ee} \simeq \sin^2(\theta_{12}) \qquad \text{for } E_\nu \gtrsim \text{few} \times 1 \text{ MeV}\,, \tag{14.74}$$

$$P^{2\nu,\rm kam}_{ee} = 1 - \sin^2(2\theta_{12})\sin^2\frac{\Delta m^2_{21} L}{4E_\nu}. \tag{14.75}$$

At present most of the precision of the solar analysis is provided by SNO and SK, for which the relevant MSW survival probability provides a direct measurement of $\sin^2\theta_{12}$, as seen in Eq. (14.74). In the MSW regime, the determination of Δm^2_{21} in solar experiments comes dominantly from the ratio between the solar potential and the Δm^2_{21} term required to simultaneously describe the CC/NC data at SNO and the undistorted spectra of ^{8}B neutrinos as measured in both SK and SNO. Conversely, KamLAND $\bar\nu_e$ survival probability proceeds dominantly as vacuum oscillations and provides a most precise determination of Δm^2_{21} via the strong effect of the oscillating phase in the distortion of the reactor energy spectrum. On the contrary, it yields a weaker constraint on θ_{12} as the vacuum oscillation probability depends on the double-valued and "flatter" function $\sin^2(2\theta_{12})$.

In what respects the interpretation of ν_μ disappearance data, at LBL experiments, the ν_μ survival probability can be expanded in the small parameters $\sin\theta_{13}$ and $\alpha \equiv \Delta m^2_{21}/\Delta m^2_{31}$ to good accuracy as [161,162]

$$\begin{aligned} P_{\nu_\mu\to\nu_\mu} &\approx 1 - \sin^2 2\theta_{\mu\mu}\sin^2\frac{\Delta m^2_{\mu\mu} L}{4E_\nu} \\ &\approx 1 - \cos^2\theta_{13}\sin^2(2\theta_{23})\sin^2\frac{\Delta m^2_{32} L}{4E_\nu} + \mathcal{O}(\alpha, s^2_{13})\,, \end{aligned} \tag{14.76}$$

with

$$\begin{aligned} \sin^2\theta_{\mu\mu} &= \cos^2\theta_{13}\sin^2\theta_{23}\,, \\ \Delta m^2_{\mu\mu} &= \sin^2\theta_{12}\Delta m^2_{31} + \cos^2\theta_{12}\Delta m^2_{32} \\ &\quad + \cos\delta_{\rm CP}\sin\theta_{13}\sin 2\theta_{12}\tan\theta_{23}\Delta m^2_{21}. \end{aligned}$$

At present ν_μ disappearance results at LBL provide the best determination of $|\Delta m^2_{32}|$ and θ_{23}, but as seen above, the probability is symmetric with respect to the octant of $\theta_{\mu\mu}$, which implies symmetry around $s^2_{23} = 0.5/c^2_{13}$.

The relevant oscillation probability for ν_e appearance at LBL experiments can be expanded at the second order in the small parameters $\sin\theta_{13}$ and α, and assuming a constant matter density it takes the form [163–165]:

$$\begin{aligned} P_{\nu_\mu\to\nu_e,(\bar\nu_\mu\to\bar\nu_e)} &\approx 4\,\sin^2\theta_{13}\,\sin^2\theta_{23}\frac{\sin^2\Delta(1-A)}{(1-A)^2} \\ &\quad + \alpha^2\sin^2 2\theta_{12}\,\cos^2\theta_{23}\frac{\sin^2 A\Delta}{A^2} \\ &\quad + 8\,\alpha\,J^{\rm max}_{\rm CP}\cos(\Delta \pm \delta_{\rm CP})\frac{\sin\Delta A}{A}\,\frac{\sin\Delta(1-A)}{1-A}\,, \end{aligned} \tag{14.77}$$

with

$$J^{\rm max}_{\rm CP} = \cos\theta_{12}\sin\theta_{12}\cos\theta_{23}\sin\theta_{23}\cos^2\theta_{13}\sin\theta_{13}\,, \tag{14.78}$$

and

$$\Delta \equiv \frac{\Delta m^2_{31} L}{4E_\nu}\,, \quad A \equiv \frac{2E_\nu V}{\Delta m^2_{31}}\,, \tag{14.79}$$

where V is the effective matter potential in the Earth's crust. Results on ν_e appearance at LBL provide us with the dominant information on leptonic CP violation. Furthermore, α, Δ, and A are sensitive to the sign of Δm^2_{32} (*i.e.*, the type of the neutrino mass ordering). The plus (minus) sign in Eq. (14.77) applies for neutrinos (antineutrinos), and for antineutrinos $V \to -V$, which implies $A \to -A$. Numerically one finds for a typical Earth crust matter density of 3 g/cm^3 that at T2K with $E \sim 0.7$ GeV, matter effects cause $\sim \pm 10\%$ differences in the rates, whereas in NOvA with $E \sim 2$ GeV, we can have $|A| \sim 0.2$. Also, $\alpha^2 \approx 10^{-3}$, which implies that the second term in the first line of Eq. (14.77) gives a very small contribution compared to the other terms. Also, the first term in Eq. (14.77) (which dominates for large θ_{13}) depends on $\sin^2\theta_{23}$ and therefore is sensitive to the octant.

The ν_e survival probability relevant for reactor experiments with medium baseline (MBL), $L \sim 1$ km, can be approximated as [162,166]:

$$P_{\nu_e\to\nu_e} = 1 - \sin^2 2\theta_{13}\sin^2\frac{\Delta m^2_{ee} L}{4E_\nu} + \mathcal{O}(\alpha^2)\,, \tag{14.80}$$

where

$$\Delta m^2_{ee} = \cos^2\theta_{12}\Delta m^2_{31} + \sin^2\theta_{12}\Delta m^2_{32}\,. \tag{14.81}$$

These MBL reactor experiments provide the most precise determination of θ_{13}. Furthermore there is an additional effect sensitive to the mass ordering when comparing the disappearance of ν_μ at LBL experiments – which is symmetric with respect to the sign of $\Delta m^2_{\mu\mu}$ given in Eq.(14.7.1) – with that of ν_e disappearance at MBL reactors which is symmetric with respect to the slightly different effective mass-squared difference Δm^2_{ee} given in Eq. (14.81).

Finally, for atmospheric neutrinos, the fluxes contain ν_e, ν_μ, $\bar\nu_e$, and $\bar\nu_\mu$, and for a good fraction of the events, neutrinos travel through the Earth's matter. In the context of 3ν mixing, the

Table 14.6: Experiments contributing to the present determination of the oscillation parameters.

Experiment	Dominant	Important
Solar Experiments	θ_{12}	Δm^2_{21} , θ_{13}
Reactor LBL (KamLAND)	Δm^2_{21}	θ_{12} , θ_{13}
Reactor MBL (Daya-Bay, Reno, D-Chooz)	θ_{13}, $\lvert\Delta m^2_{31,32}\rvert$	
Atmospheric Experiments (SK, IC-DC)		θ_{23},$\lvert\Delta m^2_{31,32}\rvert$, θ_{13},$\delta_{\rm CP}$
Accel LBL ν_μ,$\bar\nu_\mu$, Disapp (K2K, MINOS, T2K, NOνA)	$\lvert\Delta m^2_{31,32}\rvert$, θ_{23}	
Accel LBL ν_e,$\bar\nu_e$ App (MINOS, T2K, NOνA)	$\delta_{\rm CP}$	θ_{13} , θ_{23}

dominant oscillation channel of atmospheric neutrinos is $\nu_\mu \to \nu_\tau$ driven by $|\Delta m^2_{32}|$ with an amplitude controlled by θ_{23} with subleading oscillation modes, triggered by Δm^2_{21} and/or θ_{13}, which depend on the octant of θ_{23}, on the mass ordering, and on $\delta_{\rm CP}$. In that respect, an interesting observable is the deviation of e-like events relative to the no-oscillation prediction N^0_e, since in the two-flavour limit one expects $N_e = N^0_e$. Such deviation can be written in the following way (see, *e.g.*, [167]):

$$\begin{aligned}\frac{N_e}{N^0_e} - 1 \approx\ & (r\sin^2\theta_{23} - 1) P_{2\nu}(\Delta m^2_{32}, \theta_{13}) \\ & + (r\cos^2\theta_{23} - 1) P_{2\nu}(\Delta m^2_{21}, \theta_{12}) \\ & - \sin\theta_{13}\sin 2\theta_{23}\, r\, \Re(A^*_{ee} A_{\mu e})\,.\end{aligned} \tag{14.82}$$

Here $r \equiv \Phi_\mu/\Phi_e$ is the flux ratio with $r \approx 2$ in the sub-GeV range and $r \approx 2.6 \to 4.5$ in the multi-GeV range. $P_{2\nu}(\Delta m^2, \theta)$ is an effective two-flavour oscillation probability, and $A_{ee}, A_{\mu e}$ are elements of a transition amplitude matrix. The three terms appearing in Eq. (14.82) have a well-defined physical interpretation. The first term is important in the multi-GeV range and is controlled by the mixing angle θ_{13} in $P_{2\nu}(\Delta m^2_{32}, \theta_{13})$. This probability can be strongly affected by resonant matter effects [168–173]. Depending on the mass ordering, the resonance will occur either for neutrinos or antineutrinos. The second term is important for sub-GeV events, and it takes into account the effect of oscillations due to Δm^2_{21} and θ_{12} [174–177]. Via the pre-factor containing the flux ratio r both, the first and second terms in Eq. (14.82) depend on the octant of θ_{23}, though in opposite directions: the multi-GeV (sub-GeV) excess is suppressed (enhanced) for $\theta_{23} < 45°$. Finally, the last term in Eq. (14.82) is an interference term between θ_{13} and Δm^2_{21} amplitudes and this term shows also dependence on the CP phase $\delta_{\rm CP}$ [167, 177].

Subdominant three neutrino effects can also affect μ-like events. For example, for multi-GeV muon events one can write the excess in μ-like events as [178, 179]

$$\begin{aligned}\frac{N_\mu}{N^0_\mu} - 1 \approx\ & \sin^2\theta_{23}\left(\frac{1}{r} - \sin^2\theta_{23}\right) P_{2\nu}(\Delta m^2_{32}, \theta_{13}) \\ & - \frac{1}{2}\sin^2 2\theta_{23}\,[1 - \Re(A_{33})]\,.\end{aligned} \tag{14.83}$$

The first term is controlled by θ_{13} and is subject to resonant matter effects, similar to the first term in Eq. (14.82), though with a different dependence on θ_{23} and the flux ratio. In the second term, A_{33} is a probability amplitude satisfying $P_{2\nu}(\Delta m^2_{32}, \theta_{13}) = 1 - |A_{33}|^2$. In the limit $\theta_{13} = 0$ we have $\Re(A_{33}) = \cos(\Delta m^2_{32} L/2E)$, such that the second term in Eq. (14.83) just describes two-flavour $\nu_\mu \to \nu_\mu$ vacuum oscillations.

14.7.2 *3ν Oscillation Analysis*

We summarize in Table 14.6 the different experiments which dominantly contribute to the present determination of the different parameters in the chosen convention.

The table illustrates that the determination of the leptonic parameters requires global analyses of the data from the different experiments. Over the years, these analyses have been in the hands of a few phenomenological groups. We show in Table 14.7 the results from the latest analyses in Refs. [180–183]. For the sake of comparison, all results are presented in the convention of the listing section as described above.

The table illustrates the dependence of the present determination of the parameters on variations of the statistical analysis performed by the different groups and on the data samples included. In that last respect, the main difference resides in the results from Super-Kamiokande atmospheric data [94] which, at present, can only be included in this analysis by directly adding the χ^2 tabulated χ^2 map provided by the experiment.

Altogether the different analyses find consistent results, in particular on the better-known parameters, θ_{12}, θ_{13} and Δm^2_{21} and $|\Delta m^2_{32}|$. The issues which still require clarification are the mass ordering discrimination, the determination of θ_{23} and the leptonic CP phase $\delta_{\rm CP}$:

- In all analyses the best fit is for the normal mass ordering. Inverted ordering is disfavoured with a $\Delta\chi^2$, which ranges from slightly above 1.5σ – driven by the interplay of long-baseline accelerator and short-baseline reactor data – to 2.5σ when adding the atmospheric χ^2 table from Ref. [184].
- There is no statistically significant preference for the octact of θ_{23} in any of the analysis.
- The best fit for the complex phase in NO is at $\delta_{\rm CP} \sim 200°$. CP conservation (for $\delta_{\rm CP} \sim 180°$) is allowed at a confidence level (CL) of 1-2σ.

14.7.3 *Convention-independent Measures of Leptonic CP Violation in 3ν Mixing*

In the framework of 3ν mixing leptonic CP violation can also be quantified in terms of the leptonic Jarlskog invariant [185], defined by:

$$\begin{aligned}\Im\left[U_{\alpha i} U^*_{\alpha j} U^*_{\beta i} U_{\beta j}\right] &\equiv \sum_{\gamma=e,\mu,\tau}\ \sum_{k=1,2,3} J_{\rm CP}\,\epsilon_{\alpha\beta\gamma}\,\epsilon_{ijk} \\ &\equiv J^{\rm max}_{\rm CP}\,\sin\delta_{\rm CP}\,.\end{aligned} \tag{14.84}$$

With the convention in Eq. (14.33) $J^{\rm max}_{\rm CP}$ is the combination of mixing angles in Eq. (14.78). For example, from the analysis in Ref. [180, 181]

$$J^{\rm max}_{\rm CP} = 0.0330 \pm 0.0006\,(\pm 0.0019)\,, \tag{14.85}$$

at 1σ (3σ) for both orderings, and the preference of the present data for non-zero $\delta_{\rm CP}$ implies a small non-zero best fit value $J^{\rm best}_{\rm CP} = -0.009$.

The status of the determination of leptonic CP violation can also be graphically displayed by projecting the results of the global analysis in terms of leptonic unitarity triangles [186–188]. Since in the analysis U is unitary by construction, any given pair of rows or columns can be used to define a triangle in the complex plane. There are a total of six possible triangles corresponding to the unitary conditions

$$\sum_{i=1,2,3} U_{\alpha i} U^*_{\beta i} = 0 \text{ with } \alpha \neq \beta\,, \qquad \sum_{\alpha=e,\mu,\tau} U_{\alpha i} U^*_{\alpha j} = 0 \text{ with } i \neq j\,. \tag{14.86}$$

As an illustration we show in Fig. 14.9 the recasting of the allowed regions of the analysis in Ref. [180, 181] in terms of one leptonic unitarity triangle. We show the triangle corresponding to the unitarity conditions on the first and third columns (after the shown rescaling), which is the equivalent to the one usually shown for the quark sector. In this figure, the absence of CP violation would imply a flat triangle, *i.e.*, $\Im(z) = 0$. So the CL at which leptonic CP violation is being observed would be given by the CL at which the region crosses the horizontal axis. Notice however, that this representation is made *under the assumption*

Table 14.7: 3ν oscillation parameters obtained from different global analyses of neutrino data. In all cases, the numbers labeled as NO (IO) are obtained assuming NO (IO), *i.e.*, relative to the respective local minimum. SK-ATM makes reference to the tabulated χ^2 map from the Super-Kamiokande analysis of their data in Ref. [184].

of a unitary U matrix and therefore does not provide any test of unitarity in the leptonic sector.

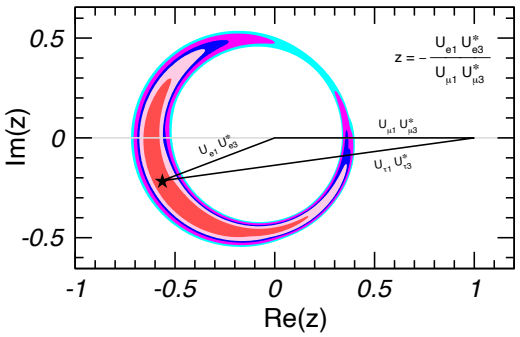

Figure 14.9: Leptonic unitarity triangle for the first and third columns of the mixing matrix. After scaling and rotating the triangle so that two of its vertices always coincide with $(0,0)$ and $(1,0)$ the figure shows the 1σ, 90%, 2σ, 99%, 3σ CL (2 dof) allowed regions of the third vertex for the NO from the analysis in Ref. [180, 181].

14.8 Beyond 3ν: Additional Neutrinos at the eV Scale

Besides the huge success of three-flavour oscillations described in Sec.14.7, as mentioned in Secs.14.6.3 and 14.6.4, there are some anomalies which cannot be explained within the 3ν framework and which have been interpreted as hints for the existence of additional neutrino states with masses at the eV scale. In brief:

- the LSND experiment [123] reported evidence for $\bar\nu_\mu \to \bar\nu_e$ transitions with $E/L \sim 1$ eV^2, where E and L are the neutrino energy and the distance between source and detector, respectively (see *Short Baseline Experiments* subsection of Sec.14.6.3).
- this effect was further explored by the MiniBooNE experiment [189], which reported a yet unexplained event excess in the low-energy region of the electron neutrino and antineutrino event spectra. No significant excess is found at higher neutrino energies. Interpreting the data in terms of oscillations, parameter values consistent with the ones from LSND were obtained, thought the test was not definitive;
- radioactive source experiments at the Gallium solar neutrino experiments both in SAGE and GALLEX/GNO obtained an event rate that is somewhat lower than expected. This result was recently confirmed by the BEST experiment [190]. If not due to uncertainties in the interaction cross-section, this effect by itself can be explained by the hypothesis of ν_e disappearance due to oscillations with $\Delta m^2 \gtrsim 1$ eV^2 ("Gallium anomaly") [191–193];
- the calculations of the neutrino flux emitted by nuclear reactors in Refs. [134, 135] predicted a neutrino rate that is a few percent higher than observed in short-baseline ($L \lesssim 100$ m) reactor experiments. This "reactor anomaly" could be explained by assuming $\bar\nu_e$ disappearance due to oscillations with $\Delta m^2 \sim 1$ eV^2 [194]. The flux predictions from [134, 135] were not supported by the reactor antineutrino flux measurement at Daya Bay [195, 196] which was consistent with the older (lower) flux predictions and the flux measurement results in the short-baseline reactor neutrino oscillation experiments. In the last years the reactor flux calculations have been revisited [197–199] and in most cases lower fluxes are predicted, in agreement with the flux measurement at Daya Bay. These new fluxes, correspondingly reduce the significance of the anomaly [200].

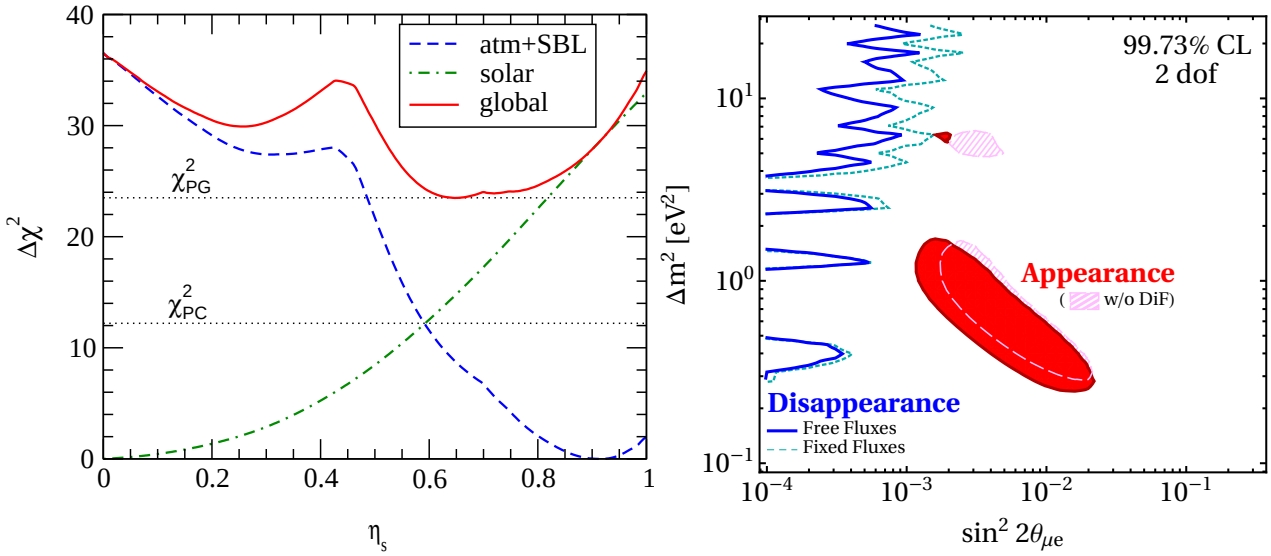

Figure 14.10: *Left*: Status of the 2+2 oscillation scenarios from Ref. [201] ($\eta_S = \sum_i |U_{is}|^2$ where i runs over the two massive states mostly relevant for solar neutrino oscillations). In the figure also shown are the values of $\chi^2_{\rm PC}$ and $\chi^2_{\rm PG}$ relevant for parameter consistency test and parameter goodness of fit, respectively. *Right*: Present status of 3+1 oscillation scenarios from Ref. [202].

These anomalies are under study by the experimental community with a set of follow-up measurements performed at SBL both at reactors and accelerators (see the corresponding subsections in Sec.14.6.4 and Sec.14.6.3).

As mentioned in Sec.14.1, whatever the extension of the SM we want to consider, it must contain only three light active neutrinos. Therefore if we need more than three light massive neutrinos, we must add sterile neutrinos to the particle content of the model.

The most immediate question as these anomalies were reported was whether they could all be consistently described in combination with the rest of the neutrino data – in particular with the negative results on the disappearance of ν_μ at short distances – if one adds those additional sterile states. Quantitatively one can start by adding a fourth massive neutrino state to the spectrum and perform a global data analysis to answer this question. Although the answer is always the same, the physical reason behind it depends on ordering assumed for the states. In brief, there are six possible four-neutrino schemes that can, in principle, accommodate the results of solar+KamLAND and atmospheric+LBL neutrino experiments as well as the SBL result. They can be divided into two classes: (2+2) and (3+1). In the (3+1) schemes, there is a group of three close-by neutrino masses (as on the 3ν schemes described in the previous section) that is separated from the fourth one by a gap of the order of 1 eV, which is responsible for the SBL oscillations. In (2+2) schemes, there are two pairs of close masses (one pair responsible for solar results and the other for atmospheric [203]) separated by the $\mathcal{O}(\text{eV})$ gap. The main difference between these two classes is the following: if a (2+2)-spectrum is realized in nature, the transition into the sterile neutrino is a solution of either the solar or the atmospheric neutrino problem, or the sterile neutrino takes part in both. Consequently, a (2+2)-spectrum is easier to test because the required mixing of sterile neutrinos in either solar and/or atmospheric oscillations would modify their effective matter potential in the Sun and in the Earth, giving distinctive effects in the solar and/or atmospheric neutrino observables. Those distinctive effects were not observed so oscillations into sterile neutrinos did not describe well either solar or atmospheric data. Consequently, as soon as the early 2000's 2+2 spectra could be ruled out already beyond 3-4 σ as seen in the left panel in Fig.14.10 taken from Ref. [201].

On the contrary, for a (3+1)-spectrum (and more generally for a $3+N$-spectrum with an arbitrary N number of sterile states), the sterile neutrino(s) could be only slightly mixed with the active ones and mainly provide a description of the SBL results. In this case, the oscillation probabilities for experiments working at $E/L \sim 1$ eV^2 take a simple form:

$$P_{\alpha\alpha} = 1 - \sin^2 2\theta_{\alpha\alpha} \sin^2 \Delta\,, \qquad P_{\mu e} = \sin^2 2\theta_{\mu e} \sin^2 \Delta\,, \quad (14.87)$$

where $\Delta \equiv \Delta m^2_{41} L/4E$ and one can define effective mixing angles

$$\sin^2 2\theta_{\alpha\alpha} \equiv 4|U_{\alpha 4}|^2(1-|U_{\alpha 4}|^2)\,, \qquad \sin^2 2\theta_{\mu e} \equiv 4|U_{\mu 4}|^2|U_{e4}|^2\,. \quad (14.88)$$

In here $\alpha = e, \mu$ and $U_{\alpha 4}$ are the elements of the lepton mixing matrix describing the mixing of the 4th neutrino mass state with the electron and muon flavour. In this scenario, there is no sensitivity to CP violation in the the Δ driven oscillations, so the relations above are valid for both neutrinos and antineutrinos. At linear order in the mixing elements one can derive a relation between the amplitudes of appearance and disappearance probabilities:

$$4 \sin^2 2\theta_{\mu e} \approx \sin^2 2\theta_{ee} \sin^2 2\theta_{\mu\mu}\,. \quad (14.89)$$

This relation implies a constraint between the possible results in disappearance and appearance experiments. Consequently, it is not trivial to find a consistent description to all the SBL anomalies. Over the years, different groups have performed a variety of such global analyses leading to different quantitative conclusions on the statistical quality of the global fit (see for example [202, 204–208], see also Refs. [209, 210] for recent reviews on the subject). Generically, the results of the global analysis show that there is significant tension between groups of different data sets – in particular between appearance and disappearance results – and Eq.(14.89) makes it difficult to obtain a good global fit as illustrated in the right panel in Fig.14.10 taken from Ref. [202] which concluded that 3+1 scenario is excluded at 4.7σ level.

A straightforward question to ask is whether the situation improves if more neutrino states at the eV scale are introduced. The simplest extension is the introduction of 2 states with eV scale mass splittings, ν_4 and ν_5. The ordering of the states can be such that Δm^2_{41} and Δm^2_{51} are both positive ("3+2"), or one of them is negative ("1+3+1"). From the point of view of the description of the data, the most important new qualitative feature is that now, non-zero CP violation at $E/L \sim$ eV^2 is possibly observable [206, 211–213]. This allows some additional freedom in fitting neutrino versus antineutrino data from LSND and MiniBooNE together. However, it still holds that a non-zero $\nu_\mu \to \nu_e$ appearance at SBL necessarily predicts SBL disappearance for both ν_e and ν_μ. So, generically, the tension between appearance and

disappearance results remains, though differences in the methodology of statistical quantification of the degree of agreement/disagreement in these scenarios can lead to different conclusions on whether they can provide a successful description of all the data [202,209,210]. Cosmological observations can provide complementary information on the number of relativistic neutrino states in thermal equilibrium in the early Universe and on the sum of their masses, which sets further constraints on light sterile neutrino scenarios (see Chapter 26 of this *Review*, "Neutrinos in cosmology").

14.9 Laboratory Probes of ν Mass Scale and its Nature

As described in Secs.14.4 and 14.5, neutrino flavour oscillations in vacuum and flavour transitions in matter only depend on the differences between the neutrino masses-squared, Δm^2_{ij}, and on the mixing matrix elements, U_{ij}. However, they are insensitive to the absolute mass scale for the neutrinos, m_i. They also give us no information on whether they are Dirac or Majorana particles.

Clearly, the observation of flavour oscillations implies a lower bound on the mass of the heavier neutrino in Δm^2_{ij}, $|m_i| \geq \sqrt{\Delta m^2_{ij}}$ for $\Delta m^2_{ij} > 0$. However, there is no upper bound on m_i. In particular, oscillation results allow the neutrino spectrum to be approximately degenerate at a mass scale that is much higher than the $\sqrt{\Delta m^2_{ij}}$ that they determine. Information of the mass scale of the neutrino is provided by other types of experiments. Here we briefly summarize the most sensitive laboratory probes of the neutrino mass scale and on whether they are Dirac or Majorana particles. Cosmological observations provide, albeit indirectly, complementary information on the neutrino mass scale as it is reviewed in Chapter 26 of this *Review*, "Neutrinos in cosmology".

14.9.1 *Constraints from Kinematics of Weak Decays*

The only model-independent information on the neutrino masses, rather than mass differences, can be extracted from energy-momentum conservation relation in reactions in which a neutrino or an antineutrino is involved.

Historically these bounds were labeled as limits on the mass of the flavour neutrino states corresponding to the charged flavour involved in the decay. Fermi proposed in 1933 such a kinematic search for the ν_e neutrino mass (which we will label here as $m^{\rm eff}_{\nu_e}$) in the end part of the beta spectra in ^{3}H beta decay $^3\mathrm{H} \to {}^3\mathrm{He} + e^- + \bar{\nu}_e$.

Because ^{3}H beta decay is a superallowed transition, the nuclear matrix elements are energy independent, so the electron spectrum is determined exclusively by the phase space

$$\begin{aligned} \frac{dN}{dE} &= C\, p\, E\, (Q-T)\sqrt{(Q-T)^2 - (m^{\rm eff}_{\nu_e})^2}\, F(E) \\ &\equiv R(E)\,\sqrt{(E_0-E)^2 - (m^{\rm eff}_{\nu_e})^2}\,. \end{aligned} \tag{14.90}$$

E_0 is the mass difference between the inital and final nucleus, $E = T + m_e$ is the total electron energy, p its momentum, $Q \equiv E_0 - m_e$ is the maximum kinetic energy of the electron and Final state Coulomb interactions are contained in the Fermi function $F(E)$. $R(E)$ in the second equality contains all the m_ν-independent factors.

The Kurie function is defined as $K(T) \equiv \sqrt{\frac{dN}{dE}\,\frac{1}{pEF(E)}}$. From Eq.(14.90), we see that if $m^{\rm eff}_{\nu_e}$=0 $K(T)$ would depend linearly on T. A non-vanishing neutrino mass then provokes a distortion from the straight-line T-dependence at the endpoint, So for $m^{\rm eff}_{\nu_e} = 0$, $T_{\rm max} = Q$, while for $m^{\rm eff}_{\nu_e} \neq 0$, $T_{\rm max} = Q - m^{\rm eff}_{\nu_e}$. In ^{3}H beta decay $Q = 18.6$ KeV is very small and therefore, this decay is more sensitive to this $m^{\rm eff}_{\nu_e}$-induced distortion.

The most recent result on the kinematic search for neutrino mass in tritium decay is from KATRIN [214], an experiment which has found so far no indication of $m_{\nu_e} \neq 0$ and sets an upper limit

$$m^{\rm eff}_{\nu_e} < 0.8\ \mathrm{eV}\,, \tag{14.91}$$

at 90% CL improving over the previous bound from the Mainz [215] and Troitsk [216] experiments which constrained $m^{\rm eff}_{\nu_e} < 2.2$ eV at 95% CL. KATRIN continues running with an estimated sensitivity limit of $m^{\rm eff}_{\nu_e} \sim 0.2$ eV. Project 8 is exploring a new technique for β-spectrometry based on cyclotron radiation [217].

An alternative isotope to Tritium is ^{163}Ho [218] which presents the advantage of a smaller $Q = 2.8$ KeV. It decays via electron capture to ^{163}Dy. Currently, there are three experiments exploring this decay to probe the neutrino mass: ECHo [219], HOLMES [220], and NuMECS [221]. These experiments are complementary to tritium-based searches from a technical point of view. Also, the decay of ^{163}Ho determines the effective electron neutrino mass as opposed to antineutrino in Tritium.

For the other flavours the present limits compiled in the listing section of the PDG read

$$m^{\rm eff}_{\nu_\mu} < 190\ \text{keV (90\% CL)} \quad \text{from} \quad \pi^- \to \mu^- + \bar{\nu}_\mu\,, \tag{14.92}$$

$$m^{\rm eff}_{\nu_\tau} < 18.2\ \text{MeV (95\% CL)} \quad \text{from} \quad \tau^- \to n\pi + \nu_\tau\,. \tag{14.93}$$

In the presence of mixing and for neutrinos with small mass differences, the distortion of the beta spectrum is given by the sum of the individual spectra generated incoherently by each neutrino massive state weighted with the relevant mixing matrix element squared [222]:

$$\frac{dN}{dE} = R(E)\sum_i |U_{ei}|^2 \sqrt{(E_0-E)^2 - m_i^2}\,\Theta(E_0 - E - m_i)\,. \tag{14.94}$$

The step function $\Theta(E_0 - E - m_i)$ arises because a neutrino with a given mass m_i can only be produced if the available energy is larger than its mass. Equation (14.94) shows the two main effects of the neutrino masses and mixings on the electron energy spectrum: First, kinks appear at the electron energies $E_e^{(i)} = E \sim E_0 - m_i$ with sizes that are determined by $|U_{ei}|^2$. Second, the endpoint shifts to $E_{\rm ep} = E_0 - m_0$, where m_0 is the lightest neutrino mass. Corrections are induced once the energy resolution of the experiment is considered. [223, 224]

In the 3-ν mixing scenario, the distortion of the spectrum can still be effectively described by a single parameter – which we will still denote as m_{ν_e} – if for all neutrino states $E_0 - E = Q - T \gg m_i$. In this case, one can expand Eq.(14.94) as:

$$\frac{dN}{dE} \simeq R(E)\sum_i |U_{ei}|^2 \sqrt{(E_0-E)^2 - (m^{\rm eff}_{\nu_e})^2}\,, \tag{14.95}$$

with

$$(m^{\rm eff}_{\nu_e})^2 = \frac{\sum_i m_i^2 |U_{ei}|^2}{\sum_i |U_{ei}|^2} = \sum_i m_i^2 |U_{ei}|^2\,, \tag{14.96}$$

where unitarity is assumed in the second equality. In this approximation, the distortion of the endpoint of the spectrum is described by a single parameter, and with the present results from KATRIN, it is bounded to be

$$\begin{aligned} 1.1\ \text{eV} \geq m^{\rm eff}_{\nu_e} &= \sqrt{\sum_i m_i^2 |U_{ei}|^2} \\ &= \begin{cases} \sqrt{m_0^2 + \Delta m^2_{21}(1 - c^2_{13}c^2_{12}) + \Delta m^2_{32} s^2_{13}} & \text{in NO}\,, \\ \sqrt{m_0^2 + \Delta m^2_{21} c^2_{13} c^2_{12} - \Delta m^2_{32} c^2_{13}} & \text{in IO}\,, \end{cases} \end{aligned} \tag{14.97}$$

where $m_0 = m_1\,(m_3)$ is the lightest neutrino mass in the NO (IO) spectrum. Correspondingly the bounds in Eqs.(14.92) and (14.93) apply to the combinations $\sum_i m_i^2 |U_{\alpha i}|^2$ for $\alpha = \mu$ and τ respectively. So with the values known of the mixing matrix elements, the strongest constraint on the absolute value of the neutrino mass comes from Tritium beta decay.

From Eq.(14.97) we see that, given the present knowledge of the neutrino mass differences and their mixing from oscillation experiments, it is possible to translate the experimental information of m_{ν_e} on a corresponding range for the lightest neutrino mass and

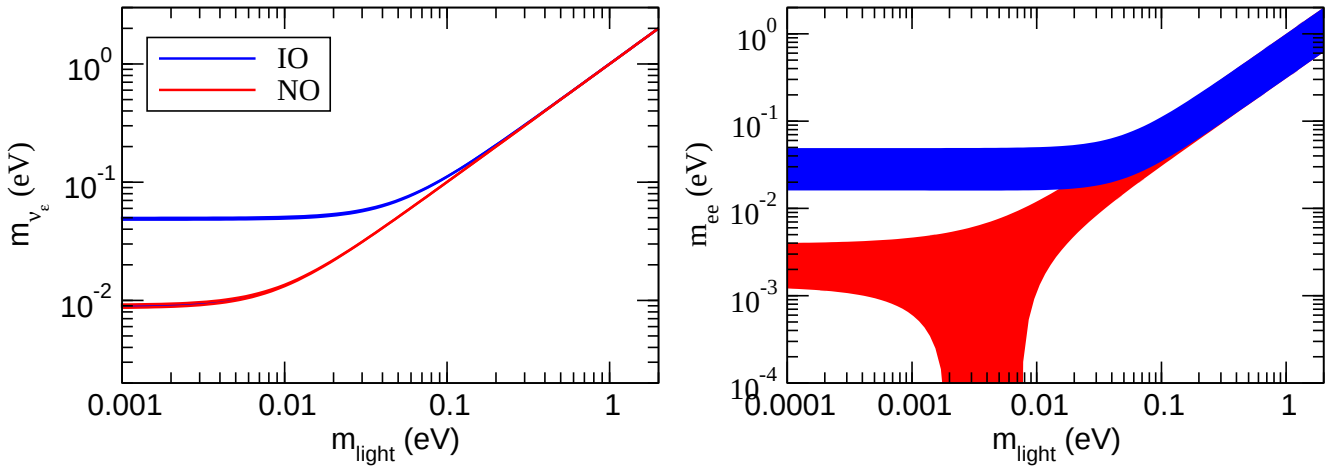

Figure 14.11: Allowed 95% CL ranges (1 dof) for the neutrino mass observable determined in ^{3}H beta decay (left panel) and in $0\nu\beta\beta$ (right panel) in the framework of 3ν mixing as a function of the lightest neutrino mass. The ranges are obtained by projecting the results of the global analysis of oscillation data (w/o SK-atm) in Ref. [180, 181]. The region for each ordering is defined with respect to its local minimum.

that such relation depends on the ordering of the states. We plot in Fig.14.11 the recasting of the allowed regions of the analysis in Ref. [180, 181] in terms of the allowed range m_{ν_e} as a function of $m_{\rm light} \equiv m_0$. In particular, one finds that the results of oscillation experiments imply a lower bound on $m_{\nu_e} > 0.048$ (0.0085) eV for IO (NO) at 95% CL.

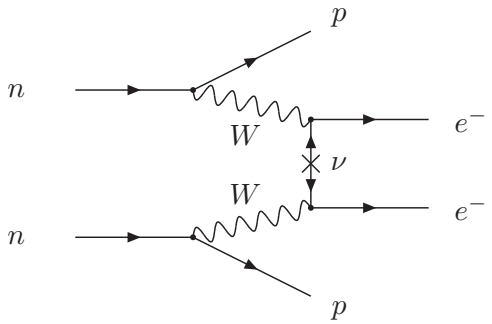

Figure 14.12: Feynman diagram for neutrinoless double-beta decay.

14.9.2 *Dirac vs. Majorana: Neutrinoless Double-beta Decay*

The most sensitive probe to whether neutrinos are Dirac or Majorana states is the neutrinoless double beta decay ($0\nu\beta\beta$):

$$(A, Z) \to (A, Z+2) + e^- + e^- . \tag{14.98}$$

In the presence of neutrino masses and mixing, the process in Eq.(14.98) can be generated at lower order in perturbation theory by the term represented in Fig.14.12. The corresponding amplitude is proportional to the product of the two leptonic currents

$$\begin{aligned} M_{\alpha\beta} &\propto \left[\bar{e}\gamma_\alpha(1-\gamma_5)\nu_e\right]\left[\bar{e}\gamma_\beta(1-\gamma_5)\nu_e\right] \\ &\propto \sum_i (U_{ei})^2 \left[\bar{e}\gamma_\alpha(1-\gamma_5)\nu_i\right]\left[\bar{e}\gamma_\beta(1-\gamma_5)\nu_i\right] . \end{aligned} \tag{14.99}$$

The neutrino propagator in Fig.14.12 can only arise from the contraction $\langle 0\,|\,\nu_i(x)\nu_i(y)^T\,|\,0\rangle$. However, if the neutrino is a Dirac particle ν_i field annihilates a neutrino state and creates an antineutrino state, and neutrino and antineutrino states are different, so the contraction $\langle 0\,|\,\nu_i(x)\nu_i(y)^T\,|\,0\rangle = 0$ and $M_{\alpha\beta} = 0$. On the other hand, if ν_i is a Majorana particle, neutrino and antineutrino are described by the same field and $\langle 0\,|\,\nu_i(x)\nu_i(y)^T\,|\,0\rangle \neq 0$.

The conclusion is that in order to induce the $0\nu\beta\beta$ decay, neutrinos must be Majorana particles. This is consistent with the fact that the process (14.98) violates the total lepton number by two units. Conversely, if $0\nu\beta\beta$ decay is observed, massive neutrinos cannot be Dirac states [225].

It is important to stress that neutrinoless double-beta decay could be dominantly induced by other new physics effects beyond that of Majorana neutrino masses. Consequently, the connection between the observation or limitation of the neutrinoless double beta decay and the neutrino mass can only be made under some assumption about the source of total lepton number violation in the model.

The observable determined by the experiments is the half-life of the decay. Under the assumption that the Majorana neutrino mass is the only source of lepton number violation at low energies, the decay half-life is given by:

$$(T^{0\nu}_{1/2})^{-1} = G^{0\nu} \left|M^{0\nu}\right|^2 \left(\frac{m_{ee}}{m_e}\right)^2 , \tag{14.100}$$

where $G^{0\nu}$ is the phase space integral taking into account the final atomic state, $|M^{0\nu}|$ is the nuclear matrix element of the transition, and m_{ee} is the *effective Majorana mass of* ν_e,

$$\begin{aligned} m_{ee} &= \left|\sum_i m_i U_{ei}^2\right| \\ &= \begin{cases} \left|m_0 c_{12}^2 c_{13}^2 + \sqrt{\Delta m_{21}^2 + m_0^2}\, s_{12}^2 c_{13}^2 e^{2i(\eta_2-\eta_1)} + \sqrt{\Delta m_{32}^2 + \Delta m_{21}^2 + m_0^2}\, s_{13}^2 e^{-2i(\delta_{\rm CP}+\eta_1)}\right| & \text{in NO}\,, \\ \left|m_0 s_{13}^2 + \sqrt{m_0^2 - \Delta m_{32}^2}\, s_{12}^2 c_{13}^2 e^{2i(\eta_2+\delta_{\rm CP})} + \sqrt{m_0^2 - \Delta m_{32}^2 - \Delta m_{21}^2}\, c_{12}^2 c_{13}^2 e^{2i(\eta_1+\delta_{\rm CP})}\right| & \text{in IO}\,, \end{cases} \end{aligned} \tag{14.101}$$

which, in addition to the masses and mixing parameters that affect the tritium beta decay spectrum, also depends on the leptonic CP-violating phases. We plot in Fig.14.11 the recasting of the allowed regions of the analysis in Ref. [180, 181] in terms of the allowed range m_{ee} as a function of $m_{\rm light} \equiv m_0$ for the two orderings. As a consequence of the dependence on the unknown Majorana phases, the allowed range of m_{ee} for a given value of $m_{\rm light}$ and ordering is substantially broader than that of m_{ν_e}. Nevertheless, the results of oscillation experiments imply a lower bound on the effective Majorana mass for the IO, which at 95%CL reads $m_{ee} > 0.016$ eV.

From Eq.(14.100) we see that nuclear structure details enter relation between the decay rate (or lifetime) and the effective Majorana mass. As a consequence, uncertainties in the nuclear structure calculations result in a spread of m_{ee} values for a given $T^{0\nu}_{1/2}$ by a factor of 2–3 [226].

We present in Sec.14.9.3 a brief description of the experimental searches for neutrinoless double-beta decay. At the time of writing of this review, the strongest bound on $0\nu\beta\beta$ decay lifetimes came for Xenon and Germanium from the KamLAND-Zen [227] and GERDA [228] experiments, respectively. They have set a bound on the corresponding half-lives of $T^{0\nu}_{1/2} > 2.3 \times 10^{26}$ yr, and $T^{0\nu}_{1/2} > 1.8 \times 10^{26}$ yr, at 90% CL. Using a variety of nuclear matrix element calculations, the corresponding upper bounds on the effective Majorana mass are

$$m_{ee} < 36 - 156 \text{ meV} \quad (14.102)$$

$$m_{ee} < 79 - 180 \text{ meV} . \quad (14.103)$$

14.9.3 *Experimental Search for Neutrinoless Double-beta Decay*

There are 35 candidate nuclei for double-beta decay. Currently, experiments using ^{136}Xe and ^{76}Ge have reported the most sensitive results of $0\nu\beta\beta$ search. Because of the uncertainties related to the nuclear matrix element, the complementarity of technologies, different backgrounds, and the investigation of the mechanism behind the $0\nu\beta\beta$ in case of a positive signal, it is important to pursue the searches with as many isotopes as possible.

The signature of $0\nu\beta\beta$ is that the sum of the energy of two electrons is equal to the Q-value of the nuclear transition. The energy from electrons is measured with either ionization, scintillation, or through phonons. In some experiments, a combination of two techniques is used to enhance the sensitivity. In the case of background-free measurement, the sensitivity to the half-life is proportional to the product of the detection efficiency of the signal ε, the source mass M, and the measurement time t. If background exists, it is proportional to $\varepsilon\sqrt{\frac{Mt}{b\Delta E}}$, where b is the background rate, and ΔE is the energy resolution.

Among the experiments using ionization detection, ultra-high-purity germanium detector provides the best sensitivity thanks to high energy resolution and low background. GERDA achieved a background level of $(5.2^{+1.6}_{-1.3}) \times 10^{-4}$ counts/(keV·kg·year) [228], which enabled a background-free search. The final result from GERDA for the half-life limit for $0\nu\beta\beta$ decay of ^{76}Ge is $T_{1/2} > 1.8 \times 10^{26}$ years at 90% CL. The Majorana Demonstrator achieved energy resolution of 2.5 keV FWHM (full width at half maximum) at the Q-value (2.039 MeV) [229] and set a half-life limit of $T_{1/2} > 8.3 \times 10^{25}$ years at 90% CL. GERDA and Majorana collaborations have united and formed, together with new groups, the LEGEND collaboration. LEGEND has adopted a phased approach toward the deployment of a tonne of enriched Ge detectors [230]. The first phase of LEGEND based on approximately 200 kg of enriched Ge, using the GERDA infrastructure at LNGS, has started and first data are being taken. The second phase of LEGEND has been approved as a one ton experiment in a new cryostat reaching a discovery sensitivity of half-lifes beyond 10^{28} years. In China, CDEX-300ν using 225 kg of enriched Ge detector is under preparation [231] in the existing CEDX-DM infrastructure at the China Jinping Underground Laboratory.

Liquid scintillator detectors have a simple structure and can utilize existing large detectors with low background environments. By adding an inner balloon to contain xenon-loaded liquid scintillator to the KamLAND detector, KamLAND-Zen uses 745 kg of xenon with 90.9% enrichment in ^{136}Xe. KamLAND-Zen reported the half-life limit of 2.3×10^{26} years at 90% CL [227]. The SNO detector has also been upgraded to be filled with a liquid scintillator in the SNO+ experiment [232]. The SNO+ detector will be loaded with 0.5% natural tellurium, corresponding to approximately 1.3 t of ^{130}Te, to search for $0\nu\beta\beta$.

With a time projection chamber, one can utilize both ionization and scintillation. EXO-200 used a liquid xenon time projection chamber with enriched Xe and reported a half-life limit of $T_{1/2} > 3.5 \times 10^{25}$ years at 90% CL [233] for ^{136}Xe. Based on the technology validated by EXO-200, nEXO plans to use about 5,000 kg of enriched xenon [234]. NEXT has been developing a high-pressure xenon gas time projection chamber with electroluminescent amplification and optical readouts. An energy resolution of 1% FWHM at the Q-value of ^{136}Xe $0\nu\beta\beta$ is demonstrated with NEXT-White detector [235].

CUORE uses a cryogenic bolometer to measure the energy in a calorimetric way. The detector composed of 988 TeO_2 bolometers for a total mass of 742 kg, corresponding to 206 kg of ^{130}Te, was operated at 10 mK. CUORE set a half-life limit of $T_{1/2} > 2.2 \times 10^{25}$ years at 90% CL for ^{130}Te [236]. For further reduction of background towards future search based on the CUORE technology, CUPID proposes to simultaneously measure the calorimetric signal and the scintillation light with a tonne-scale bolometric detector. Using the prototype the technology is demonstrated, and $0\nu\beta\beta$ is also searched for with ^{82}Se [237] and ^{100}Mo [238].

AMoRE also uses the simultaneous detection of heat and scintillation. Six ^{100}Mo-enriched and ^{48}Ca-depleted $CaMoO_4$ crystals with a total mass of 1.9 kg (AMoRE-Pilot) were operated in Yangyang underground laboratory located in South Korea, searching for $0\nu\beta\beta$ of ^{100}Mo [239]. Currently, AMoRE-I experiment [240] is under operation in Yemilab.

A tracker-calorimeter technique is employed in NEMO. Source isotopes are hosted in thin foils surrounded by a tracking detector, which in turn is surrounded by a calorimeter. Full topological event reconstruction with this configuration enables background rejection and gives additional information after discovery. The NEMO-3 experiment used 7 isotopes, with the largest mass comprised of ^{100}Mo (7 kg) [241].

15. Quark Model

Revised August 2023 by C. Amsler (Stefan Meyer Inst.), V. Crede (Florida State U.) and T. DeGrand (Colorado U., Boulder).

15.1 Introduction

Quantum chromodynamics (QCD) is the theory of strong interactions. QCD is a quantum field theory with an $SU(N_c)$ local "color" gauge symmetry with $N_c = 3$ colors and a collection of N_f "flavors" of colored fermions, the quarks. It involves a set of $N_c^2 - 1 = 8$ non-Abelian gauge fields, the gluons. QCD is believed to confine, that is, its physical states are color singlets with internal quark and gluon degrees of freedom. This review is concerned with the description of the properties (masses and matrix elements for couplings to electromagnetism and the weak intractions) of the low lying bound states of QCD. The shorthand expression for describing this physics is called the "quark model".

The spectrum of strongly interacting particles consists of a tower of many states, which can be either bosons (labelled as "mesons") or fermions (labelled as "baryons"). The spectrum of baryons and mesons exhibits a high degree of regularity. The organizational principle which best categorizes this regularity is encoded in the quark model. All descriptions of strongly interacting states use the language of the quark model. At the same time, the language is not precise. The quark model exists on many levels: at the simplest level, it is an almost dynamics-free picture of strongly interacting particles as bound states of quarks and antiquarks. As one refines the description, the quark model can become a framework with more detailed descriptions of dynamics. At its most fundamental level, it might be a description of QCD. In effective field theories of QCD at low energies the hadron spectrum is not simply given by a series of states but is the manifestation of a complex dynamics involving various types of states [1].

At its heart, the quark model assumes that mesons are bound states of quark - antiquark pairs, and baryons are bound states of three quarks. These are the minimal particle content states which can be color singlets in an $SU(3)$ gauge theory. This approach cannot be justified directly from QCD; however, there is indirect evidence that this description has some fundamental validity from the version of QCD where the number of colors N_c is taken to infinity [2–4]. In that limit, mesons are dominantly narrow (width proportional to $1/N_c$) bound states of a quark - antiquark pair, and baryons have a mass which scales as N_c.

A better justification is that this approach works. Indeed, the quark model is much older than QCD as a theory of the strong interactions (1973-1974, see the article on "50 Years of Quantum Chromodynamics" [5]). In fact, the principal issue (circa 1963-64) in strong interaction physics before QCD was to justify the success of the quark model in systemizing the properties of mesons and baryons in terms of some more fundamental dynamics (QCD).

Today one knows that this is not the whole story. There are experimentally observed states which either cannot be described, or have an uncomfortable description, as minimal quark number states. Some of them have "exotic" (non-$\bar{q}q$ or qqq) quantum numbers. Given the successes of the quark model, these are classified as "tetraquarks" ($qq\bar{q}\bar{q}$), "pentaquarks" ($qqqq\bar{q}$) or "glueballs", bound states of gluons, the gluonic degrees of freedom in QCD. Of course, such labels are imprecise: bound states with the same overall quantum numbers can mix, regardless of their internal degrees of freedom.

This review has several parts. We start by describing the properties of strongly interacting particles in terms of the properties of states made of a minimal number of quark fields which can be coupled into a color singlet – two fields (a quark and an antiquark) for the mesons, and three quarks, for a baryon. Quarks come in six flavors. We describe the properties of mesons as $\bar{q}q$ systems and baryons as qqq systems. Along the way we discuss hadronic bound states which do not fit into this classification.

Finally, at the end of this review, we present results from lattice simulations of QCD, a direct approach to the solution of QCD from its Lagrangian, without reference to models. Lattice simulations interact with the quark model in (at least) two ways: first, the interpolating fields which are used in lattice simulations are usually directly based on quark model constructions. That is the simplest way to create states with the desired quantum numbers, which can then be processed by the lattice calculation. The second way that lattice calculations interact with the quark model comes when one wishes to put the lattice calculations into some context: without the quark model, there are simply the results from the lattice calculations, and the results from experiment, and no way to understand why they are similar or different. The quark model is the framework which is almost universally used to generate that context. Of course, that statement is equally valid when one tries to systemize actual experimental data: the context is always some variation of a quark model.

15.2 Quantum numbers of the quarks

As gluons carry no intrinsic quantum numbers beyond color charge, and because color is believed to be permanently confined, the quantum numbers of strongly interacting particles are given by the quantum numbers of their constituent quarks and antiquarks.

Quarks are strongly interacting fermions with spin 1/2 and, by convention, positive parity. Antiquarks have negative parity. Quarks have the additive baryon number 1/3, antiquarks –1/3. Table 15.1 gives the other additive quantum numbers (flavors) for the three generations of quarks. They are related to the charge Q (in units of the elementary charge e) through the generalized Gell-Mann-Nishijima formula

$$\mathsf{Q} = \mathsf{I}_z + \frac{\mathcal{B} + \mathsf{S} + \mathsf{C} + \mathsf{B} + \mathsf{T}}{2} , \qquad (15.1)$$

where $\mathcal{B}$ is the baryon number. The convention is that the quark *flavor* (I_z, S, C, B, or T) has the same sign as its *charge* Q. Antiquarks have the opposite flavor signs. With this convention, any flavor carried by a charged meson has the same sign as its charge, *e.g.*, the strangeness of the K^+ ($c\bar{s}$) is +1, the bottomness of the B^+ ($u\bar{b}$) is +1, and the charm and strangeness of the D_s^- ($s\bar{c}$) are each −1.

Table 15.1: Quark quantum numbers.

	d	u	s	c	b	t
Q – electric charge	$-\frac{1}{3}$	$+\frac{2}{3}$	$-\frac{1}{3}$	$+\frac{2}{3}$	$-\frac{1}{3}$	$+\frac{2}{3}$
I – isospin	$\frac{1}{2}$	$\frac{1}{2}$	0	0	0	0
I_z – isospin z-component	$-\frac{1}{2}$	$+\frac{1}{2}$	0	0	0	0
S – strangeness	0	0	−1	0	0	0
C – charm	0	0	0	+1	0	0
B – bottomness	0	0	0	0	−1	0
T – topness	0	0	0	0	0	+1

The hypercharge is defined as

$$\mathsf{Y} = \mathcal{B} + \mathsf{S} - \frac{\mathsf{C} - \mathsf{B} + \mathsf{T}}{3} . \qquad (15.2)$$

Thus Y is equal to $\frac{1}{3}$ for the u and d quarks, $-\frac{2}{3}$ for the s quark, and 0 for all other quarks. More details and derivations on

the quark structure of mesons and baryons can be found *e.g.* in Ref. [6].

The naming scheme for hadrons has been updated by the Particle Data Group in 2023, to include the heavy "exotic" states discovered recently, the tetraquark ($qq\bar{q}\bar{q}$) and pentaquark ($qqqq\bar{q}$) candidates (see "Naming Scheme for Hadrons" in this *Review*).

15.3 Mesons

Mesons have baryon number $\mathcal{B} = 0$. In the quark model, they are $q\bar{q}'$ bound states of quarks q and antiquarks $\bar{q}'$ (the flavors of q and q' may be different).

If the orbital angular momentum of the $q\bar{q}'$ state is ℓ, then the parity P is $(-1)^{\ell+1}$. The meson spin J is given by the usual relation $|\ell - s| \leq J \leq |\ell + s|$, where $s = 0$ (antiparallel quark spins) or $s = 1$ (parallel quark spins). The charge conjugation, or C-parity $C = (-1)^{\ell+s}$, is defined only for states made of quarks and their own antiquarks. The C-parity can be generalized to the G-parity $G = (-1)^{I+\ell+s}$ for mesons made of quarks and their own antiquarks (isospin $\mathsf{I}_z = 0$), and for the charged $u\bar{d}$ and $d\bar{u}$ states (isospin $\mathsf{I} = 1$).

The mesons are classified in J^{PC} multiplets. The $\ell = 0$ states are the pseudoscalars (0^{-+}) and the vectors (1^{--}). The orbital excitations $\ell = 1$ are the scalars (0^{++}), the axial vectors (1^{++}) and (1^{+-}) *aka* pseudovectors, and the tensors (2^{++}). Assignments for many of the known mesons are given in Tables 15.2, 15.3 and 15.4. Radial excitations are denoted by the principal quantum number n. The very short lifetime of the t quark ($\rightarrow W^+b$) makes it likely that bound-state hadrons containing t quarks and/or antiquarks do not exist.

States in the natural spin-parity series $P = (-1)^J$ must, according to the above, have $s = 1$ and hence, $CP = +1$. Thus, mesons with natural spin-parity and $CP = -1$ (0^{+-}, 1^{-+}, 2^{+-}, 3^{-+}, *etc.*) are forbidden in the $q\bar{q}'$ model. The $J^{PC} = 0^{--}$ state is forbidden as well. Mesons with such *exotic* quantum numbers may exist, but would lie outside the $q\bar{q}'$ model (see section 15.4 below on exotic mesons).

Following SU(3), the nine possible $q\bar{q}'$ combinations containing the light u, d, and s quarks are grouped into an octet and a singlet of light quark mesons:

$$\mathbf{3} \otimes \overline{\mathbf{3}} = \mathbf{8} \oplus \mathbf{1} \ . \tag{15.3}$$

A fourth quark such as charm c can be included by extending SU(3) to SU(4). However, SU(4) is badly broken owing to the much heavier c quark. Nevertheless, in an SU(4) classification, the sixteen mesons are grouped into a 15-plet and a singlet:

$$\mathbf{4} \otimes \overline{\mathbf{4}} = \mathbf{15} \oplus \mathbf{1} \ . \tag{15.4}$$

The *weight diagrams* for the ground-state pseudoscalar (0^{-+}) and vector (1^{--}) mesons are depicted in Fig. 15.1. The light quark mesons are members of nonets building the middle plane in Fig. 15.1(a) and (b).

Isoscalar states with the same J^{PC} mix, but mixing between the two light quark isoscalar mesons, and the much heavier charmonium and bottomonium states, are generally assumed to be negligible. In the following, we shall use the generic names a for the $\mathsf{I} = 1$, K for the $\mathsf{I} = 1/2$, f and f' for the $\mathsf{I} = 0$ members of the light quark nonets. Thus, the physical isoscalars are mixtures of the SU(3) wave function ψ_8 and ψ_1:

$$f' = \psi_8 \cos\theta - \psi_1 \sin\theta \ , \tag{15.5}$$

$$f = \psi_8 \sin\theta + \psi_1 \cos\theta \ , \tag{15.6}$$

where θ is the nonet mixing angle and

$$\psi_8 = \frac{1}{\sqrt{6}}(u\bar{u} + d\bar{d} - 2s\bar{s}) \ , \tag{15.7}$$

$$\psi_1 = \frac{1}{\sqrt{3}}(u\bar{u} + d\bar{d} + s\bar{s}) \ . \tag{15.8}$$

The mixing relations are often rewritten to exhibit the $u\bar{u} + d\bar{d}$ and $s\bar{s}$ components which decouple for the "ideal" mixing angle

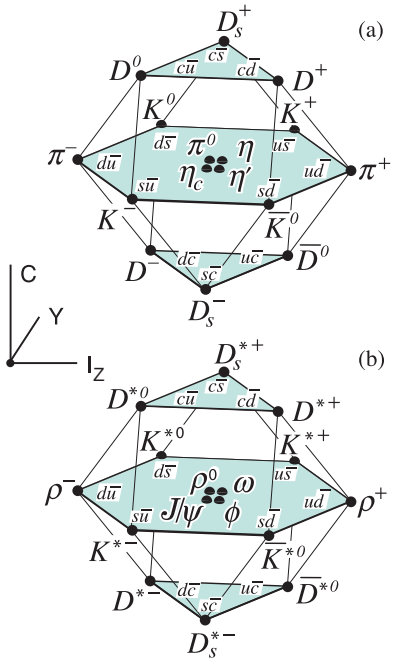

Figure 15.1: SU(4) weight diagram showing the 16-plets for the pseudoscalar (a) and vector mesons (b) made of the u, d, s, and c quarks as a function of isospin I_z, charm C, and hypercharge $\mathsf{Y} = \mathcal{B} + \mathsf{S} - \frac{\mathsf{C}}{3}$. The nonets of light mesons occupy the central planes to which the $c\bar{c}$ states have been added.

θ_i, such that $\tan\theta_i = 1/\sqrt{2}$ (or $\theta_i = 35.3°$). Defining $\alpha = \theta + 54.7°$, one obtains the physical isoscalar state in the flavor basis

$$f' = \frac{1}{\sqrt{2}}(u\bar{u} + d\bar{d})\cos\alpha - s\bar{s} \ \sin\alpha \ , \tag{15.9}$$

and its orthogonal partner f (replace α by α –90°). Thus for ideal mixing ($\alpha_i = 90°$), the f' becomes pure $s\bar{s}$ and the f pure $u\bar{u} + d\bar{d}$. The mixing angle θ can be derived by diagonalizing the mass matrix

$$\begin{pmatrix} m_8 & m_{81} \\ m_{18} & m_1 \end{pmatrix} . \tag{15.10}$$

The mass eigenvalues are $m_{f'}$ and m_f. The mixing angle is given by

$$\tan\theta = \frac{m_8 - m_{f'}}{m_{81}} \ . \tag{15.11}$$

Calculating m_8 and m_{81} from the wave functions Eq. (15.7) and Eq. (15.8), and expressing the quark masses as a function of the $\mathsf{I} = 1/2$ and $\mathsf{I} = 1$ meson masses, one obtains

$$\tan\theta = \frac{4m_K - m_a - 3m_{f'}}{2\sqrt{2}(m_a - m_K)} \ , \tag{15.12}$$

which also determines the sign of θ. Alternatively, one can express the mixing angle as a function of all nonet masses. The octet mass is given by

$$m_8 = m_{f'}\cos^2\theta + m_f \sin^2\theta \tag{15.13}$$

whence

$$\tan^2\theta = \frac{4m_K - m_a - 3m_{f'}}{-4m_K + m_a + 3m_f} \ . \tag{15.14}$$

Eliminating θ from Eq. (15.12) and Eq. (15.14) leads to the sum rule [14]

$$(m_f + m_{f'})(4m_K - m_a) - 3m_f m_{f'} = 8m_K^2 - 8m_K m_a + 3m_a^2. \tag{15.15}$$

This relation is verified for the ground-state vector mesons. We identify the $\phi(1020)$ with the f' and the $\omega(783)$ with the f. Thus

$$\phi(1020) = \psi_8 \cos\theta_V - \psi_1 \sin\theta_V \ , \tag{15.16}$$

$$\omega(782) = \psi_8 \sin\theta_V + \psi_1 \cos\theta_V \ , \tag{15.17}$$

Table 15.2: Suggested $q\bar{q}$ quark-model assignments for the lightest mesons made of u, d and s quarks. Mesons in boldface are included in the Summary Table. The wave functions f and f' are given in the text (Eq. (15.9)) and the singlet-octet mixing angles in Table 15.5 below for the well established nonets. The classification of the 0^{++} mesons is controversial: (i) the scalars $a_0(980)$, $K_0^*(700)$, $f_0(980)$ and $f_0(500)$, omitted from the table, are often considered to be four-quark states, but are also proposed for the ground state scalar nonet (see the chapter "Scalar Mesons below 1 GeV" in this *Review*); (ii) there are three isoscalar 0^{++} mesons, $f_0(1370)$, $f_0(1500)$ and $f_0(1710)$, both $f_0(1500)$ and $f_0(1710)$ being proposed as glueballs. The three states are expected to mix. The isoscalar assignments in the 2^1S_0 (0^{-+}) nonet are also tentative. Details and alternative schemes can be found in "Spectroscopy of Light Meson Resonances" in this *Review*.
[a] The $1^{+\pm}$ and $2^{-\pm}$ isospin $\frac{1}{2}$ states mix. In particular, the K_{1A} and K_{1B} are nearly equal mixtures of the $K_1(1270)$ and $K_1(1400)$ [7]. The $2^{-\pm}$ mixed partner of the $K_2(1770)$ is the established $K_2(1820)$.
[b] The physical vector mesons are mixtures of 1^3D_1 and 2^3S_1 (for a discussion see [8]).
[c] This state has also been proposed as a tetraquark state [9].
[d] The $\eta(1475)$ and $\eta(1405)$ (not shown) may be manifestations of a single state [10].
[e] This state has also been proposed as the ground state tensor glueball [11, 12].

with the vector mixing angle $\theta_V = 36.5°$ from Eq. (15.14), very close to ideal mixing. Thus $\phi(1020)$ is nearly pure $s\bar{s}$. For ideal mixing, Eq. (15.12) and Eq. (15.14) lead to the relations

$$m_K = \frac{m_f + m_{f'}}{2} \ , \quad m_a = m_f \ , \tag{15.18}$$

which are satisfied for the vector mesons.

The situation for the pseudoscalar and scalar mesons is not so clear cut, either theoretically or experimentally. For the pseudoscalars, the mixing angle is small. This can be understood qualitatively via gluon-line counting of the mixing process. The size of the mixing process between the nonstrange and strange mass bases scales as α_s^2, not α_s^3, because of two rather than three gluon exchange as it does for the vector mesons. It may also be that the lightest isoscalar pseudoscalars mix more strongly with excited states or with states of substantial non-$\bar{q}q$ content, as will be discussed below.

In fact a large mixing from hadronic loops is expected for scalar mesons, no matter what model is assumed for $q\bar{q}$ pair production [15]. A variety of analysis methods lead to similar results: First, for these states, Eq. (15.15) is satisfied only approximately. Then Eq. (15.12) and Eq. (15.14) lead to somewhat different values for the mixing angle. Identifying the η with the f' one gets

$$\eta = \psi_8 \cos\theta_P - \psi_1 \sin\theta_P \ , \tag{15.19}$$

$$\eta' = \psi_8 \sin\theta_P + \psi_1 \cos\theta_P \ . \tag{15.20}$$

Following chiral perturbation theory, the meson masses in the mass formulae (Eq. (15.12) and Eq. (15.14)) might be replaced by their squares. Table 15.5 lists the mixing angle $\theta_{\rm lin}$ from Eq. (15.14) (using the neutral members of the nonets) and the corresponding $\theta_{\rm quad}$ obtained by replacing the meson masses by their squares throughout. The mixing angles in the 1^{--}, 2^{++} and 3^{--} nonets are not far from ideal, while larger $s\bar{s}$-$(u\bar{u}+d\bar{d})$ mixing is predicted from hadronic loops in the 0^{++}, 0^{-+} and $1^{+\pm}$ nonets [15].

The pseudoscalar mixing angle θ_P can also be measured by comparing the partial widths for radiative J/ψ decay into a vector and a pseudoscalar [16], radiative $\phi(1020)$ decay into η and η' [17], radiative decays between pseudoscalar and vector mesons [18], or $\bar{p}p$ annihilation at rest into a pair of vector and pseudoscalar or into two pseudoscalars [19, 20]. One obtains a mixing angle between –10° and –20°. More recently, a lattice QCD simulation, Ref. [21], has successfully reproduced the masses of the η and η', and as a byproduct find a mixing angle $\theta_{lin} = -14.1(2.8)°$. We return to this point in Sec. 15.8.

The nonet mixing angles can be measured in $\gamma\gamma$ collisions, *e.g.*, for the 0^{-+}, 0^{++}, and 2^{++} nonets. In the quark model, the amplitude for the coupling of neutral mesons to two photons is proportional to $\sum_i Q_i^2$, where Q_i is the charge of the i-th quark.

Table 15.5: Singlet-octet mixing angles for the well established nonets from the linear mass formula Eq. (15.14) and its quadratic version in which the masses are squared. The 1^{++} and 1^{+-} nonet mixing angles depend on the mixing angle θ_{K_1} between K_{1A} and K_{1B}. The recommended values are ∼23° and ∼28° for 1^{++} and 1^{+-}, respectively, with θ_{K_1}∼35° [7].

$n^{2s+1}\ell_J$	J^{PC}	$\theta_{\rm quad}$ [°]	$\theta_{\rm lin}$ [°]
1^1S_0	0^{-+}	−11.3	−24.5
1^3S_1	1^{--}	39.2	36.5
1^3P_2	2^{++}	29.6	28.0
1^3D_3	3^{--}	31.8	30.8

The 2γ partial width of an isoscalar meson with mass m is then given in terms of the mixing angle α by

$$\Gamma_{2\gamma} = C(5\cos\alpha - \sqrt{2}\sin\alpha)^2 m^3 \ , \tag{15.21}$$

for f' and f ($\alpha \to \alpha - 90°$). The coupling C may depend on the meson mass. It is often assumed to be a constant in the nonet. For the isovector a, one finds $\Gamma_{2\gamma} = 9\,C\,m^3$. Thus the members of an ideally mixed nonet couple to 2γ with partial widths in the ratios $f : f' : a = 25 : 2 : 9$. For tensor mesons, one finds from the ratios of the measured 2γ partial widths for the $f_2(1270)$ and $f_2'(1525)$ mesons a mixing angle α_T of (81± 1)°, or $\theta_T = (27 \pm 1)°$, in accord with the linear mass formula. For the pseudoscalars, one finds from the ratios of partial widths $\Gamma(\eta' \to 2\gamma)/\Gamma(\eta \to 2\gamma)$ a mixing angle $\theta_P = (-18 \pm 2)°$, while the ratio $\Gamma(\eta' \to 2\gamma)/\Gamma(\pi^0 \to 2\gamma)$ leads to ∼ –24 °. SU(3) breaking effects for pseudoscalars are discussed in [22].

The partial width Γ for the decay of a scalar or a tensor meson into a pair of pseudoscalar mesons is model-dependent. Following Ref. [23],

$$\Gamma = C \times \gamma^2 \times |F(q)|^2 \times q \ , \tag{15.22}$$

where C is a nonet constant, q the momentum of the decay products, $F(q)$ a form factor, and γ^2 the SU(3) coupling. Details and explicit expressions for γ^2 and $F(q)$ are given in "Spectroscopy of Light Meson Resonances". The decay of a $q\bar{q}$ meson into a pair of mesons involves the creation of a $q\bar{q}$ pair, and SU(3) symmetry assumes that the matrix elements for the creation of $s\bar{s}$, $u\bar{u}$, and $d\bar{d}$ pairs are equal. An excellent fit to the tensor meson decay widths is obtained assuming SU(3) symmetry and a pseudoscalar mixing angle $\theta_P \simeq -17$ ° [23].

The analysis of resonances is complicated by the presence of thresholds such as $K\bar{K}$ in $a_0(980) \to \eta\pi$ or $f_0(980) \to \pi\pi$, which

affect the resonance masses and widths. A particularly nasty kinematic effect is the triangle singularity in which one of the primary decay daughters in turn decays and is emitted backwards, catching up and scattering with the second primary product. This mechanism generates fake peaks in the final state and has been proposed as alternative explanation for several meson (and baryon) signals. Prominent examples are the $\eta(1475) \to K^*(\to K\pi)\bar{K}$ and $\eta(1410) \to a_0(980)(\to \eta\pi)\pi$ signals which could be due to one single state [10] (as shown in Table 15.2).

Furthermore, to parametrize resonances, many data analyses resort to Breit-Wigner amplitudes which are not suitable to describe broad interfering mesons with the same quantum numbers, as they violate unitarity. This is in particular the case in the mass range above 1500 MeV where radial and orbital excitations, e.g. of broad scalar and tensor mesons, start to accumulate. A better approach is to determine the T-matrix poles in the complex plane, where resonances are usually located on the second Riemann sheet.

15.4 Exotic mesons

There are two classes of colorless exotic mesons allowed in QCD: multiquark states (section 15.4.1) and mesons with active gluons, bound states of gluons (the glueballs, section 15.4.2) and $q\bar{q}$ states with "valence" gluons (the hybrids, section 15.4.3). The first class contains the simplest system consisting of two quarks and two antiquarks (tetraquarks). Compact tetraquarks (also called "diquonium" in the older literature) are made of diquarks and antidiquarks. Hadroquarkonia consist of a pair of heavy quark and antiquark in a compact core surrounded by a light-quark cloud. In hadronic "molecules" the building blocks are color-neutral hadrons bound by meson exchanges.

15.4.1 *Tetraquarks*

The existence of a light nonet composed of four quarks (tetraquarks) with masses below 1 GeV was suggested a long time ago [24,25]. Coupling two triplets of light quarks u, d, and s, one obtains nine states, of which the six symmetric (uu, dd, ss, $ud+du$, $us+su$, $ds+sd$) form the six dimensional representation $\mathbf{6}$, while the three antisymmetric ($ud-du$, $us-su$, $ds-sd$) form the three dimensional representation $\overline{\mathbf{3}}$ of SU(3):

$$\mathbf{3} \otimes \mathbf{3} = \mathbf{6} \oplus \overline{\mathbf{3}} \ . \tag{15.23}$$

Hence for tetraquarks one gets the reduction

$$\begin{aligned} &\mathbf{3} \otimes \mathbf{3} \otimes \overline{\mathbf{3}} \otimes \overline{\mathbf{3}} \\ &= \mathbf{6} \oplus \overline{\mathbf{3}} \otimes \overline{\mathbf{6}} \otimes \mathbf{3} \\ &= \overline{\mathbf{3}} \otimes \mathbf{3} \oplus \mathbf{6} \otimes \overline{\mathbf{6}} \oplus \mathbf{6} \otimes \mathbf{3} \oplus \overline{\mathbf{3}} \otimes \overline{\mathbf{6}} \\ &= \mathbf{9} \oplus \mathbf{36} \oplus \mathbf{18} \oplus \overline{\mathbf{18}}. \end{aligned} \tag{15.24}$$

Combining with spin and color and requiring antisymmetry for diquarks and antidiquarks, one finds for ground states (zero angular momenta) that the most deeply bound tetraquarks (and hence the lightest ones) form a nonet and are scalar mesons (see also [6]). The masses are estimated to be below 900 MeV. The strange quark determines the mass splittings and one obtains a mass inverted spectrum with a light isosinglet ($f_0(500)$), a medium heavy isodoublet ($K_0^*(700)$) and a heavy isotriplet ($a_0(980)$) + isosinglet ($f_0(980)$). In alternative schemes these states build the lightest $q\bar{q}$ scalar nonet (for details see "Scalar mesons below 1 GeV" in this *"Review"*).

A plethora of new heavy multiquark candidates have been reported in the charmonium spectrum (Fig. 15.2). Details and references can be found in the review "Heavy non-$q\bar{q}$ Mesons", see also Refs. [26–28].

The most prominent one is the $\chi_{c1}(3872)$ (was $X(3872)$), first observed by BELLE in 2003 in B-decays in the final state $J/\psi\,\pi^+\pi^-$ [29] and firmly established by many experiments (Babar, BESIII, CDF, D0, LHCb) in several production modes (e^+e^-, Λ_b decay, $\bar{p}p$, pp). This narrow state (< 1 MeV) decays mainly into $D^0\bar{D}^{0*}$ and is right at the $D^0\bar{D}^{0*}$ threshold. Its composition is believed to be mostly molecular, bound by pion exchange. Its existence was already predicted in 1991 [30]. Many non-$c\bar{c}$ candidates have been reported since then above the open charm threshold, with quantum numbers compatible with $c\bar{c}$, but which are not expected in the pure charmonium spectrum. In addition, one observes isovector (charged) mesons decaying into $c\bar{c}$ states plus a charged pion or kaon. (They are listed in this *Review* under "Other mesons".) For example, the 1^{+-} $T_{c\bar{c}1}(3900)^+$ (was $Z_c(3900)^+$) and $T_{c\bar{c}s1}(4000)^+$ (was $Z_{cs}(4000)^-$) cannot be pure charmonia, but are compatible with $c\bar{c}u\bar{d}$ and $c\bar{c}s\bar{u}$, respectively. They could belong to the same nonet, hence identifying the other multiplet members might shed light on the structure of such states.

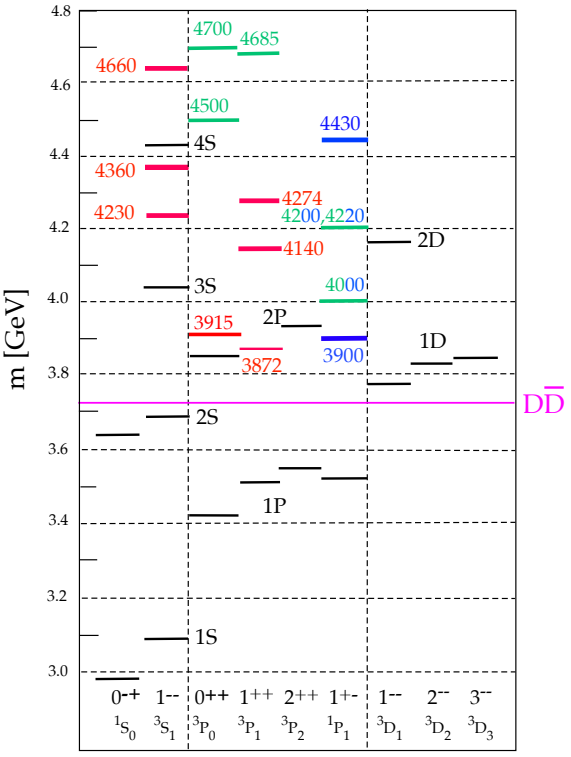

Figure 15.2: Mass spectrum with known $I^G(J^{PC})$ observed in the charmonium region. The $D\bar{D}$ line shows the open charm threshold. The well-known $c\bar{c}$ mesons are shown in black. (The 1^1D_2 η_{c2}, expected around 3800 MeV, has not been seen yet.) The established additional observed states are shown in red, and the states needing confirmation (i.e. omitted from the Summary Tables) are labeled in green. The blue color denotes exotic isovectors.

Even more remarkable are the observations by LHCb of a doubly charmed state $T_{cc}(3875)^+$ ($cc\bar{u}\bar{d}$)) [31] at the $D_0D_0^*$ threshold and of a $T_{cc\bar{c}\bar{c}}(6900)$ [32] decaying into a pair of $J/\psi(1S)$. Similar states begin to emerge also in the bottomonium spectrum, such as the 1^{+-} $T_{b\bar{b}1}(10610)^+$ (was $Z_b(10610)^+$) and $T_{b\bar{b}1}(10650)^+$ (was $Z_b(10650)^+$), both $b\bar{b}u\bar{d}$. Many of these states may be hadronic modules made of charge conjugated pairs of mesons such as $D^{(*)}, D_s^{(*)}$ or their excitations, and their B and B^* counterparts. They could also be mimicked by kinematical effects such as triangle singularities.

15.4.2 *Glueballs*

QCD predicts the existence of extra isoscalar mesons which cannot be addressed by the quark model. In the pure gauge theory they contain only gluons. The ground state glueball is predicted by lattice gauge theories to be 0^{++}, the first excited state 2^{++}. Errors on the mass predictions are large. From Ref. [33] one obtains 1750 (50) (80) MeV for the mass of the lightest 0^{++} glueball from quenched QCD. As an example for the glueball mass spectrum, we show in Fig. 15.3 a calculation from [34]. A mass of 1710 MeV is predicted for the ground state, also with an error of about 100 MeV. Earlier work by other groups produced masses at 1650 MeV [35] and 1550 MeV [36] (see also [37]. The first excited

state has a mass of about 2.4 GeV, and the lightest glueball with exotic quantum numbers (2^{+-}) has a mass of about 4 GeV.

These calculations are made in the so-called "quenched approximation" which neglects $q\bar{q}$ loops. However, both glue and $q\bar{q}$ states couple to singlet scalar mesons. Therefore glueballs will mix with nearby $q\bar{q}$ states of the same quantum numbers. The first results from lattice calculations, which include these effects, indicate that the mass shifts are small. We return to a discussion of this point in Sec. 15.8, see also Fig. 15.15.

The existence of three singlet scalar mesons around 1.5 GeV suggests additional degrees of freedom such as glue, since only two mesons are predicted in this mass range (as indicated in Table 15.2). The $f_0(1500)$ [23, 38] or, alternatively, the $f_0(1710)$ [35], have been proposed as candidates for the scalar glueball, both states having considerable mixing also with the $f_0(1370)$. Following Ref. [39] the glue is distributed among the 0^{++} isoscalars $q\bar{q}$ mesons around 2 GeV. Other mixing schemes, in particular with the $f_0(500)$ and the $f_0(980)$, have also been proposed [40]. According to a holographic model of low-energy QCD scalar glueballs decay strongly into kaons and η mesons, in good agreement with data on the $f_0(1710)$ [41]. Details can be found in the review "Spectroscopy of Light Meson Resonances" and in Ref. [42]. See also the review "Scalar Mesons below 1 GeV" in this *Review*.

15.4.3 *Hybrids*

Mesons made of $q\bar{q}$ pairs bound by excited gluons ($q\bar{q}g$) are also predicted. Early model estimates placed them in the 1.9 GeV mass region, according to gluon flux tube models [43]. In the bag model there are four nonets, among them an exotic 1^{-+}, around or above 1.4 GeV [44, 45].

Lattice QCD calculations show that the lightest hybrid is an exotic 1^{-+} state, at a mass around 2 GeV [46–48]. Fig. 15.13 will show an example of the spectroscopy from one group's [48] simulation.

There are so far two candidates for exotic states with quantum numbers 1^{-+}, the $\pi_1(1400)$ and $\pi_1(1600)$, which could be hybrids or four-quark states. However, a recent combined re-analysis of π_1 production in diffractive $\pi^- p$ interaction and low energy $\bar{p}p$ annihilation leads to a single pole at ∼1560 MeV with a width of ∼390 MeV, although a two-pole scenario cannot be excluded [49]. Recently BESIII has reported evidence for the existence of a 1^{-+} $\eta_1(1855) \to \eta\eta'$ [50] which could be one of the isoscalar partners of the $\pi_1(1600)$ in the 1^{-+} hybrid nonet [51]. (For details and references, see the review "Spectroscopy of Light Meson Resonances" in this *Review*.)

15.5 Baryons: qqq states

Baryons are fermions with baryon number $\mathcal{B} = 1$, *i.e.*, in the most general case, they are composed of three quarks plus any number of quark - antiquark pairs. Until recently, all established baryons were consistent with 3-quark (qqq) configurations, which we mainly discuss in this section. However, in 2015 the LHCb collaboration published first evidence for charmed 'pentaquark' states of minimal quark content $c\bar{c}uud$ at invariant masses close to 4.4 GeV [52]. More refined LHCb experiments have revealed evidence for four such states called $P_{c\bar{c}}(4312)^+$, $P_{c\bar{c}}(4380)^+$, $P_{c\bar{c}}(4440)^+$, and $P_{c\bar{c}}(4457)^+$ [53]. These states are located close to the thresholds of the production of ordinary baryon-meson pairs like $\Sigma_c^+ \bar{D}^0$ and $\Sigma_c^+ \bar{D}^{\star 0}$ and are consistent with the predictions in terms of molecular-like states [54, 55]. A nice overview on the discussion of pentaquark and tetraquark states is given in Ref. [56]. See also the article on "Pentaquarks" in this *Review*.

The color part of the baryon wave function is an SU(3) singlet, a completely antisymmetric state of the three colors. Since the quarks are fermions, the wave function must be antisymmetric under interchange of any two equal-mass quarks (up and down quarks in the limit of isospin symmetry). Thus, it can be written as

$$|\, qqq \,\rangle_A = |\, \text{color} \,\rangle_A \times |\, \text{space, spin, flavor} \,\rangle_S, \qquad (15.25)$$

where the subscripts S and A indicate symmetry or antisymmetry under interchange of any two equal-mass quarks. Note the contrast with the state function for the three nucleons in ^{3}H or ^{3}He:

$$|\, NNN \,\rangle_A = |\, \text{space, spin, isospin} \,\rangle_A. \qquad (15.26)$$

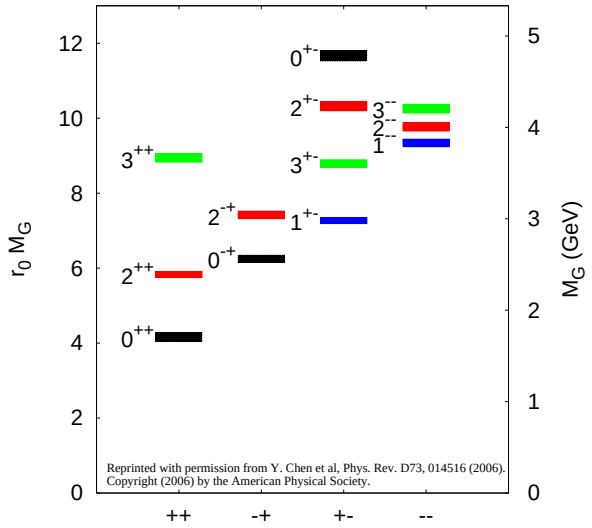

Figure 15.3: Predicted glueball spectrum from the lattice in quenched approximation (from [34]).

This difference has major implications for the internal structure, magnetic moments, *etc.* (For a nice discussion, see [57].)

15.5.1 *Light baryons*

The "ordinary" light-flavor baryons are made up of u, d, and s quarks. The three flavors imply an approximate SU(3) flavor symmetry, which requires that baryons made of these quarks belong to the multiplets on the right side of

$$\mathbf{3} \otimes \mathbf{3} \otimes \mathbf{3} = \mathbf{10}_S \oplus \mathbf{8}_M \oplus \mathbf{8}_M \oplus \mathbf{1}_A \qquad (15.27)$$

(see the section on "SU(n) Multiplets and Young Diagrams" in this *Review*). Here the subscripts indicate symmetric, mixed-symmetry, or antisymmetric states under interchange of any two quarks. The **1** is a $|uds\rangle$ singlet state (Λ_1), and the octet contains a similar state (Λ_8). If these have the same spin and parity, they can mix. The mechanism is the same as for the mesons (see above). In the ground state multiplet, the SU(3) flavor singlet Λ_1 is forbidden by Fermi statistics. The section on "SU(3) Isoscalar Factors and Representation Matrices," shows how relative decay rates in, say, $\mathbf{10} \to \mathbf{8} \otimes \mathbf{8}$ decays may be calculated.

For the light-flavor baryons (no c or b quark), flavor and spin may be combined in an approximate flavor-spin SU(6), in which the six basic states are $d\uparrow$, $d\downarrow$, $\cdots$, $s\downarrow$ ($\uparrow, \downarrow$ = spin up, down). Then the baryons belong to the multiplets on the right side of

$$\mathbf{6} \otimes \mathbf{6} \otimes \mathbf{6} = \mathbf{56}_S \oplus \mathbf{70}_M \oplus \mathbf{70}_M \oplus \mathbf{20}_A. \qquad (15.28)$$

These SU(6) multiplets decompose into flavor SU(3) multiplets as follows:

$$\mathbf{56} = {}^4\mathbf{10} \oplus {}^2\mathbf{8} \qquad (15.29a)$$

$$\mathbf{70} = {}^2\mathbf{10} \oplus {}^4\mathbf{8} \oplus {}^2\mathbf{8} \oplus {}^2\mathbf{1} \qquad (15.29b)$$

$$\mathbf{20} = {}^2\mathbf{8} \oplus {}^4\mathbf{1}, \qquad (15.29c)$$

where the superscript $(2S+1)$ gives the net spin S of the quarks for each particle in the SU(3) multiplet. The $J^P = 1/2^+$ octet containing the nucleon and the $J^P = 3/2^+$ decuplet containing the $\Delta(1232)$ together make up the "ground-state" 56-plet, in which the orbital angular momenta between the quark pairs are zero (so that the spatial part of the state function is trivially symmetric). The **70** and **20** require some excitation of the spatial part of the wave function in order to make the overall wave function symmetric. States with nonzero orbital angular momenta are classified in SU(6)⊗O(3) supermultiplets.

It is useful to classify the baryons into bands that have the same number N of quanta of excitation. Each band consists of a number of supermultiplets, specified by (D, L_N^P), where D is the dimensionality of the SU(6) representation, L is the total quark

orbital angular momentum, and P is the total parity. Supermultiplets contained in bands up to N = 12 are given in [58]. The N = 0 band (with positive parity), which contains the nucleon and $\Delta(1232)$, consists only of the $(56,0^+_0)$ supermultiplet. The N = 1 band (with negative parity) consists only of the $(70,1^-_1)$ multiplet and contains the negative-parity baryons with masses below about 1.9 GeV. The N = 2 band (with positive parity) contains five supermultiplets: $(56,0^+_2)$, $(70,0^+_2)$, $(56,2^+_2)$, $(70,2^+_2)$, and $(20,1^+_2)$, where the $(56,0^+_0)$ represents the multiplet that contains the first radial excitations having the same quantum numbers as the ground state.

The wave functions of the non-strange baryons in the harmonic oscillator basis are often labeled by $|X^{2S+1}L_\pi J^P\rangle$, where S, L, J, P are as above, $X = N$ or Δ, and $\pi = S, M$ or A denotes the symmetry of the spatial wave function. The possible model states for the bands with N=0,1,2 are given in Table 15.7. The assignment of experimentally observed states is only complete and well established up to the N=1 band. Some more tentative assignments for higher multiplets are suggested in [59].

In Table 15.6, quark-model assignments are given for many of the established baryons whose SU(6)⊗O(3) compositions are relatively unmixed. Apart from the mixing of the Λ singlet and octet states, one must, however, keep in mind that states with same J^P but different L, S combinations can also mix. In the quark model with one-gluon exchange motivated interactions, the size of the mixing is determined by the relative strength of the tensor term with respect to the contact term (see below). The mixing is more important for the decay patterns of the states than for their positions. An example are the lowest lying $(70, 1^-_1)$ states with J^P=1/2$^-$ and 3/2$^-$. The physical states are

$$|\,N(1535)1/2^-\rangle = \cos(\Theta_S)|N^2P_M1/2^-\rangle - \sin(\Theta_S)|N^4P_M1/2^-\rangle \quad (15.30)$$

$$|\,N(1520)3/2^-\rangle = \cos(\Theta_D)|N^2P_M3/2^-\rangle - \sin(\Theta)_D|N^4P_M3/2^-\rangle \quad (15.31)$$

and the orthogonal combinations for $N(1650)1/2^-$ and $N(1700)3/2^-$. The mixing is large for the J^P=1/2$^-$ states ($\Theta_S \approx$ -32^o), but small for the J^P=3/2$^-$ states ($\Theta_D \approx +6^o$) [61–63].

All baryons of the ground state multiplets are known. Many of their properties, in particular their masses, are in good agreement with even the most basic versions of the quark model, including harmonic (or linear) confinement and a spin-spin interaction, which is responsible for the octet - decuplet mass shifts. A consistent description of the ground-state electroweak properties, however, requires refined relativistic constituent quark models.

The situation for the excited states is much less clear. The assignment of some experimentally observed states with strange quarks to model configurations is only tentative and in many cases candidates are completely missing. Melde, Plessas and Sengl [60] have calculated baryon properties in relativistic constituent quark models, using one-gluon exchange and Goldstone-boson exchange for the modeling of the hyperfine interactions (see Sec. 15.7 on Dynamics). Both types of models give qualitatively comparable results and in geneeral, underestimate experimentally observed decay widths. Nevertheless, in particular on the basis of the observed decay patterns, the authors have assigned some additional states with strangeness to the SU(3) multiplets and suggest reassignments for a few others. Among the new assignments are states with weak experimental evidence (two or three star ratings) and partly without firm spin/parity assignments, so that further experimental efforts are necessary before final conclusions can be drawn. We have added their suggestions in Table 15.6.

In the non-strange sector there are two main problems which are illustrated in Fig. 15.4, where the experimentally observed excitation spectrum of the nucleon (N and Δ resonances) is compared to the results of a typical quark model calculation [64]. The lowest states from the N=2 band, the $N(1440)1/2^+$, and the $\Delta(1600)3/2^+$, appear lower than the negative parity states from the N=1 band (see Table 15.7) and much lower than predicted by most models. Also negative parity Δ states from the N=3 band ($\Delta(1900)1/2^-$, $\Delta(1940)3/2^-$, and $\Delta(1930)5/2-$) are too low in energy. The low lying states show a clustering in groups of levels around 1700 MeV and 1900 MeV for $N^\star$ states and around 1900 MeV for Δ states which is not reflected in models.

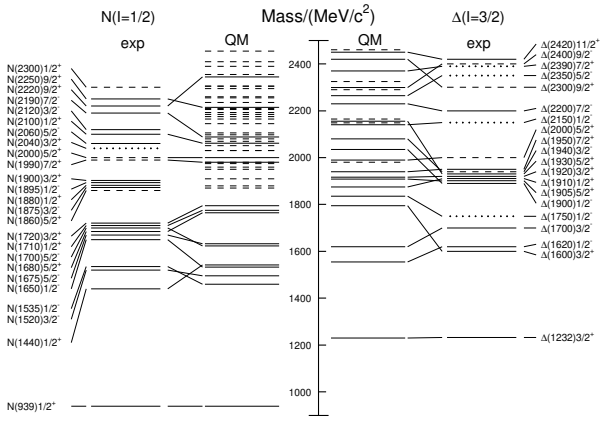

Figure 15.4: Excitation spectrum of the nucleon. Compared are the positions of the excited states identified in experiment, to those predicted by a relativized quark model calculation. Left hand side: isospin $I = 1/2$ N-states, right hand side: isospin $I = 3/2$ Δ-states. Experimental: (columns labeled 'exp'), three- and four-star states are indicated by full lines (two-star dashed lines, one-star dotted lines). At the very left and right of the figure, the spectroscopic notation of these states is given. Quark model [64, 65]: (columns labeled 'QM'), all states for the N=1,2 bands, low-lying states for the N=3,4,5 bands. Full lines: at least tentative assignment to observed states, dashed lines: so far no observed counterparts. Many of the assignments between predicted and observed states are highly tentative.

Furthermore, many more states are predicted than observed. This has been known for a long time as the 'missing resonance' problem [61]. Up to an excitation energy of 2.4 GeV, about 45 N states are predicted, but only 20 are established (four- or three-star; see Note on N and Δ Resonances for the rating of the status of resonances) and 5 are tentative (two- or one-star). However, there is some recent progress. For the N=2 band, candidates have been identified for almost all predicted states with the exception of the $(20,1^+_2)$. The total number of states has perhaps not significantly changed but the number of states with four- or three-star rating has increased from 14 to 20 compared to the 2018 PDG particle listings. Most of this progress is due to the programs concentrating on the study of meson photoproduction reactions, while the most recent partial wave analysis of elastic pion scattering and charge exchange data by Arndt and collaborators [66] found no evidence for almost half of the states listed in this review (and included in Fig. 15.4). Such analyses are of course biased against resonances which couple only weakly to the $N\pi$ channel. Quark model predictions for the couplings to other hadronic channels and to photons are given in Ref. [64]. The large experimental effort ongoing at several electron accelerators to study the baryon resonance spectrum with real and virtual photon-induced meson production reactions includes the search for as-yet-unobserved states, as well as detailed studies of the properties of the low lying states (decay patterns, electromagnetic couplings, magnetic moments, *etc.*) (see Ref. [67] for reviews). There are two major new aspects of this program. The investigation of single and double polarization observables allows, via the study of interference terms, access to small partial waves that do not leave a footprint in unpolarized cross sections. An example for the impact of such data is given by a comparison of results from different multipole analyses of pion photoproduction [68]. It shows clearly that with the inclusion of polarization observables the reaction model results start to converge. This will in the near future much improve the database for excited baryons in the light quark sector.

The other aspect is the study of final states with meson pairs, in particular $\pi\pi$ and $\pi\eta$ pairs, which has made much progress during the last few years. This is important for higher lying states, which in the quark model may have both possible oscillations ex-

Table 15.6: Quark-model assignments for some of the known baryons in terms of a flavor-spin SU(6) basis. Only the dominant representation is listed. Assignments for several states, especially for the $\Lambda(1810)$, $\Lambda(2350)$, $\Xi(1620)$, $\Xi(1690)$, $\Xi(1820)$, and $\Xi(2030)$, are merely educated guesses.

cited. Such states can be expected to decay in sequential processes de-exciting the two oscillations step-by-step so that they couple strongly to multiple-meson final states but not to single-meson production. Detailed analyses of such data are for example given in [69,70] and had already significant impact on partial wave analyses.

The excitation spectrum of hyperons containing s-quarks is even less well explored. Many experimental results date back to before 2000, although parameters listed in the review are in many cases updated by more modern partial wave analyses. A recent review on the quark model interpretation of the Λ and Σ states is given in Ref. [71], a new Ω^- state was reported in the ΞK mass spectrum with high significance from the Belle experiment [72] with a likely $J^P = \frac{3}{2}^-$ classification, and Belle also reported on the most significant evidence so far for the $\Xi(1620)$ in the $\Xi\pi$ mass spectrum [73], which has now warranted an upgrade of this resonance from one star to two stars. In the near future, significant progress on hyperon spectroscopy is expected from JLab using the K_L facility in conjunction with the GlueX exprimental setup, J-PARC using the K^- beam at the extended hadron facility, and the PANDA experiment at FAIR [74,75].

In quark models, the number of excited states is determined by the effective degrees of freedom, while their ordering and decay properties are related to the residual quark - quark interaction. An overview of quark models for baryons is given in [76], recent discussions of baryon spectroscopy are given in [59, 77]. The effective degrees of freedom in the standard nonrelativistic quark model are three equivalent valence quarks with one-gluon exchange-motivated, flavor-independent color-magnetic interactions. The QCD aspect of gluon-gluon interactions is emphasized by the hypercentral quark model [78,79], which includes in a natural way three-body forces between the quarks. A different class of models uses interactions which give rise to a quark - diquark clustering of the baryons: for a review see [80]. If there is a tightly bound diquark, only two degrees of freedom are available at low energies, and thus *fewer* states are predicted. Furthermore, selection rules in the decay pattern may arise from the quantum numbers of the diquark. However, we note that the recent identification of new N^* resonances seriously questions the older static diquark-quark model since these resonances are likely members of the $(70,2^+_2)$, which requires both oscillators in the baryon to be excited. *More* states are predicted by collective models of the baryon like the algebraic approach in [81]. In this approach, the quantum numbers of the valence quarks are distributed over a Y-shaped string-like configuration, and additional states arise *e.g.*, from vibrations of the strings. *More* states are also predicted in the framework of flux-tube models, see [82], which are motivated by lattice QCD. In addition to the quark degrees of freedom, flux-tubes responsible for the confinement of the quarks are considered as degrees of freedom. These models include hybrid baryons containing explicit excitations of the gluon fields. However, since all half integral J^P quantum numbers are possible for ordinary baryons, such 'exotics' will be very hard to identify, and probably always mix with ordinary states. So far, the experimentally observed number of states is still far lower even than predicted by the quark–diquark models.

The influence of chiral symmetry on the excitation spectrum of the nucleon has been debated from a somewhat different perspective. Chiral symmetry, the fundamental symmetry of QCD, is strongly broken for the low lying states, resulting in large mass differences of parity partners like the J^P=1/2$^+$ $N(938)1/2^+$ ground state and the J^P=1/2$^-$ $N(1535)1/2^-$ excitation. However, at higher excitation energies there is some evidence for parity doublets and even some very tentative suggestions for full chiral multiplets of $N^\star$ and Δ resonances. An effective restoration of chiral symmetry at high excitation energies due to a decoupling from the quark condensate of the vacuum has been discussed (see [83] for recent reviews) as a possible cause. In this case, the mass generating mechanisms for low and high lying states would be essentially different. As a further consequence, the parity doublets would decouple from pions, so that experimental bias would be worse. However, parity doublets might also arise from the spin-orbital dynamics of the 3-quark system. Presently, the status of the data does not allow final conclusions.

The most recent developments on the theory side include progress in understanding the physics of baryons [84,85] by using the Dyson-Schwinger equations of QCD and Bethe-Salpeter equations [86, 87]. In this approach, baryons are relativistic bound states of three quarks, and the treatment of their interactions arising from QCD is non-perturbative, incorporating aspects of confinement and dynamical symmetry breaking. Two paths to solving the three-body problem are taken: direct solution of the three-body Faddeev equation, and decomposition of baryons into quark-diquark systems, with all quark pairs able to constitute the diquark. Therefore, these descriptions are different from the older static diquark-quark pictures of the baryon. Moreover, the first unquenched lattice-QCD calculations for the excitation spectrum have been presented and are discussed in Sec. 15.8. The results are basically consistent with the level counting of SU(6)⊗O(3) in the standard non-relativistic quark model and show no indication for quark-diquark structures or parity doubling. Consequently, there is as yet no indication from lattice that the mis-match between the excitation spectrum predicted by the standard quark model and experimental observations is due to inappropriate degrees of freedom in the quark model.

15.5.2 *Charmed and bottom baryons*

The naming scheme for baryons with c or b quarks follows that of the light baryons: the Λ is an isosinglet and the Σ an isotriplet with one heavy (s, c or b) quark. The Ξ is an isodoublet which contains two heavy quarks, and the Ω an isosinglet with three heavy quarks. The number of c or b quarks is indicated by the subscripts c or b. Hyperons are baryons with at least one s quark.

For charmed baryons the addition of the c quark to the light quarks extends the flavor symmetry to SU(4)$_f$. Due to the large mass of the c quark, this symmetry is much more strongly broken than the SU(3)$_f$ of the three light quarks. Nevertheless, the SU(4)$_f$ representation is still useful for bookkeeping purposes. With the additive charm quantum number C the baryons are classified in a 3-dimensional representation with the three coordinates (I$_z$, Y , C). Figure 15.5 shows the SU(4)$_f$ weight diagrams.

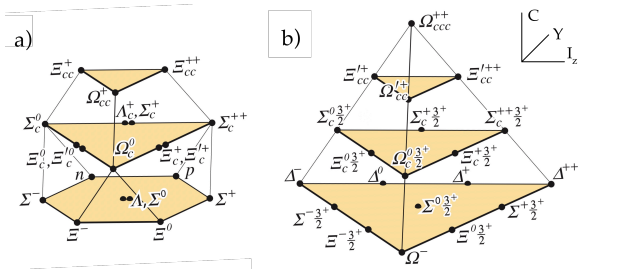

Figure 15.5: SU(4)$_f$ multiplets of ground state baryons made of u, d, s, and c quarks. (a) The spin $\frac{1}{2}$ 20-plet extends the charmless SU(3)$_f$ octet to C = 1,2; (b) the spin $\frac{3}{2}$ 20-plet extends the SU(3)$_f$ decuplet to C = 1, 2, 3.

With four quarks the 64 possible configurations decompose into

$$\mathbf{4} \otimes \mathbf{4} \otimes \mathbf{4} = \bar{\mathbf{4}}_A \oplus \mathbf{20}_S \oplus \mathbf{20}_{MS} \oplus \mathbf{20}_{MA}, \qquad (15.32)$$

(for a review on $SU(N)$ symmetries see *e.g.* [88]). The subscripts S and A refer to the symmetry and antisymmetry properties of the flavor wave functions. The flavor symmetric 20_S multiplet, associated with spin-$\frac{3}{2}$ baryons, contains the charmless SU(3)$_f$ decuplet at the bottom level. The 20_{MS} and 20_{MA} multiplets correspond to the mixed symmetric and mixed antisymmetric flavour wave functions of the spin-$\frac{1}{2}$ baryons, with the charmless octet baryons at the bottom level. There are two dsc and two usc spin-$\frac{1}{2}$ states, labeled Ξ_c^0, $\Xi_c'^{\,0}$ and Ξ_c^+, $\Xi_c'^{+}$. This is because one of the qq pairs can have spin 1 (symmetric) or spin 0 (antisymmetric), giving both the total spin $j = \frac{1}{2}$ with the third quark (see also Fig. 15.6 below).

For C = 1 baryons the flavor decomposition of the diquark,

made of u, d, or s quarks, is

$$\mathbf{3} \otimes \mathbf{3} = \bar{\mathbf{3}}_A \oplus \mathbf{6}_S. \quad (15.33)$$

For ground-state baryons, the overall antisymmetry of baryon wave function (including color) requires the light diquark to be symmetric under the exchange of spin and flavor, hence both symmetric or both antisymmetric, that is spin 1 for the $\mathbf{6}_S$ and spin 0 for the $\bar{\mathbf{3}}_A$. The $\bar{\mathbf{3}}$ then combines with the c quark to form the $J^P = 1/2^+$ states, while the $\mathbf{6}$ combines to form $J^P = 1/2^+$ or $J^P = 3/2^+$. The weight diagrams of the $\bar{\mathbf{3}}$ and $\mathbf{6}$ ground-state representations are shown in Fig. 15.6. Within each multiplet the $\mathsf{C} = 1$ baryons obey isospin and SU(3)$_f$ mass relations at the expected orders.

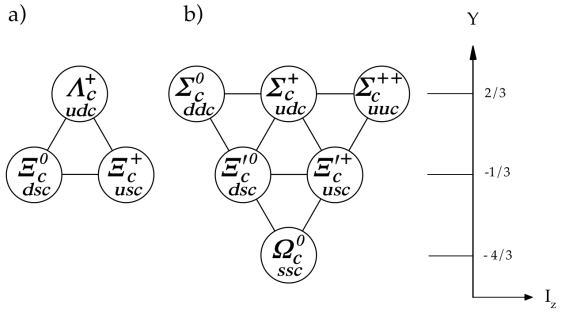

Figure 15.6: The SU(3)$_f$ $\bar{\mathbf{3}}$ (a) and $\mathbf{6}$ (b) ground state $J^P = 1/2^+$ representations. The structure of the $\mathbf{6}$ ground state with $J^P = 3/2^+$ is identical to the one in (b).

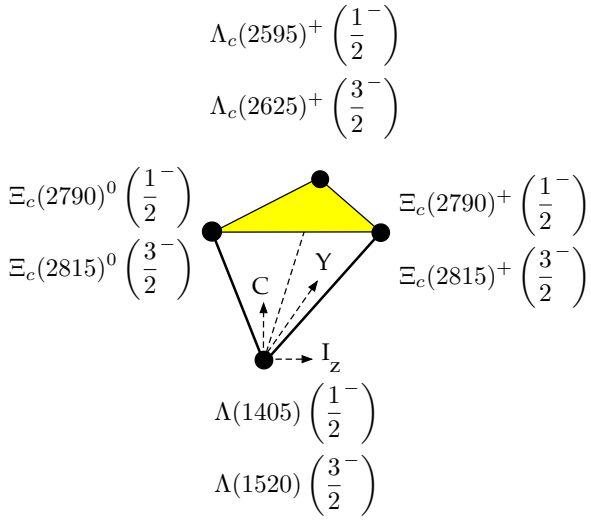

Figure 15.7: Weight diagram of the $\bar{\mathbf{4}}$ SU(4)$_f$ multiplet with the experimentally observed negative parity baryons.

The antisymmetric quadruplet in (15.32) does not exist in the ground state but is realized for the first orbital excitations ($L = 1$). Figure 15.7 shows the weight diagram with the experimentally observed states. In the quark model the quadruplet consists of four baryons with spins coupling to $\frac{1}{2}$, leading to four $L = 1$ excitations with $J^P = \frac{1}{2}^-$ and four excitations with $\frac{3}{2}^-$. The charmed ones are the partners of the $\Lambda(1405)$ and $\Lambda(1520)$ singlets of SU(3)$_f$.

For a detailed review on charmed baryons see Ref. [77]. Quark model predictions for baryons with two heavy quarks are given in Ref. [89] and lattice results for doubly and triply charmed states are discussed in Sec. 15.8 of this *Review*.

The $\mathsf{C} = 1$ ground state baryons have all been observed. Due to their relatively narrow widths the states are much easier to isolate than the light quark baryon resonances which require intricate partial wave analyses. The production cross sections are small, but the recent measurements at the e^+e^- B-factories, at the $p\bar{p}$ Tevatron collider, and at LHCb have boosted the field. The LHCb collaboration has published evidence for five new narrow Ω_c^0 states (css) [90] in proton-proton collisions. Four of these states have been confirmed by the Belle experiment in e^+e^- collisions [91]. Their quantum numbers are still unknown, but they could correspond to the $L = 1$ ssc orbital excitations. Constituent quark models, lattice QCD, quark-diquark models, molecular models, and pentaquark states, have been discussed to describe their structure (see e.g. [92] for references). In the meantime, also four Ω_b^- states of the bss type have been reported from LHCb [92]. They lie in a narrow range between 6316 - 6350 MeV, but since their intrinsic widths are on the order of just a few MeV, they are well separated in the invariant mass spectra. Spectroscopy and theory in this field is rapidly evolving.

LHCb has also reported a doubly charmed Ξ_{cc}^{++} (ccu) baryon [93]. The quantum numbers of this state are undetermined, but its significance is already rated three stars in the current compilation. Doubly charmed baryons have a very different structure from light baryons, more resembling heavy 'double-star' systems with attached light 'planets', which opens a new window for QCD properties. The first candidate for a doubly charmed baryon Ξ_{cc}^+ (ccd) had been reported earlier by the SELEX experiment [94, 95]. A significance of 6.3σ was claimed for the $\Lambda_c^+ K^- \pi^+$ decay and 4.8σ for pD^+K- but searches by other experiments have not confimed it so far (see *e.g.* [96] and Refs. therein) and it is not included in the particle listings. The SELEX and LHCb masses lie in the predicted 3500 – 3700 MeV mass range (see *e.g.* [89]). The LHCb Ξ_{cc}^{++} state lies about 100 MeV above the SELEX one, with a mass splitting far too large for ucc and dcc isospin partners. However, it has also been discussed that due to the different production mechanisms this is not necessarily a contradiction [97].

Figure 15.8 shows the spectrum of the established singly-charmed baryons (3* and 4* baryons in the *Listings* with known quantum numbers). The parity of the Λ_c^+ is that of the c quark, defined as positive. Spin and parity have not been determined experimentally for most of the states. They follow the ordering and expectation from the quark model. Candidates for $L = 2$ orbital excitations of the Λ_c (with $J^P = \frac{3}{2}^+$ and $J^P = \frac{5}{2}^+$) have already been observed, as well as a $\frac{3}{2}^-$ state at 2940 MeV, possibly a radial $L = 1$ excitation [98].

The same SU(4)$_f$ multiplets can be constructed for the bottom baryons by replacing the c quark by a b quark.The established 3* and 4* bottom baryons are shown in Fig.15.8. The quadruplet $\bar{\mathbf{4}}$ contains the two negative parity candidates $\Lambda_b(5912)^0$ and $\Lambda_b(5920)^0$. It appears that the confining potential is only weakly flavour dependent. For example, the mass difference between the Ξ_b and the Λ_b is roughly the same as that between the Ξ_c and the Λ_c, the mass splitting between the spin-$\frac{1}{2}$ Ω_b and the Λ_b close to that between the spin-$\frac{1}{2}$ Ω_c and the Λ_c. The spin-$\frac{3}{2}$ states are also heavier than the spin-$\frac{1}{2}$ ones, in agreement with expectations from the spin-spin force.

The bottom hadrons can also be embedded in a larger SU(5)$_f$ group that accounts for all baryons constructed from the five quark flavors. (The existence of baryons with t-quarks is very unlikely due to the short lifetime of the t-quark.) One predicts the decomposition

$$\mathbf{5} \otimes \mathbf{5} \otimes \mathbf{5} = \overline{\mathbf{10}}_A \oplus \mathbf{40}_{MS} \oplus \mathbf{40}_{MA} \oplus \mathbf{35}_S. \quad (15.34)$$

The decuplet is not realized in the ground state. The two 40-plets have mixed symmetry ($\frac{1}{2}$-spin) and the 35-plet is symmetric ($\frac{3}{2}$-spin). The SU(4)$_f$ spin-$\frac{1}{2}$ multiplet in Fig. 15.5 contains 20 spin-$\frac{1}{2}$ baryons and the corresponding one with bottom quarks an additional 12, giving together 32 states. Similarly there are 30 spin-$\frac{3}{2}$ baryons. One expects 75 ground state mesons from (15.34). Thus 13 ground state baryons containing both b and c quarks are predicted (8 spin-$\frac{1}{2}$ [$4\Omega + 4\Xi$] and 5 spin-$\frac{3}{2}$ [$3\Omega + 2\Xi$]).

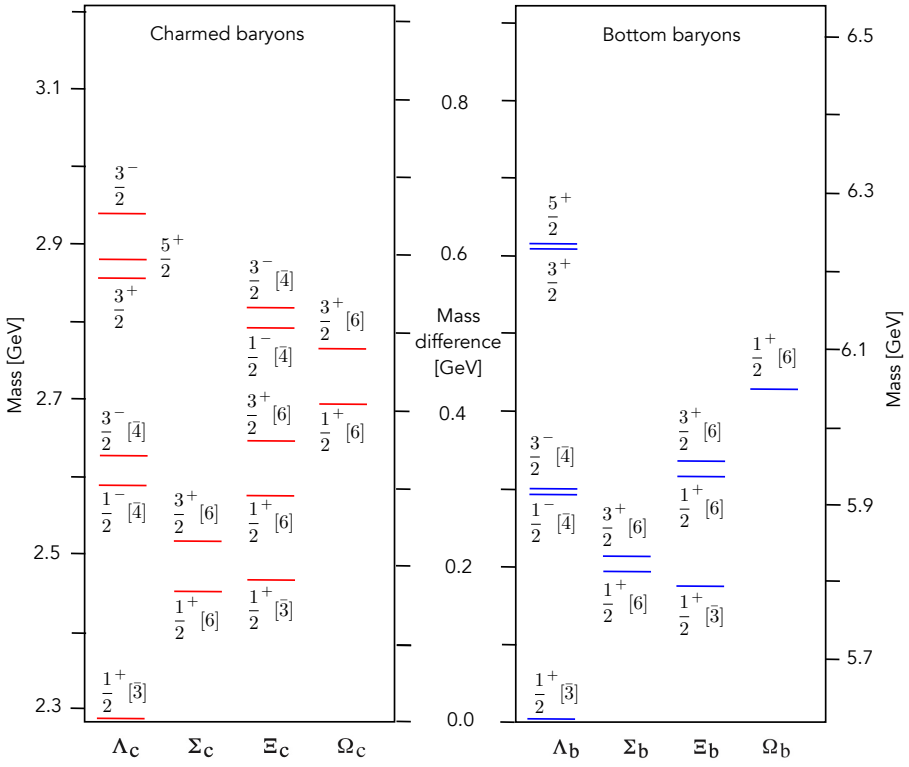

Figure 15.8: Mass spectrum of the established C = 1 charmed and B = –1 bottom baryons with known J^P. The flavor symmetry assignments are given by the square brackets. According to their isospins the $\Sigma_{c,b}$ ($\Xi_{c,b}$) consist of three (two) charged or neutral states that are nearly degenerate.

15.6 Magnetic moments

The magnetic dipole moment of a baryon is conventionally written relative to the mass of the proton:

$$\vec{\mu}_B = g_B \mu_N \vec{s}, \tag{15.35}$$

where $\mu_N = \frac{e}{2m_p}$ is the nuclear magneton (in natural units). The factor g_B is calculated by adding the quark contributions. The magnetic moment of quark i with charge $q_i e$ and constituent mass m_i is $\vec{\mu}_i = 2(\frac{q_i e}{2m_i})\vec{s}$, hence for the three light quarks,

$$\mu_u = \frac{2}{3}\kappa_u, \quad \mu_d = -\frac{1}{3}\kappa_d, \quad \mu_s = -\frac{1}{3}\kappa_s, \quad \text{with } \kappa_i \equiv \frac{e}{2m_i}. \tag{15.36}$$

The magnetic dipole moment of a baryon is then given by

$$\mu_B = \sum_{i=1}^{3} \langle B\uparrow | \mu_i \sigma_{zi} | B\uparrow \rangle, \tag{15.37}$$

where $|B\uparrow\rangle$ is the wavefunction for a baryon with its spin along the z-axis and $\vec{\sigma} = 2\vec{s}$. Since the quark model uses the totally *symmetric* SU(6) wavefunctions (flavor SU(3) × spin SU(2)) one predicts for the proton:

$$\mu_p = \frac{4}{3}\mu_u - \frac{1}{3}\mu_d = \frac{e}{2m} \equiv \kappa, \tag{15.38}$$

assuming $m_u = m_d \simeq m$ (for the detailed derivation see *e.g.* Ref. [6]). For the magnetic moment of the neutron one obtains likewise

$$\mu_n = -\frac{1}{3}\mu_u + \frac{4}{3}\mu_d = -\frac{2}{3}\kappa, \tag{15.39}$$

which leads to the simple prediction $\mu_n/\mu_p = g_n/g_p = -2/3$.

The famous Frisch and Stern experiment showed for the first time that $g_p \sim 5.58 \gg 2$. Modern measurements are performed in electromagnetic traps, see the *Listings*, while the magnetic moment of the neutron is measured with cold neutron beams. The experimental ratio $\mu_n/\mu_p = -0.6849793 \pm 0.0000003$ is impressively close to the prediction of the quark model (note that using instead the *antisymmetric* SU(6) wavefunctions would lead to $\mu_n/\mu_p = -2$ [6]). The constituent mass m of the u and d quarks can be estimated from (15.35) and (15.38): $m = 2m_p/g_p \simeq 336$ MeV.

The magnetic moment of the Λ is easy to predict: the diquark ud has isospin $i = 0$, since $i(s) = 0$ and $i(\Lambda) = 0$, and is therefore an antisymmetric isospin state. The symmetric quark model then also requires the spin to be zero, so that the magnetic moment of the Λ stems from the s quark:

$$\mu_\Lambda = \mu_s = -\frac{1}{3}\kappa_s. \tag{15.40}$$

The magnetic moment of the Λ is obtained from the Larmor precession frequency of the polarization vector in an homogeneous magnetic field. The latter is derived from the asymmetric distribution of the proton in $\Lambda \to \pi^- p$ [99]. The experimental result is listed in Table 15.8. The constituent mass of the s quark is then $m_s = -m\mu_p/3\mu_\Lambda = 509$ MeV.

The magnetic moments of the other baryons (Table 15.8) are predicted from κ and κ_s. The magnetic moment of the Σ^+ is obtained by replacing the d quark in (15.38) by an s quark, and for the Σ^- the u quark by an s quark in (15.39). The magnetic moment of the Σ^+ has also been measured with the precession method using its decay into $p\pi^0$ [100], that of the $\Sigma^- \to n\pi^-$ likewise, or by detecting the X-rays emitted by cascading Σ^- captured in the Coulomb shells of target atoms. The magnetic moment is then derived from the fine-structure splitting [101].

The magnetic moments of the Ξ^0, Ξ^- and Ω^- are obtained from the polarization of the Λ in the decays $\Lambda\pi^0$, $\Lambda\pi^-$ and ΛK^-, respectively. The SU(6) wavefunction of the (spin 3/2) Ω^- is the product of the two symmetric SU(3) flavor and SU(2) spin

Table 15.8: Quark model predictions and measured magnetic dipole moments of the ground state baryons in units of μ_N; $\kappa \equiv \frac{e}{2m} = 2.793$ μ_N and $\kappa_s \equiv \frac{e}{2m_s} = -3\mu_\Lambda = 1.84\ \mu_N$. $^\dagger \Sigma^0 \to \Lambda$ transition magnetic moment.

Baryon	Quark model			Experimental value		
p	κ		input	2.793		
n	$-\frac{2}{3}\kappa$	=	–1.86	–1.913		
Λ	$-\frac{1}{3}\kappa_s$		input	–0.6138	±	0.0047
Σ^+	$\frac{8}{9}\kappa + \frac{1}{9}\kappa_s$	=	2.68	2.458	±	0.010
Σ^0	$\frac{2}{9}\kappa + \frac{1}{9}\kappa_s$	=	0.82			
$\Sigma^{0\dagger}$	$-\frac{1}{\sqrt{3}}\kappa$	=	–1.61	–1.61	±	0.08
Σ^-	$-\frac{4}{9}\kappa + \frac{1}{9}\kappa_s$	=	–1.04	–1.160	±	0.025
Ξ^0	$-\frac{2}{9}\kappa - \frac{4}{9}\kappa_s$	=	–1.44	–1.250	±	0.014
Ξ^-	$\frac{1}{9}\kappa - \frac{4}{9}\kappa_s$	=	–0.51	–0.6507	±	0.0025
Ω^-	$-\kappa_s$	=	–1.84	–2.024	±	0.056
Δ^{++}	2κ	=	5.58	4.52	±	0.67
Δ^+	κ	=	2.79	2.3	-	4.5

wavefunctions. Summing over the three s quarks one gets

$$\mu_{\Omega^-} = \sum_{i=1}^{3} \langle \Omega^- \uparrow | \mu_i \sigma_{zi} | \Omega^- \uparrow \rangle = 3\mu_s = 3\mu_\Lambda. \qquad (15.41)$$

The magnetic moment of the Ω^- is hard to measure, because the Ω^- is unpolarized at high energies, in contrast to the other hyperons. Polarized Ω^- hyperons have been obtained from polarized Λ and Ξ^0 impinging on a nuclear target [102].

In quark models with full isospin symmetry the magnetic moments of the Δ-resonances are simply related to the magnetic moment of the proton by $\mu_\Delta = Q_\Delta \cdot \mu_N$, ($Q_\Delta$ = charge) i.e. the moment of the Δ^+ should equal the proton moment and the moment of the Δ^{++} should be twice as large (sum of the three u-quarks). Magnetic moments of the decuplet baryons (with the exception of the Ω^-) are very difficult to measure because their lifetimes are so short that spin precession techniques cannot be used. For the Δ one can profit from an electromagnetic spin-reorientation transition inside the large width of the state. This leads to the emission of a magnetic dipole photon in reactions like $\pi^+ p \to \pi^+ p\gamma$ or $\gamma p \to \pi^0 p\gamma'$ which is related to the magnetic moment of the resonance. The first reaction has been used to study the magnetic moment of the Δ^{++} by measuring the left-right asymmetry with polarized protons [103]. The second one was used for the Δ^+ state [104, 105]. Taking all experimental and systematic uncertainties into account the result spans the range from (2.3 - 4.5)μ_N, covering the quark model prediction of $\approx 2.8\mu_N$, but is not very precise.

Table 15.8 lists the current experimental values for the magnetic moments of the ground state baryons, together with the predictions from the quark model. There are significant discrepancies, but given its crudeness, the quark model performs surprisingly well.

15.7 Dynamics

Quantum chromodynamics (QCD) is well-established as the theory for the strong interactions. As such, one of the goals of QCD is to predict the spectrum of strongly-interacting particles. To date, the only first-principles calculations of spectroscopy from QCD use lattice methods. These are the subject of Sec. 15.8. These calculations are difficult and unwieldy, and many interesting questions do not have a good lattice-based method of solution. Therefore, it is natural to build models, whose ingredients are abstracted from QCD, or from the low-energy limit of QCD (such as chiral Lagrangians) or from the data itself.

Phenomenological models for light quark systems typically include

1. A confining interaction, which is generally spin-independent (*e.g.*, harmonic oscillator or linear confinement);
2. A strange quark mass somewhat larger than the up and down quark masses, in order to split the SU(3) multiplets;
3. Different types of spin-dependent interactions:

   a) commonly used is a color-magnetic flavor-independent interaction modeled after the effects of gluon exchange in QCD (see *e.g.*, Ref. [106]). For example, in the S-wave states, there is a spin-spin hyperfine interaction of the form

   $$H_{HF} = -\alpha_S M \sum_{i>j} (\vec{\sigma}\lambda_a)_i (\vec{\sigma}\lambda_a)_j, \qquad (15.42)$$

   where M is a constant with units of energy, λ_a ($a = 1, \cdots, 8,$) is the set of SU(3) unitary spin matrices, defined in the review "SU(3) Isoscalar Factors and Representation Matrices," and the sum runs over constituent quarks or antiquarks. Spin-orbit interactions, although allowed, seem to be small in general, but a tensor term is responsible for the mixing of states with the same J^P but different L, S combinations.

   b) other approaches include flavor-dependent short-range quark forces from instanton effects (see *e.g.*, [107,108]). This interaction acts only on scalar, isoscalar pairs of quarks in a relative S-wave state:

   $$\langle q^2; S, L, T | W | q^2; S, L, T \rangle = -4g\delta_{S,0}\delta_{L,0}\delta_{I,0}\mathcal{W} \qquad (15.43)$$

   where $\mathcal{W}$ is the radial matrix element of the contact interaction.

   c) a rather different and somewhat controversial approach is based on flavor-dependent spin-spin forces arising from one-boson exchange. The interaction term is of the form:

   $$H_{HF} \propto \sum_{i<j} V(\vec{r}_{ij}) \lambda_i^F \cdot \lambda_j^F \vec{\sigma}_i \cdot \vec{\sigma}_j \qquad (15.44)$$

   where the λ_i^F are in flavor space (see *e.g.*, Ref. [109]).
4. In the case of spin-spin interactions, a flavor-symmetric interaction for mixing $q\bar{q}$ configurations of different flavors (*e.g.*, $u\bar{u} \leftrightarrow d\bar{d} \leftrightarrow s\bar{s}$), in isoscalar channels, so as to reproduce *e.g.*, the η - η' and ω - ϕ mesons.

Systems with heavy quarks have their own approaches. Besides potential models to deal with $Q\bar{Q}$ spectroscopy (which are similar to what we have just described for light quarks) there are a variety of effective field theories built on QCD. Nonrelativistic QCD or NRQCD is a nonrelativistic reduction of the QCD Lagrangian, written as an expansion in powers of the heavy quarks' velocities. Its expressions are often used in lattice calculations. Terms in the Lagrangian have obvious quark model analogs, but are derived directly from QCD. For example, the heavy quark potential is a derived quantity, extracted from simulations.

There are also many versions of heavy quark effective theory (HQET), an expansion in the inverse mass of the heavy constituent. The physics input is one of decoupling of scales: the interactions of the heavy quarks take place at short distance while the light degrees of freedom involve long distance dynamics, so to some degree they decouple. The form of terms in the expansion is fixed (often by symmetry) but the coefficients are not. These approaches allow one to interpolate from the charm sector to the bottom one, or from masses of mesons to baryons. For example, a Hamiltonian for one or more heavy quarks bound to light degrees of freedom could be written as

$$H_l^Q = m_Q + e_l + \frac{\kappa_l}{2m_Q} + \frac{s_l}{2m_Q} \vec{S} \cdot \vec{j}_l + \ldots \qquad (15.45)$$

where m_Q is the mass of the heavy quark (or heavy quarks where the heavy quarks are treated as a single dynamical object) and $\vec{S}$ is the angular momentum carried by the heavy degrees of freedom. e_l, κ_l and $\vec{j}_l$ involve the light degrees of freedom. We will see an example of the use of this formula in the next section.

15.8 Lattice Calculations of Hadronic Spectroscopy

Lattice calculations are a major source of information about QCD masses and matrix elements. The necessary theoretical background is given in Sec. 17 of this *Review*. Here we confine ourselves to some general comments and illustrations of lattice calculations for spectroscopy.

It might seem a bit out of place to have a section about lattice calculations in a review of the quark model, since to many readers, the quark model is just a model while QCD could be thought of as a construct which is something deeper than a model. But this review is, despite its title, actually an introduction to the spectroscopy and related quantities of the strong interactions. From that perspective, a presentation of lattice results is entirely appropriate.

The input to lattice calculations is a discretized version of the QCD Lagrangian. Lattice calculations measure correlation functions via Monte Carlo simulation and physical observables are determined through fits of the lattice data to theoretical expectations. It is fair to say that all lattice calculations make extensive use of quark model ideas – for example, the operators used to create and annihilate hadrons are almost always based on the quark model.

There is only a sporadic literature connecting lattice results to the quark model (one recent example is [110]) but of course the qualitative understanding of lattice results depends as heavily on quark model ideas as does the qualitative understanding of experimental data.

In general, the cleanest lattice results come from computations of processes in which there is only one particle in the simulation volume. These quantities include masses of hadrons, simple decay constants, like pseudoscalar meson decay constants, and semileptonic form factors (such as the ones appropriate to $B \to Dl\nu$, $Kl\nu$, $\pi l\nu$). The cleanest predictions for masses are for states which are far below any thresholds to open channels, since the effects of final state interactions are not yet under complete control on the lattice. As a simple corollary, the lightest state in a channel is easier to study than the heavier ones.

Good-quality modern lattice calculations will present multipart error budgets with their predictions. Part of the uncertainty is statistical, from sample size. Typically, the quoted statistical uncertainty includes uncertainty from a fit: it is rare that a simulation computes one global quantity which is the desired observable. Simulations which include virtual quark-antiquark pairs (also known as "dynamical quarks" or "sea quarks") are often done at up and down quark mass values heavier than the experimental ones, and it is then necessary to extrapolate in these quark masses. Simulations can be carried out at the physical values of the heavier quarks' masses. They are always done at nonzero lattice spacing, and so it is necessary to extrapolate to zero lattice spacing. Some theoretical input is needed to do this. Much of the uncertainty in these extrapolations is systematic, from the choice of fitting function. Other systematics include the effect of finite simulation volume, the number of flavors of dynamical quarks actually simulated, and technical issues with how these dynamical quarks are included. The particular choice of a fiducial mass (to normalize other predictions) is not standardized; there are many possible choices, each with its own set of strengths and weaknesses, and determining it usually requires a second lattice simulation from that used to calculate the quantity under consideration.

A systematic error of major historical interest is the "quenched approximation," in which dynamical quarks are simply left out of the simulation. This was done because the addition of these virtual pairs presented an expensive computational problem. No generally-accepted methodology has ever allowed one to correct for quenching effects, short of redoing all calculations with dynamical quarks. (All light degrees of freedom must be included in any realistic simulation of a quantum field theory.) Advances in algorithms and computer hardware have rendered it obsolete.

With these brief remarks, we turn to examples. The field of lattice QCD simulations is vast, and so it is not possible to give a comprehensive review of them in a small space. The history of lattice QCD simulations is a story of thirty years of incremental improvements in physical understanding, algorithm development, and ever faster computers, which have combined to bring the field to a present state where it is possible to carry out very high quality calculations. We present a few representative illustrations, to show the current state of the art.

15.8.1 *Spectroscopy of low-lying states*

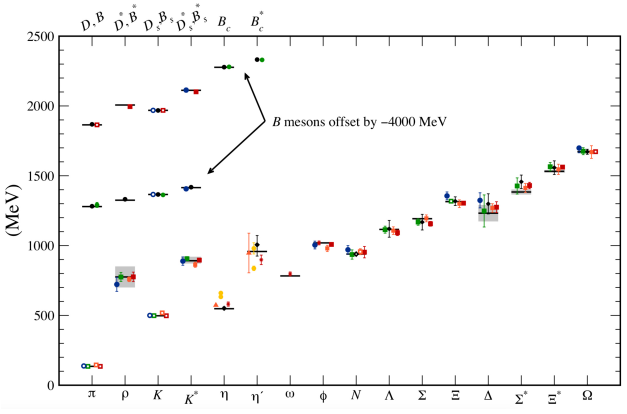

Figure 15.9: Hadron spectrum from lattice QCD. Comprehensive results for mesons and baryons are from MILC [111, 112], PACS-CS [113], BMW [114], QCDSF [115], and ETM [116]. Results for η and η' are from RBC & UKQCD [21], Hadron Spectrum [117] (also the only ω mass), UKQCD [118], and Michael, Ottnad, and Urbach [119]. Results for heavy-light hadrons from Fermilab-MILC [120], HPQCD [121, 122], and Mohler and Woloshyn [123]. Circles, squares, diamonds, and triangles stand for staggered, Wilson, twisted-mass Wilson, and chiral sea quarks, respectively. Asterisks represent anisotropic lattices. Open symbols denote the masses used to fix parameters. Filled symbols (and asterisks) denote results. Red, orange, yellow, green, and blue stand for increasing numbers of ensembles (i.e., lattice spacing and sea quark mass) Black symbols stand for results with 2+1+1 flavors of sea quarks. Horizontal bars (gray boxes) denote experimentally measured masses (widths). b-flavored meson masses are offset by −4000 MeV.

One of the first goals of large scale lattice simulations was to compute masses of the lightest states in all of the "conventional" $q\bar{q}$ and qqq channels. We illustrate results from many groups in Fig. 15.9, a comprehensive summary from 2012 provided by A. Kronfeld (private communication; see also [124]).

Mesons with a valence structure of identical quark - antiquark pairs such as the eta or eta-prime, $|\eta\rangle \sim \alpha|\bar{u}u + \bar{d}d\rangle + \beta|\bar{s}s\rangle$, present more of a challenge, because one must include the effects of "annihilation graphs" for the valence q and $\bar{q}$. Many groups, among them Refs. [21, 118, 125, 126], have reported calculations of the η and η' mesons. The most recent calculation is that of Ref. [126], which finds masses of 554.7 ± 9.2 and 930 ± 21 MeV for the η and η'.

The spectroscopy of mesons containing heavy quarks is truly a high-precision endeavor. These simulations typically use NRQCD for $Q\bar{Q}$ bound states. Figs. 15.10 and 15.11 show the low lying mass spectrum for charmonium and bottomonium states from several different groups [122, 127–130]. Most, but not all, of the results are for the lightest state with a given value of quantum numbers. We return to this point below.

Fig. 15.12 shows a compilation of lattice results for doubly and triply charmed baryons, provided by S. Meinel [138]. The position of the observed Ξ_{cc}^{+} [93] is also shown. Note that the lattice calculations for the mass of this state were predictions, not postdictions.

15.8.2 *Excited state spectroscopy*

A close look at Fig. 15.9 reveals an issue: while many of the states shown in it are stable under the strong interactions, some of them (the vector mesons, the Delta) are not. They are resonances. And so are all the excited states of hadrons listed in the PDG be

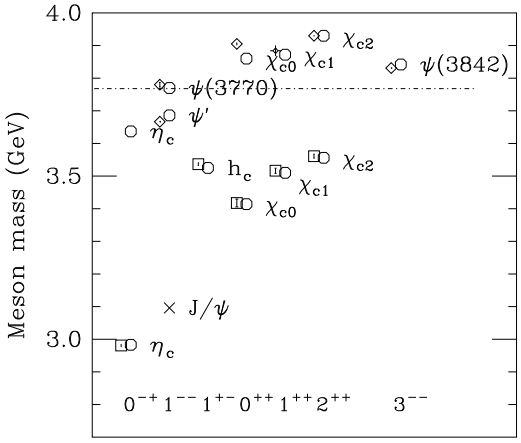

Figure 15.10: Selected spectroscopy of the $\bar{c}c$ spectrum, compared to lattice data from Ref. [127] in squares, from Refs. [128, 129] in diamonds, and from Ref. [130] as a fancy diamond. Particles whose masses are used to fix lattice parameters by Ref. [127] are shown with crosses; octagons label experimental values. The upper χ_{c1} state is also known as $X(3872)$. The dotted line shows the threshold value for two charmed mesons.

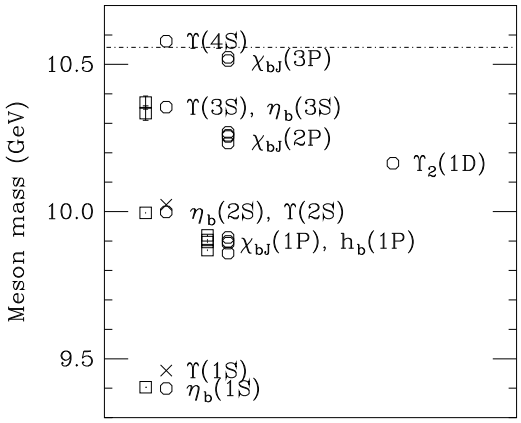

Figure 15.11: Spectroscopy of the $\bar{b}b$ system, adapted from Ref. [122]. Particles whose masses are used to fix lattice parameters are shown with crosses; octagons label experimental values, and lattice results are shown as squares. The dotted line shows the threshold value for two bottom mesons.

they "ordinary'," or "exotic." How do lattice calculations deal with such states? This is actually a complicated business, which is an active area of research.

There are two issues involving excited state spectroscopy, which are entangled in any lattice calculation:

1. There are many states with the same quantum numbers, all of which contribute to lattice observables
2. In finite volume, states do not decay, they only mix.

To explain what is going on, we have to describe how a lattice calculation determines a mass. This is done by measuring an observable which involves the creation of a set of quark and gluon fields at some point on the lattice and their annihilation at other points on the lattice. To find the energies of zero momentum states, the operators are averaged over position and the observable is

$$C_{ij}(t) = \sum_x \langle O_i(x,t) O_j(0,0)\rangle \propto \sum_n \langle 0|O_i|n\rangle \langle n|O_j|0\rangle \exp(-E_n t). \tag{15.46}$$

E_n is the energy of the nth hadronic state with the quantum numbers of the source or sink. The reader can see that by taking t large, the correlator is dominated by the contribution from the lightest state, decaying with t as $\exp(-E_{min}t)$. This is a positive thing if one is interested in the ground state, but the contribution of excited states is exponentially suppressed at large t. The size of a given state's contribution, $\langle 0|O_i|n\rangle$, can provide information about the content of the state.

As we move away from hadrons which can be created by the simplest quark model operators (appropriate to the lightest meson and baryon multiplets) we encounter a host of new problems: either no good interpolating fields, or too many possible interpolating fields, and many states with the same quantum numbers. Techniques for dealing with these interrelated problems vary from collaboration to collaboration, but all share common features: typically, correlation functions from many different interpolating fields are used, and the signal is extracted in what amounts to a variational calculation using the chosen operator basis. In addition to mass spectra, wave function information can be garnered from the form of the best variational wave function.

These calculations give towers of excited states, but the states are not resonances. Lattice calculations do not see decays directly because they are done in boxes of some finite size. Generally, the energies of the single particle states do not depend strongly on the box size. Multiple particle states, such as two particle states with equal and opposite momenta, are different, though. The finite box size quantizes the allowed values of momentum and the spectrum of states, which would be a continuum in infinite volume, is just a discrete tower. As the box size is varied, some of these states can approach the energies of single particle states, and the nearby states will mix and split, participating in a quantum mechanical avoided level crossing. The mixing and splitting of single and multiparticle states is the finite volume data which is used to infer how states in the continuum interact.

As a simple example, two positive energy but interacting particles in a one dimensional box have a spatial wave function which looks like $\cos(k|z| + \delta)$ where δ is the phase shift due to their interaction. Periodic boundary conditions in a finite box of length L give a quantization condition to the allowed momentum of the state ($kL + 2\delta(E) = 0 \mod 2\pi$, for example) which involves the phase shift. Simulations with many values of L and operators for states carrying many values of momentum can be combined into information about phase shifts, and then to statements about the location(s) of singularities in the complex energy plane.

The techniques for studying excited states of mesons and baryons, glueballs, and exotics are similar. They all use a large basis of trial states: the progression with time started with minimum quark content states, then added more complicated states (pairs of mesons or tetraquark states), then carried out simulations with multiple volumes with the goal of extracting resonance properties. The older single volume studies typically presented results for many quantum numbers, which give a broad (though incomplete) view of the QCD spectrum.

An example of meson spectroscopy where this is done, by [48], is shown in Fig. 15.13. The quark masses are still heavier than their physical values, so the pion is at 392 MeV. The authors can assign a relative composition of nonstrange and strange quark content to their states, observing, for example, a nonstrange ω and a strange ϕ. Some states also have a substantial component of gluonic excitation. Note especially the three exotic channels $J^{PC} = 1^{-+}$, 0^{+-}, and 2^{+-}, with states around 2 GeV. These calculations will become more realistic as the quark masses are carried lower and resonance effects are included.

The interesting physics questions of excited baryon spectroscopy to be addressed are precisely those enumerated in the last section. An example of a calculation involving only single particle states in a single volume, due to Ref. [139], is shown in Fig. 15.14. Notice that the pion is not yet at its physical value. The lightest positive parity state is the nucleon, and the Roper resonance has not yet appeared as a light state.

Glueballs present similar issues. In Fig. 15.3 we showed a figure from [34] presenting a lattice prediction for the glueball mass spectrum in quenched approximation. A true QCD prediction of the glueball spectrum requires dynamical light quarks, some way to deal with the mixing of glue states and quark-antiquark (and beyond) states and (because glueball operators are intrinsically

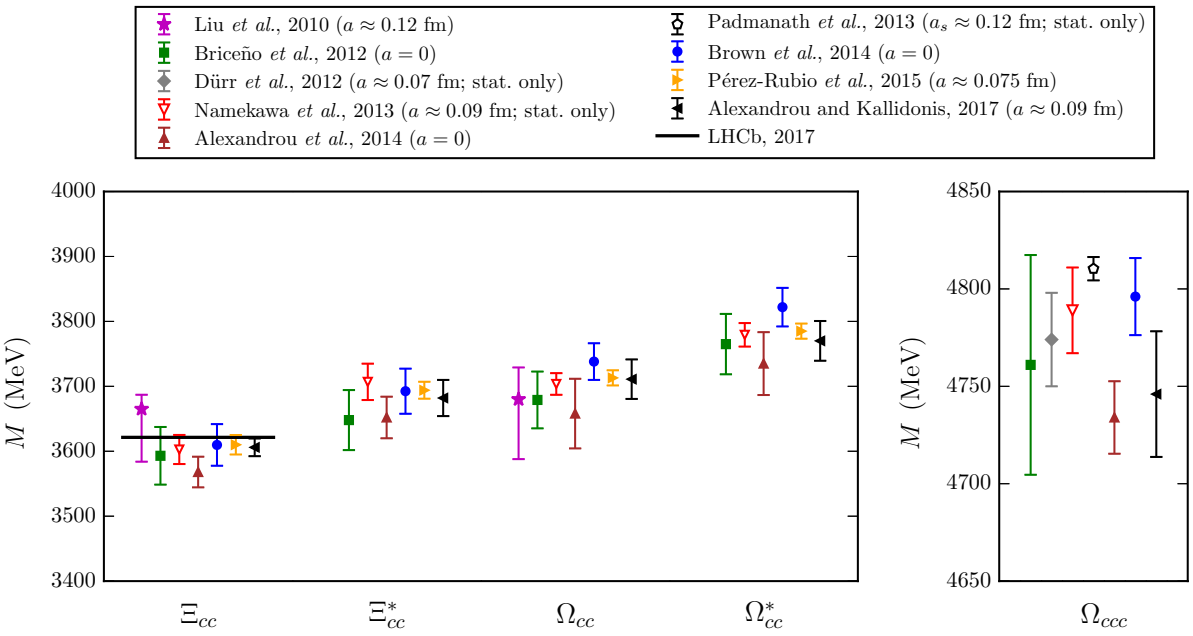

Figure 15.12: Comparison of lattice QCD results for the doubly and triply charmed baryon masses. Labels are Liu, *et al.*, [131]; Briceno, *et al.*, [132]; Namekawa, *et al.*, [133]; Padmanath, *et al.*, [134]; Alexandrou, *et al.*, [116]; Brown, *et al.*, [135]; Perez-Rubio *et al.*, [136]; Alexandrou and Kallidonis 2017, [137]. Only calculations with dynamical light quarks are included; for the doubly charmed baryons, only calculations were performed at or extrapolated to the physical pion mass are shown. Results without estimates of systematic uncertainties are labeled "stat. only". The lattice spacing values used in the calculations are also given; $a = 0$ indicates that the results have been extrapolated to the continuum limit. In the plot of the doubly charmed baryons, the position of the experimentally observed Ξ_{cc}^{+} state [93] is shown with a horizontal line.

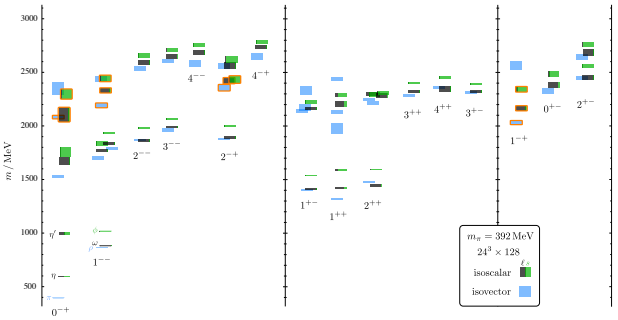

Figure 15.13: Isoscalar (green and black) and isovector (blue) spectrum from Ref. [48]. States are labeled J^{PC}. The quark mass is heavier than its physical value; $m_\pi = 392$ MeV. The vertical height of each box indicates the statistical uncertainty in the mass. Black and green indicate relative nonstrange and strange composition. Orange outlines show states with a large chromomagnetic component to their wave function, which the authors argue are hybrid states. Note the exotic states in the three rightmost columns.

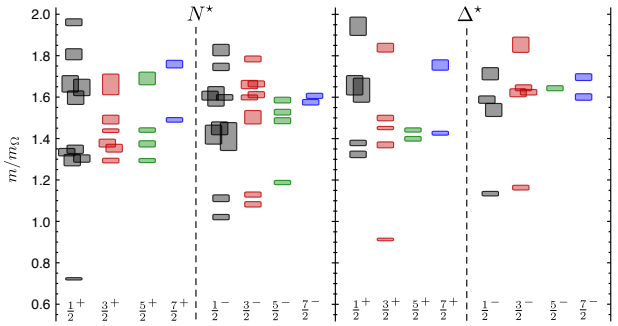

Figure 15.14: Spin-identified spectrum of nucleons and deltas, from lattices where $m_\pi = 396$ MeV, in units of the calculated Ω mass, from Ref. [139]. The colors just correspond to the different J assignments: grey for $J = 1/2$, red for $J = 3/2$, green for 5/2, blue for $J = 7/2$.

noisy) high statistics. Early studies which include the 0^{++} channel are Refs. [140,141]. Fig. 15.15 shows results from [140], done with dynamical u, d and s quarks at two lattice spacings, 0.123 and 0.092 fm, with pion masses at 280 and 360 MeV respectively, along with comparisons to the quenched lattice calculation of [33] and to experimental isosinglet mesons. This study shows that the effects of quenching seem to be small at its relatively heavy pion masses.

Calculations of resonance properties are more recent. Two body decays with a single open channel, such as the rho coupled to two pions, have a large literature. A review [142] summarizes the situation, and example of a calculation of the rho meson decay width is [143]. (See also [144].) The mass and decay width of the $f_0(500)$ have recently been computed in [145] and [146] and those of other mesons in [147]. Ref. [148] studies the decay width of the $\Delta(1238)$.

Studies which observe a large basis of states across many volumes can probe excited state spectroscopy as resonances. These calculations are just beginning and the ones we know about are still performed at unphysically heavy quark masses. Examples include the decays of an exotic $J^{PC} = 1^{-+}$ resonance [149] and the spectroscopy of J^{--} resonances [150]. The results of Refs. [128, 129] in Fig. 15.10 come from similar analyses. We expect to see considerable progress in this area over the next few years.

We conclude this section with some remarks about unusual states containing heavy quarks. Lattice calculations relevant to the extra states observed in the charmonium and bottomonium spectrum (Sec. 15.4) are difficult, because the states sit high in the spectrum of most channels, because of the number of nearby multiparticle states, and because it is necessary to have the technology to study heavy and light quarks together.

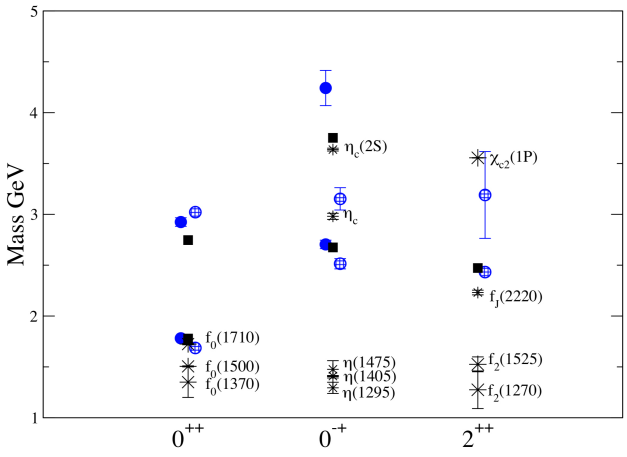

Figure 15.15: Lattice QCD predictions for glueball masses. The open and closed circles are the larger and smaller lattice spacing data of the full QCD calculation of glueball masses of Ref. [140], at pion masses of 280 and 360 MeV. Squares are the quenched data for glueball masses of Ref. [33]. The bursts labeled by particle names are experimental states with the appropriate quantum numbers.

Some lattice calculations are used as input for phenomenological studies of hybrids. The theoretical motivation is that one can imagine states made of a heavy $Q\bar{Q}$ pair along with excitations of light degrees of freedom, viewed as an excited states of the string connecting them. The analogy is to an excited state of a diatomic molecule. The heavy quark potential, the potential from orbitally excited gluon configurations, and the "string breaking" potential (from the interaction between static sources and static-light mesons) are used as inputs in Born - Oppenheimer and coupled channel calculations for systems whose constituents include heavy quarks and antiquarks. Examples of such calculations include Refs. [151–153].

The system with the largest lattice literature is a bound state of two heavy quarks and two light antiquarks, for example $bb\bar{u}\bar{d}$. The story begins with the spectroscopy of doubly and triply charmed baryons in Fig. 15.12; the lattice calculations in that figure were performed in 2010 - 2017. In 2017 two groups of authors [154,155] realized that one could extrapolate from the masses of $Q\bar{q}$, Qqq, and QQq states (Q for a heavy quark, $\bar{q}$ for a light antiquark) to predict the mass of a $QQ\bar{q}\bar{q}$ tetraquark. The $QQ\bar{q}\bar{q}$ state would be stable if the mass of the Q were heavy enough. (This basically arises because the QQ diquark is in an attractive color-triplet state and the effective binding energy scales as $\alpha_s^2 m_Q$.) The $J^P = 1^+$ $bb\bar{u}\bar{d}$ state was expected to be stable. Simultaneously, a lattice calculation [156] of the mass of a $bb\bar{u}\bar{d}$ state showed that it was below threshold to fall apart into a pair of B mesons. The $I(J^P) = 0(1^+)$ state is predicted to be stable by about 128(26) MeV [157] or 189(10) MeV [156]. (These authors put the $bb\bar{s}\bar{d}$ state at 98 MeV below threshold.) These numbers are in reasonable agreement with phenomenological estimates from Refs. [154, 155].

These states are easier for the lattice theorist to study than other exotics because they are the lightest single particle states in their channels. They are difficult because they are just barely bound, and the usual approximation for a lattice calculation of unphysically heavy light quarks tends to raise their mass. The calculations have to include multiple trial states: the tetraquark itself plus pairs of mesons.

The situation with regard to the recently discovered $T_{cc}(3875)^+$ [158] is still unsettled. Both lattice calculations and HQET estimates put a $cc\bar{u}\bar{d}$ state right at threshold, which is a difficult place to explore on the lattice (or by any other method, for that matter). The $T_{cc}(3875)^+$ is seen in $D^0 D^0 \pi^+$ and researchers studying three body decays on the lattice (an open problem, at present) mark it as an obvious research target.

15.8.3 *Electromagnetic effects*

As a final part of spectroscopy we mention electromagnetic mass splittings (such as the neutron - proton mass difference). They are interesting but difficult. These calculations are important for determining the values of the quark masses (for a discussion see Sec. 60 in this Review). Knowing that the neutron is heavier than the proton tells us that these splittings have a complicated origin. One part of the shift is because the up and down quarks have slightly different masses. The second is that the quarks have (different) charges. Phenomenologists (compare Ref. [159]) combine Coulomb forces and spin-dependent electromagnetic hyperfine interactions to model their charge effects. In order to compute hadronic mass differences on the lattice, electromagnetic interactions must be included in the simulations. This creates a host of technical issues. An important one is that electromagnetic interactions are long range, but lattice simulations are done in finite volumes. The theoretical situation is summarized in the recent Flavour Lattice Averaging Group (FLAG) review [160]. A 2014 calculation, Ref. [161], presented the first results for electromagnetic mass splittings in the baryon octet, with good agreement with observation. Refs. [162–164] have performed calculations for meson splittings.

There is a small lattice literature associated with magnetic moments of baryons. The calculations are done by including a static magnetic field in the simulation and computing the energy difference between baryons in different spin states. We are aware of no calculations at physical quark masses. A recent calculation [165] used 800 and 450 MeV pions. When expressed in units of the nucleon magneton at the simulation point ($e/(2M_N(m_\pi))$) the moments are in reasonable agreement with experiment and with quark model expectations.

16. Heavy-Quark and Soft-Collinear Effective Theory

Revised August 2023 by C.W. Bauer (LBNL) and M. Neubert (PRISMA, Mainz Inst. for Theor. Physics, JG U.).

16.1 Effective Field Theories

Quantum field theories provide the most precise computational tools for describing physics at the highest energies. One of their characteristic features is that they almost inevitably involve multiple length scales. When trying to determine the value of an observable, quantum field theory demands that all possible virtual states and hence all particles be included in the calculation. Since these particles have widely different masses, the final prediction is sensitive to many scales. This fact represents a formidable challenge from a practical point of view. No realistic quantum field theories can be solved exactly, so that one needs to resort to approximation schemes; these, however, are typically most straightforward when only a single scale is involved at a time.

Effective field theories (EFTs) provide a general theoretical framework to deal with the multi-scale problems of realistic quantum field theories. This framework aims at reducing such problems to a combination of separate and simpler single-scale problems; simultaneously, however, it provides an organization scheme whereby the other scales are not omitted but allowed to play their role in a separate step of the computation. The philosophy and basic principles of this approach are very generic, and correspondingly EFTs represent a widely used method in many different areas of high-energy physics, from the low-energy scales of atomic and nuclear physics to the high-energy scales of (partly yet unknown) elementary-particle physics, see [1–3] for some early references. EFTs can play a role both within analytic perturbative computations and in the context of non-perturbative numerical simulations. One of the simplest applications of EFTs to particle physics concerns the description of an underlying theory that is only probed at energy scales $E < \Lambda$. Any particle with mass $m > \Lambda$ cannot be produced as a real state and therefore only leads to short-distance virtual effects. Thus, one can construct an effective theory in which the quantum fluctuations of such heavy particles are "integrated out" from the generating functional for Green functions. This results in a simpler theory containing only those degrees of freedom that are relevant to the energy scales under consideration. In fact, the standard model of particle physics itself is widely viewed as an EFT of some yet unknown, more fundamental theory [4, 5].

The development of any effective theory starts by identifying the degrees of freedom that are relevant to describe the physics at a given energy (or length) scale and constructing the Lagrangian describing the interactions among these fields. Short-distance quantum fluctuations associated with much smaller length scales are absorbed into the coefficients of the various operators in the effective theory. These coefficients are determined in a matching procedure, by requiring that the EFT reproduces the matrix elements of the full theory up to power corrections. In many cases the effective Lagrangian exhibits enhanced symmetries compared with the fundamental theory, giving non-trivial relations between different observables.

16.2 Heavy-Quark Effective Theory

Heavy-quark systems provide prime examples for applications of the EFT technology, because the hierarchy $m_Q \gg \Lambda_{\rm QCD}$ (with $Q = b, c$) provides a natural separation of scales. Physics at the scale m_Q is of a short-distance nature and can be treated perturbatively, while for heavy-quark systems there is always also some hadronic physics governed by the confinement scale $\Lambda_{\rm QCD}$ of the strong interaction. Being able to separate the short-distance and long-distance effects associated with these two scales is crucial for any quantitative description. For instance, if the long-distance hadronic matrix elements are obtained from lattice QCD, then it is necessary to analytically compute the effects of short-wavelength modes that do not fit on the lattice. In many other instances, the long-distance physics can be encoded in a small number of hadronic parameters.

16.2.1 *General idea and derivation of the effective Lagrangian*

The simplest effective theory for heavy-quark systems is the heavy-quark effective theory (HQET) [6–9] (see [10, 11] for detailed discussions). It provides a simplified description of the soft interactions of a single heavy quark with light partons. This includes the interactions that bind the heavy quark with other light partons inside heavy mesons and baryons.

A softly interacting heavy quark is nearly on-shell. Its momentum may be decomposed as $p_Q = m_Q v + k$, where v is the 4-velocity of the hadron containing the heavy quark. The "residual momentum" k results from the soft interactions of the heavy quark with its environment and satisfies $v \cdot k \sim \Lambda_{\rm QCD}$ and $k^2 \sim \Lambda^2_{\rm QCD}$, which in the rest frame of the heavy hadron reduces to $k^\mu \sim \Lambda_{\rm QCD}$. In the limit $m_Q \gg \Lambda_{\rm QCD}$, the soft interactions do not change the 4-velocity of the heavy quark, which is therefore a conserved quantum number that is often used as a label on the effective heavy-quark fields.

A nearly on-shell Dirac spinor has two large and two small components. We define

$$Q(x) = e^{-im_Q v\cdot x}\,[h_v(x) + H_v(x)]\,, \tag{16.1}$$

where

$$h_v(x) = e^{im_Q v\cdot x}\,\frac{1+\not{v}}{2}\,Q(x)\,, \qquad H_v(x) = e^{im_Q v\cdot x}\,\frac{1-\not{v}}{2}\,Q(x) \tag{16.2}$$

are the large ("upper") and small ("lower") components of the spinor field, respectively. The extraction of the phase factor in (16.1) implies that the fields h_v and H_v carry the residual momentum k. The field H_v is $1/m_Q$ suppressed relative to h_v and describes quantum fluctuations far off the mass shell. Integrating it out using its equations of motion yields the HQET Lagrangian

$$\mathcal{L}_{\rm HQET} = \bar h_v\, iv\cdot D_s\, h_v + \frac{1}{2m_Q}\left[\bar h_v (iD_s)^2 h_v + C_{\rm mag}(\mu)\,\frac{g}{2}\,\bar h_v\,\sigma_{\mu\nu}\,G_s^{\mu\nu} h_v\right] + \dots\,. \tag{16.3}$$

The covariant derivative $iD_s^\mu = i\partial^\mu + gA_s^\mu$ and the field strength $G_s^{\mu\nu}$ contain only the soft gluon field. Hard gluons have been integrated out, and their effects are contained in the Wilson coefficients of the operators in the effective Lagrangian. From the leading operator one derives the Feynman rules of HQET. The new operators entering at subleading order are referred to as the "kinetic energy" and "chromo-magnetic interaction". The kinetic-energy operator corresponds to the first correction term in the Taylor expansion of the relativistic energy $E = m_Q + \vec p^{\,2}/2m_Q + \dots$. Lorentz invariance, which is encoded as a reparametrization invariance of the effective Lagrangian [12], ensures that its Wilson coefficient is not renormalized ($C_{\rm kin} \equiv 1$). The coefficient $C_{\rm mag}$ of the chromo-magnetic operator receives corrections starting at one-loop order [6].

16.2.2 *Spin-flavor symmetry*

The leading term in the HQET Lagrangian exhibits a global spin-flavor symmetry. Its physical meaning is that, in the infinite mass limit, the properties of hadronic systems containing a single heavy quark are insensitive to the spin and flavor of the heavy quark [13, 14]. The spin symmetry results from the fact that there are no Dirac matrices in the leading term of the effective Lagrangian in (16.3), implying that the interactions of the heavy quark with soft gluons leave its spin unchanged. The flavor symmetry arises since the mass of the heavy quark does not appear at leading order. For n_Q heavy quarks moving at the same velocity, one can simply extend (16.3) by summing over n_Q identical terms for heavy-quark fields h_v^i. The result is invariant under rotations in flavor space. When combined with the spin symmetry, the symmetry group becomes promoted to $SU(2n_Q)$. These symmetries are broken by the operators at subleading power in the $1/m_Q$ expansion.

The spin-flavor symmetry leads to many interesting relations between the properties of hadrons containing a heavy quark. The

most direct consequences concern the spectroscopy of such states [15]. In the heavy-quark limit, the spin of the heavy quark and the total angular momentum j of the light degrees of freedom are separately conserved by the strong interactions. Because of heavy-quark symmetry, the dynamics is independent of the spin and mass of the heavy quark. Hadronic states can thus be classified by the quantum numbers (flavor, spin, parity, etc.) of the light degrees of freedom. The spin symmetry predicts that, for fixed $j \neq 0$, there is a doublet of degenerate states with total spin $J = j \pm \frac{1}{2}$. The flavor symmetry relates the properties of states with different heavy-quark flavor.

16.2.3 *Weak decay form factors*

Of particular interest are the relations between the weak decay form factors of heavy mesons, which parametrize hadronic matrix elements of currents between two mesons containing a heavy quark. These relations have been derived by Isgur and Wise [14], generalizing ideas developed by Nussinov and Wetzel [16] and Voloshin and Shifman [17]. For the purpose of this discussion, it is convenient to work with a mass-independent normalization of meson states and use velocity rather than momentum variables.

Consider the elastic scattering of a pseudoscalar meson, $P(v) \to P(v')$, induced by an external vector current coupled to the heavy quark contained in P, which acts as a color source moving with the meson's velocity v. The action of the current is to replace instantaneously the color source by one moving at velocity v'. Soft gluons need to be exchanged in order to rearrange the light degrees of freedom and build up the final state meson moving at velocity v'. This rearrangement leads to a form-factor suppression. The important observation is that, in the $m_Q \to \infty$ limit, the form factor can only depend on the Lorentz boost $\gamma = v \cdot v'$ connecting the rest frames of the initial and final-state mesons (as long as $\gamma = \mathcal{O}(1)$). In the effective theory the hadronic matrix element describing the scattering process can therefore be written as

$$\langle P(v')|\, \bar h_{v'} \gamma^\mu h_v \,|P(v)\rangle = \xi(v\cdot v')(v+v')^\mu, \tag{16.4}$$

with a form factor $\xi(v \cdot v')$ that is real and independent of m_Q. By flavor symmetry, the form factor remains identical when one replaces the heavy quark Q in one of the meson states by a heavy quark Q' of a different flavor, thereby turning P into another pseudoscalar meson P'. At the same time, the current becomes a flavor-changing vector current. This universal form factor is called the Isgur-Wise function [14]. For equal velocities the vector current $J^\mu = \bar h_v \gamma^\mu h_v$ is conserved in the effective theory, irrespective of the flavor of the heavy quarks. The corresponding conserved charges are the generators of the flavor symmetry. It follows that the Isgur-Wise function is normalized at the point of equal velocities: $\xi(1) = 1$. Since the recoil energy of the daughter meson P' in the rest frame of the parent meson P is $E_{\rm recoil} = m_{P'}\,(v\cdot v'-1)$, the point $v \cdot v' = 1$ is referred to as the zero-recoil limit. The heavy-quark spin symmetry leads to additional relations among weak decay form factors. It can be used to relate matrix elements involving vector mesons to those involving pseudoscalar mesons, which once again can be described completely in terms of the universal Isgur-Wise function.

The form factor relations imposed by heavy-quark symmetry describe the semileptonic decay processes $\bar B \to D\,\ell\,\bar\nu$ and $\bar B \to D^*\ell\,\bar\nu$ in the limit of infinite heavy-quark masses. They are model-independent consequences of QCD. The known normalization of the Isgur-Wise function at zero recoil can be used to obtain a model-independent measurement of the element $|V_{cb}|$ of the Cabibbo-Kobayashi-Maskawa (CKM) matrix. The semileptonic decay $\bar B \to D^*\ell\,\bar\nu$ is particularly well suited for this purpose [18]. Experimentally this is a very clean mode, since the reconstruction of the D^* meson mass provides a powerful rejection against background. From the theoretical point of view, it is ideal since the decay rate at zero recoil is protected by Luke's theorem against first-order power corrections in $1/m_Q$ [19]. This is described in more detail in Section 12. Corrections to the heavy-quark symmetry relations for the $\bar B \to D^{(*)}$ form factors near zero recoil can also be constrained using sum rules derived in the small-velocity limit [20, 21].

16.2.4 *Decoupling transformation*

At leading order in $1/m_Q$, the couplings of soft gluons to heavy quarks in the effective Lagrangian (16.3) can be removed by the field redefinition $h_v(x) = Y_v(x)\, h_v^{(0)}(x)$, where $Y_v(x)$ is a soft Wilson line along the direction of v, extending from minus infinity to the point x. In terms of the new fields the leading-order HQET Lagrangian becomes $\mathcal{L}_{\rm HQET} = \bar h_v^{(0)} iv\cdot\partial\, h_v^{(0)}$. It describes a free theory as far as the strong interactions of heavy quarks are concerned. However, the theory is nevertheless non-trivial in the presence of external sources. Consider, e.g., the case of a weak-interaction heavy-quark current

$$\bar h_{v'}\gamma^\mu(1-\gamma_5)h_v = \bar h_{v'}^{(0)}\gamma^\mu(1-\gamma_5)\, Y_{v'}^\dagger Y_v\, h_v^{(0)}, \tag{16.5}$$

where v and v' are the velocities of the heavy mesons containing the heavy quarks. Unless the two velocities are equal, corresponding to the zero-recoil limit discussed above, the object $Y_{v'}^\dagger Y_v$ is non-trivial, and hence the soft gluons do not decouple from the heavy quarks inside the current operator. One may interpret $Y_{v'}^\dagger Y_v$ as a Wilson loop with a cusp at the point x, where the two paths parallel to the different velocity vectors intersect. The presence of the cusp leads to non-trivial ultra-violet behavior (for $v \neq v'$), which is described by a cusp anomalous dimension $\Gamma_{\rm cusp}(v\cdot v')$ that was calculated at two-loop order in [22]. It coincides with the velocity-dependent anomalous dimension of heavy-quark currents, which was introduced in the context of HQET in [23]. The interpretation of heavy quarks as Wilson lines is a useful tool, which was put forward in one of the very first papers on the subject [6]. This technology will be useful in the study of the interactions of heavy quarks with collinear degrees of freedom discussed later in this review.

16.2.5 *Heavy-quark expansion for inclusive decays*

The theoretical description of inclusive decays of hadrons containing a heavy quark exploits two observations [24–28]: bound-state effects related to the initial state can be calculated using the heavy-quark expansion, and the fact that the final state consists of a sum over many hadronic channels eliminates the sensitivity to the properties of individual final-state hadrons. The second feature rests on the hypothesis of quark-hadron duality, i.e. the assumption that decay rates are calculable in QCD after a smearing procedure has been applied [29]. In semileptonic decays, the integration over the lepton spectrum provides a smearing over the invariant hadronic mass of the final state (global duality). For nonleptonic decays, where the total hadronic mass is fixed, the summation over many hadronic final states provides an averaging (local duality). Since global duality is a much weaker assumption, the theoretical control of inclusive semileptonic decays is on firmer footing.

Using the optical theorem, the inclusive decay width of a hadron H_b containing a b quark can be written in the form

$$\Gamma(H_b) = \frac{1}{M_{H_b}}\,{\rm Im}\,\langle H_b|\, i\int {\rm d}^4x\, T\,\{\mathcal{H}_{\rm eff}(x), \mathcal{H}_{\rm eff}(0)\}\,|H_b\rangle\,. \tag{16.6}$$

The effective weak Hamiltonian for b-quark decays consists of dimension-6 four-fermion operators and dipole operators [30]. Because of the large mass of the b quark, it follows that the separation of fields in the time-ordered product in (16.6) is small, of order $x \sim 1/m_b$. It is thus possible to construct an operator-product expansion (OPE) for the time-ordered product, in which it is represented as a series of local operators in HQET. The leading operator $\bar h_v h_v$ has a trivial matrix element. The next contributions arise at $\mathcal{O}(1/m_b^2)$ and give rise to two parameters $\mu_\pi^2(H_b)$ and $\mu_G^2(H_b)$, which are defined as the matrix elements of the heavy-quark kinetic energy and chromo-magnetic interaction inside the hadron H_b, respectively [31]. For the ground-state heavy mesons and baryons, one has $\mu_G^2(B) = 3(m_{B^*}^2 - m_B^2)/4 \simeq 0.36\,{\rm GeV}^2$ and $\mu_G^2(\Lambda_b) = 0$. Thus, the total inclusive decay rate of a hadron H_b

can be written as [25,26]

$$\Gamma(H_b) = \frac{G_F^2 m_b^5 |V_{cb}|^2}{192\pi^3}\left[c_1 + c_2\,\frac{\mu_\pi^2(H_b)}{2m_b^2} + c_3\,\frac{\mu_G^2(H_b)}{2m_b^2} + \mathcal{O}\Big(\frac{1}{m_b^3}\Big) + \dots\right], \tag{16.7}$$

where the prefactor arises from the loop integrations and is proportional to the fifth power of the b-quark mass. The coefficient functions c_i are calculable order by order in perturbation theory. While c_1 corresponds to the decay rate of a free heavy quark, the higher-order coefficients systematically account for bound-state effects. The coefficients of the subleading operators and of the leading operator at third order in $1/m_b$ have been calculated at NLO [32–36]. At tree level the heavy-quark expansion has been performed up to fifth order in $1/m_b$ [37].

From the fully inclusive width in (16.7) one can obtain the lifetime of a heavy hadron via $\tau(H_b) = 1/\Gamma(H_b)$. Due to the universality of the leading term in the heavy-quark expansion, lifetime ratios such as $\tau(B^-)/\tau(\bar B^0)$, $\tau(\bar B_s^0)/\tau(\bar B^0)$ and $\tau(\Lambda_b)/\tau(\bar B^0)$ are particularly sensitive to the hadronic parameters determining the power corrections in the expansion. In order to understand these ratios theoretically, it is necessary to include phase-space enhanced power corrections of order $(\Lambda_{\rm QCD}/m_b)^3$ [38,39] as well as short-distance perturbative effects [40] in the calculation (see [41] for a discussion of the corresponding calculations).

A formula analogous to (16.7) can be derived for differential distributions in specific inclusive decay processes, assuming that these distributions are integrated over a sufficiently large region of phase space to ensure quark-hadron duality. Important examples are the distributions in the lepton energy and the lepton invariant mass, as well as moments of the invariant hadronic mass distribution in the semileptonic processes $\bar B \to X_u\,\ell\,\bar\nu$ and $\bar B \to X_c\,\ell\,\bar\nu$. A global fit of semileptonic decay distributions can be used to determine the CKM matrix elements $|V_{ub}|$ and $|V_{cb}|$ along with heavy-quark parameters such as the masses m_b, m_c and the hadronic parameters $\mu_\pi^2(B)$, $\mu_G^2(B)$. These determinations provide some of the most accurate values for these parameters (see e.g. [42–45]).

16.2.6 *Shape functions and non-local power corrections*

In certain regions of phase space, in which the hadronic final state in an inclusive heavy-hadron decay is made up of light energetic partons, the local OPE for inclusive decays must be replaced by a more complicated expansion involving hadronic matrix elements of non-local light-ray operators [46,47]. Prominent examples are the radiative decay $\bar B \to X_s\gamma$ for large photon energy E_γ near $m_B/2$, and the semileptonic decay $\bar B \to X_u\,\ell\,\bar\nu$ at large lepton energy or small hadronic invariant mass. In these cases, the differential decay rates at leading order in the heavy-quark expansion can be written in the factorized form $d\Gamma = H\,J\otimes S$ [48], where the hard function H and the jet function J are calculable in perturbation theory. The characteristic scales for these functions are set by m_b and $(m_b\Lambda_{\rm QCD})^{1/2}$, respectively. The soft function

$$S(\omega) = \int \frac{dt}{4\pi}\, e^{-i\omega t}\,\langle \bar B(v)|\,\bar h_v(tn) Y_n(tn) Y_n^\dagger(0) h_v(0)|\bar B(v)\rangle \tag{16.8}$$

is a non-perturbative object called the shape function [46,47]. Here Y_n are soft Wilson lines along a light-like direction n aligned with the momentum of the hadronic final-state jet. The jet function and the shape function share a common variable $\omega \sim \Lambda_{\rm QCD}$, and the symbol $\otimes$ denotes a convolution in this variable.

While the hard functions are different for the decays $\bar B \to X_s\gamma$ and $\bar B \to X_u\,\ell\bar\nu$, the jet and soft functions are identical at leading order in $\Lambda_{\rm QCD}/m_Q$. This is particularly important for the shape function, which introduces non-perturbative physics into the theoretical predictions for the decay rates in the regions of experimental interest. The fact that both processes depend on the same non-perturbative function makes it possible to use the measured shape of the $\bar B \to X_s\gamma$ photon spectrum to reduce the theoretical uncertainties in the determination of the CKM element $|V_{ub}|$ from semileptonic decays. In higher orders of the heavy-quark expansion, an increasing number of subleading jet and soft functions are required to describe the decay distributions [49]. These have been analyzed in detail at order $1/m_b$ [50–52]. In the case of $\bar B \to X_s\gamma$ (and also in the related case of $\bar B \to X_s\ell\bar\ell$), some of these non-local effects survive in the total decay rate and give rise to irreducible hadronic uncertainties [53]. The technology for deriving the corresponding factorization theorems relies on the soft-collinear effective theory, to which we now turn.

16.3 Soft-Collinear Effective Theory

As discussed in the previous section, soft gluons that bind a heavy quark inside a heavy meson cannot change the virtuality of that heavy quark by a significant amount. The ratio $\Lambda_{\rm QCD}/m_Q$ provides the expansion parameter in HQET, which is a small parameter since $m_Q \gg \Lambda_{\rm QCD}$. This obviously does not work when considering light quarks. However, if the energy Q (not to be confused with the flavor of a heavy quark) of the quarks is large, the ratio $\Lambda_{\rm QCD}/Q$ provides a small parameter, which can be used to construct an effective theory. One major difference to HQET is that light energetic quarks cannot only emit soft gluons, but they can also emit collinear gluons (an energetic gluon in the same direction as the original quark), without parametrically changing their virtuality. Thus, to fully reproduce the long-distance physics of energetic quarks requires that one includes their interactions with both soft and collinear particles. The resulting effective theory is therefore called soft-collinear effective theory (SCET) [54–57] (see [58] for a review).

A single energetic particle can always be boosted to a frame where all momentum components have similar size, in which case there is no small expansion parameter. Thus, the presence of energetic particles must refer to a reference frame defined by external kinematics. SCET has a wide range of applications; some examples are the production of energetic, light states in the decay of a heavy particle in its rest frame, the production of energetic jets in collider environments, and the scattering of energetic particles off a target at rest. In this brief review we will outline the main features of this effective theory and mention a few selected applications.

16.3.1 *General idea of the expansion*

Consider a quark with virtuality much less than its energy Q, moving along the direction $\vec n$. It is convenient to parameterize the momentum p_n of this particle in terms of its light-cone components, defined by $(p_n^-, p_n^+, p_n^\perp) = (\bar n\cdot p_n, n\cdot p_n, p_n^\perp)$, where $n^\mu = (1,\vec n)$ and $\bar n^\mu = (1,-\vec n)$ are light-like reference vectors, and $n\cdot p_n^\perp = \bar n\cdot p_n^\perp = 0$. The subscript n on the momentum indicates the direction of the collinear particle. In terms of these light-cone components, the virtuality satisfies $p_n^2 = p_n^+ p_n^- + p_n^{\perp 2}$. The individual components of the momentum obey

$$(p_n^-, p_n^+, p_n^\perp) \sim Q(1,\lambda^2,\lambda)\,, \tag{16.9}$$

where $\lambda^2 = p^2/Q^2$ is the expansion parameter of SCET. The virtuality of such an energetic particle remains parametrically unchanged if it interacts with energetic particles in the same direction n, or with soft particles with momentum scaling as

$$(p_s^-, p_s^+, p_s^\perp) \sim Q(\lambda^2,\lambda^2,\lambda^2)\,. \tag{16.10}$$

SCET is constructed in such a way as to reproduce the long-distance dynamics arising from the interactions of collinear and soft degrees of freedom.

In the above power counting the transverse momenta of soft degrees of freedom scale as $p_s^\perp \sim Q\lambda^2$, which is much smaller than the transverse momenta $p_c^\perp \sim Q\lambda$ of collinear fields. This theory is usually called SCET$_{\rm I}$. If the external kinematics require that the transverse momenta of both soft and collinear fields are of the same size, $p_c^\perp \sim p_s^\perp$, then the appropriate degrees of freedom have the scaling $p_c \sim Q(1,\lambda^2,\lambda)$ and $p_s \sim Q(\lambda,\lambda,\lambda)$. This theory is usually called SCET$_{\rm II}$ and is required, e.g., for exclusive hadronic decays such as $\bar B \to D\pi$, where the virtuality of both collinear and soft degrees of freedom are set by $\Lambda_{\rm QCD}$, or for the description of transverse-momentum distributions at colliders. SCET$_{\rm I}$ power counting is assumed in the following sections, while SCET$_{\rm II}$ is discussed in more detail in 16.3.6.

16.3.2 *Leading-order Lagrangian*

The derivation of the SCET Lagrangian follows similar steps as described for HQET in Section 16.2.1. One begins by deriving the Lagrangian for a theory containing only a single collinear sector. Similar to HQET, one separates the full QCD field into two components, $q_n(x) = \psi_n(x) + \eta_n(x)$, where (with $n \cdot \bar{n} = 2$)

$$\psi_n(x) = \frac{\not{n}\bar{\not{n}}}{4}\, q_n(x)\,, \qquad \eta_n(x) = \frac{\bar{\not{n}}\not{n}}{4}\, q_n(x)\,. \tag{16.11}$$

The degrees of freedom described by the field η_n are far off shell and can therefore be eliminated using its equation of motion. This gives

$$\mathcal{L}_n = \bar{\psi}_n(x) \left[in\cdot D + i\not{D}^\perp \frac{1}{i\bar{n}\cdot D}\, i\not{D}^\perp \right] \frac{\bar{\not{n}}}{2}\, \psi_n(x)\,. \tag{16.12}$$

As a next step, one separates the large and small momentum components by decomposing the collinear momentum into a "label" and a residual momentum, $p^\mu = P^\mu + k^\mu$ with $n \cdot P = 0$. One then performs a phase redefinition on the collinear fields, such that $\psi_n(x) = e^{-iP\cdot x}\, \xi_n(x)$. Derivatives acting on the fields $\xi_n(x)$ now only pick out the residual momentum. Since unlike in HQET the label momentum in SCET is not conserved, one defines a label operator $\mathcal{P}^\mu$ acting as $\mathcal{P}^\mu \xi_n(x) = P^\mu \xi_n(x)$ [56], as well as a corresponding covariant label operator $i\mathcal{D}_n^\mu = \mathcal{P}^\mu + gA_n^\mu(x)$. Note that at leading order in power counting $i\mathcal{D}_n^\mu$ does not contain the soft gluon field. This leads to the final SCET Lagrangian [56,57,59,60]

$$\mathcal{L}_n = \bar{\xi}_n(x) \left[in\cdot D_n + gn\cdot A_s + i\not{\mathcal{D}}_n^\perp \frac{1}{i\bar{n}\cdot \mathcal{D}_n}\, i\not{\mathcal{D}}_n^\perp \right] \frac{\bar{\not{n}}}{2}\, \xi_n(x) + \dots\,, \tag{16.13}$$

where we have split $in\cdot D$ into a collinear piece $in\cdot D_n = in\cdot\partial + gn\cdot A_n$ and a soft piece $gn\cdot A_s$. This latter term gives rise to the only interaction between a collinear quark and soft gluons at leading power in λ. The ellipses represent higher-order interactions between soft and collinear particles.

The Lagrangian describing collinear fields in different light-like directions is simply given by the sum of the Lagrangians for each direction n, i.e. $\mathcal{L} = \sum_n \mathcal{L}_n$. The soft gluons are the same in each individual Lagrangian. An alternative way to understand the separation between large and small momentum components is to derive the Lagrangian of SCET in position space [60]. In this case no label operators are required, but the collinear field operators are separated by a light-like distance. An important difference between SCET and HQET is that the SCET Lagrangian is not corrected by short distance fluctuations. The physical reason is that in the construction described above no high-momentum modes have been integrated out [60]. Such hard modes arise when different collinear sectors are coupled via some external current (e.g. in jet production at e^+e^- or hadron colliders), or when collinear particles are produced in the rest frame of a decaying heavy object (such as in B decays). Short-distance effects are then incorporated in the Wilson coefficients of the external source operators.

16.3.3 *Collinear gauge invariance and Wilson lines*

An important aspect of SCET concerns the implementation of local gauge invariance. Because the effective field operators describe modes with certain momentum scalings, the effective Lagrangian respects only residual gauge symmetries. One of them satisfies the collinear scaling

$$(\bar{n}\cdot\partial, n\cdot\partial, \partial^\perp)\, U_n(x) \sim Q(1, \lambda^2, \lambda)\, U_n(x)\,, \tag{16.14}$$

and one the soft scaling

$$(\bar{n}\cdot\partial, n\cdot\partial, \partial^\perp)\, U_s(x) \sim Q(\lambda^2, \lambda^2, \lambda^2)\, U_s(x)\,. \tag{16.15}$$

While the soft gauge transformation is common for all fields, collinear fields in different directions each transform under their own collinear gauge transformation. In other words, each collinear sector has to be separately gauge invariant under its collinear gauge transformation. This requires the introduction of collinear Wilson lines [56]

$$W_n(x) = \mathrm{P}\exp\left[-ig \int_{-\infty}^0 ds\, \bar{n}\cdot A_n(s\bar{n} + x) \right], \tag{16.16}$$

which transform under collinear gauge transformations according to $W_n \to U_n W_n$. Thus, the combination $\chi_n \equiv W_n^\dagger \psi_n$ is gauge invariant. In a similar manner, one can define the gauge-invariant gluon field $B_n^\mu = g^{-1} W_n^\dagger\, iD_n^\mu\, W_n$ [61, 62]. Collinear operators in SCET are typically constructed from such collinearly gauge-invariant building blocks.

16.3.4 *Derivation of factorization theorems*

One of the important applications of SCET is to understand how to factorize cross sections or decay rates involving energetic particles moving in different directions into simpler quantities that can either be calculated perturbatively or determined from data. For the purpose of this discussion, we focus on factorization in the context of collider physics. Note that factorization theorems have been around for much longer than SCET (see [63] for a review). However, the effective theory allows for a conceptually simpler understanding of certain classes of factorization theorems [61], since most simplifications happen already at the level of the Lagrangian. The discussion in this section is valid to leading order in the power counting of the effective theory.

As discussed in the previous section, the Lagrangian of SCET does not involve any direct couplings between collinear particles moving in different directions. A process involving highly energetic initial- and/or final-state particles moving along different directions n_i is therefore described in SCET by operators involving gauge-invariant collinear building blocks for each direction, which only interact amongst each other via soft gluon exchange. At leading power, soft gluons couple to collinear quarks only through the term $\bar{\xi}_n\, gn\cdot A_s\, (\bar{\not{n}}/2)\, \xi_n$ in the effective Lagrangian in (16.13), which is similar to the coupling of soft gluons to heavy quarks in HQET, see Section 16.2.4. This coupling, and the corresponding coupling to collinear gluons can be removed by means of the field redefinitions [57]

$$\psi_n(x) = Y_n(x)\, \psi_n^{(0)}(x)\,, \qquad A_n^a(x) = Y_n^{ab}(x)\, A_n^{b(0)}(x)\,, \tag{16.17}$$

where the soft Wilson lines Y_n and Y_n^{ab} live in the fundamental and adjoint representations of $SU(3)$, respectively. Each collinear building block gives rise to a soft Wilson line. After this decoupling, the different collinear sectors no longer interact with each other and the soft interactions are entirely encoded in the product of soft Wilson lines. This is the basis of factorization proofs in SCET.

The simplest applications of this formalism concern inclusive processes, such as the Drell-Yan production of electroweak bosons in the threshold region, $pp \to Z/H + X_s$, where X_s is a final state containing only soft particles, and event shape distributions in e^+e^- collisions in the two-jet limit. For Drell-Yan the factorization formula is given by [61, 64]

$$\begin{aligned} \sigma(pp \to ZX_s) &= \sum_q H_q(\mu) \left[f_{q/p}(\mu)\, f_{\bar{q}/p}(\mu) \right] \otimes S_F(\mu)\,, \\ \sigma(pp \to HX_s) &= H_g(\mu) \left[f_{g/p}(\mu)\, f_{g/p}(\mu) \right] \otimes S_A(\mu)\,, \end{aligned} \tag{16.18}$$

where the collinear matrix elements give rise to the parton distributions $f_{a/p}(\mu)$, the soft function are vacuum matrix element of the soft Wilson lines in the fundamental or adjoint representation, and the hard functions are the squares of the Wilson coefficients of the relevant SCET operators. The convolution symbol indicates a convolution over the longitudinal momentum fractions of the colliding partons. The objects in the factorization theorem depend on the renormalization scale μ, whereas the cross sections are scale independent. Solving the renormalization group equations (RGE) allows to resum large logarithms in the cross section (see below).

For event shapes such as thrust T, no initial-state partons are present, and the factorization formula takes the form (with $\tau = 1 - T$) [65, 66]

$$\frac{d\sigma}{d\tau} = H(\mu) \left[J_n(\mu) J_{\bar{n}}(\mu) \right] \otimes S_{n\bar{n}}(\mu)\,, \tag{16.19}$$

where the the jet functions are vacuum matrix elements of the outgoing collinear quark fields, which are convoluted with the soft

function $S_{n\bar{n}}$ defined as another vacuum matrix element of the soft Wilson lines.

For a more general high-energy scattering process such as $pp \to N$ jets, where the incoming protons move along directions $n_{a,b}$ and the jets define directions $n_1, \dots, n_N$, the factorization theorem for the differential cross section can be written as

$$d\sigma \sim \sum_{ab} H_{ab\dots N}(\mu) \left[B_{a/p}(\mu)\, B_{b/p}(\mu)\right] \otimes \left[J_1(\mu) \dots J_N(\mu)\right] \otimes S_{ab\dots N}(\mu)\,. \tag{16.20}$$

where the beam functions are generalized parton distributions [67] and the jet functions depend on the algorithm used to define the jets. It should be mentioned that the most difficult part of traditional factorization proofs involves showing that so-called Glauber gluons do not spoil the above factorization theorem [68]. The description of Glauber effects within SCET [69] has been developed in [70], where a closed form for the effective Lagrangian describing these interactions was derived. The formalism has been extended to Glauber quarks in [71]. In this context, a proof of factorization requires demonstrating that this Lagrangian has no impact on a particular cross section. If an observable is non-global, in the sense that energetic radiation is restricted to certain regions in phase space, the above factorization theorem needs to be generalized [72–74].

16.3.5 *Resummation of large logarithms*

Many processes of interest depend on multiple scales which can be widely separated. The perturbative series of such processes depends logarithmically on large scale ratios. For high-energy processes involving soft and collinear particles, there can be up to two powers of large logarithms for each power of the coupling constant. These double logarithms are referred to as Sudakov logarithms and can spoil the perturbative expansion.

SCET can be used to sum large logarithms L using renormalization-group equations. This reorganizes the perturbative series in such a way that the product $\alpha_s L$ is treated as an $\mathcal{O}(1)$ parameter. In many cases, one can write a perturbative series for the logarithm of a cross section, such that

$$\sigma \sim \exp\left[L\, g_0(\alpha_s L) + g_1(\alpha_s L) + \alpha_s\, g_2(\alpha_s L) + \dots\right], \tag{16.21}$$

with functions $g_n(x)$ that need to be determined. Note that each term in this series in the exponent is one power of α_s suppressed relative to the previous term.

The important ingredient in achieving this resummation is the fact that SCET factorizes a given cross section into simpler pieces, each of which depends on a single physical scale. The only dependence on that scale can arise through logarithms of its ratio with the renormalization scale μ. Thus, for each of the components in the factorization theorem one can choose a renormalization scale μ for which the large logarithmic terms are absent. Of course, the factorization formula requires a common renormalization scale μ in all its components, and one therefore has to use the renormalization group (RG) to evolve the various component functions from their preferred scale to the common scale μ. A novel feature of RG equations in SCET, as opposed to other EFTs, is that the anomalous dimensions entering the evolution equations of the hard, beam, jet and soft functions in a factorization formula such as (16.20) contain a single power of the logarithm of the relevant energy scale. For example, the anomalous dimension γ_H of the hard function has the form

$$\gamma_H(\mu) = c_H\, \Gamma_{\rm cusp}(\alpha_s)\, \ln\frac{Q^2}{\mu^2} + \gamma(\alpha_s)\,, \tag{16.22}$$

where c_H is a process-dependent coefficient and $\Gamma_{\rm cusp}$ denotes the so-called cusp anomalous dimension [22, 75]. Collinear and soft functions have similar anomalous dimensions, which also involve a cusp and a non-cusp part. The non-cusp part γ of the anomalous dimensions is process (and observable) dependent. The presence of a logarithm in the anomalous dimension is characteristic of Sudakov problems and arises since the perturbative series contains double logarithms of scale ratios.

Solving the RG equations one can systematically resum all large logarithms of scale ratios in the factorized cross section and express the functions $g_n(\alpha_s L)$ introduced above in terms of ratios of running coupling constants. In order to compute the first two terms $L\, g_0(\alpha_s L) + g_1(\alpha_s L)$ in $\ln\sigma$, corresponding to the next-to-leading logarithmic (NLL) approximation, one needs two-loop expressions for the cusp anomalous dimension and β function, one-loop expressions for the non-cusp pieces in the anomalous dimensions, and tree-level matching conditions for all component functions at their characteristic scales. To calculate the next term $\alpha_s g_2(\alpha_s L)$ in the expansion, corresponding to NNLL order, one needs to go one order higher in the loop expansion, and so on.

16.3.6 *Factorization and resummation in* $\mathbf{SCET_{II}}$

The effective theory $\mathrm{SCET_{II}}$ contains collinear and soft particles with momenta scaling as $(p_n^-, p_n^+, p_n^\perp) \sim Q(1, \lambda^2, \lambda)$ and $(p_s^-, p_s^+, p_s^\perp) \sim Q(\lambda, \lambda, \lambda)$. They have the same small virtuality ($p_n^2 \sim p_s^2 \sim Q^2\lambda^2$) but differ in their rapidities. An important class of observables, for which this scaling is relevant, contains cross sections for processes in which the transverse momenta of particles are constrained by external kinematics. The prime example are the transverse-momentum distributions of electroweak gauge bosons or Higgs bosons produced at hadron colliders. The parton transverse momenta are constrained by the fact that their vector sum must be equal and opposite to the transverse momentum q_T of the boson. Standard RG evolution in the effective theory controls the logarithms arising from the fact that the virtualities of the collinear and soft modes are much smaller than the hard scale Q in the process (the boson mass). However, additional large logarithms arise since the rapidities of collinear and soft modes are parametrically different, such that $e^{|y_c - y_s|} \sim 1/\lambda$. These logarithms can be traced to a new source of divergences and an unusual failure of dimensional regularization. They need to be factorized in the cross section and resummed by other means.

Two approaches exist for how to deal with the additional rapidity logarithms in SCET. In the approach of [76], they are interpreted as a consequence of a "collinear anomaly" of the effective theory $\mathrm{SCET_{II}}$, resulting from the fact that a classical rescaling symmetry of the effective Lagrangian is broken by quantum effects. The extra large logarithms can be resummed by means of simple differential equations, which typically state that, to all orders in perturbation theory (and in an appropriate space), the logarithm of the cross section contains only a single extra logarithm of $\lambda \sim q_T/Q$ not contained in the hard function. Another approach to resum the rapidity logarithms uses the "rapidity renormalization group" [77], in which the relevant differential equations are obtained by considering a new type of scale variation in a parameter ν, which separates the phase space for collinear and soft particles along a hyperbola in the (p_-, p_+) plane. In contrast to the standard RG, there is no running coupling involved in the ν evolution, since the different contributions live at the same virtuality.

As an important application, consider the Higgs-boson production cross section in gluon fusion at the LHC, defined with a jet veto stating that no jet in the final state has transverse momentum above a threshold $p_T^{\rm veto}$, which can be factorized in the form [78,79]

$$\begin{aligned}\sigma(p_T^{\rm veto}) = {}& H(m_H, \mu) \left(\frac{\nu_B}{\nu_S}\right)^{-2F_{gg}(R, p_T^{\rm veto}, \mu)} S_{gg}(R, p_T^{\rm veto}, \mu, \frac{\nu_S}{p_T^{\rm veto}}) \\ & \times \int_\tau^1 \frac{dz}{z}\, B_{g/P}\Big(z, R, p_T^{\rm veto}, \mu, \frac{\nu_B}{m_H}\Big)\, B_{g/P}\Big(\frac{\tau}{z}, R, p_T^{\rm veto}, \mu, \frac{\nu_B}{m_H}\Big)\,,\end{aligned} \tag{16.23}$$

where $\tau = m_H^2/s$, and $\mu \sim p_T^{\rm veto}$ is a common factorization scale. The beam functions $B_{g/P}$, the soft function S_{gg} and the exponent F_{gg} all depend on the jet radius R as well as the jet clustering algorithm. The scale dependence of the hard function H is controlled by standard RG evolution in SCET. The beam functions can be factorized further into calculable collinear kernels convoluted with parton distribution functions. In addition to the renormalization scale μ, the beam and soft functions depend on

two rapidity scales $\nu_B \sim m_H$ and $\nu_S \sim p_T^{\rm veto}$, respectively. In [78] the default values $\nu_B = m_H$ and $\nu_S = p_T^{\rm veto}$ are used for these scales, and the soft function S_{gg} is absorbed into the beam functions. In [79] the exponent F_{gg} is called $-\gamma_\nu^g/2$. The second factor on the right-hand side of the factorization formula (16.23), which resums large rapidity logarithms, implies that the logarithm of the jet-veto cross section contains a single large logarithm $\ln\sigma = -2F_{gg}(R, p_T^{\rm veto}, \mu)\ \ln(m_H/p_T^{\rm veto}) + \ldots$ not contained in the hard function. Its coefficient can be calculated in fixed-order perturbation theory.

$\rm SCET_{II}$ also plays an important role in the study of factorization for a variety of exclusive B meson decays, such as $\bar B \to \pi\ell\bar\nu$, $\bar B \to K^*\gamma$ and $\bar B \to \pi\pi$, for which the virtualities of energetic (collinear) final-state particles are of order $\Lambda_{\rm QCD}$, which is also the scale for the soft light degrees of freedom contained in the initial-state B meson.

16.3.7 *Applications*

Most of the applications of SCET are either in flavor physics, where the decay of a heavy B meson can give rise to energetic light partons, or in collider physics, where the presence of jets naturally leads to collimated sets of energetic particles. For some of these applications alternative approaches existed before the invention of SCET, but the effective theory has opened up alternative ways to understand the physics of these processes. For many examples, however, SCET has allowed new insights and new applications.

The investigation of heavy-to-light form factors has been instrumental for understanding factorization in exclusive semileptonic B decays [80]. SCET has also provided a field-theoretic basis for the QCD factorization approach to exclusive, non-leptonic decays of B mesons [81]. Using SCET methods, proofs of factorization were derived for the color-allowed decay $\bar B^0 \to D^+\pi^-$ [82], the color-suppressed decay $\bar B^0 \to D^0\pi^0$ [83], and the radiative decay $\bar B \to K^*\gamma$ [84]. In recent years, the factorization approach has been extended to include QED effects [85, 86]. Further examples are factorization theorems and the resummation of endpoint logarithms for quarkonia production [87], the resummation of large logarithmic terms for the thrust [88] and jet broadening [89] distributions in e^+e^- annihilation beyond NLL order, the development of new factorizable observables to veto extra jets [67,90], all-order factorization theorems for processes containing electroweak Sudakov logarithms [91], and the resummation of threshold (soft gluon) logarithms in momentum space for several important processes at hadron colliders [64, 92, 93]. There has also been a lot of activity describing p_T-based resummation at hadron colliders. Prominent examples are the transverse-momentum distributions of electroweak bosons [76, 77, 94], which give access to the p_T-dependent parton distribution functions. Higher-order resummations of event shape distributions [88], combined with two-loop fixed-order expressions [95, 96] and including nonperturbative effects by means of a shape function, have been used for an accurate determination of the strong coupling constant α_s [97, 98]. A method based on N-jettiness ($\mathcal{T}_N$) slicing [99, 100] has provided a new way of performing the IR subtractions needed for precise fixed-order calculations, using the fact that the singular dependence on $\mathcal{T}_N$ can be calculated using SCET at NNLO. This has been used to compute various processes with final states containing up to one hard, colored particle [101–105]. Calculations of the leading power corrections in $\mathcal{T}_0/Q$ [106, 107] have helped to improved the numerical stability of the method. The N-jettiness slicing method has also been used in the combination of higher-order resummation with parton showers [108–110]. Finally, SCET has given new insights into the jet substructure methods (see [111] for a review).

A novel type of SCET factorization theorem is needed to describe non-global observables, in which energetic radiation is limited to certain regions of phase space, e.g. inside jets. Jet events play a prominent role in collider physics, because they closely mirror the underlying short-distance dynamics. In the theoretical description of such observables one encounters so-called "non-global" logarithms (NGLs) [112, 113], whose resummation cannot be performed using standard techniques. Using SCET, this problem has been reduced to the solution of a RG evolution equation derived from a novel type of factorization theorem, in which the hard and soft functions are operators in color space and in the (infinite) space of parton multiplicities [72,74] (see also [73, 114]). In e^+e^- collisions, solving the RGE in the large-N_c limit using parton-shower techniques [115] gives a result that agrees with the solution of the BSM integral equation for the NGLs [116]. The first application of this formalism was to the light jet mass distribution [117], and the extension of the resummation to NLL accuracy has been accomplished in [118, 119]. Non-global observables at hadron colliders are yet more intricate, since Glauber-gluon exchange between the colliding partons lead to a new type of double logarithmic corrections in high orders of perturbation theory, the so-called superleading logarithms (SLLs) [120, 121]. Based on the corresponding SCET factorization theorem, the all-order resummation of SLLs has been accomplished for arbitrary $pp \to n$ jet processes [122].

Recent years have seen a strong effort to push the applications of SCET factorization and resummation techniques to next-to-leading power (NLP) in the expansion in λ. The subleading SCET Lagrangian [60,123,124] and current operators arising in B-meson decays and their anomalous dimensions [59,60,125–127] have been studied a long time ago. For important collider processes, such as Drell-Yan or Higgs production, the general sets of operators have been identified [128–130], and several of their anomalous dimensions have been calculated [130, 131]. Resummed results at subleading power have been presented for event shapes [132] and the Drell-Yan process [133]. More applications of SCET can be found in Section 6.4 of the review article [134].

16.4 Open issues and perspectives

HQET has successfully passed many experimental tests, and there are not many open questions that still need to be addressed. One concept that has not been derived from first principles is the notion of quark-hadron duality, which underlies the application of HQET to the description of inclusive decays of B mesons. The validity of global duality (at energies even lower than those relevant in B decays) has been tested experimentally using high-precision data on semileptonic B decays and on hadronic τ decays. However, assigning a theoretical uncertainty due to possible duality violations remains a difficult task. Another known issue is that the measured values of the CKM elements $|V_{ub}|$ and $|V_{cb}|$ extracted from exclusive or inclusive decays of B mesons differ from each other by several standard deviations (see Section 76). This measurement relies on the heavy-quark limit, and the uncertainty quoted includes a theoretical estimate of the effect of power corrections arising from the finite b-quark mass. It remains an open question whether the discrepancy is due to underestimated theoretical or experimental uncertainties.

SCET, on the other hand, is still an active field of research, and new results are being obtained regularly. In particular, it has been realized that at NLP SCET factorization theorems generically suffer from endpoint-divergent convolution integrals [135–140]. To remove these divergences, one uses exact D-dimensional refactorization conditions, which relate different terms in the NLP factorization theorem in the singular limits, to rearrange these terms in such a way that the endpoint divergences are systematically removed. Successful applications of this technique include the NLP factorization theorem for the b-quark induced contribution to the diphoton decay amplitude of the Higgs boson [139, 141] and the $gg \to H$ production amplitude [142], the "off-diagonal gluon thrust" in e^+e^- collisions [143], and the NLP factorization theorems for some exclusive [144, 145] and inclusive [146] B-meson decays. On the other hand, for some other processes, such as electron-muon backward scattering [147], the factorization of endpoint singularities is still a subject of ongoing research.

Another active field concerns the further study and applications of Glauber gluons and quarks in SCET and their relation to the BFKL equation familiar from small-x physics [114, 148]. The theoretical formalism developed in [70, 71] sets the basis for a solid understanding of the impact of Glauber exchanges on factorization theorems. Moreover, using the rapidity renormalization group one can derive the BFKL equation in the presence of a single Glauber exchange describing forward scattering [70, 148] and for small x resummation in deep inelastic scattering [149]. Glauber gluons play an important role in SCET-based analysis of

jet propagation in dense QCD media [150–152], which gives rise to the jet-quenching phenomenon in heavy-ion collisions. They are also a crucial ingredient in studies of violations of collinear factorization at hadron colliders [69, 153–157].

We close this short review by mentioning a particularly nice application combining the methods of heavy-particle EFTs such as HQET and non-relativistic QCD with SCET in the context of describing the interactions of heavy dark matter (with mass $M \gg v$) with SM particles. In [158] it was realized that the interactions of heavy, weakly interacting massive particles (WIMPs) with nuclear targets can be described in a model-independent way using heavy-particle EFTs. The WIMPs are charged under $SU(2)_L$ and can interact with electroweak gauge bosons and the Higgs boson. The WIMP EFT was later extended by describing the produced, highly energetic electroweak gauge bosons in terms of soft or collinear fields in SCET [159–161]. This allows one to systematically separate all relevant mass scales, resum electroweak Sudakov logarithms and disentangle the so-called Sommerfeld enhancement from the short-distance hard annihilation process.

17. Lattice Quantum Chromodynamics

Revised August 2023 by S. Hashimoto (KEK) and S.R. Sharpe (U. Washington), written September 2011 with J. Laiho (Syracuse U.)

Many physical processes considered in the Review of Particle Properties (RPP) involve hadrons. The properties of hadrons—which are composed of quarks and gluons—are governed primarily by Quantum Chromodynamics (QCD) (with small corrections from Quantum Electrodynamics [QED]). Theoretical calculations of these properties require non-perturbative methods, and Lattice Quantum Chromodynamics (LQCD) is a tool to carry out such calculations. It has been successfully applied to many properties of hadrons. Most important for the RPP are the calculation of electroweak decay constants and form factors, which are needed to extract Cabbibo-Kobayashi-Maskawa (CKM) matrix elements when combined with the corresponding experimental measurements. LQCD has also been used to determine other fundamental parameters of the standard model, in particular the strong gauge coupling and quark masses, as well as to predict hadronic contributions to the anomalous magnetic moment of the muon, $g_\mu - 2$.

This review describes the theoretical foundations of LQCD and sketches the methods used to calculate the quantities relevant for the RPP. It also describes the various sources of error that must be controlled in a LQCD calculation. Results for hadronic quantities are found in the corresponding dedicated reviews.

17.1 Lattice regularization of QCD

Gauge theories form the building blocks of the Standard Model. While the SU(2) and U(1) parts have weak couplings and can be studied accurately with perturbative methods, the SU(3) component—QCD—is only amenable to a perturbative treatment at high energies. The growth of the gauge coupling in the infrared—the flip-side of asymptotic freedom—requires the use of non-perturbative methods to determine the low energy properties of QCD. Lattice gauge theory, proposed by K. Wilson in 1974 [1], provides such a method, for it gives a non-perturbative definition of vector-like gauge field theories such as QCD. In lattice regularized QCD—commonly called lattice QCD or LQCD—Euclidean space-time is discretized, usually on a hypercubic lattice with lattice spacing a, with quark fields placed on sites and gauge fields on the links between sites. The lattice spacing plays the role of the ultraviolet regulator, rendering the quantum field theory finite. The continuum theory is recovered by taking the limit of vanishing lattice spacing, which can be reached by tuning the bare gauge coupling to zero according to the renormalization group.

Unlike dimensional regularization, which is commonly used in continuum QCD calculations, the definition of LQCD does not rely on the perturbative expansion. Indeed, LQCD allows non-perturbative calculations by numerical evaluation of the path integral that defines the theory.

Practical LQCD calculations are limited by the availability of computational resources and the efficiency of algorithms. Because of this, LQCD results come with both statistical and systematic errors, the former arising from the use of Monte-Carlo integration, the latter, for example, from the use of non-zero values of a. There are also different ways in which the QCD action can be discretized, and all must give consistent results in the continuum limit, $a \to 0$. It is the purpose of this review to provide an outline of the methods of LQCD, with particular focus on applications to particle physics, and an overview of the various sources of error. This should allow the reader to better understand the LQCD results that are presented in other reviews, primarily those on "Quark Masses," "Quark Model," "Quantum Chromodynamics," "CKM quark-mixing matrix," "V_{ud}, V_{us}, Cabibbo angle and CKM Unitarity," "Leptonic Decays of Charged Pseudoscalar Mesons," "B^0-$\bar{B}^0$ Mixing," and "Semileptonic b-Hadron Decays, Determination of V_{cb} and V_{ub}." For more extensive explanations the reader should consult the available textbooks or lecture notes, the most up-to-date of which are Refs. [2–4].

17.1.1 *Gauge invariance, gluon fields and the gluon action*

A key feature of the lattice formulation of QCD is that it preserves gauge invariance. This is in contrast to perturbative calculations, where gauge fixing is an essential step. The preservation of gauge invariance leads to considerable simplifications, e.g., restricting the form of operators that can mix under renormalization.

The gauge transformations of lattice quark fields are just as in the continuum: $q(x) \longrightarrow V(x)q(x)$ and $\bar{q}(x) \longrightarrow \bar{q}(x)V^\dagger(x)$, with $V(x)$ an arbitrary element of SU(3). The only difference is that the Euclidean space-time positions x are restricted to lie on the sites of the lattice, i.e. $x = a(n_1, n_2, n_3, n_4)$ for a hypercubic lattice, with the n_j being integers. Quark bilinears involving different lattice points can be made gauge invariant by introducing the gluon field $U_\mu(x)$. For example, for adjacent points the bilinear is $\bar{q}(x)U_\mu(x)q(x+a\hat{\mu})$, with $\hat{\mu}$ the unit vector in the μ'th direction. (This form is used in the construction of the lattice covariant derivative.) This is illustrated in Fig. 17.1. The gluon field (or "gauge link") is an element of the group, SU(3), in contrast to the continuum field A_μ which takes values in the Lie algebra. The bilinear is invariant if U_μ transforms as $U_\mu(x) \to V(x)U_\mu(x)V^\dagger(x+a\hat{\mu})$. The lattice gluon field is naturally associated with the link joining x and $x+a\hat{\mu}$, and corresponds in the continuum to a Wilson line connecting these two points, $\mathrm{P}\exp(i\int_x^{x+a\hat{\mu}} dx_\mu A_\mu^{\rm cont}(x))$ (where P indicates a path-ordered integral, and the superscript on A_μ indicates that it is a continuum field). The trace of a product of the $U_\mu(x)$ around any closed loop is easily seen to be gauge invariant and is the lattice version of a Wilson loop.

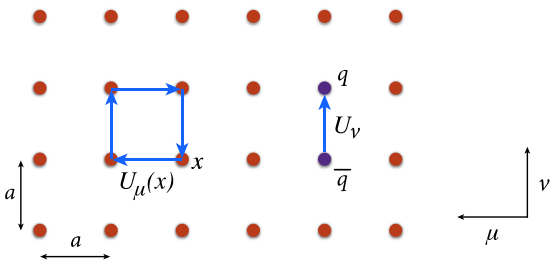

Figure 17.1: Sketch of a two-dimensional slice through the $\mu-\nu$ plane of a lattice, showing gluon fields lying on links and forming either the plaquette product appearing in the gauge action or a component of the covariant derivative connecting quark and antiquark fields.

The simplest possible gauge action, usually called the Wilson gauge action, is given by the product of gauge links around ele-

mentary plaquettes:

$$S_g = \beta \sum_{x,\mu<\nu} [1 - \frac{1}{3}\mathrm{ReTr}[U_\mu(x)U_\nu(x+a\hat{\mu})U_\mu^\dagger(x+a\hat{\nu})U_\nu^\dagger(x)]] \,. \tag{17.1}$$

This is illustrated in Fig. 17.1. For small a, assuming that the fields are slowly varying, one can expand the action in powers of a using $U_\mu(x) = \exp(iaA_\mu(x))$. Keeping only the leading non-vanishing term, and replacing the sum with an integral, one finds the continuum form,

$$S_g \longrightarrow \int d^4x \frac{1}{4g_{\rm lat}^2}\mathrm{Tr}[F_{\mu\nu}^2(x)] \,, \quad (F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu]) \tag{17.2}$$

as long as one chooses $\beta = 6/g_{\rm lat}^2$ for the lattice coupling. In this expression, $g_{\rm lat}$ is the bare gauge coupling in the lattice scheme, which can be related (by combining continuum and lattice perturbation theory) to a more conventional gauge coupling such as that in the $\overline{\rm MS}$ scheme (see Sec. 17.3.4 below).

In practice, the lattice spacing a is non-zero, leading to discretization errors. In particular, the lattice breaks Euclidean rotational invariance (which is the Euclidean version of Lorentz invariance) down to a discrete hypercubic subgroup. One wants to reduce discretization errors as much as possible. A very useful tool for understanding and then reducing discretization errors is the Symanzik effective action: the interactions of quarks and gluons with momenta low compared to the lattice cutoff ($|p| \ll 1/a$) are described by a continuum action consisting of the standard continuum terms (e.g., the gauge action given in Eq. (17.2)) augmented by higher dimensional operators suppressed by powers of a [5]. For the Wilson lattice gauge action, the leading corrections to the continuum terms come in at $\mathcal{O}(a^2)$. They take the form $\sum_j a^2 c_j O_6^{(j)}$, with the sum running over all dimension-six operators $O_6^{(j)}$ allowed by the *lattice* symmetries, and c_j unknown coefficients. Some of these operators violate Euclidean rotational invariance, and all of them lead to discretization errors of the form $a^2\Lambda^2$ (up to $\log(a)$ corrections that will be discussed below), where Λ is a typical momentum scale for the quantity being calculated. These errors can, however, be reduced by adding corresponding operators to the lattice action and tuning their coefficients to eliminate the dimension-six operators in the effective action to a given order in perturbation theory or even non-perturbatively. This is the idea of the Symanzik improvement program [5]. In the case of the gauge action, one adds Wilson loops involving six gauge links (as opposed to the four links needed for the original plaquette action, Eq. (17.1)) to define the $\mathcal{O}(a^2)$ improved (or "Symanzik") action [6]. In practical implementations, the improvement is either at tree-level (so that residual errors are proportional to $\alpha_s a^2$, where the coupling is evaluated at a scale $\sim 1/a$), or at one-loop order (errors proportional to $\alpha_s^2 a^2$). Another popular choice is motivated by studies of renormalization group (RG) flow. It has the same terms as the $\mathcal{O}(a^2)$ improved action but with different coefficients, and is called the RG-improved or "Iwasaki" action [7].

17.1.2 *Lattice fermions*

Discretizing the fermion action turns out to involve subtle issues, and the range of actions being used is more extensive than for gauge fields. Recall that the continuum fermion action is $S_f = \int d^4x \bar{q}[D_\mu\gamma_\mu + m_q]q$, where $D_\mu = \partial_\mu + iA_\mu$ is the gauge-covariant derivative. The simplest discretization replaces the derivative with a symmetric difference:

$$D_\mu q(x) \longrightarrow \frac{1}{2a}[U_\mu(x)q(x+a\hat{\mu}) - U_\mu(x-a\hat{\mu})^\dagger q(x-a\hat{\mu})] \,. \tag{17.3}$$

The factors of U_μ ensure that $D_\mu q(x)$ transforms under gauge transformations in the same way as $q(x)$, so that the discretized version of $\bar{q}(x)\gamma_\mu D_\mu q(x)$ is gauge invariant. The choice in Eq. (17.3) leads to the so-called naive fermion action. This, however, suffers from the fermion doubling problem—in d dimensions it describes 2^d equivalent fermion fields in the continuum limit. The appearance of the extra "doubler" fermions is related to the deeper theoretical problem of formulating chirally symmetric fermions on the lattice. This is encapsulated by the Nielsen-Ninomiya theorem [8]: one cannot define lattice fermions having exact chiral symmetry of the standard form $\delta q = \epsilon\gamma_5 q$, $\delta\bar{q} = \epsilon\bar{q}\gamma_5$ (ϵ is infinitesimal) without producing doublers. Naive lattice fermions do have chiral symmetry but at the cost of introducing 15 unwanted doublers (for $d = 4$).

There are a number of different strategies for dealing with the doubling problem, each with their own theoretical and computational advantages and disadvantages. Wilson fermions [1] add a term proportional to $a\bar{q}\Delta q$ to the fermion action (the "Wilson term"—in which Δ is a covariant lattice Laplacian). This gives a mass of $\mathcal{O}(1/a)$ to the doublers, so that they decouple in the continuum limit. The Wilson term, however, violates chiral symmetry at non-zero lattice spacing, and introduces discretization errors linear in a. A commonly used variant that eliminates the $\mathcal{O}(a)$ discretization error is the $\mathcal{O}(a)$-improved Wilson (or "clover") action [9]. In this application of Symanzik improvement, methods have been developed to remove $\mathcal{O}(a)$ terms non-perturbatively using auxiliary simulations to tune parameters [10]. Such "non-perturbative improvement" is of great practical importance as it brings the discretization error from the fermion action down to the same level as that from the gauge action.

The advantages of Wilson fermions are their theoretical simplicity and relatively low computational cost. Their main disadvantage is the lack of chiral symmetry, which makes them difficult to use in cases where mixing with wrong chirality operators can occur, particularly if this involves divergences proportional to powers of $1/a$. A related problem is the presence of potential numerical instabilities due to spurious near-zero modes of the lattice Dirac operator. There are, however, studies that successfully ameliorate the problems due to the lack of chiral symmetry and increase the range of quantities for which Wilson fermions can be used (see, e.g., Refs. [11–13]).

Twisted-mass fermions [14] are a variant of Wilson fermions in which two flavors are treated together with an isospin-breaking mass term (the "twisted mass" term). The main advantage of this approach is that all errors linear in a are automatically removed (without the need for tuning of parameters) by a clever choice of twisted mass and operators [15]. A disadvantage is the presence of isospin breaking effects (such as a splitting between charged and neutral pion masses even when up and down quarks are degenerate), which, however, vanish as $a^2\Lambda^2$ in the continuum limit. Strange and charm quarks can be added as a second pair, with a term added to split their masses [16, 17].

Staggered fermions are a reduced version of naive fermions in which there is only a single fermion Dirac component on each lattice site, with the full Dirac structure built up from neighboring sites [18]. They have the advantages of being somewhat faster to simulate than Wilson-like fermions, of preserving some chiral symmetry, and of having discretization errors of $\mathcal{O}(a^2)$. Their disadvantage is that they retain some of the doublers (3 for $d = 4$). The action thus describes four degenerate fermions in the continuum limit. These are usually called "tastes", to distinguish them from physical flavors, and the corresponding SU(4) symmetry is referred to as the "taste symmetry". The preserved chiral symmetry in this formulation has non-singlet taste. Practical applications usually introduce one staggered fermion for each physical flavor, and remove contributions from the unwanted tastes by taking the fourth-root of the fermion determinant appearing in the path integral. The validity of this "rooting" procedure is not obvious because taste symmetry is violated for non-zero lattice spacing. Theoretical arguments, supported by numerical evidence, suggest that the procedure is valid as long as one takes the continuum limit before approaching the light quark mass region [19]. Additional issues arise for the valence quarks (those appearing in quark propagators, as described in Sec. 17.2 below), where rooting is not possible, and one must ignore the extra tastes, or account for them by including appropriate factors [20], which can be nontrivial in applications involving baryons [21].

Just as for Wilson fermions, the staggered action can be improved, so as to reduce discretization errors. The Asqtad (*a*-

squared tadpole improved) action [22] was used until recently in many large scale simulations [23]. More recent calculations use the HISQ (highly improved staggered quark) action, introduced in Ref. [24]. At tree-level it removes both $\mathcal{O}(a^2)$ errors and, to lowest order in the quark speed v/c, $\mathcal{O}([am]^4)$ errors. It also substantially reduces effects caused by taste-symmetry breaking. This makes it attractive not only for light quarks, but means that it is also quite accurate for heavy quarks because it suppresses $(am)^n$ errors. It is being used to directly simulate charm quarks and to approach direct simulations of bottom quarks (for early studies, see, e.g., [25–27]).

There is an important class of lattice fermions, "Ginsparg-Wilson fermions," that possess a continuum-like chiral symmetry without introducing unwanted doublers. The lattice Dirac operator D for these fermions satisfies the Ginsparg-Wilson relation $D\gamma_5 + \gamma_5 D = aD\gamma_5 D$ [28]. In the continuum, the right-hand-side vanishes, leading to chiral symmetry. On the lattice, it is non-vanishing, but with a particular form (with two factors of D) that restricts the violations of chiral symmetry in Ward-Takahashi identities to short-distance terms that do not contribute to physical matrix elements [29]. In fact, one can define a modified chiral transformation on the lattice (by including dependence on the gauge fields) such that Ginsparg-Wilson fermions have an exact chiral symmetry for on-shell quantities [30]. The net result is that such fermions essentially have the same properties under chiral transformations as do continuum fermions, including the index theorem [29]. Their leading discretization errors are of $\mathcal{O}(a^2)$.

Two types of Ginsparg-Wilson fermions are currently being used in large-scale numerical simulations. The first is Domain-wall fermions (DWF). These are defined on a five-dimensional space, in which the fifth dimension is fictitious [31]. The action is chosen so that the low-lying modes are chiral, with left- and right-handed modes localized on opposite four-dimensional surfaces. For an infinite fifth dimension, these fermions satisfy the Ginsparg-Wilson relation. In practice, the fifth dimension is kept finite, and there remains a small, controllable violation of chiral symmetry. The second type is Overlap fermions. These appeared from a completely different context and have an explicit form that exactly satisfies the Ginsparg-Wilson relation [32]. Their numerical implementation requires an approximation of the matrix sign function of a Wilson-like fermion operator, and various approaches are being used. In fact, it is possible to rewrite these approximations in terms of a five-dimensional formulation, showing that the DWF and Overlap approaches are essentially equivalent [33, 34]. Numerically, the five-dimensional approach appears to be more computationally efficient.

The various lattice fermion formulations are often combined with the technique of link smearing. Here one couples the fermions to a smoother gauge link, defined by averaging with adjacent links in a gauge invariant manner. Several closely related implementations are being used. All reduce the coupling of fermions to the short-distance fluctuations in the gauge field, leading to an improvement in the numerical stability and speed of algorithms. One cannot perform this smearing too aggressively, however, since the smearing may distort short distance physics and enhance discretization errors.

As noted above, each fermion formulation has its own advantages and disadvantages. For instance, domain-wall and overlap fermions are theoretically preferred as they have chiral symmetry without doublers, but their computational cost is greater than for other choices. If the physics application of interest and the target precision do not require near-exact chiral symmetry, there is no strong motivation to use these expensive formulations. On the other hand, there is a class of applications (including the calculation of the $\Delta I = 1/2$ amplitude for $K \to \pi\pi$ decays [35–37] and the S-parameter [38]) where chiral symmetry plays an essential role and for which the use of Ginsparg-Wilson fermions is strongly favored.

17.1.3 *Heavy quarks on the lattice*

The fermion formulations described in the previous subsection can be used straightforwardly only for quarks whose masses are small compared to the lattice cutoff, $m_q \lessapprox 1/a$. This is because there are discretization errors proportional to powers of am_q, and if $am_q \gtrapprox 1$ these errors are large and uncontrolled. Present LQCD simulations typically have cutoffs in the range of $1/a$ = 2–5 GeV (corresponding to $a \approx 0.1$–0.04 fm). Thus, while for the up, down and strange quarks one has $am_q \ll 1$, for bottom quarks (with $m_b \approx 4.5$ GeV) one must use alternative approaches. Charm quarks ($m_c \approx 1.5$ GeV) are an intermediate case, allowing simulations using both direct and alternative approaches, although increasingly the direct approach is being used.

For the charm quark, the straightforward approach is to simultaneously reduce the lattice spacing and to improve the fermion action so as to reduce the size of errors proportional to powers of am_c. This approach has been followed successfully using the HISQ, twisted-mass and domain-wall actions [24, 25, 27, 39–41]. It is important to note, however, that reducing a increases the computational cost because an increased number of lattice points are needed for the same physical volume. One cannot reduce the spatial size below 2–3 fm without introducing significant finite volume errors. Present lattices have typical sizes of $\sim 64^3 \times 128$ (with the long direction being Euclidean time), and thus allow a lattice cutoff up to $1/a \sim$ 4–6 GeV.

This approach can, to some extent, be extended to the bottom quark, by the use of simulations with small lattice spacings [26,42]. This has been pursued with the HISQ action [43], using lattices of size up to $144^3 \times 288$ and lattice spacings down to $a \approx 0.03$ fm ($1/a \approx 6.6$ GeV). Extrapolation in m_b is still needed [44], however, and this makes use of the mass dependence predicted by Heavy Quark Effective Theory (HQET). Small lattice spacings are also helpful for the simulations of quarkonium for which a different heavy-quark mass scaling is expected. See Ref. [45] for a recent study.

Alternative approaches for discretizing heavy quarks are motivated by effective field theories. For a bottom quark in heavy-light hadrons, one can use HQET to expand about the infinite quark-mass limit. In this limit, the bottom quark is a static color source, and one can straightforwardly write the corresponding lattice action [46]. Corrections, proportional to powers of $1/m_b$, can be introduced as operator insertions, with coefficients that can be determined non-perturbatively using existing techniques [47]. This method allows the continuum limit to be taken controlling all $1/m_b$ corrections.

Another way of introducing the $1/m_b$ corrections is to include the relevant terms in the effective action. This leads to a non-relativistic QCD (NRQCD) action, in which the heavy quark is described by a two-component spinor [48]. This approach has the advantage over HQET that it can also be used for heavy-heavy systems, such as the Upsilon states. Moreover, the bottom quark can be treated without any extrapolation in m_b. A disadvantage is that some of the parameters in this effective theory are determined perturbatively (at tree-level or at one-loop [49]), which limits the precision of the final results. Although discretization effects can be controlled with good numerical precision for a range of lattice spacings, these artifacts cannot be extrapolated away by taking the lattice spacing to zero. This is because NRQCD is a non-relativistic effective field theory and so ceases to work when the cutoff π/a becomes much larger than the heavy-quark mass. In practice these effects are accounted for in the error budget.

This problem can be avoided if one uses HQET power counting to analyze and reduce discretization effects for heavy quarks while using conventional fermion actions [50]. For instance, one can tune the parameters of an improved Wilson quark action so that the leading HQET corrections to the static quark limit are correctly accounted for. As the lattice spacing becomes finer, the action smoothly goes over to that of a light Wilson quark action, where the continuum limit can be taken as usual. In principle, one can improve the action in the heavy quark regime up to arbitrarily high orders using HQET, but so far large-scale simulations have typically used clover improved Wilson quarks, where tuning the parameters of the action corresponds to including all corrections through next-to-leading order in HQET. Three different methods for tuning the parameters of the clover action are being used: the Fermilab [50], Tsukuba [51] and Columbia [52] approaches. An advantage of this HQET approach is that the c and b quarks can be treated on the same footing. Parameter tuning has been done

perturbatively, as in NRQCD, or using non-perturbative tuning of some of the parameters [53,54]. One can improve the effective theory including the terms beyond the next-to-leading order. The Oktay-Kronfeld action that includes dimension-six and -seven operators has been constructed [55] and used in large-scale numerical calculations [56].

Another approach is the "ratio method" introduced in Ref. [57]. Here one uses quarks with masses lying at, or slightly above, the charm mass m_c, which can be simulated with a relativistic action, and extrapolates to m_b incorporating the behavior predicted by HQET. The particular implementation relies on the use of ratios. As an example, consider the B meson decay constant f_B. According to HQET, this scales as $1/\sqrt{m_B}$ for $m_B \gg \Lambda_{\rm QCD}$, up to a logarithmic dependence that is calculable in perturbative QCD (but will be suppressed in the following). Here m_B is the B meson mass, which differs from m_b by $\sim \Lambda_{\rm QCD}$. One considers the ratio $y(\lambda, m_{b'}) \equiv f_{B''}\sqrt{m_{B''}}/f_{B'}\sqrt{m_{B'}}$ for fictitious B mesons containing b quarks with unphysical masses $m_{b'}$ and $m_{b''} = \lambda m_{b'}$. HQET implies that $y(\lambda, m_{b'})$ approaches unity for large $m_{b'}$ and any fixed $\lambda > 1$. The ratios are evaluated on the lattice for the sequence of masses $m_{b'} = m_c$, λm_c, $\lambda^2 m_c$, all well below the physical m_b, and for each the continuum limit is taken. The form of the ratio for larger values of $m_{b'}$ is obtained by fitting, incorporating the constraints implied by HQET. The result for $f_B\sqrt{m_B}$ is then obtained as a product of y's with $f_D\sqrt{m_D}$ [58].

17.1.4 *QED on the lattice*

Quarks in nature are electrically charged, and the resultant coupling to photons leads to shifts in the properties of hadrons that are generically of $\mathcal{O}(\alpha_{\rm EM})$. Thus, for example, the proton mass is increased by ~ 1 MeV relative to that of the neutron due to its overall charge although this effect is more than compensated for by the ~ 2.5 MeV relative decrease due to the up quark being lighter than the down quark [59]. This example shows that once pure QCD, isospin-symmetric lattice calculations reach percent-level accuracy, further improvement requires the inclusion of effects due to both electromagnetism and the up-down mass difference. This level of accuracy has in fact been obtained for various quantities, e.g., light hadron masses and decay constants (see Ref. [60]), and simulations including isospin-breaking and QED effects are becoming more common.

One approach for including QED is to treat electromagnetic gauge fields in a similar fashion to those of QCD. This extension is straightforward, although some new subtleties arise. The essential change is that the quark must now propagate through a background field containing both gluons and photons. The gauge field U_μ that appears in the covariant derivative of Eq. (17.3) is extended from an SU(3) matrix to one living in U(3): $U_\mu \to U_\mu e^{iaqeA_\mu^{\rm EM}}$. Here $A_\mu^{\rm EM}$ is the photon field, e the electromagnetic coupling, and q the charge of the quark, e.g., $q = 2/3$ for up and $-1/3$ for down and strange quarks. The lattice action for the photon that is typically used is a discretized version of the continuum action Eq. (17.2), rather than the form used for the gluons, Eq. (17.1). This "non-compact" action has the advantage that it is quadratic in $A_\mu^{\rm EM}$, which simplifies the QED part of the generation of configurations.

One subtlety that arises is that Gauss' law forbids a charged particle in a box with periodic boundary conditions. This can be overcome by including a uniform background charge, which can be shown to be equivalent to removing the zero-momentum mode from the photon field, an approach denoted QED$_L$ [61]. However, this modification leads to enhanced finite-volume dependence for physical quantities, scaling as $1/L^n$ with $n = 1, 2, \cdots$. This should be compared to the $\exp(-m_\pi L)$ dependence expected for many quantities (as discussed in Sec. 17.1.6.2 below). Methods to remove the leading few powers of $1/L$ have been developed [62,63], and there is a promising alternative approach in which QED effects are calculated analytically in infinite volume [64]. Finally we note that there is an alternative approach using so-called C^* boundary conditions that avoids the Gauss' law issue altogether, although the numerical application is still at an early stage [65,66].

Substantial progress on including QED and isospin-breaking effects has been made over the last few years. The direct approach of using different up and down-quark masses and simulating QED has been successfully carried out for a range of quark masses approaching the physical values [59, 67–69]. Alternative approaches have also been used: reweighting the QCD fields *a posteriori* [70], using a massive photon [71], and keeping only the linear term in an expansion in $\alpha_{\rm EM}$ about the QCD only case [72, 73], with the latter approach by now the most popular. Most calculations to date have included QED effects for the valence quarks but not the sea quarks (the "electro-quenched approximation"). [41, 74–77].

The QED corrections to processes including leptons, such as the leptonic and semileptonic decays of hadrons, involve additional diagrams in which a photon propagator bridges between a hadron and a lepton. Such diagrams induce infrared divergences that cancel against soft photon radiation (Bloch-Nordsieck theorem [78]). Methods have been developed to implement this cancellation in lattice calculations, treating the soft photon analytically [62], and results have been reported for leptonic pion and kaon decays [79–81]. An application to semi-leptonic decays has been developed [64, 82].

17.1.5 *Basic inputs for lattice calculations*

Since LQCD is nothing but a regularization of QCD, the renormalizability of QCD implies that the number of input parameters in LQCD is the same as for continuum QCD—the strong gauge coupling $\alpha_s = g^2/(4\pi)$, the quark masses for each flavor, and the CP violating phase θ. The θ parameter is usually assumed to be zero, while the other parameters must be determined using experimental inputs.

17.1.5.1 *Lattice spacing*

In QCD, the gauge coupling is a function of scale. With lattice regularization, this scale is the inverse lattice spacing $1/a$, and choosing the bare gauge coupling is equivalent to fixing the lattice spacing.

In principle, a can be determined using any dimensionful quantity measured accurately by experiments. For example, using the mass of hadron H one has $a = (am_H)^{\rm lat}/m_H^{\rm exp}$. One chooses quantities that can be calculated accurately on the lattice, and that are only weakly dependent on the quark masses. The latter property minimizes errors from extrapolating or interpolating to the physical light quark masses or from mistuning of other quark masses.

Commonly used choices are the spin-averaged 1S-1P or 1S-2S splittings in the Upsilon system, the masses of the Ξ and Ω^- baryons, and the pion decay constant f_π. Ultimately, all choices must give consistent results for a, and that this is the case provides a highly non-trivial check of both the calculational method and of QCD.

Many recent lattice calculations use intermediate length scales in place of a direct determination of the lattice spacing. These length scales, which we denote $\mathcal{R}$, have the advantage that they can be precisely, and relatively cheaply, computed numerically. Examples are r_0, derived from the heavy quark potential [83], and t_0 and w_0, determined from the gradient flow of the gauge field [84]. These scales are used in the following manner, explained here in the context of calculating a quantity Q with mass dimension d (e.g. a decay constant for which $d = 1$). In the first step, one calculates the dimensionless quantities $a^d Q$ and $\mathcal{R}/a$ in a given lattice calculation, and forms the product $(a^d Q)\times(\mathcal{R}/a)^d = Q\mathcal{R}^d$. In a second step, one uses results available from previous dedicated lattice calculations that have determined $\mathcal{R}$ in physical units (i.e. fm) by relating them to physical quantities as discussed above. Then one obtains $Q = (Q\mathcal{R}^d)/\mathcal{R}^d$. The use of intermediate quantities is reviewed in the latest edition of the Flavor Lattice Averaging Group (FLAG) report [85].

17.1.5.2 *Light quark masses*

In LQCD simulations, the up, down and strange quarks are usually referred to as the light quarks, in the sense that $m_q < \Lambda_{\rm QCD}$. (The standard definition of $\Lambda_{\rm QCD}$ is given in the "Quantum Chromodynamics" review; in this review we are using it only to indicate the approximate non-perturbative scale of QCD.) This condition is stronger than that used above to distinguish quarks with small discretization errors, $m_q < 1/a$. Loop effects from light quarks must be included in the simulations to accurately represent QCD.

At present, most simulations are done in the isospin symmetric limit $m_u = m_d \equiv m_\ell < m_s$, with charm-quark loops either excluded (referred to as "$N_f = 2+1$" simulations) or included (denoted "$N_f = 2+1+1$" simulations). As noted above, precision is now reaching the point where isospin breaking effects must be included. To do so without approximation requires simulating with non-degenerate up and down quarks (leading to $N_f = 1+1+1$ or $1+1+1+1$ simulations) as well as including electromagnetism (as described above).

We now describe the tuning of m_ℓ, m_s and m_c to their physical values. (For brevity, we ignore isospin violation in the following discussion.) The most commonly used quantities for these tunings are, respectively, m_π, m_K and m_{η_c}. If the scale is being set by m_Ω, then one adjusts the lattice quark masses until the ratios m_π/m_Ω, m_K/m_Ω and m_{η_c}/m_Ω take their physical values. In the past, most calculations needed to extrapolate to the physical value of m_ℓ (typically using forms based on chiral perturbation theory [ChPT]), while simulating directly at or near to the physical values of m_s and m_c. Present calculations are increasingly done with physical or near physical values of m_ℓ, requiring at most only a short extrapolation or interpolation.

17.1.5.3 *Heavy quark masses*

The b quark is usually treated only as a valence quark, with no loop effects included. The errors introduced by this approximation can be estimated to be $\sim \alpha_s(m_b)\Lambda^2_{\rm QCD}/m_b^2$ and are likely to be very small. In the past, the same approximation has been made for the c quark, leading to errors $\sim \alpha_s(m_c)\Lambda^2_{\rm QCD}/m_c^2$. (See Ref. [86] for a quantitative estimate of the effects of including the charm quark on some low energy physical quantities, and Ref. [87] for similar estimates for B-meson matrix elements.) For high precision, however, dynamical charm quarks are necessary, and some of the most recent simulations now include them.

The b quark mass can be tuned by setting heavy-heavy (Υ) or heavy-light (B) meson masses to their experimental values. Consistency between these two determinations provides an important check that the determination of parameters in the heavy quark lattice formulations is being done correctly (see, e.g., Ref. [26,88,89]). For instance, the b quark masses obtained from heavy-light [44] and heavy-heavy [77] mesons are in excellent agreement within the precision of 0.5%.

17.1.6 *Sources of systematic error*

Lattice results have statistical and systematic errors that must be quantified for any calculation in order for the result to be a useful input to phenomenology. The statistical error is due to the use of Monte Carlo importance sampling to evaluate the path integral (a method discussed below). There are, in addition, a number of systematic errors that are always present to some degree in lattice calculations, although the size of any given error depends on the particular quantity under consideration and the parameters of the ensembles being used. The most common lattice errors are reviewed below.

Although not strictly a systematic error, it is important to note that the presence of long auto-correlations in the sequence of lattice configurations generated by the Monte Carlo method can lead to underestimates of statistical errors [90]. It is known that the global topological charge of the gauge fields decorrelates very slowly with certain algorithms [90, 91]. The effect of poorly sampling topological charge is expected to be most significant for the pion mass and related quantities [92–94]. This issue becomes more relevant as the precision of the final results improves. The problem of slow decorrelation of topology can be mitigated using open boundary conditions, for which the global topological charge is not quantized [95].

17.1.6.1 *Continuum limit*

Physical results are obtained in the limit that the lattice spacing a goes to zero. The Symanzik effective theory (SET) determines the scaling of lattice artefacts with a. Most lattice calculations use improved actions with leading discretization errors of $\mathcal{O}(\alpha_s a\Lambda)$, $\mathcal{O}(a^2\Lambda^2)$, or $\mathcal{O}(\alpha_s a^2\Lambda^2)$, where Λ is a typical momentum scale in the system. Knowledge of the scaling of the leading discretization errors allows controlled extrapolation to $a = 0$ when multiple lattice spacings are available, as in current state-of-the-art calculations. Residual errors arise from the exclusion of sub-leading a dependence from the fits, either that due to prefactors containing powers of $\log(a)$, or from higher powers of a. The former can, in principle, be understood using the SET, and first studies of this have been undertaken [96–98].

For many quantities the typical momentum scale in the system is $\sim \Lambda_{\rm QCD} \approx 300$ MeV. Discretization errors are expected to be larger for quantities involving larger scales, for example form factors or decays involving particles with momenta or masses larger than $\Lambda_{\rm QCD}$.

17.1.6.2 *Infinite volume limit*

LQCD calculations are necessarily carried out in finite space-time boxes, leading to departures of physical quantities (masses, decay constants, etc.) from their measured, infinite volume values. These finite-volume shifts are an important systematic that must be estimated and minimized.

Typical lattices are asymmetric, with N_s points in the three spatial directions and N_t in the (Euclidean) temporal direction. The spatial and temporal sizes in physical units are thus $L_s = aN_s$ and $L_t = aN_t$, respectively. (Anisotropic lattice spacings are also sometimes used, as discussed below in Sec. 17.2.2.) Typically, $L_t \geq 2L_s$, a longer temporal direction being used to allow excited-state contributions to correlators to decay. This means that the dominant impact of using finite volume is from the presence of a finite spatial box.

The highest-precision LQCD calculations are of quantities involving no more than a single strongly-interacting particle in initial and final states. For such quantities, once the volume exceeds about 2 fm (so that the particle is not "squeezed"), the dominant finite-volume effect comes from virtual pions wrapping around the lattice in the spatial directions. This effect is exponentially suppressed as the volume becomes large, roughly as $\sim \exp(-m_\pi L_s)$, and has been estimated using ChPT [99] or other methods [100]. These estimates suggest that finite volume shifts are sub-percent effects when $m_\pi L_s \gtrsim 4$, and most large-scale simulations use lattices satisfying this condition. (See also Sec. 2.1.1 of the FLAG report [85] for more detailed discussion concerning the conditions required to control finite volume effects.) This becomes challenging as one approaches the physical pion mass, for which $L_s \gtrsim 5$ fm is required.

Finite volume errors are usually determined by repeating the simulations on two or more different volumes (with other parameters fixed). If different volumes are not available, the ChPT estimate can be used, often inflated to account for the fact that the ChPT calculation is truncated at some order.

In the future, LQCD calculations involving more than a single hadron will become increasingly precise. Examples include the calculation of resonance parameters and the $K \to \pi\pi$ amplitudes. Finite volume effects are much larger in these cases, with power-law terms (e.g., $1/L_s^3$) in addition to exponential dependence. Indeed, as will be discussed in Sec. 17.2.4, one can use the volume dependence to indirectly extract infinite-volume quantities such as scattering lengths. Doing so, however, requires a set of lattice volumes satisfying $m_\pi L_s \gtrsim 4$ and is thus more challenging than for single-particle quantities.

17.1.6.3 *Chiral extrapolation*

Until recently, an important source of systematic error in LQCD calculations was the need to extrapolate in m_u and m_d (or, equivalently, in m_π). This extrapolation was usually done using functional forms based on ChPT, or with analytic functions, with the difference between different fits used as an estimate of the systematic error, which was often substantial. Increasingly, however, calculations work directly at, or very close to, the physical quark masses. This either removes entirely, or greatly reduces, the uncertainties in the extrapolation, such that this error is subdominant.

17.1.6.4 *Operator matching*

Many of the quantities that LQCD can precisely calculate involve hadronic matrix elements of operators from the electroweak Hamiltonian. Examples include the pion and kaon decay constants, semileptonic form factors and the kaon mixing parameter

B_K (the latter defined in Eq. (17.13)). The operators in the lattice matrix elements are defined in the lattice regularization scheme. To be used in tests of the Standard Model, however, they must be matched to the continuum regularization scheme in which the corresponding Wilson coefficients have been calculated. The only case in which such matching is not needed is if the operator is a conserved or partially conserved current. Similar matching is also needed for the conversion of lattice bare quark masses to those in the continuum $\overline{\rm MS}$ scheme.

Several methods are used to calculate the matching factors: perturbation theory (usually to one- or two-loop order), non-perturbative renormalization (NPR) using Landau-gauge quark and gluon external states [101], NPR using gauge-invariant methods based on the Schrödinger functional [102], NPR using gauge-invariant short-distance hadron correlators [103], and NPR using gauge-invariant heavy-heavy correlators [27,104]. The NPR methods replace truncation errors (which can only be approximately estimated) by statistical and systematic errors that can be determined reliably and systematically reduced.

An issue that arises in some of such calculations (e.g., for quark masses and B_K) is that, using NPR with Landau-gauge quark and gluon external states, one ends up with operators regularized in a MOM-like scheme (or a Schrödinger-functional scheme), rather than the $\overline{\rm MS}$ scheme mostly used for calculating the Wilson coefficients. To make contact with this scheme requires a purely continuum perturbative matching calculation supplemented by the operator product expansion (OPE). (The importance of power corrections is emphasized in [105].) The resultant truncation error of perturbative expansion and OPE can be minimized by pushing up the momentum scale at which the matching is done using step-scaling techniques as part of the NPR calculation [106].

It should also be noted that this final step in the conversion to the $\overline{\rm MS}$ scheme could be avoided if continuum calculations used a MOM-like scheme or if one imposes a renormalization condition for quantities that are calculable both in the $\overline{\rm MS}$ scheme and in LQCD, such as the hadron correlators at short distances (see, e.g., Ref. [107]).

17.2 Methods and status

Once the lattice action is chosen, it is straightforward to define the quantum theory using the path integral formulation. The Euclidean-space partition function is

$$Z = \int [dU] \prod_f [dq_f][d\bar{q}_f] e^{-S_g[U] - \sum_f \bar{q}_f (D[U]+m_f) q_f} \,, \quad (17.4)$$

where link variables are integrated over the SU(3) manifold, q_f and $\bar{q}_f$ are Grassmann (anti-commuting) quark and antiquark fields of flavor f, and $D[U]$ is the chosen lattice Dirac operator with m_f the quark mass in lattice units. Integrating out the quark and antiquark fields, one arrives at a form suitable for simulation:

$$Z = \int [dU] e^{-S_g[U]} \prod_f \det(D[U]+m_f) \,. \quad (17.5)$$

The building blocks for calculations are expectation values of multi-local gauge-invariant operators, also known as "correlation functions",

$$\langle \mathcal{O}(U,q,\bar{q}) \rangle = (1/Z) \int [dU] \prod_f [dq_f][d\bar{q}_f] \mathcal{O}(U,q,\bar{q}) e^{-S_g[U] - \sum_f \bar{q}_f (D[U]+m_f) q_f} \,. \quad (17.6)$$

If the operators depend on the (anti-)quark fields q_f and $\bar{q}_f$, then integrating these fields out leads not only to the fermion determinant but also, through Wick's theorem, to a series of quark "propagators", $(D[U]+m_f)^{-1}$, connecting the positions of the fields.

This set-up allows one to choose, by hand, the masses of the quarks in the determinant (the sea quarks) differently from those in the propagators (valence quarks). This is called "partial quenching", and is used by some calculations as a way of obtaining more data points from which to extrapolate both sea and valence quarks to their physical values.

17.2.1 *Monte-Carlo method*

Since the number of integration variables U is huge ($N_s^3 \times N_t \times 4 \times 8$), direct numerical integration is impractical and one has to use Monte-Carlo techniques. In this method, one generates a Markov chain of gauge configurations (a "configuration" being the set of U's on all links) distributed according to the probability measure $[dU] e^{-S_g[U]} \prod_f \det(D[U]+m_f)$. Once the configurations are generated, expectation values $\langle \mathcal{O}(U,q,\bar{q}) \rangle$ are calculated by averaging over those configurations. In this way the configurations can be used for many different calculations, and there are several large collections of ensembles of configurations (with a range of values of a, lattice sizes and quark masses) that are publicly available through the International Lattice Data Grid (ILDG) [108]. As the number of the configurations, N, is increased, the error decreases as $1/\sqrt{N}$.

The most challenging part of the generation of gauge configurations is the need to include the fermion determinant. Direct evaluation of the determinant is not feasible, as it requires $\mathcal{O}((N_s^3 \times N_t)^3)$ computations. Instead, one rewrites it in terms of "pseudo-fermion" fields ϕ (auxiliary fermion fields with bosonic statistics). For example, for two degenerate quarks one has

$$\det(D[U]+m_f)^2 = \int [d\phi] e^{-\phi^\dagger ((D[U]+m_f)(D[U]+m_f)^\dagger)^{-1} \phi} \,. \quad (17.7)$$

By treating the pseudo-fermions as additional integration variables in the path integral, one obtains a totally bosonic representation. The price one pays is that the pseudo-fermion effective action is highly non-local since it includes the inverse Dirac operator $(D[U]+m_f)^{-1}$. Thus, the large sparse matrix $(D[U]+m)$ has to be inverted every time one needs an evaluation of the effective action.

Present simulations generate gauge configurations using the Hybrid Monte Carlo (HMC) algorithm [109], or variants thereof. This algorithm combines molecular dynamics (MD) evolution [110–112] in a fictitious time (which is also discretized) with a Metropolis "accept-reject" step [113]. It makes a global update of the configuration, and is made exact by the Metropolis step. In its original form it can be used only for two degenerate flavors, but extensions (particularly the rational HMC [114]) are available for single flavors. Considerable speed-up of the algorithms has been achieved over the last two decades using a variety of techniques.

All these algorithms spend the bulk of their computational time on the repeated inversion of $(D[U]+m)$ acting on a source (which is required at every step of the MD evolution). Inversions are done using a variety of iterative algorithms, e.g., the conjugate gradient algorithm. In this class of algorithms, computational cost is determined by the condition number of the matrix, which is the ratio of maximum and minimum eigenvalues. For $(D[U]+m)$ the smallest eigenvalue is $\approx m$, and the cost is inversely proportional to the quark mass. This is a major reason why simulations at the physical light quark masses are challenging.

Algorithmic improvements have significantly reduced this problem. The main idea is to separate different length scales [115,116]. Since the low eigenvalues of $(D[U]+m)$ are associated with long wavelength quark modes, one may project the problem onto that of a coarse-grained lattice by averaging the field within a block of sublattices and carrying out the inversion on this coarse lattice. The result is then fed back to the original lattice as an efficient *preconditioner* for the iterative solver, and the whole procedure may be nested multiple times. Variants of such methods have been implemented, specifically domain-decomposition [117, 118], deflation [119–122] and multigrid [123,124]. They are increasingly used in large-scale lattice simulations.

A practical concern is the inevitable presence of correlations between configurations in the Markov chain. These are characterized by an auto-correlation length in the fictitious MD time. One aims to use configurations separated in MD time by greater than this auto-correlation length. In practice, it is difficult to

measure this length accurately, see, e.g., [125], and this leads to some uncertainty in the resulting statistical errors, as well as the possibility of insufficient equilibration.

The computational cost of gauge generation grows with the lattice volume, $V_{\rm lat} = N_s^3 N_t$, as $V_{\rm lat}^{1+\delta}$. Here $\delta = 1/4$ for the HMC algorithm [126] and can be reduced slightly using modern variants. Such growth with $V_{\rm lat}$ provides a (time-dependent) limit on the largest lattice volumes that can be simulated. At present, the largest lattices being used have $N_s = 144$ and $N_t = 288$ or $N_s = N_T = 160$. Typically, one aims to create an ensemble of $\sim 10^3$ statistically independent configurations at each choice of parameters (a, m_q and $V_{\rm lat}$). For most physical quantities of interest, this is sufficient to make the resulting statistical errors smaller than or comparable to the systematic errors. Recently, the master-field approach is being investigated [13, 127, 128]. It aims to create a large-volume ensemble and repeat the calculation of physical quantities in different small patches of the entire lattice. Translational invariance guarantees that the correct average is obtained with fewer configurations than in the traditional approach, with the advantage of reduced finite-volume effects [129].

In the past, the cost of generating gauge configurations was larger than that of performing "measurements" on those configurations. However, as the number of quantities being calculated and their complexity has increased, the balance has shifted to the point that the total cost of measurements exceeds that of generation. Sharing the configurations, e.g. through the ILDG, has become more common, and a number of groups are utilizing them to compute a wide variety of quantities, as partly covered by the following sections.

17.2.2 *Two-point functions*

One can extract properties of stable hadrons from two-point correlation functions, $\langle O_X(x) O_Y^\dagger(0)\rangle$. Here $O_{X,Y}(x)$ are operators that have non-zero overlaps with the hadronic state of interest $|H\rangle$, *i.e.* $\langle 0|O_{X,Y}(x)|H\rangle \neq 0$. On the lattice, the two-point correlation function can be constructed, using Wick's theorem, from the quark propagators $(D[U] + m_f)^{-1}_{x0}$ from the insertion point of the source operator $O_Y(0)$ to the sink operator $O_X(x)$. An average over gauge configurations yields the estimate of $\langle O_X(x) O_Y^\dagger(0)\rangle$.

One usually Fourier transforms in the spatial directions and considers correlators as a function of Euclidean time:

$$C_{XY}(t;\boldsymbol{p}) = \sum_{\boldsymbol{x}} \langle O_X(t,\boldsymbol{x}) O_Y^\dagger(0)\rangle e^{-i\boldsymbol{p}\cdot\boldsymbol{x}}. \tag{17.8}$$

(Here and throughout this section all quantities are expressed in dimensionless lattice units, so that, for example, $\boldsymbol{p} = a\boldsymbol{p}_{\rm phys}$.) By inserting a complete set of states having spatial momentum $\boldsymbol{p}$, the two-point function can be written as

$$C_{XY}(t;\boldsymbol{p}) = \sum_{i=0}^{\infty} \frac{1}{2E_i(\boldsymbol{p})} \langle 0|O_X(0)|H_i(\boldsymbol{p})\rangle \langle H_i(\boldsymbol{p})|O_Y^\dagger(0)|0\rangle e^{-E_i(\boldsymbol{p})t}, \tag{17.9}$$

where the energy of the i-th state $E_i(\boldsymbol{p})$ appears in the eigenvalue of the Euclidean time evolution operator e^{-Ht}, $e^{-E_i(\boldsymbol{p})t}$. The factor of $1/[2E_i(\boldsymbol{p})]$ is due to the relativistic normalization used for the states. For large enough t, the dominant contribution is that of the lowest energy state $|H_0(\boldsymbol{p})\rangle$:

$$C_{XY}(t) \overset{t\to\infty}{\longrightarrow} \frac{1}{2E_0(\boldsymbol{p})} \langle 0|O_X(0)|H_0(\boldsymbol{p})\rangle \langle H_0(\boldsymbol{p})|O_Y^\dagger(0)|0\rangle e^{-E_0(\boldsymbol{p})t}\,. \tag{17.10}$$

One can thus obtain the energy $E_0(\boldsymbol{p})$, which equals the hadron mass m_H when $\boldsymbol{p} = 0$, and the product of matrix elements $\langle 0|O_X(0)|H_i(\boldsymbol{p})\rangle \langle H_i(\boldsymbol{p})|O_Y^\dagger(0)|0\rangle$.

This method can be used to determine the masses of all the stable (in QCD) mesons and baryons by making appropriate choices of operators. For example, if one uses the axial current, $O_X = O_Y = A_\mu = \bar{d}\gamma_\mu\gamma_5 u$, then one can determine m_{π^+} from the rate of exponential fall-off, and in addition the decay constant f_π from the coefficient of the exponential.

The expression given in (17.9) for the correlator $C_{XY}(t;\boldsymbol{p})$ shows how, in principle, one can determine the energies of the excited hadron states having the same quantum numbers as the operators $O_{X,Y}$, by fitting the correlation function to a sum of exponentials, including both ground-state and excited-state contributions. It is important to do this in order to obtain accurate results for the ground-state parameters. To reliably identify excited-state parameters in practice, one often needs to use a large basis of operators with a variety of overlaps, $\langle 0|O|H\rangle$, with the different states, and to adopt a variational approach, such as that of [130]. Use of an anisotropic lattices in which a_t, the lattice spacing in the time direction, is smaller than its spatial counterpart, a_s, allows more temporal samples of the correlation function at small times where there is a signal for excited states. Using these and and other technical improvements, extensive excited-state spectra have been obtained [131–136].

A complication arises for states with high spins ($j \geq 4$ for bosons) because the spatial rotation group on the lattice is a discrete subgroup of the continuum group SO(3). This implies that lattice operators, even when chosen to lie in irreducible representations of the lattice rotation group, have overlap with states that have a number of values of j in the continuum limit [137]. For example $j = 0$ operators can also create mesons with $j = 4$. Methods to overcome this problem in practice are available [131, 138] and have been used successfully.

The two-point function (17.8) contains, in principle, information on all possible states having the quantum numbers of the operator O. Thus, if O is chosen to be a vector current, it can be used to estimate the hadronic vacuum polarization function contribution to the muon anomalous magnetic moment, as discussed in Sec. 17.3.6.

17.2.3 *Three-point functions*

Hadronic matrix elements needed to calculate semileptonic form factors and neutral meson mixing amplitudes can be computed from three-point correlation functions. We discuss here, as a representative example, the $D \to K$ amplitude. As in the case of two-point correlation functions one constructs operators O_D and O_K having overlap, respectively, with the D and K mesons. We are interested in calculating the matrix element $\langle K|V_\mu|D\rangle$, with $V_\mu = \bar{c}\gamma_\mu s$ the flavor-changing vector current.

To obtain this, we use the three-point correlator

$$C_{KV_\mu D}(t_x, t_y; \boldsymbol{p}) = \sum_{\boldsymbol{x},\boldsymbol{y}} \langle O_K(t_x,\boldsymbol{x}) V_\mu(0) O_D^\dagger(t_y,\boldsymbol{y})\rangle e^{-i\boldsymbol{p}\cdot\boldsymbol{x}}\,, \tag{17.11}$$

and focus on the limit $t_x \to \infty$, $t_y \to -\infty$. In this example we set the D-meson at rest while the kaon carries three-momentum $\boldsymbol{p}$. Momentum conservation then implies that the weak operator V_μ inserts three-momentum $-\boldsymbol{p}$. Inserting a complete set of states between each pair of operators, we find

$$C_{KV_\mu D}(t_x, t_y; \boldsymbol{p}) = \sum_{i,j} \frac{1}{2m_{D_i} 2E_{K_j}(\boldsymbol{p})} e^{-m_{D_i} t_x - E_{K_j}(\boldsymbol{p})|t_y|} \times \langle 0|O_K(0)|K_j(\boldsymbol{p})\rangle \langle K_j(\boldsymbol{p})|V_\mu(0)|D_i(\boldsymbol{0})\rangle \langle D_i(\boldsymbol{0})|O_D^\dagger(0)|0\rangle. \tag{17.12}$$

The matrix element $\langle K_i(\boldsymbol{p})|V_\mu(0)|D_j(\boldsymbol{0})\rangle$ can then be extracted, since all other quantities in this expression can be obtained from two-point correlation functions. Typically, one is interested in the weak matrix elements of ground states, such as the lightest pseudo-scalar mesons. In the limit of large separation between the three operators in Euclidean time, the three-point correlation function yields the weak matrix element of the transition between ground states. The extraction of the ground state is not always straightforward, especially when a significant contribution is expected from states with an extra pion. An example relevant to $B \to \pi\ell\nu$ decay is discussed in Ref. [139].

From (17.12) the matrix element $\langle K_i(\boldsymbol{p})|V_\mu(0)|D_j(\boldsymbol{0})\rangle$ is obtained at several discretized values of momentum $\boldsymbol{p}$, given by a multiple of $2\pi/L$ in each spatial direction. Each momentum corresponds to a certain value of the momentum transfer

$q^2 = (m_D - E_K(\boldsymbol{p}))^2 - \boldsymbol{p}^2$. The restriction on the available momentum can be relaxed by introducing twisted boundary conditions [140–142], which are a generalization of (anti-)periodic boundary conditions in the spatial directions that allows a general $U(1)$ phase upon translation by distance L. The choice of phase leads to a quark momentum that does not have to be a multiple of $2\pi/L$. The method has been applied in a number of lattice calculations.

To interpolate in q^2, the so-called z parametrization [143–146] is often employed. It takes account of the analytic structure of the form factor in the complex q^2 plane, and a polynomial expansion in z is justified.

17.2.4 *Scattering amplitudes and resonances*

The methods described thus far yield matrix elements involving single, stable particles (where by stable we mean here absolutely stable to strong interaction decays). Most of the particles listed in the Review of Particle Properties are, however, unstable—they are resonances decaying into final states consisting of multiple strongly interacting particles. LQCD simulations cannot directly calculate resonance properties, but methods have been developed to do so indirectly for resonances coupled to two-particle final states in the elastic regime, starting from the seminal work of Lüscher [147].

The difficulty faced by LQCD calculations is that, to obtain resonance properties, or, more generally, scattering phase-shifts, one must calculate multi-particle scattering amplitudes in momentum space and put the external particles on their mass-shells. This requires analytically continuing from Euclidean to Minkowski momenta. Although it is straightforward in LQCD to generalize the methods described above to calculate four- and higher-point correlation functions, one necessarily obtains them at a discrete and finite set of Euclidean momenta. Analytic continuation to $p_E^2 = -m^2$ is then an ill-posed and numerically unstable problem. The same problem arises for single-particle states, but can be largely overcome by picking out the exponential fall-off of the Euclidean correlator, as described above. With a multi-particle state there is no corresponding trick, except for two particles at threshold [148], although recent ideas using smeared correlators and advanced spectral-reconstruction methods offer hope for future progress [149, 150].

What LQCD can calculate are the energies of the eigenstates of the QCD Hamiltonian in a finite box. The energies of states containing two stable particles, e.g., two pions, clearly depend on the interactions between the particles. It is possible to invert this dependence and, with plausible assumptions, determine the scattering phase-shifts at a discrete set of momenta from a calculation of the two-particle energy levels for a variety of spatial volumes [147]. This is a challenging calculation, but it has been carried through in several channels with quark masses approaching physical values. Channels studied include $\pi\pi$ (for $I = 2$, 1 and 0), $\bar{K}K$, $K\pi$, $\pi\omega$, $\pi\phi$, KD, DD^*, $B\pi$, and $N\pi$. For recent comprehensive reviews see [151, 152]. Extensions to nucleon interactions are being actively studied [153]. The formalism has been generalized to three particles (both identical and non-degenerate, and including spin) [154], and has been applied in lattice calculations of $3\pi^+$, $2\pi^+ + K^+$, $\pi^+ + 2K^+$, and $3K^*$ systems [155] as well as to the $I = 1$ three-pion channel [156]. For recent reviews, see [152, 157].

It is also possible to extend the methodology to calculate electroweak decay amplitudes to two particles below the inelastic threshold, e.g., $A(K \to \pi\pi)$ [158]. Results for both the $\Delta I = 3/2$ and 1/2 amplitudes with physical quark masses have been obtained [35–37, 159], the former now including a controlled continuum limit [160]. First results for the CP-violating quantity ϵ' have been obtained [35, 36].

Partial extensions of the formalism above the elastic threshold have been worked out, in particular for the case of multiple two-particle channels [161]. Another theoretical extension is to allow the calculation of form factors between a stable particle and a resonance [162] , and between two resonances [163]. The former has been used to calculate the $\gamma\pi \to \rho$ amplitude, albeit for unphysically large quark masses [164, 165], as well as $\gamma K \to K^*$ [166]. Finally, the formalism for using LQCD to calculate electroweak decays or transitions to three particles, e.g $\gamma^* \to 3\pi$ and $K \to 3\pi$, has recently been worked out [167, 168].

While a systematic extension to decays with many multi-particle channels, e.g., hadronic B decays, has, however, yet to be formulated, some interesting new ideas have been proposed [150, 169, 170], including a method to compute inclusive decay rates or cross sections [171, 172]. The latter represents the inclusive processes using the Compton amplitude, in which two currents are inserted and all possible final states are created between the two [150]. The relative weight among different final states depends on the Euclidean time separation between the current, from which one can extract the inclusive rates. First calculations have been reported [173, 174]. A related approach has been recently applied to provide a lattice determination of the inclusive semileptonic τ decay rate [175].

17.2.5 *Status of LQCD simulations*

Until the 1990s, most large-scale lattice simulations were limited to the "quenched" approximation, wherein the fermion determinant is omitted from the path integral. While much of the basic methodology was developed in this era, the results obtained had uncontrolled systematic errors and were not suitable for use in placing precision constraints on the Standard Model. During the 1990s, more extensive simulations including the fermion determinant (also known as simulations with "dynamical" or "sea" quarks) were begun, but with unphysically heavy quark masses ($m_\ell \sim 50 - 100$ MeV), such that the extrapolation to the physical light quark masses was a source of large systematic errors [176]. During the 2000s, advances in both algorithms and computers allowed simulations to reach much smaller quark masses ($m_\ell \sim 10 - 20$ MeV) such that LQCD calculations of selected quantities with all sources of error controlled and small became available. Their results played an important role in constraints on the CKM matrix and other phenomenological analyses. In the last decade, simulations directly at the physical isospin-symmetric light quark masses have become standard, removing the need for a chiral extrapolation and thus significantly reducing the overall error. The present frontier, as noted above, is the inclusion of isospin breaking. This will be needed to push the accuracy of calculations below the percent level.

On a more qualitative level, analytic and numerical results from LQCD have demonstrated that QCD confines color and spontaneously breaks chiral symmetry. Confinement can be seen as a linearly rising potential between heavy quark and anti-quark in the absence of quark loops. Analytically, this can be shown in the strong coupling limit $g_{\rm lat} \to \infty$ [1]. At weaker couplings there are precise numerical calculations of the potential that clearly show that this behavior persists in the continuum limit [177–179].

Chiral symmetry breaking was also demonstrated in the strong coupling limit on the lattice [18, 180], and there have been a number of numerical studies showing that this holds also in the continuum limit. The accumulation of low-lying modes of the Dirac operator, which is the analog of Cooper pair condensation in superconductors, has been observed, yielding a determination of the chiral condensate [181–187]. Many relations among physical quantities that can be derived under the assumption of broken chiral symmetry have been confirmed by a number of lattice groups [188].

17.3 Physics applications

In this section we describe the main applications of LQCD that are both computationally mature and relevant for the determination of particle properties.

A general feature to keep in mind is that, since there are many different choices for lattice actions, all of which lead to the same continuum theory, a crucial test is that results for any given quantity are consistent. In many cases, different lattice calculations are completely independent and often have very different systematic errors. Thus, final agreement, if found, is a highly non-trivial check, just as it is for different experimental measurements.

The number, variety and precision of the calculations has progressed to the point that an international collaboration, FLAG, has been formed, which aims to collect all lattice results of relevance for a variety of phenomenologically interesting quantities

and provide averages of those results that pass appropriate quality criteria. The averages attempt to account for possible correlations between results (which can arise, for example, if they use common gauge configurations). The quantities considered are those we discuss in this section, with the exception of the hadron spectrum, as well as the intermediate scale-setting quantities discussed earlier. The most recent FLAG review is from 2021 [85] (see also older editions, Refs. [60, 188]). The interested reader can consult this review for very extensive discussions of the details of the calculations and of the sources of systematic errors.

We stress that the results we quote below are those obtained using the physical complement of light quarks (i.e. $N_f = 2+1$ or $2+1+1$ simulations).

17.3.1 *Spectrum*

The most basic prediction of LQCD is of the hadron spectrum. Once the input parameters are fixed as described in Sec. 17.1.5, the masses or resonance parameters of all other states can be predicted. This includes hadrons composed of light (u, d and s) quarks, as well as heavy-light and heavy-heavy hadrons. It also includes quark-model exotics (e.g., $J^{PC} = 1^{-+}$ mesons) and glueballs. Thus, in principle, LQCD calculations should be able to reproduce many of the experimental results compiled in the Review of Particle Properties. Doing so would test both that the error budgets of LQCD calculations are accurate and that QCD indeed describes the strong interactions in the low-energy domain. The importance of the latter test can hardly be overstated.

What is the status of this fundamental test? As discussed in Sec. 1.2, LQCD calculations are most straightforward for stable, low-lying hadrons. Calculations of the properties of resonances that can decay into only two particles are more challenging, but are becoming standard in the meson sector, with the frontier being decays involving baryons. As noted above, the formalism for resonances decaying to three particles exists, but has yet to be applied to resonant channels other than in pioneering calculations. It is also more technically challenging to calculate masses of flavor singlet states (which can annihilate into purely gluonic intermediate states) than those of flavor non-singlets, although again algorithmic and computational advances have begun to make such calculations accessible, including first calculations that reach physical quark masses [189].

The present status for light hadrons is that fully controlled results are available for the masses of the octet light baryons, while results with less than complete control are available for the decuplet baryon resonances, the vector meson resonances and the η and η'. This is discussed in the "Quark Model" review—see, in particular, Fig. 15.9. In addition, it has been possible to calculate the isospin splitting in light mesons and baryons (due to the up-down mass difference and the incorporation of QED). There are also extensive results for heavy-light (D and B systems) and heavy-heavy (J/ψ and Υ systems). All present results, which are discussed in the "Quark Model" review, are consistent with experimental values, and several predictions have been made. We refer the reader to that review for references to the relevant work.

17.3.2 *Decay constants and bag parameters*

The pseudo-scalar decay constants can be determined from two-point correlation functions involving the axial-vector current, as discussed in Sec. 17.2.2. The decay constant f_P of a meson P is extracted from the weak matrix element involving the axial-vector current using the definition $\langle 0|A_\mu(x)|P(\boldsymbol{p})\rangle = f_P p_\mu \exp(-ip\cdot x)$, where p_μ is the momentum of P and $A_\mu(x)$ is the axial-vector current. (In practice, results with the smallest errors are obtained using the pseudo-scalar density $P(x) = \bar{q}(x)\gamma_5 q(x)$ instead of $A_\mu(x)$.) Since they are among the simplest quantities to calculate, decay constants provide good benchmarks for lattice methods, in addition to being important inputs for flavor physics phenomenology in their own right. Results from several lattice groups for the pion and kaon decay constants now have sub-percent errors. The decay constants in the charm and bottom sectors, f_D, f_{D_s}, f_B, and f_{B_s}, have also been calculated using the various heavy quark formulations on the lattice outlined in Sec. 17.1.3. The precision has reached sub-percent errors for charmed mesons, and percent-level errors for bottom mesons. Lattice results for all of these decay constants are discussed in detail in the review "Leptonic Decays of Charged Pseudoscalar Mesons."

Another important lattice quantity is the kaon bag parameter, B_K, which is needed to turn the precise measurement of CP-violation in kaon mixing into a constraint on the Standard Model. It is defined by

$$\frac{8}{3} m_K^2 f_K^2 B_K(\mu) = \langle \overline{K}^0 | Q_{\Delta S=2}(\mu) | K^0 \rangle, \tag{17.13}$$

where m_K is the kaon mass, f_K is the kaon decay constant, $Q_{\Delta S=2} = \bar{s}\gamma_\mu(1-\gamma_5)d\bar{s}\gamma_\mu(1-\gamma_5)d$ is the four-quark operator of the effective electroweak Hamiltonian and μ is the renormalization scale. The short distance contribution to the electroweak Hamiltonian can be calculated perturbatively, but the hadronic matrix element parameterized by B_K must be computed using non-perturbative methods. In order to be of use to phenomenology, the renormalization factor of the four-quark operator must be matched to a continuum renormalization scheme, e.g., to $\overline{\rm MS}$, as described in Sec. 17.1.6.4. Determinations with percent-level precision using different fermion actions and $N_f = 2+1$ light sea quarks are now available using DWF [190], staggered fermions [191], DWF valence on staggered sea quarks [192], and Wilson fermions [11]. The results are all consistent, and the present FLAG average is $\hat{B}_K = 0.7625(97)$ [85] for its renormalization group invariant definition (for original papers, see [11, 192–194]).

The bag parameters for B and B_s meson mixing are defined analogously to that for kaon mixing. The B and B_s mesons contain a valence b-quark so that calculations of these quantities must use one of the methods for heavy quarks described above. Calculations have been done using NRQCD [195, 196], the Fermilab formalism [87], and static heavy quarks [197]. All results are consistent. The FLAG averages for the quantities relevant for B_s and B mixing with $N_f = 2+1$, which are based on results from Refs. [87, 195, 197], are $f_{B_s}\sqrt{\hat{B}_{B_s}} = 274(8)$ MeV and $f_B\sqrt{\hat{B}_B} = 225(9)$ MeV, with their ratio (which is somewhat better determined) being $\xi = 1.206(17)$. FLAG also quotes an "average" for $N_f = 2+1+1$, which comes from a single calculation [196] and gives $f_{B_s}\sqrt{\hat{B}_{B_s}} = 256(6)$ MeV $f_B\sqrt{\hat{B}_B} = 211(6)$ MeV, and $\xi = 1.216(16)$. These are consistent with the $N_f = 2+1$ results at the 2σ level. Errors for quantities involving b quarks are typically larger than those for quantities involving only light quarks, although the difference has steadily decreased in recent years.

For the K, D and B systems, one can also consider the matrix elements of four-fermion operators that arise in beyond-the-standard-model (BSM) theories, which can have a different chiral structure. Knowledge of these matrix elements allows one to constrain the parameters of the BSM theories, and is complementary to direct searches at the LHC. Reliable results are now available from lattice calculations, and are reviewed by FLAG in the case of kaon mixing [85]. Complete results for D and B mixing are presented in Ref. [198, 199] and Ref. [87, 200], respectively.

The results for mixing matrix elements are used in the reviews "The CKM Quark-Mixing Matrix," and "$B^0 - \bar{B}^0$ Mixing."

17.3.3 *Form factors ($K \to \pi\ell\nu$, $D \to K\ell\nu$, $B \to \pi\ell\nu$, $B \to D^{(*)}\ell\nu$, etc.)*

Semileptonic decay rates can be used to extract CKM matrix elements once the semileptonic form factors are known from lattice calculations. For example, the matrix element of a pseudo-scalar meson P undergoing semileptonic decay to another pseudo-scalar meson D is mediated by the vector current, and can be written in terms of form factors as

$$\langle D(p_D)|V_\mu|P(p_P)\rangle = f_+(q^2)(p_D+p_P-\Delta)_\mu + f_0(q^2)\Delta_\mu\,, \tag{17.14}$$

where $q = p_D - p_P$, $\Delta_\mu = (m_D^2 - m_P^2)q_\mu/q^2$ and V_μ is the quark vector current. For K and D meson decays, the shapes of the form factors are well determined by experiment and the value of $f_+(q^2)$ at some reference value of q^2 is needed from the lattice in order to extract CKM matrix elements. Lattice calculations of the form factor shapes may provide further consistency checks. Typically, $f_+(q^2)$ dominates the decay rate, since the contribution from $f_0(q^2)$ is suppressed when the final state lepton is light.

The form factor $f_+(0)$ for $K \to \pi\ell\nu$ decays is highly constrained by the Ademollo-Gatto theorem [201] and chiral symmetry. Old estimates using chiral perturbation theory combined with quark models quote sub-percent precision [202], though they suffer from some model dependence. Utilizing the constraint from the vector current conservation that $f_+(0)$ is normalized to unity in the limit of degenerate up and strange quark masses, the lattice calculation can be made very precise and has now matched the precision of the phenomenological estimates [203–210]. The present FLAG average (from $N_f = 2+1+1$ simulations) is $f_+(0) = 0.9698(17)$, based on Refs. [210].

Charmed meson semileptonic decays have been calculated by different groups using methods similar to those used for charm decay constants, and results are steadily improving in precision [211–216]. Charmed baryon decays have also be computed using a similar method [217, 218].

For semileptonic decays involving a bottom quark, one can use HQET or NRQCD to control the discretization errors of the bottom quark. HQET is also used to constrain the extrapolation of the lattice results obtained in the lower heavy-quark mass region using relativistic lattice fermion actions.

The form factors for the semileptonic decay $B \to \pi\ell\nu$ (and the similar decay $B_s \to K\ell\nu$) have been calculated in unquenched lattice QCD by a number of groups [219–228]. These B semileptonic form factors are difficult to calculate at low q^2, *i.e.* when the mass of the B-meson must be balanced by a large pion momentum, in order to transfer a large momentum to the lepton pair. The low q^2 region has large discretization errors and very large statistical errors, while the high q^2 region is much more accessible to the lattice. For experiment, the opposite is true. To combine lattice and experimental results it has proved helpful to use the z-parameter expansion [143–146]. This provides a theoretically constrained parameterization of the entire q^2 range, and allows one to obtain $|V_{ub}|$ without model dependence [229]. Analyticity and unitarity can be used to obtain further constraints, including extra information on susceptibilities relevant to the form factors in the time-like region [146, 230–233].

The semileptonic decays $B \to D\ell\nu$ and $B \to D^*\ell\nu$ (and the similar decays $B_s \to D_s\ell\nu$ and $B_s \to D_s^*\ell\nu$) can be used to extract $|V_{cb}|$ once the corresponding form factors are known. The lattice calculation is most precise at zero recoil since the bulk of the systematic error cancels for appropriate ratios between $B \to D^{(*)}$ and $B \to B$ or $D^{(*)} \to D^{(*)}$ [234]. The unquenched calculation of the $B \to D^{(*)}\ell\nu$ form factor at zero recoil has been performed with various formulations for the heavy quark [235]. Calculations at non-zero recoil have also now been performed to constrain the functional form of the form factor, which can be used to extrapolate the experimental data to the zero-recoil point or to determine $|V_{cb}|$ directly at the non-zero recoil points [42,236–241]. The range of q^2 that can be handled for B-meson decays in lattice QCD is growing as more accurate results become available on finer lattices. Comparison of the shape of the form factors between lattice calculations and experiments factors provides non-trivial cross checks. Semileptonic decays of the Λ_b baryon can also be used to constrain $|V_{cb}|$ and $|V_{ub}|$ using lattice calculations of the relevant form factors [242].

The rare decays $B \to K\ell^+\ell^-$ involve matrix elements similar to those needed for semileptonic decays, Eq. (17.14), except that the vector current V_μ is replaced by the operators $\bar{s}\gamma^\mu(1-\gamma_5)b$ or $\bar{s}\sigma^{\mu\nu}(1+\gamma_5)b$. Lattice calculations of the corresponding form factors involve similar techniques to those for the semileptonic form factors. The range of q^2 for which lattice calculations can be done is being extended, as above, but here there is an intermediate q^2 region where $c\bar{c}$ resonances are present and this must be avoided. Recent lattice calculations [223, 243, 244] suggest some tension with the experimentally observed decay rate. In these calculations, the long-distance contribution from decay chain $b \to sc\bar{c} \to s\ell^+\ell^-$ is ignored. Systematic errors including such long-distance contributions need to be carefully studied before drawing any definite conclusions. A similar study for baryonic decay mode $\Lambda_b \to \Lambda\ell^+\ell^-$ can be found in Ref. [245].

The results discussed in this section are used in the reviews "The CKM Quark-Mixing Matrix," "V_{ud}, V_{us}, the Cabibbo Angle and CKM Unitarity," and "Semileptonic b-hadron decays, determination of V_{cb}, V_{ub}."

17.3.4 *Strong gauge coupling*

As explained in Sec. 17.1.5.1, for a given lattice action, the choice of bare lattice gauge coupling, $g_{\rm lat}$, determines the lattice spacing a. If one then calculates a as described in Sec. 17.1.5.1, one knows the strong gauge coupling in the bare lattice scheme at the scale $1/a$, $\alpha_{\rm lat} = g_{\rm lat}^2/(4\pi)$. This is not, however, useful for comparing to results for α_s obtained from other inputs, such as deep inelastic scattering or jet shape variables. This is because the latter results give α_s in the $\overline{\rm MS}$ scheme, which is commonly used in such analyses, and the conversion factor between the lattice and $\overline{\rm MS}$ schemes is known to converge extremely poorly in perturbation theory. Instead, one must use a method which directly determines α_s on the lattice in a scheme closer to $\overline{\rm MS}$.

Several such methods have been used, all following a similar strategy. One calculates a short-distance quantity K both perturbatively ($K^{\rm PT}$) and non-perturbatively ($K^{\rm NP}$) on the lattice, and requires equality: $K^{\rm NP} = K^{\rm PT} = \sum_{i=0}^{n} c_i \alpha_s^i$. Solving this equation one obtains α_s at a scale related to the quantity being used. Often, α_s thus obtained is not defined in the conventional $\overline{\rm MS}$ scheme, and one has to convert among the different schemes using perturbation theory. Unlike for the bare lattice scheme, the required conversion factors are reasonably convergent. As a final step, one uses the renormalization group to run the resulting coupling to a canonical scale (such as M_Z).

In the work of the HPQCD collaboration [246, 247], the short-distance quantities are Wilson loops of several sizes and their ratios. These quantities are perturbatively calculated through $\mathcal{O}(\alpha_s^3)$ using the V-scheme defined through the heavy quark potential. The coefficients of even higher orders are estimated using the data at various values of a. In addition, this work obtains a result for α_s by matching with $\alpha_{\rm lat}$ in a tadpole-improved scheme that improves convergence.

Another choice of short-distance quantities is to use current-current correlators. Appropriate moments of these correlators are ultraviolet finite, and by matching lattice results to the *continuum* perturbative predictions, one can directly extract the $\overline{\rm MS}$ coupling [248]. The method can be applied for light meson correlators [249–252] as well as heavy meson correlators [40, 247, 253–256]. Yet another choice of short-distance quantity is the static-quark potential, where the lattice result for the potential is compared to perturbative calculations; this method was used to compute α_s within 2+1 flavor QCD [257–262]. There is also a determination of α_s from a comparison of lattice data for the ghost-gluon coupling with that of perturbation theory [263, 264].

With a definition of α_s given using the Schrödinger functional, one can non-perturbatively control the evolution of α_s to high-energy scales, such as 100 GeV, where the perturbative expansion converges very well. This method developed by the ALPHA collaboration [106] has been applied to 2+1-flavor QCD in [265–267].

The various lattice methods for calculating α_s have significantly different sources of systematic error. The FLAG review [85] reports an estimate $\alpha_{\overline{\rm MS}}^{(5)}(M_Z) = 0.1184(8)$, based on Refs. [247, 252, 254, 262, 265, 267–269]. A comparison to other phenomenological determinations can be found in the "Quantum Chromodynamics" review.

17.3.5 *Quark masses*

Once the quark mass parameters are tuned in the lattice action, the remaining task is to convert them to those of the conventional definition. Since the quarks do not appear as asymptotic states due to confinement, the pole mass of the quark propagator is not a physical quantity. Instead, one defines the quark mass after subtracting the ultra-violet divergences in some particular way. The conventional choice is again the $\overline{\rm MS}$ scheme at a canonical scale such as 2 or 3 GeV. Ratios such as m_c/m_s and m_b/m_c are also useful as they are free from multiplicative renormalization (in a mass-independent scheme), and can be computed precisely in lattice QCD, with a precision of 0.2% for m_c/m_s [44] and 0.3% for m_b/m_c [77].

As discussed in Sec. 17.1.6.4, one must convert the lattice bare quark mass to that in the $\overline{\rm MS}$ scheme. Older calculations did so

directly using low-order perturbation theory; most recent calculations use an intermediate NPR method (e.g., RI/MOM or RI/SMOM) which is then converted to the $\overline{\rm MS}$ scheme using three-loop perturbation theory (see, e.g., [41, 190, 270–274]).

Alternatively, one can use a definition based on the Schrödinger functional, which allows one to evolve the quark mass to a high scale non-perturbatively [275, 276], where perturbative matching to the $\overline{\rm MS}$ scheme can be done accurately.

Other approaches available for heavy quarks are to match current-current correlators at short distances calculated on the lattice to those obtained in continuum perturbation theory in the $\overline{\rm MS}$ scheme [40, 77, 247, 253–255], or to use HQET mass relations [273, 277]. This has allowed an accurate determination of m_c and m_b [104, 247, 254].

The ratio method for heavy quarks (discussed earlier) can also be used to determine m_b [278].

Results are summarized in the review of "Quark Masses."

17.3.6 *Other physical quantities of interest*

In some physics applications, one is interested in the two-point correlation function $\langle O_X(x) O_Y^\dagger(0)\rangle$ for all values of the separation x, not just its asymptotic form for large separations (which is used to determine the hadron spectrum as sketched in Sec. 17.2.2). A topical example, related to the evaluation of the Standard Model contribution to the muon anomalous magnetic moment $g-2$, is the hadronic vacuum polarization function $\Pi_{\mu\nu}(x) = \langle V_\mu(x) V_\nu(0)\rangle$ and its Fourier transform $\Pi_{\mu\nu}(q^2)$. Since the lattice is in Euclidean space-time, only space-like momenta, $q^2 = -Q^2 < 0$, are accessible. Nevertheless, this quantity is of significant interest. It determines the running of the QED coupling constant $\alpha_{\rm QED}$, for which non-perturbative effects arise from quark loops. First lattice calculations appeared recently [279, 280]. It is also related by a dispersion relation to the cross section for $e^+e^- \to$ hadrons, and is needed for a first-principles calculation of the "hadronic vacuum polarization" contribution to the muon anomalous magnetic moment a_μ. Following the pioneering work or Ref. [281], there have been many lattice calculations of this contribution. The status as of March 2020 is summarized in the White Paper of the $g-2$ Theory Initiative [282]. More recent calculations are those of Refs. [283–285].

Since the relevant scale is set by the muon mass m_μ, this quantity is most sensitive to the low-energy region $Q^2 \simeq m_\mu^2$ of $\Pi_{\mu\nu}(-Q^2)$, where the long-range contribution of multi-body states become relevant. The lattice calculation is challenging because of this and also because the necessary precision is high (below 0.5%). Many systematic effects must be carefully studied and controlled in order to achieve this precision, including finite volume errors [286], errors from the chiral-continuum extrapolations [285], isospin breaking [287, 288], quark-line disconnected diagrams [288, 289], and QED corrections [288, 290, 291]. One lattice calculation has achieved the required sub-percent precision [283], a level that is comparable to the determination of the HVP contribution using dispersion relations based on e^+e^- scattering data (the "data-driven" approach). The lattice result is in tension with the data-driven approach by 2.1σ. In order to facilitate the comparison among different lattice calculations with controlled systematic errors, the so-called "intermediate window quantity" was introduced [288]. It essentially eliminates short-distance and long-distance contributions to the hadronic vacuum polarization and focuses in the region where the lattice calculation provides the best accuracy. The results from various lattice collaborations [283, 291–293] are in good agreement but disagree with the corresponding data-driven estimate at the level of 3.8σ. This discrepancy between the lattice and data-driven results needs to be understood before drawing any conclusion about new-physics contribution to the muon $g-2$.

Calculations of the light-by-light scattering contribution to a_μ have been performed. These involve the calculations of four-point correlation functions with various external momenta. Ingenious methods to evaluate the contribution to a_μ have been developed by two groups and the results are in good agreement [294].

There are other quantities for which lattice calculations can make a significant contribution to establishing a quantitative understanding of hadronic processes. One example is the long-distance contribution to the neutral kaon mass splitting, ΔM_K. This also requires the evaluation of a four-point function, constructed from the two-point functions described above by the insertion of two electroweak Hamiltonians [295,296]. Another example is the long-distance contribution to ϵ_K, which provides a correction to the contribution of the mixing parameter B_K, and has also be computed recently [297]. Rare kaon decays $K \to \pi\ell^+\ell^-$ and $K \to \pi\nu\bar\nu$ are also important processes for which first lattice studies have appeared [298]. A related process is $\pi^0 \to e^+e^-$, which has recently been studied on the lattice [299]. Radiative leptonic decays $\pi \to \ell\nu\gamma^{(*)}$, $K \to \ell\nu\gamma^{(*)}$, and $D \to \ell\nu\gamma^{(*)}$ also include two operator insertions, i.e. an electroweak Hamiltonian and an electromagnetic current, and similar techniques developed for the rare decays can be applied. First lattice results have appeared [64, 300]. Finally, we note that similar lattice methods allow the calculation of the γW box contribution to the radiative corrections to semileptonic decays of pions and kaons [301]. The extension to neutron β decay is an important next step, as this promises to reduce the theoretical uncertainty in the extraction of $|V_{ud}|$ from neutron decays. Firs results have appeared recently [302].

17.3.7 *Other applications of lattice QCD*

In this review we have concentrated on applications of LQCD that are relevant to the quantities discussed in the Review of Particle Properties. We have not considered at all several other applications that are being actively pursued by simulations. Here we list the major such applications. The reader can consult the aforementioned texts [2–4] for further details, as well as the proceedings of recent lattice conferences [303], and several recent white papers [304]

LQCD can be used, in principle, to simulate QCD at non-zero temperature and density, and in particular to study how confinement and chiral-symmetry breaking are lost as T and μ (the chemical potential) are increased. For example, as T is increased at $\mu = 0$, It is found that, for the physical values of the quark masses, the deconfinement and chiral-symmetry-restoration transitions are smooth crossovers, rather than phase transitions, and that they occur together. This is of relevance to heavy-ion collisions, the early Universe and neutron-star structure. In practice, finite temperature simulations are computationally tractable and relatively mature, while simulations at finite μ suffer from a "sign problem" and are at a rudimentary stage.

Another topic under active investigation is nucleon structure and inter-nucleon interactions. The simplest nucleon matrix elements are calculable with a precision that is now starting to rival that for some mesonic quantities. Of particular interest are those of the axial current (leading to g_A) and of the scalar density (with $\langle N|\bar s s|N\rangle$ needed for dark matter searches), both of which are reviewed by FLAG [85]. Other such matrix elements provide information on the parton distribution functions (PDFs), including their low moments. Recently, methods to directly access PDFs have been developed (see Ref. [305] for a recent review). Also, neutrino-nucleon scattering matrix elements play a crucial role in the estimate of the expected event rate in the current and future neutrino experiments, such as T2K and DUNE. The lattice computation of the matrix elements is similar to those of the meson semi-leptonic decays and the lattice results are reaching the required precision as summarized in [306].

Finally, we note that there is much recent interest in studying QCD-like theories with more fermions, possibly in other representations of the gauge group (see, e.g., [307]). The main interest is to find nearly conformal theories which might be candidates for "walking technicolor" models.

17.4 Outlook

While LQCD calculations have made major strides in the last decade, and are now playing an important role in constraining the Standard Model, there are many calculations that could be done in principle but are not yet mature due to limitations in computational resources. As we move to exascale resources (10^{18} floating point operations per second), the list of mature calculations will grow. Examples that we expect to mature in the next few years

are results for B meson and Λ_b baryon form factors covering the full range of q^2; results for excited hadrons, including quark-model exotics, at close to physical light-quark masses; results for structure functions and related parton distribution functions; results for a variety of nucleon matrix elements; $K \to \pi\pi$ amplitudes (allowing a precise prediction of ϵ'/ϵ from the Standard Model); hadronic vacuum polarization contributions to $g_\mu - 2$, the running of $\alpha_{\rm EM}$ and α_s (the status of the first of which was discussed in Sec. 17.3.6); $\pi \to \gamma\gamma$ and related amplitudes; long-distance contributions to $\overline{K} \leftrightarrow K$ mixing; the light-by-light contribution to $g_\mu - 2$; and determinations of long distance contributions to rare kaon decays such as $K \to \pi\nu\bar{\nu}$. There will also be steady improvement in the precision attained for the mature quantities discussed above. As already noted, for several of these quantities, attaining the desired precision will require the inclusion of isospin-breaking and electromagnetic effects.

17.5 Acknowledgments

We are grateful to Jack Laiho for his collaboration on previous editions of this review, and to Christine Davies, Takashi Kaneko, and Stefan Meinel for comments and suggestions.

18. Structure Functions

Revised August 2023 by E.C. Aschenauer (BNL), R.S. Thorne (UCL) and R. Yoshida (ANL).

18.1 Deep inelastic scattering

High-energy lepton-nucleon scattering plays a key role in determining the partonic structure of the proton. The process $\ell N \to \ell' X$ is illustrated in Fig. 18.1. The filled circle in this figure represents the internal structure of the proton which can be expressed in terms of structure functions.

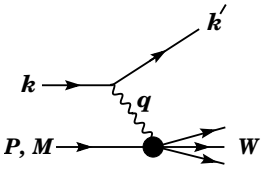

Figure 18.1: Kinematic quantities for the description of deep inelastic scattering. The quantities k and k' are the four-momenta of the incoming and outgoing leptons, P is the four-momentum of a nucleon with mass M, and W is the mass of the recoiling system X. The exchanged particle is a γ, $W^{\pm}$, or Z; it transfers four-momentum $q = k - k'$ to the nucleon.

Invariant quantities:

$\nu = \frac{q\cdot P}{M} = E - E'$ is the lepton's energy loss in the nucleon rest frame (in earlier literature sometimes $\nu = q \cdot P$). Here, E and E' are the initial and final lepton energies in the nucleon rest frame.

$Q^2 = -q^2 = 2(EE' - \overrightarrow{k}\cdot\overrightarrow{k}') - m_\ell^2 - m_{\ell'}^2$ where $m_\ell(m_{\ell'})$ is the initial (final) lepton mass. If $EE'\sin^2(\theta/2) \gg m_\ell^2,\, m_{\ell'}^2$, then

$\approx 4EE'\sin^2(\theta/2)$, where θ is the lepton's scattering angle with respect to the lepton beam direction.

$x = \frac{Q^2}{2M\nu}$ where, in the parton model, x is the fraction of the nucleon's momentum carried by the struck quark. Beyond leading order the equation remains the definition of x, but this is no longer identical to nucleon momentum fraction.

$y = \frac{q\cdot P}{k\cdot P} = \frac{\nu}{E}$ is the fraction of the lepton's energy lost in the nucleon rest frame.

$W^2 = (P+q)^2 = M^2 + 2M\nu - Q^2$ is the mass squared of the system X recoiling against the scattered lepton.

$s = (k+P)^2 = \frac{Q^2}{xy} + M^2 + m_\ell^2$ is the center-of-mass energy squared of the lepton-nucleon system.

The process in Fig. 18.1 is called deep ($Q^2 \gg M^2$) inelastic ($W^2 \gg M^2$) scattering (DIS). In what follows, the masses of the initial and scattered leptons, m_ℓ and $m_{\ell'}$, are neglected.

18.1.1 *DIS cross sections*

The double-differential cross section for deep inelastic scattering can be expressed in terms of kinematic variables in several ways.

$$\frac{d^2\sigma}{dx\,dy} = x\,(s-M^2)\,\frac{d^2\sigma}{dx\,dQ^2} = \frac{2\pi\,M\nu}{E'}\frac{d^2\sigma}{d\Omega_{\rm Nrest}\,dE'}\,. \qquad (18.1)$$

In lowest-order perturbation theory, the cross section for the scattering of polarized leptons on polarized nucleons can be expressed in terms of the products of leptonic and hadronic tensors associated with the coupling of the exchanged bosons at the upper and lower vertices in Fig. 18.1 (see Refs. [1–4])

$$\frac{d^2\sigma}{dxdy} \;=\; \frac{2\pi y\alpha^2}{Q^4}\,\sum_j\,\eta_j\,L_j^{\mu\nu}\,W_{\mu\nu}^j\,. \qquad (18.2)$$

For neutral-current processes, the summation is over $j = \gamma, Z$ and γZ representing photon and Z exchange and the interference between them, whereas for charged-current interactions there is only W exchange, $j = W$. (For transverse nucleon polarization, there is a dependence on the azimuthal angle of the scattered lepton.) The lepton tensor $L_{\mu\nu}$ is associated with the coupling of the exchange boson to the leptons. For incoming leptons of charge $e = \pm 1$ and helicity $\lambda = \pm 1$,

$$\begin{aligned}
L^{\gamma}_{\mu\nu} &= 2\left(k_\mu k'_\nu + k'_\mu k_\nu - (k\cdot k' - m_\ell^2)g_{\mu\nu} - i\lambda\varepsilon_{\mu\nu\alpha\beta}k^\alpha k'^\beta\right),\\
L^{\gamma Z}_{\mu\nu} &= (g_V^e + e\lambda g_A^e)\,L^{\gamma}_{\mu\nu}, \quad L^{Z}_{\mu\nu} = (g_V^e + e\lambda g_A^e)^2\,L^{\gamma}_{\mu\nu},\\
L^{W}_{\mu\nu} &= (1+e\lambda)^2\,L^{\gamma}_{\mu\nu},
\end{aligned} \qquad (18.3)$$

where $g_V^e = -\frac{1}{2} + 2\sin^2\theta_W$, $\quad g_A^e = -\frac{1}{2}$.

Although here the helicity basis is adopted, an alternative approach is to express the tensors in Eq. (18.3) in terms of the polarization of the lepton.

The factors η_j in Eq. (18.2) denote the ratios of the corresponding propagators and couplings to the photon propagator and coupling squared

$$\begin{aligned}
\eta_\gamma &= 1\;;\;\eta_{\gamma Z} = \left(\frac{G_F M_Z^2}{2\sqrt{2}\pi\alpha}\right)\left(\frac{Q^2}{Q^2+M_Z^2}\right);\\
\eta_Z &= \eta_{\gamma Z}^2\;;\;\eta_W = \tfrac{1}{2}\left(\frac{G_F M_W^2}{4\pi\alpha}\,\frac{Q^2}{Q^2+M_W^2}\right)^2.
\end{aligned} \qquad (18.4)$$

The hadronic tensor, which describes the interaction of the appropriate electroweak currents with the target nucleon, is given by

$$W_{\mu\nu} \;=\; \frac{1}{4\pi}\int d^4z\,e^{iq\cdot z}\,\left\langle P,S\left|\left[J_\mu^\dagger(z),J_\nu(0)\right]\right|P,S\right\rangle, \qquad (18.5)$$

where J_α is the hadronic contribution to the electromagnetic, or weak current and S denotes the nucleon-spin 4-vector, with $S^2 = -M^2$ and $S\cdot P = 0$.

18.2 Structure functions of the proton

The structure functions are defined in terms of the hadronic tensor (see Refs. [1–3])

$$\begin{aligned}
W_{\mu\nu} &= \left(-g_{\mu\nu} + \frac{q_\mu q_\nu}{q^2}\right)F_1(x,Q^2) + \frac{\hat{P}_\mu\hat{P}_\nu}{P\cdot q}\,F_2(x,Q^2)\\
&- i\varepsilon_{\mu\nu\alpha\beta}\,\frac{q^\alpha P^\beta}{2P\cdot q}\,F_3(x,Q^2)\\
&+ i\varepsilon_{\mu\nu\alpha\beta}\,\frac{q^\alpha}{P\cdot q}\left[S^\beta g_1(x,Q^2) + \left(S^\beta - \frac{S\cdot q}{P\cdot q}\,P^\beta\right)g_2(x,Q^2)\right]\\
&+ \frac{1}{P\cdot q}\left[\tfrac{1}{2}\left(\hat{P}_\mu\hat{S}_\nu + \hat{S}_\mu\hat{P}_\nu\right) - \frac{S\cdot q}{P\cdot q}\,\hat{P}_\mu\hat{P}_\nu\right]g_3(x,Q^2)\\
&+ \frac{S\cdot q}{P\cdot q}\left[\frac{\hat{P}_\mu\hat{P}_\nu}{P\cdot q}\,g_4(x,Q^2) + \left(-g_{\mu\nu} + \frac{q_\mu q_\nu}{q^2}\right)g_5(x,Q^2)\right]
\end{aligned} \qquad (18.6)$$

where

$$\hat{P}_\mu \;=\; P_\mu - \frac{P\cdot q}{q^2}\,q_\mu, \qquad \hat{S}_\mu \;=\; S_\mu - \frac{S\cdot q}{q^2}\,q_\mu\,. \qquad (18.7)$$

In [2],the definition of $W_{\mu\nu}$ with $\mu \leftrightarrow \nu$ is adopted, which changes the sign of the $\varepsilon_{\mu\nu\alpha\beta}$ terms in Eq. (18.6), although the formulae given below are unchanged. Ref. [1] tabulates the relation between the structure functions defined in Eq. (18.6) and other choices available in the literature.

The cross sections for neutral- and charged-current deep inelastic scattering on unpolarized nucleons can be written in terms of

the structure functions in the generic form

$$\frac{d^2\sigma^i}{dxdy} = \frac{4\pi\alpha^2}{xyQ^2}\,\eta^i\left\{\left(1 - y - \frac{x^2y^2M^2}{Q^2}\right)F_2^i + y^2xF_1^i \mp \left(y - \frac{y^2}{2}\right)xF_3^i\right\}, \tag{18.8}$$

where i = NC, CC corresponds to neutral-current ($eN \to eX$) or charged-current ($eN \to \nu X$ or $\nu N \to eX$) processes, respectively. For incoming neutrinos, $L^W_{\mu\nu}$ of Eq. (18.3) is still true, but with e, λ corresponding to the outgoing charged lepton. In the last term of Eq. (18.8), the $-$ sign is taken for an incoming e^+ or $\overline{\nu}$ and the $+$ sign for an incoming e^- or ν. The factor $\eta^{\rm NC} = 1$ for unpolarized $e^\pm$ beams, whereas

$$\eta^{\rm CC} = (1 \pm \lambda)^2\eta_W \tag{18.9}$$

with $\pm$ for $\ell^\pm$; and where λ is the helicity of the incoming lepton and η_W is defined in Eq. (18.4); for incoming neutrinos $\eta^{\rm CC} = 4\eta_W$. The CC structure functions, which derive exclusively from W exchange, are

$$F_1^{\rm CC} = F_1^W,\ F_2^{\rm CC} = F_2^W,\ xF_3^{\rm CC} = xF_3^W. \tag{18.10}$$

The NC structure functions $F_2^\gamma, F_2^{\gamma Z}, F_2^Z$ are, for $e^\pm N \to e^\pm X$, given by [5],

$$F_2^{\rm NC} = F_2^\gamma - (g_V^e \pm \lambda g_A^e)\eta_{\gamma Z}F_2^{\gamma Z} + ({g_V^e}^2 + {g_A^e}^2 \pm 2\lambda g_V^e g_A^e)\,\eta_Z F_2^Z \tag{18.11}$$

and similarly for $F_1^{\rm NC}$, whereas

$$xF_3^{\rm NC} = -(g_A^e \pm \lambda g_V^e)\eta_{\gamma Z}xF_3^{\gamma Z} + [2g_V^e g_A^e \pm \lambda({g_V^e}^2 + {g_A^e}^2)]\eta_Z xF_3^Z\,. \tag{18.12}$$

The polarized cross-section difference

$$\Delta\sigma = \sigma(\lambda_n = -1, \lambda_\ell) - \sigma(\lambda_n = 1, \lambda_\ell)\,, \tag{18.13}$$

where λ_ℓ, λ_n are the helicities (± 1) of the incoming lepton and nucleon, respectively, may be expressed in terms of the five structure functions $g_{1,\ldots 5}(x, Q^2)$ of Eq. (18.6). Explicitly,

$$\frac{d^2\Delta\sigma^i}{dxdy} = \frac{8\pi\alpha^2}{xyQ^2}\,\eta^i\left\{-\lambda_\ell y\left(2 - y - 2x^2y^2\frac{M^2}{Q^2}\right)xg_1^i + \lambda_\ell 4x^3y^2\,\frac{M^2}{Q^2}\,g_2^i + 2x^2y\frac{M^2}{Q^2}\left(1 - y - x^2y^2\frac{M^2}{Q^2}\right)g_3^i - \left(1 + 2x^2y\frac{M^2}{Q^2}\right)\left[\left(1 - y - x^2y^2\frac{M^2}{Q^2}\right)g_4^i + xy^2g_5^i\right]\right\} \tag{18.14}$$

with i = NC or CC as before. The Eq. (18.13) corresponds to the difference of antiparallel minus parallel spins of the incoming particles for e^- or ν initiated reactions, but the difference of parallel minus antiparallel for e^+ or $\overline{\nu}$ initiated processes. For longitudinal nucleon polarization, the contributions of g_2 and g_3 are suppressed by powers of M^2/Q^2. These structure functions give an unsuppressed contribution to the cross section for transverse polarization [1], but in this case the cross-section difference vanishes as $M/Q \to 0$.

Because the same tensor structure occurs in the spin-dependent and spin-independent parts of the hadronic tensor of Eq. (18.6) in the $M^2/Q^2 \to 0$ limit, the differential cross-section difference of Eq. (18.14) may be obtained from the differential cross section Eq. (18.8) by replacing

$$F_1 \to -g_5\,,\quad F_2 \to -g_4\,,\quad F_3 \to 2g_1\,, \tag{18.15}$$

and multiplying by two, since the total cross section is the average over the initial-state polarizations. In this limit, Eq. (18.8) and Eq. (18.14) may be written in the form

$$\frac{d^2\sigma^i}{dxdy} = \frac{2\pi\alpha^2}{xyQ^2}\,\eta^i\left[Y_+F_2^i \mp Y_-xF_3^i - y^2F_L^i\right],$$

$$\frac{d^2\Delta\sigma^i}{dxdy} = \frac{4\pi\alpha^2}{xyQ^2}\,\eta^i\left[-Y_+g_4^i \mp Y_-2xg_1^i + y^2g_L^i\right], \tag{18.16}$$

with i = NC or CC, where $Y_\pm = 1 \pm (1-y)^2$ and

$$F_L^i = F_2^i - 2xF_1^i\,,\qquad g_L^i = g_4^i - 2xg_5^i\,. \tag{18.17}$$

In the naive quark-parton model, the analogy with the Callan-Gross relations [6] $F_L^i = 0$, are the Dicus relations [7] $g_L^i = 0$. Therefore, there are only two independent polarized structure functions: g_1 (parity conserving) and g_5 (parity violating), in analogy with the unpolarized structure functions F_1 and F_3.

18.2.1 *Structure functions in the quark parton model*

In the naive quark-parton model [8, 9], contributions to the structure functions F^i and g^i can be expressed in terms of the quark distribution functions $q(x, Q^2)$ of the proton, where $q = u, \overline{u}, d, \overline{d}$ etc. The quantity $q(x, Q^2)dx$ is the number of quarks (or antiquarks) of designated flavor that carry a momentum fraction between x and $x + dx$ of the proton's momentum in a frame in which the proton momentum is large. One of the most striking predictions of the quark-parton model is that the structure functions F_i, g_i *scale*, i.e., $F_i(x, Q^2) \to F_i(x)$ in the Bjorken limit that Q^2 and $\nu \to \infty$ with x fixed [10]. This property is related to the assumption that the transverse momentum of the partons in the infinite-momentum frame of the proton is small.

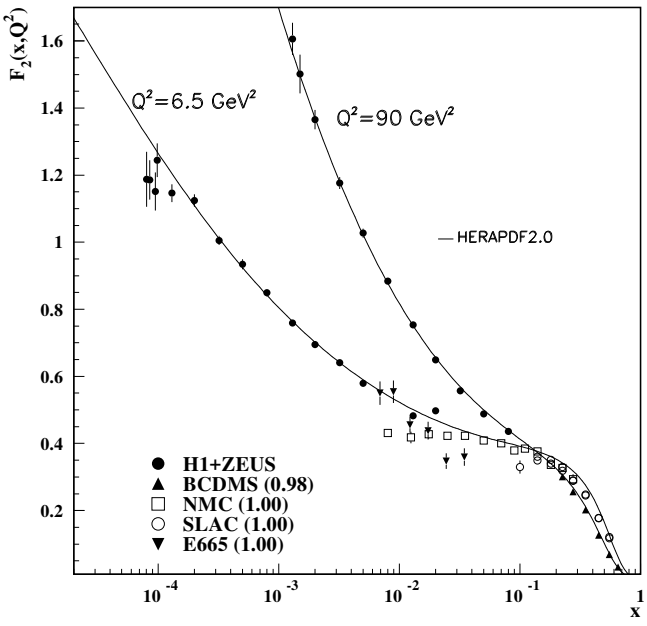

Figure 18.2: The proton structure function F_2^p given at two Q^2 values (6.5 GeV^2 and 90 GeV^2), which exhibit scaling at the 'pivot' point $x \sim 0.14$. See the captions in Fig. 18.10 and Fig. 18.12 for the references of the data. The various data sets have been renormalized by the factors shown in brackets in the key to the plot, which were globally determined in a previous HERAPDF analysis [11]. The curves were obtained using the PDFs from the HERAPDF analysis [12]. In practice, data for the reduced cross section, $F_2(x, Q^2) - (y^2/Y_+)F_L(x, Q^2)$, were fitted, rather than F_2 and F_L separately. The agreement between data and theory at low Q^2 and x can be improved by a positive higher-twist correction to $F_L(x, Q^2)$ [13, 14] (see Fig. 8 of Ref. [14]), or small-x resummation [15, 16].

For the neutral-current processes $ep \to eX$,

$$\begin{aligned}
\left[F_2^\gamma,\ F_2^{\gamma Z},\ F_2^Z\right] &= x\sum_q \left[e_q^2,\ 2e_q g_V^q,\ {g_V^q}^2 + {g_A^q}^2\right]\ (q+\overline{q})\ , \\
\left[F_3^\gamma,\ F_3^{\gamma Z},\ F_3^Z\right] &= \sum_q \left[0,\ 2e_q g_A^q,\ 2g_V^q g_A^q\right]\ (q-\overline{q})\ , \\
\left[g_1^\gamma,\ g_1^{\gamma Z},\ g_1^Z\right] &= \tfrac{1}{2}\sum_q \left[e_q^2,\ 2e_q g_V^q,\ {g_V^q}^2 + {g_A^q}^2\right]\ (\Delta q+\Delta\overline{q})\ , \\
\left[g_5^\gamma,\ g_5^{\gamma Z},\ g_5^Z\right] &= \sum_q \left[0,\ e_q g_A^q,\ g_V^q g_A^q\right]\ (\Delta\overline{q}-\Delta q)\ ,
\end{aligned} \tag{18.18}$$

where $g_V^q = \pm\frac{1}{2} - 2e_q \sin^2\theta_W$ and $g_A^q = \pm\frac{1}{2}$, with $\pm$ according to whether q is a $u-$ or $d-$type quark respectively. The quantity Δq is the difference $q\uparrow - q\downarrow$ of the distributions with the quark spin parallel and antiparallel to the proton spin.

For the charged-current processes $e^- p \to \nu X$ and $\overline{\nu} p \to e^+ X$, the structure functions are:

$$\begin{aligned}
F_2^{W^-} &= 2x(u + \overline{d} + \overline{s} + c\ldots)\ , \\
F_3^{W^-} &= 2(u - \overline{d} - \overline{s} + c\ldots)\ , \\
g_1^{W^-} &= (\Delta u + \Delta\overline{d} + \Delta\overline{s} + \Delta c\ldots)\ , \\
g_5^{W^-} &= (-\Delta u + \Delta\overline{d} + \Delta\overline{s} - \Delta c\ldots)\ ,
\end{aligned} \tag{18.19}$$

where only the active flavors have been kept and where CKM mixing has been neglected. For $e^+ p \to \overline{\nu} X$ and $\nu p \to e^- X$, the structure functions F^{W^+}, g^{W^+} are obtained by the flavor interchanges $d \leftrightarrow u, s \leftrightarrow c$ in the expressions for F^{W^-}, g^{W^-}. The structure functions for scattering on a neutron are obtained from those of the proton by the interchange $u \leftrightarrow d$. For both the neutral- and charged-current processes, the quark-parton model predicts $2xF_1^i = F_2^i$ and $g_4^i = 2xg_5^i$.

Neglecting masses, the structure functions g_2 and g_3 contribute only to scattering from transversely polarized nucleons, and have no simple interpretation in terms of the quark-parton model. They arise from off-diagonal matrix elements $\langle P,\lambda'|[J_\mu^\dagger(z), J_\nu(0)]|P,\lambda\rangle$, where the proton helicities satisfy $\lambda' \neq \lambda$. In fact, the leading-twist contributions to both g_2 and g_3 are both twist-2 and twist-3, which contribute at the same order of Q^2. The Wandzura-Wilczek relation [17] expresses the twist-2 part of g_2 in terms of g_1 as

$$g_2^i(x) \;=\; -g_1^i(x) \;+\; \int_x^1 \frac{dy}{y}\, g_1^i(y)\ . \tag{18.20}$$

However, the twist-3 component of g_2 is unknown. Similarly, there is a relation expressing the twist-2 part of g_3 in terms of g_4. A complete set of relations, including M^2/Q^2 effects, can be found in [18].

18.2.2 *Structure functions and QCD*

In QCD, there are perturbative corrections to the partonic cross sections defining structure functions. Also, the radiation of hard gluons from the quarks violates the assumption that the transverse momentum of the partons is small, leading to logarithmic scaling violations, which are particularly large at small x, see Fig. 18.2. The radiation of gluons produces the evolution of the partons and structure functions. As Q^2 increases, more and more gluons are radiated, which in turn split into $q\overline{q}$ pairs. This process leads both to the softening of the initial quark momentum distributions and to the growth of the gluon density and the $q\overline{q}$ sea as x decreases.

For $Q^2 \gg M^2$, the structure functions satisfy the factorization theorem [19],

$$F_i = \sum_a C_i^a \otimes f_a + \mathcal{O}(M^2/Q^2), \tag{18.21}$$

where $\otimes$ denotes the convolution integral

$$C \otimes f \;=\; \int_x^1 \frac{dy}{y}\, C(y)\, f\left(\frac{x}{y}\right)\ , \tag{18.22}$$

and where the coefficient functions C_i^a, where $a = g$ or q, are given as a power series in α_s. The scale-dependent parton distribution $f_a(x,\mu^2)$ corresponds, at a given x, to the density of parton a in the proton integrated over transverse momentum k_t up to the factorization scale μ. Typically, μ is the scale of the probe Q. For parton distributions x always refers to the nucleon momentum fraction of the parton, whereas for structure functions it retains the definition in Sec. 18.1. The parton evolution in μ is described in QCD by a DGLAP equation (see Refs. [20–23]) which has the schematic form

$$\frac{\partial f_a}{\partial \ln\mu^2} \sim \frac{\alpha_s(\mu^2)}{2\pi}\sum_b (P_{ab} \otimes f_b)\ , \tag{18.23}$$

where the P_{ab}, which describe the parton splitting $b \to a$, are also given as a power series in α_s. Although perturbative QCD can predict, via Eq. (18.23), the evolution of the parton distribution functions from a particular scale, μ_0, these DGLAP equations cannot predict them *a priori* at any particular μ_0. Thus they must be measured at a starting point μ_0 before the predictions of QCD can be compared to the data at other scales, μ. In general, all observables involving a hard hadronic interaction (such as structure functions) can be expressed as a convolution of calculable, process-dependent coefficient functions and these universal parton distributions, e.g. Eq. (18.21).

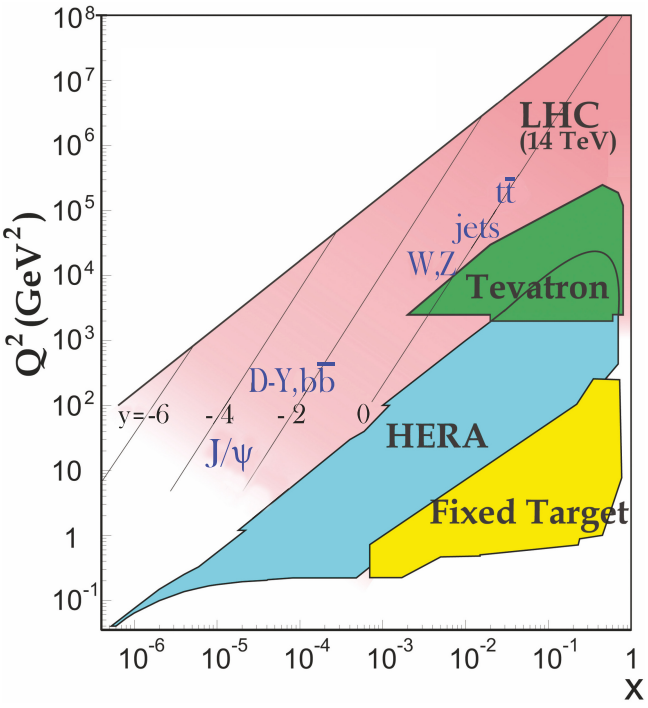

Figure 18.3: Kinematic domains in x and Q^2 probed by fixed-target and collider experiments, where here Q^2 can refer either the literal Q^2 for deep inelastic scattering, or the hard scale of the process in hadron-hadron collisions, e.g. invariant mass or transverse momentum p_T^2. Some of the final states accessible at the LHC are indicated in the appropriate regions, where y is the rapidity. The incoming partons have $x_{1,2} = (Q/14\ \text{TeV})e^{\pm y}$ where Q is the hard scale of the process shown in blue in the figure. For example, open charm production [24] and exclusive J/ψ and Υ production [25] at high $|y|$ at the LHC may probe the gluon PDF down to $x \sim 10^{-5}$.

Table 18.1: The main processes relevant to global PDF analyses, ordered in three groups: fixed-target experiments, HERA and the $p\bar{p}$ Tevatron / pp LHC. For each process we give an indication of their dominant partonic subprocesses, the primary partons which are probed and the approximate range of x constrained by the data. This list expands as more processes are measured and calculated with sufficient precision.

Process	Subprocess	Partons	x range
$\ell^\pm \{p,n\} \to \ell^\pm X$	$\gamma^* q \to q$	$q, \bar{q}, g$	$x \gtrsim 0.01$
$\ell^\pm n/p \to \ell^\pm X$	$\gamma^* d/u \to d/u$	d/u	$x \gtrsim 0.01$
$pp \to \mu^+\mu^- X$	$u\bar{u}, d\bar{d} \to \gamma^*$	$\bar{q}$	$0.015 \lesssim x \lesssim 0.35$
$pn/pp \to \mu^+\mu^- X$	$(u\bar{d})/(u\bar{u}) \to \gamma^*$	$\bar{d}/\bar{u}$	$0.015 \lesssim x \lesssim 0.35$
$\nu(\bar{\nu})\, N \to \mu^-(\mu^+) X$	$W^* q \to q'$	$q, \bar{q}$	$0.01 \lesssim x \lesssim 0.5$
$\nu N \to \mu^-\mu^+ X$	$W^* s \to c$	s	$0.01 \lesssim x \lesssim 0.2$
$\bar{\nu} N \to \mu^+\mu^- X$	$W^* \bar{s} \to \bar{c}$	$\bar{s}$	$0.01 \lesssim x \lesssim 0.2$
$e^\pm p \to e^\pm X$	$\gamma^* q \to q$	$g, q, \bar{q}$	$10^{-4} \lesssim x \lesssim 0.1$
$e^+ p \to \bar{\nu} X$	$W^+ \{d,s\} \to \{u,c\}$	d, s	$x \gtrsim 0.01$
$e^\pm p \to e^\pm c\bar{c}X, e^\pm b\bar{b}X$	$\gamma^* c \to c$, $\gamma^* g \to c\bar{c}$	c, b, g	$10^{-4} \lesssim x \lesssim 0.01$
$e^\pm p \to$ jet$+X$	$\gamma^* g \to q\bar{q}$	g	$0.01 \lesssim x \lesssim 0.1$
$p\bar{p}, pp \to$ jet(dijet)$+X$	$gg, gq, qq \to 2j$	g, q	$0.00005 \lesssim x \lesssim 0.5$
$p\bar{p} \to (W^\pm \to \ell^\pm\nu)\, X$	$ud \to W^+, \bar{u}\bar{d} \to W^-$	$u, d, s, \bar{u}, \bar{d}, \bar{s}$	$x \gtrsim 0.05$
$pp \to (W^\pm \to \ell^\pm\nu)\, X$	$u\bar{d} \to W^+, d\bar{u} \to W^-$	$u, d, s, \bar{u}, \bar{d}, \bar{s}, g$	$x \gtrsim 0.001$
$p\bar{p}(pp) \to (Z \to \ell^+\ell^-)X$	$uu, dd, ..(u\bar{u}, ..) \to Z$	$u, d, s, ..(g)$	$x \gtrsim 0.001$
$pp \to W^- c,\ W^+\bar{c}$	$gs \to W^- c$	$s, \bar{s}$	$x \sim 0.01$
$pp \to (\gamma^* \to \ell^+\ell^-)X$	$u\bar{u}, d\bar{d}, .. \to \gamma^*$	$\bar{q}, g$	$x \gtrsim 10^{-5}$
$pp \to (\gamma^* \to \ell^+\ell^-)X$	$u\gamma, d\gamma, .. \to \gamma^*$	γ	$x \gtrsim 10^{-2}$
$pp \to b\bar{b}\, X,\ \ t\bar{t}X$	$gg \to b\bar{b},\ \ t\bar{t}$	g	$x \gtrsim 10^{-5}, 10^{-2}$
$pp \to t(\bar{t})\, X,$	$bu(\bar{b}d) \to td(\bar{t}u)$	$b, d/u$	$x \gtrsim 10^{-2}$
$pp \to$ exclusive $J/\psi, \Upsilon$	$\gamma^*(gg) \to J/\psi, \Upsilon$	g	$x \gtrsim 10^{-5}, 10^{-4}$
$pp \to \gamma\, X$	$gq \to \gamma q,\ g\bar{q} \to \gamma\bar{q}$	g	$x \gtrsim 0.005$

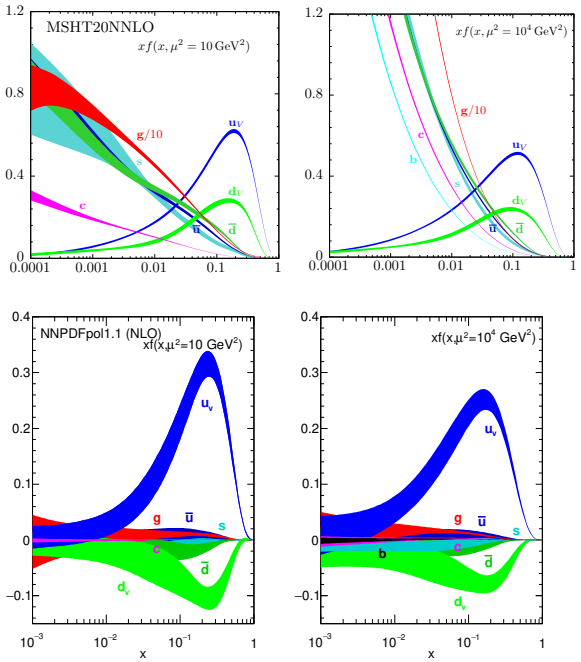

Figure 18.4: The bands are x times the unpolarized parton distributions $f(x)$ (where $f = u_v, d_v, \overline{u}, \overline{d}, s \simeq \bar{s}, c = \bar{c}, b = \bar{b}, g$) obtained in the NNLO MSHT20 global analysis [26] (top) at scales $\mu^2 = 10$ GeV^2 (left) and $\mu^2 = 10^4$ GeV^2 (right), with $\alpha_s(M_Z^2) = 0.118$. The polarized parton distributions $f(x)$ obtained in the NLO NNPDFpol1.1 fit [27] (bottom).

It is often convenient to write the evolution equations in terms of the gluon, non-singlet (q^{NS}) and singlet (q^S) quark distributions, such that

$$q^{NS} \;=\; q_i - \overline{q}_i \quad (\text{or } q_i - q_j), \qquad q^S \;=\; \sum_i (q_i + \overline{q}_i)\ . \quad (18.24)$$

The non-singlet distributions have non-zero values of flavor quantum numbers, such as isospin and baryon number. The DGLAP evolution equations then take the form

$$\frac{\partial q^{NS}}{\partial \ln \mu^2} = \frac{\alpha_s(\mu^2)}{2\pi}\, P_{qq} \otimes q^{NS}\ ,$$

$$\frac{\partial}{\partial \ln \mu^2} \begin{pmatrix} q^S \\ g \end{pmatrix} = \frac{\alpha_s(\mu^2)}{2\pi} \begin{pmatrix} P_{qq} & 2n_f\, P_{qg} \\ P_{gq} & P_{gg} \end{pmatrix} \otimes \begin{pmatrix} q^S \\ g \end{pmatrix}, \quad (18.25)$$

where P are splitting functions that describe the probability of a given parton splitting into two others, and n_f is the number of (active) quark flavors. The leading-order Altarelli-Parisi [22] splitting functions are

$$P_{qq} = \frac{4}{3}\left[\frac{1+x^2}{(1-x)}\right]_+ = \frac{4}{3}\left[\frac{1+x^2}{(1-x)_+}\right] + 2\delta(1-x)\ , \quad (18.26)$$

$$P_{qg} = \frac{1}{2}\left[x^2 + (1-x)^2\right]\ ,\ P_{gq} = \frac{4}{3}\left[\frac{1+(1-x)^2}{x}\right]\ , \quad (18.27)$$

$$P_{gg} = 6\left[\frac{1-x}{x} + x(1-x) + \frac{x}{(1-x)_+}\right] + \left[\frac{11}{2} - \frac{n_f}{3}\right]\delta(1-x), \quad (18.28)$$

where the notation $[F(x)]_+$ defines a distribution such that for any sufficiently regular test function, $f(x)$,

$$\int_0^1 dx f(x)[F(x)]_+ = \int_0^1 dx\ (f(x) - f(1))F(x)\ . \quad (18.29)$$

In general, the splitting functions can be expressed as a power series in α_s. The series contains both terms proportional to $\ln \mu^2$ and to $\ln(1/x)$ and $\ln(1-x)$. The leading-order DGLAP evolution sums up the $(\alpha_s \ln \mu^2)^n$ contributions, while at next-to-leading order (NLO) the sum over the $\alpha_s(\alpha_s \ln \mu^2)^{n-1}$ terms is included [28, 29]. The NNLO contributions to the splitting functions and the DIS coefficient functions are also all known [30–32], as are the N^{3}LO corrections to the coefficient functions [33]. Some Mellin moments of the N^{3}LO splitting functions are also known [34], together with some other pieces of specific information.

In the kinematic region of very small x, one may also sum leading terms in $\ln(1/x)$, independent of the value of $\ln \mu^2$. At leading order, LLx, this is done by the BFKL equation for the unintegrated distributions (see Refs. [35, 36].) The leading-order $(\alpha_s \ln(1/x))^n$ terms result in a power-like growth, $x^{-\omega}$ with $\omega = (12\alpha_s \ln 2)/\pi$, at asymptotic values of $\ln 1/x$. The next-to-leading $\ln 1/x$ (NLLx) contributions are also available [37, 38]. They are so large (and negative) that the results initially appeared to be perturbatively unstable. Methods, based on a combination of collinear and small-x resummations, have been developed which reorganize the perturbative series into a more stable hierarchy [39–42], and this has been used as the basis for a framework for including the corrections in phenomenological studies [43, 44]. There are some limited indications that small-x resummations become necessary for sufficient precision for $x \lesssim 10^{-3}$ at low scales [15, 16]. At sufficiently small x it is expected that evolution should also be affected by non-linear/saturation effects due to a high density of partons, i.e. the gluon density would be so high that gluon-gluon recombination effects would become significant, see [45–47] for reviews. However, there is not yet any very convincing indication for a non-linear regime for $Q^2 \gtrsim 2$ GeV^2 in hadron DIS. Better evidence for saturation may be found in more exclu-

sive final states such as dihadron correlations in proton-nucleus collisions, e.g. [48, 49].

The precision of the experimental data demands that at least NLO, and preferably NNLO, DGLAP evolution be used in comparisons between QCD theory and experiment. Beyond the leading order, it is necessary to specify, and to use consistently, both a renormalization and a factorization scheme. The renormalization scheme used almost universally is the modified minimal subtraction ($\overline{\rm MS}$) scheme [50, 51]. The most popular choices for the factorization scheme is also $\overline{\rm MS}$ [52]. Historically, sometimes the DIS [53] scheme was adopted, in which there are no higher-order corrections to the F_2 structure function, and this was extended to a specific definition appropriate to small x [54]. assimilated in the parton distribution functions.

The discussion above relates to the Q^2 behavior of leading-twist (twist-2) contributions to the structure functions. Higher-twist terms, which involve their own non-perturbative input, exist. These die off as powers of Q; specifically twist-n terms are damped by $1/Q^{n-2}$. Provided a cut, say $W^2 > 15$ GeV^2 is imposed, the higher-twist terms appear to be numerically unimportant for Q^2 above a few GeV^2, except possibly for very small x and more definitely for x close to 1 [55–57], though it is important to note that they are likely to be larger in $xF_3(x, Q^2)$ than in $F_2(x, Q^2)$ (see e.g. [58]) due to a lack of a constraining sum rule for $xF_3(x, Q^2)$.

18.3 Determination of parton distributions

The parton distribution functions (PDFs) can be determined from an analysis of data for deep inelastic lepton-nucleon scattering and for related hard-scattering processes initiated by nucleons; see Refs. [59–65] for reviews. Table 18.1 highlights some of the processes and their primary sensitivity to PDFs. LHC data are playing an increasing role [66], and new processes are continually being added to the list. Fixed-target and collider experiments have complementary kinematic reach (as is shown in Fig. 18.3), which enables the determination of PDFs over a wide range in x and μ^2. As more precise LHC data for $W^{\pm}$, Z, γ, jet, $b\bar{b}$ and $t\bar{t}$ production become available, tighter constraints on the PDFs are expected in a wider kinematic range. At present about half the constraint on PDFs comes from LHC data [26], but much of the constraint still comes from structure functions.

Recent determinations and releases of the unpolarized PDFs up to NNLO have been made by five groups: MSHT [26], NNPDF [67], CT [68], ATLAS [69] and ABMP [70]. The CJ group produce PDFs at NLO and concentrate on the high x, low Q^2 regime, including data with lower kinematic cuts [71]. All groups start evolution at $Q_0^2 = 1-4$ GeV^2. Most groups use input PDFs of the form $xf = x^a(...)(1-x)^b$ with 14-32 free parameters in total. In these cases the PDF uncertainties are made available using the "Hessian" formulation. The free parameters are expanded around their best fit values, and orthogonal eigenvector sets of PDFs depending on linear combinations of the parameter variations are obtained. The uncertainty is then the quadratic sum of the uncertainties arising from each eigenvector. The NNPDF group combines a Monte Carlo representation of the probability measure in the space of PDFs with the use of neural networks. Fits are performed to a very large number of "replica" data sets obtained by allowing individual data points to fluctuate randomly by amounts determined by the size of the data uncertainties. This results in a set of replicas of unbiased PDF sets. In this case the best prediction is the average obtained using all PDF replicas and the uncertainty is the standard deviation over all replicas. It is possible to convert the eigenvectors of Hessian-based PDFs to Monte Carlo replicas [72] and *vice versa* [73]. Recently accumulated information on N^{3}LO calculation has been used by MSHT in order to produce a first set of approximate N^{3}LO global PDFs [74] together with theoretical uncertainties, and an alternative approach to theoretical uncertainty has been made in [75].

In these analyses, the u, d and s quarks are taken to be massless, but the treatment of the heavy c and b quark masses, m_Q, differs, and has a long history, which may be traced from Refs. [76–87]. The MSHT, CT, NNPDF and HERAPDF analyses use different variants of the General-Mass Variable-Flavour-Number Scheme (GM-VFNS). This combines fixed-order contributions to the coefficient functions (or partonic cross sections) calculated with the full m_Q dependence, with the all-order resummation of contributions via DGLAP evolution in which the heavy quarks are treated as massless after starting evolution at some transition point. Transition matrix elements are computed, following [79], which provide the boundary conditions between n_f and $n_f + 1$ PDFs. The ABMP analysis uses for structure function calculations a FFNS where only the three light (massless) quarks enter the evolution, while the heavy quarks enter the partonic cross sections with their full m_Q dependence. The GM-VFNS and FFNS approaches yield different results: in particular $\alpha_s(M_Z^2)$ and the large-x gluon PDF at large Q^2 are both significantly smaller in the FFNS. It has been argued [56, 57, 86] that the difference is due to the slow convergence of the $\ln^n(Q^2/m_Q^2)$ terms in certain regions in a FFNS. The final HERA combination of heavy flavour structure function data has been published [88], and the evolution of these measurements and their interpretation may be traced in [89].

The recent determinations of the groups fitting a variety of data and using a GM-VFNS (MSHT, NNPDF and CT) have converged, so that now a good agreement has been achieved between the resulting PDFs. Indeed, the recent global fit PDF sets, CT18 [68], MSHT2018 [26], and NNPDF3.1 [90], have been combined [91] using the Monte Carlo approach [72] mentioned above. The single combined set of PDFs is discussed in detail in Ref. [92].

For illustration, we show in Fig. 18.4 the PDFs obtained in the NNLO MSHT analysis [26] at scales $\mu^2 = 10$ and 10^4 GeV^2 (and an equivalent plot for polarized PDFs from NNPDF [27]). The values of α_s found by MSHT [93] may be taken as representative of those resulting from the GM-VFNS analyses

$$\text{NLO} : \alpha_s(M_Z^2) = 0.1203 \pm 0.0015,$$

$$\text{NNLO} : \alpha_s(M_Z^2) = 0.1174 \pm 0.0013,$$

where the error (at 68% C.L.) corresponds to the uncertainties resulting from the data fitted (the uncertainty that might be expected from the neglect of higher orders is at least as large). A similar results is found by the NNPDF group [94], who find $\alpha_s(M_Z^2) = 0.1185 \pm 0.0012$ at NNLO and the CT group [68], who obtain $\alpha_s(M_Z^2) = 0.1164 \pm 0.0026$. The ABMP analysis [70],which uses a FFNS, finds $\alpha_s(M_Z^2) = 0.1147 \pm 0.0011$ at NNLO.

As a first step towards the inclusion of higher order electroweak corrections a recent development has been a vastly increased understanding of the photon content of the proton. Sets of PDFs with a photon contribution were considered in Refs. [95–97]. However, due to weak data constraints, the uncertainty was extremely large. Subsequently, there has been a much improved understanding of the separation into elastic and inelastic contributions [98–100]. This gives much more theoretical precision, since the elastic contribution, arising from coherent emission of a photon from the proton, can be directly related to the well-known proton electric and magnetic form factors; the model dependence of the inelastic (incoherent) contribution, related to the quark PDFs, is at the level of tens of percent. A final and decisive development directly relating the entire photon contribution to the proton structure function [101] resulted in a determination of the photon content of the proton as precise as that of the light quarks. The framework has been applied within global fits to PDFs via an iterative procedure in [102] and to provide the low-scale input photon PDF in [103, 104]. A further development is the calculation of photon-initiated collider processes directly from structure functions [105].

There are also some calculations of PDFs using lattice QCD, see [106,107] for a recent review. There has been significant recent progress in the development of efficient algorithms for generating ensembles of gauge field configurations and in tools for extracting the required information from correlation functions. However, there remain a number of sources of systematic uncertainty; discretization effects, pion mass dependence, finite volume effects, excited state contamination and renormalization, which need to be determined and ideally minimised. Moreover, PDFs cannot be determined directly in Euclidean lattice QCD because they depend on quantum fields at light-like separations. Traditionally

the lattice has been used to determine matrix elements of twist two operators which can be related to integer moments of PDFs. Until recently these did not always agree well with determinations using global fit PDFs [106]. However, there have been recent improvements [108–110], though uncertainties are still relatively large. An alternative approach [111] suggested the computation of the matrix elements of frame-dependent, equal-time correlators in the large momentum limit. This leads to so-called Quasi-PDFs, which in the infinite momentum frame can be related to light-cone PDFs via a matching procedure, and there is the closely related psuedo PDF appraoch [112]. Recent results using physical values of the light quark masses are in [113–117].

Comprehensive sets of PDFs are available from the LHAPDF library [118], which can be linked directly into a user's programme to provide access to recent PDFs in a standard format. This also includes many nuclear and polarized PDFs.

Nuclear PDFs: The study of the parton distributions for nucleons within nuclei, so-called nuclear parton distribution functions (nPDFs), is now reaching a level of maturity and sophistication similar to nucleon PDFs (and some nuclear target data is often included in determinations of nucleon PDFs), though they are still typically performed at NLO in perturbative QCD. The PDFs are also a function of the nucleon number of the nucleus, A. The nPDFs are obtained via fits to deep inelastic scattering data and dilepton (Drell-Yan) and pion production from proton-nucleus, and most recently also from jet and heavy flavour production data. There are a number of recent examples of NLO analyses, TUJU21 [119], nCTEQ15HQ(HiX) [120, 121], EPPS21 [122],nNNPDF3.0 [123], while NNLO analyses with a smaller selection of data types now also exist [119, 124, 125]. A comparison of the nuclear modification factors for nCTEQ15HQ [120], EPPS21 [122] and nNNPDF3.0 [123] is shown in Fig. 18.6 where, for example, for the up quark $R_u^{\rm Pb} = (Z_{Pb}u_{Pb} + (A_{Pb} - Z_{Pb})d_{Pb})/(Z_{Pb}u_p + (A_{Pb} - Z_{Pb})d_p)$ i.e. it involves "physical" nuclear PDFs and is normalised such that $R_u^{\rm Pb} = 1$ corresponds to no nuclear effects.

Much of the heavy-nucleus data included are in the form of ratios to proton or deuteron measurements. Initially most nuclear PDFs were related to a particular proton PDF via a nuclear modification factor, i.e.

$$f_i^{p/A}(x, Q^2) = R_i^A(x, Q^2) f_i^p(x, Q^2). \qquad (18.30)$$

However, it is now common to parameterise the nuclear PDFs directly but so that they become equal to proton PDFs in the limit $A = 1$, and this approch has been adopted in [119–121, 123]. There is some variation in whether charged current neutrino DIS data is used as well as neutral current DIS data since there is no clear compatibility in the modification factors obtained [126, 127]. Recently, LHC data from vector boson production [128–131] in proton-lead collisions has been used along with DIS data in most fits, though the most recent data [132] shows some tendency to require NNLO corrections. LHC jet data [133] has been included in some fits [122, 123] giving extra constraint on the gluon within nuclei. Further information at smaller x values is also obtained from heavy meson production at LHCb [134]. Single inclusive hadron production e.g. [135, 136], is already sometimes used. All the PDF extractions above are based on the Hessian formulation, except for the NNPDF studies which use Monte Carlo replicas. Agreement between the different nuclear PDFs is generally good, though uncertainty is still large compared to proton PDFs. As well as improved constraints from further LHC data, nPDFs would be very significantly improved by data from a potential high-energy Electron-Ion Collider [137–139].

Double Parton Distributions Double parton scattering (DPS) occurs when two pairs of partons initiate two distinct hard scattering processes in a single collision. It becomes more prevalent at higher collider energies as the parton flux increases. Hence, it is becoming relevant at the LHC, and even moreso for planning of higher energy colliders. It has a long theoretical history [140–144], and in recent years experimental studies have started. DPS is often supressed, but this is less the case in certain kinematic regions, e.g. when the total transverse momentum of the two hard-scattering processes is small [145–148], when they have a large rapidity separation [149, 150], or when single particle production is supressed by coupling constants, e.g. like-sign W production [151]. There have been results with some evidence for DPS found from both the Tevatron [152, 153] involving final states with multijets and photons, and at the LHC [154–156] in states with multiple vector bosons or mesons. Recent developments have been involved in putting the theoretical foundations of DPS on a much more rigorous footing and describing it in terms of well-defined double partons distributions (DPDs) which extend the concept of parton distribution functions (PDFs) to the case of two partons [145–148, 157–159]. The current knowledge of DPDs is still limited, though there are a number of attempts to impose theoretical constrains as a limit on the forms [160–162]. The DPDs can be calculated quite accurately when the tranverse separtion of the two partons is small, since in this limit the observed partons are produced by a splitting from a single parton. This limit is complicated by potential double counting [148], and an approach to deal with this has been devised [159]. The full splitting functions for DPS have been calculated at LO [148], and there is progress at NLO, e.g. [163].

Polarized PDFs: For spin-dependent structure functions, data exists for a more restricted range of Q^2 and has lower precision, so that the scaling violations are not seen so clearly. However, spin-dependent (or polarized) parton distributions have been extracted by comparison to data using NLO global analyses which include measurements of the g_1 structure function in inclusive polarized DIS, 'flavour-tagged' semi-inclusive DIS data, open–charm production in DIS and results from polarized pp scattering at RHIC. There are recent results on DIS from JLAB [164] (for g_1^n/F_1^n), COMPASS [165, 166] and CLAS [167]. NLO analyses are given in Refs. [168–171] and more recent extractions [172, 173]. Improved parton-to-hadron fragmentation functions, needed to describe the semi-inclusive DIS (SIDIS) data, can be found in Refs. [174–177].

The DSSV collaboration includes in their NLO analysis to extract polarized PDFs all the world data, inclusive and semi-inclusive DIS, double spin asymmetries in jet [178], dijet [179] and inclusive π^0-production [180], but not yet the single spin asymmetries in $W^\pm, Z^0$ production [181, 182]. A determination [183], using the NNPDF methodology, concentrates just on the inclusive polarized DIS data, and finds the uncertainties on the polarized gluon PDF have been underestimated in the earlier analyses. An update to this [27], where jet and $W^\pm$ data from pp collisions

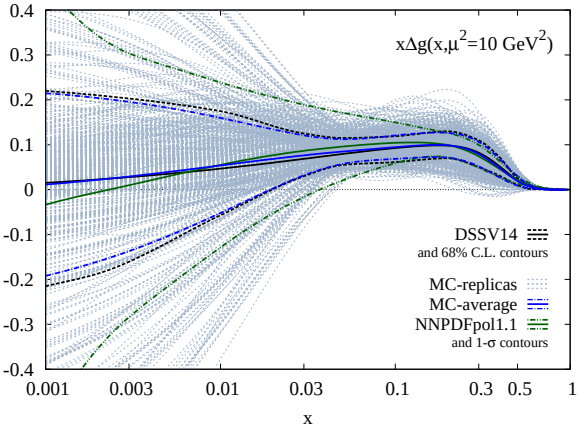

Figure 18.5: Ensemble of replicas (dotted blue lines) for the NLO gluon helicity density $\Delta g(x, Q^2)$ at $Q^2 = 10$ GeV^2 shown along with its statistical average (solid blue line) and variance (dot-dashed blue lines). The corresponding results from the DSSV14 fit (black lines) [172] and the NNPDFpol1.1 analysis (green lines) [27] are shown for comparison. Figure taken from Ref. [184].

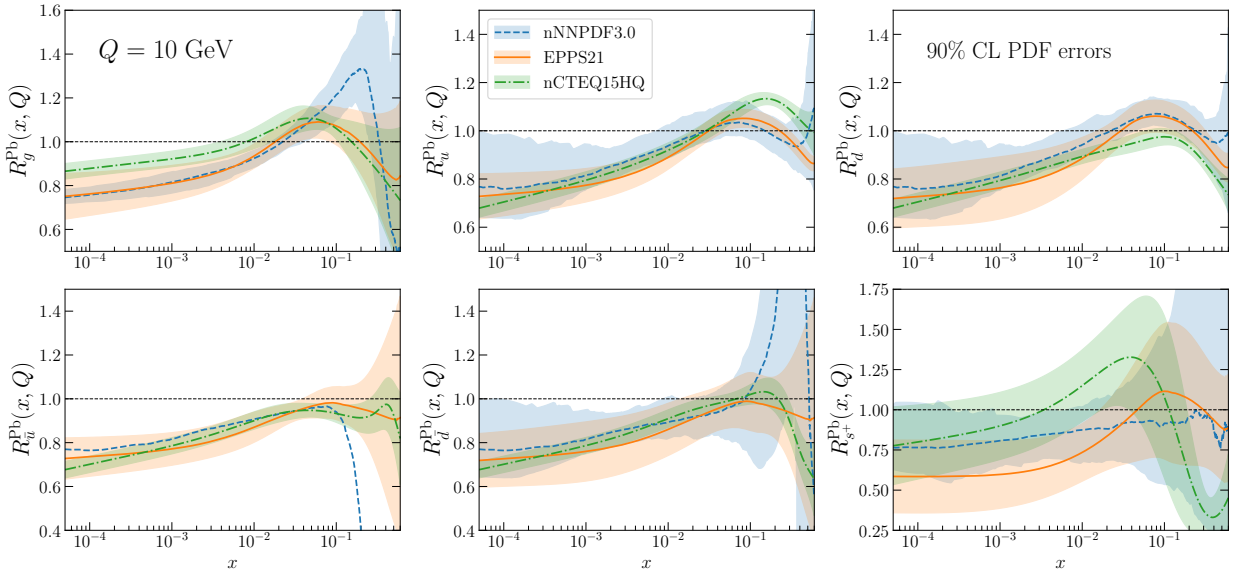

Figure 18.6: Comparison of the nNNPDF3.0, nCTEQ15HQ and EPPS21 nuclear PDFs. The curves shown are ratios to the result in the limit of no nuclear corrections. Plot from NNPDF collaboration (Juan Rojo – private communication).

and open–charm DIS data have been included via reweighting, reduces the uncertainty and suggests a positive polarized gluon PDF. The evidence for a positive gluon polarization is strengthened by the most recent jet [185–187] and inclusive π^0 [188] data. The DSSV group has recently implemented a Monte Carlo sampling strategy to extract helicity parton densities and their uncertainties from a reference set of longitudinally polarized scattering data [184]. A simultaneous extraction of spin-dependent parton distributions and fragmentation functions has recently also been performed [189]. Calculations of polarised PDFs on the lattice are frequently produced by the same studies as for unpolarised PDFs. These are usually in better agreement with the corresponding moments obtained from global fits, than the unpolarised PDFs, and also tend to have much more competitive uncertainties, see [106, 107] for a review and e.g. [109, 190] for more recent results.

A comparison of the polarized gluon PDFs obtained in the NLO analyses of NNPDF [27] and DSSV [184] is shown in Fig. 18.5 at scale $\mu^2 = 10$ GeV^2. The world data of the inclusive structure function g_1 for proton and deuterium included in these analysis are shown in Fig. 18.16 and Fig. 18.17.

18.4 The hadronic structure of the photon

Besides the *direct* interactions of the photon, it is possible for it to fluctuate into a hadronic state via the process $\gamma \to q\bar{q}$. While in this state, the partonic content of the photon may be *resolved*, for example, through the process $e^+e^- \to e^+e^-\gamma^\star\gamma \to e^+e^-X$, where the virtual photon emitted by the DIS lepton probes the hadronic structure of the quasi-real photon emitted by the other lepton. The perturbative LO QED contributions to this process with $\gamma \to q\bar{q}$ in conjunction with $\gamma^\star q(\bar{q}) \to q(\bar{q})$, are subject to QCD corrections due to the radiation of gluons from these quarks.

Often the equivalent-photon approximation is used to express the differential cross section for deep inelastic electron–photon scattering in terms of the structure functions of the transverse quasi-real photon times a flux factor N_γ^T (for these incoming quasi-real photons of transverse polarization)

$$\frac{d^2\sigma}{dxdQ^2} = N_\gamma^T \frac{2\pi\alpha^2}{xQ^4}\left[\left(1+(1-y)^2\right)F_2^\gamma(x,Q^2) - y^2 F_L^\gamma(x,Q^2)\right], \tag{18.31}$$

where we have used $F_2^\gamma = 2xF_T^\gamma + F_L^\gamma$ (where F_T is the transverse structure function), not to be confused with F_2^γ of Sec. 18.2. Complete formulae are given, for example, in the comprehensive review of [191].

The hadronic photon structure function, F_2^γ, evolves with increasing Q^2 from the 'hadron-like' behavior, calculable via the vector-meson-dominance model, to the dominating 'point-like' behaviour, calculable in perturbative QCD. Due to the point-like coupling, the logarithmic evolution of F_2^γ with Q^2 has a *positive* slope for all values of x, see Fig. 18.18. The 'loss' of quarks at large x due to gluon radiation is over-compensated by the 'creation' of quarks via the point-like $\gamma \to q\bar{q}$ coupling. The logarithmic evolution was first predicted in the quark–parton model ($\gamma^\star\gamma \to q\bar{q}$) [192, 193], and then an improved expression was obtained using QCD corrections in the limit of large Q^2 [194]. The evolution is now known to NLO [195–197]. The NLO data analyses to determine the parton densities of the photon can be found in Refs. [198–200].

18.5 Diffractive DIS (DDIS)

Some 10% of DIS events are diffractive, $\gamma^* p \to X + p$, in which the slightly deflected proton and the cluster X of outgoing hadrons are well-separated in rapidity [201]. Besides x and Q^2, two extra

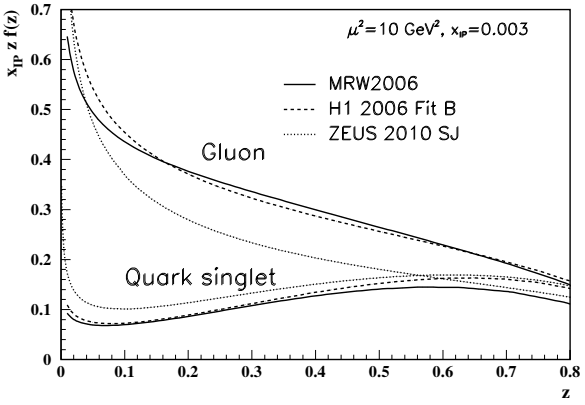

Figure 18.7: Diffractive parton distributions, $x_{I\!P}\, z f_{a/p}^{\rm D}$, obtained from fitting to the ZEUS data with $Q^2 > 5$ GeV^2 [202],H1 data with $Q^2 > 8.5$ GeV^2 assuming Regge factorization [203], and from MRW2006 [204] using a more perturbative QCD approach [204]. Only the Pomeron contributions are shown and not the secondary Reggeon contributions, which are negligible at the value of $x_{I\!P} = 0.003$ chosen here. The H1 2007 Jets distribution [205] is similar to H1 2006 Fit B.

variables are needed to describe a DDIS event: the fraction $x_{I\!P}$ of

the proton's momentum transferred across the rapidity gap and t, the square of the 4-momentum transfer of the proton. The DDIS data [206, 207] are usually analysed using two levels of factorization. First, the diffractive structure function $F_2^{\rm D}$ satisfies *collinear factorization*, and can be expressed as the convolution [208]

$$F_2^{\rm D} = \sum_{a=q,g} C_2^a \otimes f_{a/p}^{\rm D}, \tag{18.32}$$

with the same coefficient functions as in DIS (see Eq. (18.21)), and where the diffractive parton distributions $f_{a/p}^{\rm D}$ $(a = q, g)$ satisfy DGLAP evolution. Second, *Regge factorization* is assumed [209],

$$f_{a/p}^{\rm D}(x_{I\!P}, t, z, \mu^2) = f_{I\!P/p}(x_{I\!P}, t)\, f_{a/I\!P}(z, \mu^2), \tag{18.33}$$

where $f_{a/I\!P}$ are the parton densities of the Pomeron, which itself is treated like a hadron, and $z \in [x/x_{I\!P}, 1]$ is the fraction of the Pomeron's momentum carried by the parton entering the hard subprocess. The Pomeron flux factor $f_{I\!P/p}(x_{I\!P}, t)$ is taken from Regge phenomenology. There are also secondary Reggeon contributions to Eq. (18.33). A sample of the t-integrated diffractive parton densities, obtained in this way, is shown in Fig. 18.7. A more recent extraction of the parton densities may be found in [210].

Although collinear factorization holds as $\mu^2 \to \infty$, there are non-negligible corrections for finite μ^2 and small $x_{I\!P}$. Besides the *resolved* interactions of the Pomeron, the perturbative QCD Pomeron may also interact *directly* with the hard subprocess, giving rise to an inhomogeneous evolution equation for the diffractive parton densities analogous to the photon case. The results of the MRW analysis [204],which includes these contributions, are also shown in Fig. 18.7.

Unlike the inclusive case, the diffractive parton densities cannot be directly used to calculate diffractive hadron-hadron cross sections, since account must first be taken of "soft" rescattering effects.

18.6 Three-dimensional structure of hadrons

Generalized parton distributions (GPDs) and their compliment, transverse momentum dependent distributions (TMDs) describe the three-dimensional structure of hadrons. While GPDs encode the transverse position of a parton in a nucleon, TMDs, encompassing both the parton distributions (TMD PDF) and fragmentation functions (TMD FF), encode their transverse momenta and lead to observable transverse momenta in the final state. Both TMDs and GPDs derive, via integration over the appropriate variable, from Wigner distributions [211–213] that depend on the average transverse momentum and position of partons.

18.6.1 *Generalized parton distributions*

The parton distributions of the proton of Sec. 18.3 are given by the diagonal matrix elements $\langle P, \lambda | \hat{O} | P, \lambda \rangle$, where P and λ are the 4-momentum and helicity of the proton, and $\hat{O}$ is a twist-2 quark or gluon operator. However, there is new information in the so-called generalised parton distributions (GPDs) defined in terms of the off-diagonal matrix elements $\langle P', \lambda' | \hat{O} | P, \lambda \rangle$; see Refs. [214–219] for reviews. Unlike the diagonal PDFs, the GPDs cannot be regarded as parton densities, but are to be interpreted as probability amplitudes.

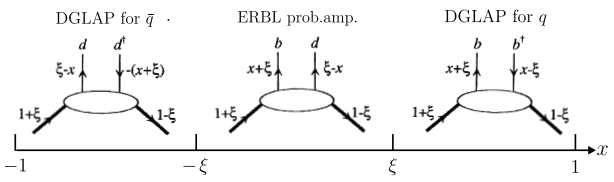

Figure 18.8: Schematic diagrams of the three distinct kinematic regions of the imaginary part of H_q. The proton and quark momentum fractions refer to $\bar{P}^+$, and x covers the interval (-1,1). In the ERBL domain the GPDs are generalisations of distribution amplitudes which occur in processes such as $p\bar{p} \to J/\psi$.

The physical significance of GPDs is best seen using light-cone coordinates, $z^\pm = (z^0 \pm z^3)/\sqrt{2}$, and in the light-cone gauge, $A^+ = 0$. It is conventional to define the generalised quark distributions in terms of quark operators at light-like separation

$$\begin{aligned} &F_q(x, \xi, t) = \\ &\frac{1}{2} \int \frac{dz^-}{2\pi} e^{ix\bar{P}^+ z^-} \langle P' | \bar{\psi}(-z/2) \gamma^+ \psi(z/2) | P \rangle \Big|_{z^+ = z^1 = z^2 = 0} \\ &\qquad = \frac{1}{2\bar{P}^+} \\ &\times \left(H_q(x, \xi, t)\ \bar{u}(P') \gamma^+ u(P) + E_q(x, \xi, t)\ \bar{u}(P') \frac{i\sigma^{+\alpha} \Delta_\alpha}{2m} u(P) \right) \end{aligned} \tag{18.34}$$

with $\bar{P} = (P + P')/2$ and $\Delta = P' - P$, and where we have suppressed the helicity labels of the protons and spinors. We now have two extra kinematic variables:

$$t = \Delta^2, \qquad \xi = -\Delta^+/(P + P')^+. \tag{18.35}$$

We see that $-1 \le \xi \le 1$. Similarly, we may define GPDs $\tilde{H}_q$ and $\tilde{E}_q$ with an additional γ_5 between the quark operators in Eq. (18.34); and also an analogous set of gluon GPDs, H_g, E_g, $\tilde{H}_g$ and $\tilde{E}_g$. After a Fourier transform with respect to the transverse components of Δ, we are able to describe the spatial distribution of partons in the impact parameter plane in terms of GPDs [220, 221].

For $P' = P$, $\lambda' = \lambda$ the matrix elements reduce to the ordinary PDFs of Sec. 18.2.1

$$H_q(x, 0, 0) = q(x), \quad H_q(-x, 0, 0) = -\bar{q}(x), \quad H_g(x, 0, 0) = xg(x), \tag{18.36}$$

$$\tilde{H}_q(x, 0, 0) = \Delta q(x),\ \tilde{H}_q(-x, 0, 0) = \Delta\bar{q}(x),\ \tilde{H}_g(x, 0, 0) = x\Delta g(x), \tag{18.37}$$

where $\Delta q = q\uparrow - q\downarrow$ as in Eq. (18.18). No corresponding relations exist for E, $\tilde{E}$ as they decouple in the forward limit, $\Delta = 0$.

The functions H_g, E_g are even in x, and $\tilde{H}_g, \tilde{E}_g$ are odd functions of x. We can introduce valence and 'singlet' quark distributions which are even and odd functions of x respectively. For example

$$H_q^V(x, \xi, t) \equiv H_q(x, \xi, t) + H_q(-x, \xi, t) = H_q^V(-x, \xi, t), \tag{18.38}$$

$$H_q^S(x, \xi, t) \equiv H_q(x, \xi, t) - H_q(-x, \xi, t) = -H_q^S(-x, \xi, t). \tag{18.39}$$

All the GPDs satisfy relations of the form

$$H(x, -\xi, t) = H(x, \xi, t) \qquad \text{and} \qquad H(x, -\xi, t)^* = H(x, \xi, t), \tag{18.40}$$

and so are real-valued functions. Moreover, the moments of GPDs, that is the x integrals of $x^n H_q$ etc., are *polynomials* in ξ of order $n + 1$. Another important property of GPDs are Ji's sum rule [214]

$$\frac{1}{2} \int_{-1}^{1} dx\ x\, (H_q(x, \xi, t) + E_q(x, \xi, t)) = J_q(t), \tag{18.41}$$

where $J_q(0)$ is the total angular momentum carried by quarks and antiquarks of flavour q, with a similar relation for gluons.

To visualize the physical content of H_q, we Fourier expand ψ and $\bar{\psi}$ in terms of quark, antiquark creation (b, d) and annihilation $(b^\dagger, d^\dagger)$ operators, and sketch the result in Fig. 18.8. There are two types of domain: (i) the time-like or 'annihilation' domain, with $|x| < |\xi|$, where the GPDs describe the wave functions of a t-channel $q\bar{q}$ (or gluon) pair and evolve according to modified ERBL equations [222,223]; (ii) the space-like or 'scattering' domain, with $|x| > |\xi|$, where the GPDs generalise the familiar $\bar{q}$, q (and gluon) PDFs and describe processes such as 'deeply virtual Compton scattering' $(\gamma^* p \to \gamma p)$, $\gamma p \to J/\psi p$, etc., and evolve according to modified DGLAP equations. The splitting functions for the evolution of GPDs are known to NLO [224–226].

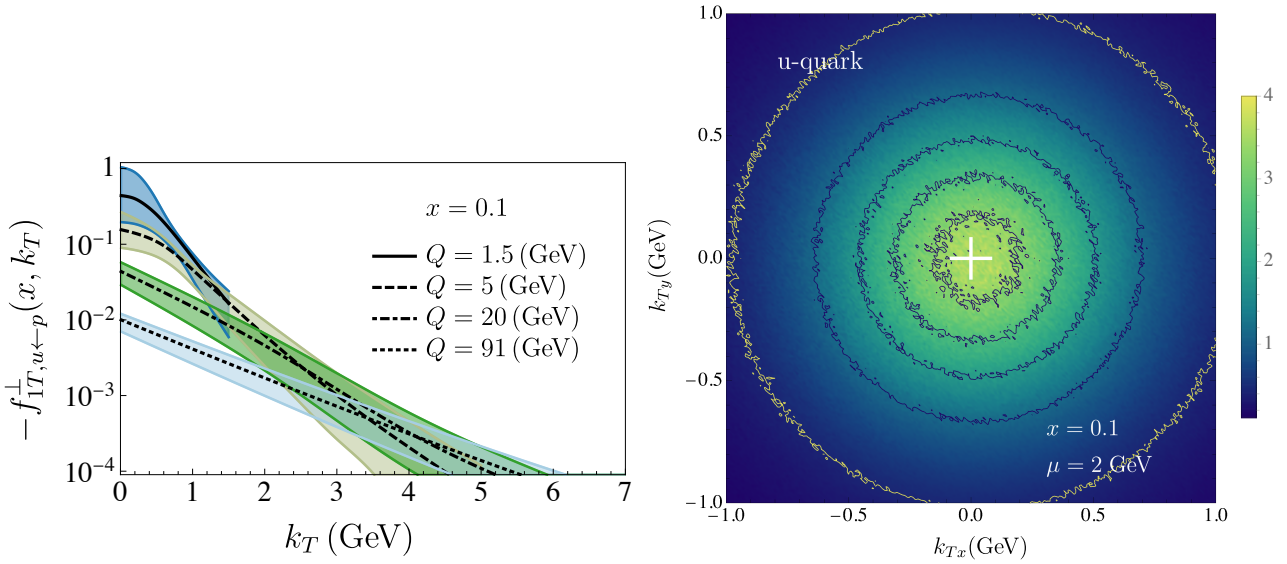

Figure 18.9: (Left) Sivers function in the momentum space for u quark [227] at $x = 0.1$ as a function of transverse momentum k_T for different values of Q. The bands are 68%CI. (Right) Momentum space density function as defined in [227] for the unpolarized u quark in a proton totally polarized in the y direction. The white cross indicates the origin with respect to which a shift of the distribution along the x-direction due to the Sivers function can be seen. The width of the patterns in the plot roughly indicates the uncertainty of the extraction.

GPDs describe new aspects of proton structure and must be determined from experiment. We can parametrise them in terms of 'double distributions' [228,229], which reduce to diagonal PDFs as $\xi \to 0$. Alternatively, flexible $SO(3)$-based parametrisations have been used to determine GPDs from DVCS data [230,231]; a more recent summary may be found in Ref. [232,233].

18.6.2 *Transverse momentum dependent distributions*

For a proton, there are eight independent transverse dependent distribution (TMD) PDFs, at leading twist, three of which correspond to the usual unpolarized, longitudinally polarized and transversely polarized quark parton distributions [234,235]. The novel TMD PDFs have physical interpretations. For example, the Sivers function [236] represents the distribution of unpolarized partons inside a transversely polarized hadron. For (pseudo)scalar particles, such as kaon and pions, there are two independent leading-twist TMD FFs, one being the ordinary unpolarized fragmentation function and the other the Collins FF [237] which is related to the probability of a polarized quark fragmenting into an unpolarized hadron.

Factorization of TMDs has been shown for semi-inclusive DIS, for the Drell-Yan process as well as for electron-position annihilation into dihadrons [238–243]. Recently first TMD global fits have become available [244–252], although potential problems with consistent descriptions are highlighted in remain [253–255]. The results of a recent extraction of Sivers function from a global fit to polarized Semi-Inclusive DIS, polarized pion-induced Drell-Yan and W+-/Z boson production data is shown in Fig. 18.9 [227].

Because TMD PDFs encode nonperturbative information about transverse momentum and polarization degrees of freedom, they are important for descriptions of multi-scale, non-inclusive collider observables, for example, production of electroweak gauge bosons at LHC [256] and can have an effect on determination of the W boson mass [257]. The combination of TMD PDFs and FFs can give consistent global description of spin and azimuthal asymmetries and provide predictions. Some recent reviews of this rapidly developing field are given here [256, 258–261].

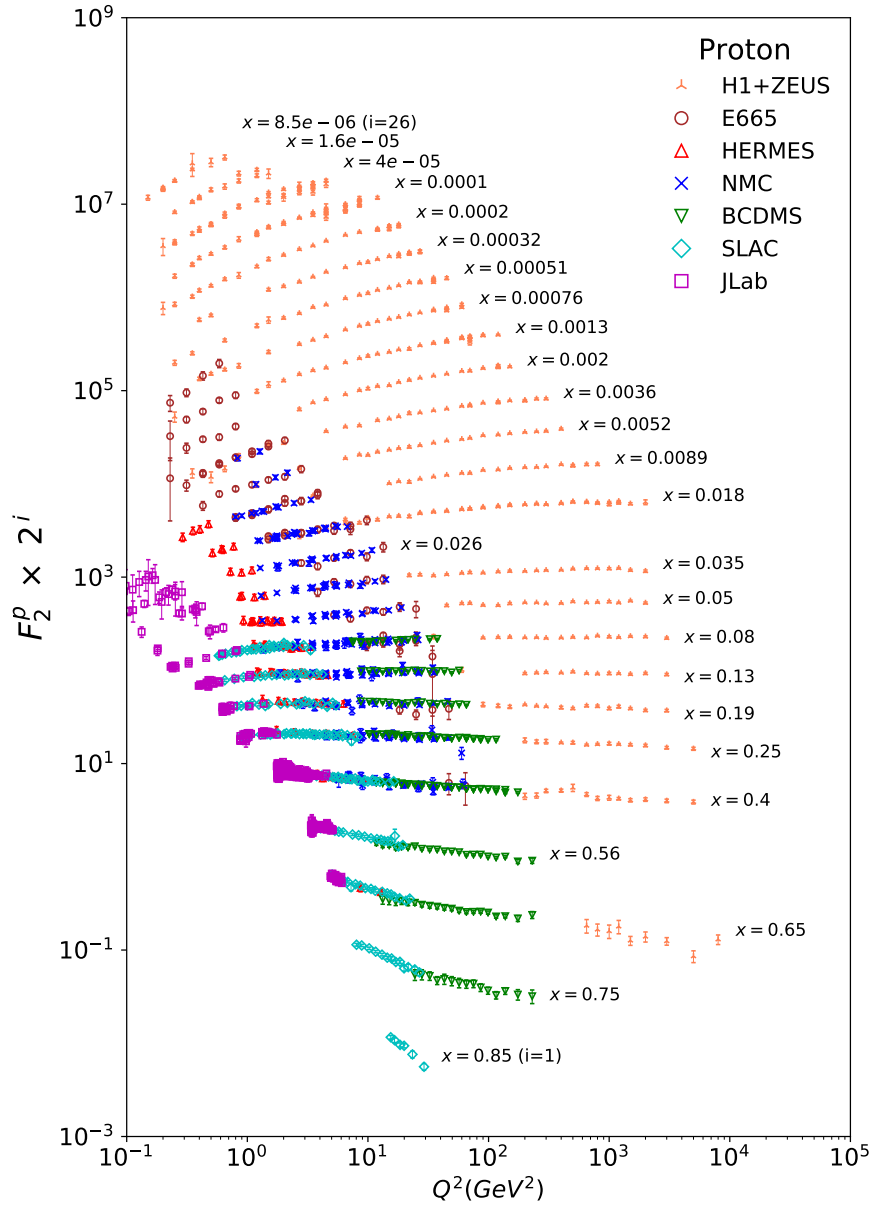

Figure 18.10: The proton structure function F_2^p measured in electromagnetic scattering of electrons and positrons on protons, and for electrons/positrons (SLAC,HERMES,JLAB) and muons (BCDMS, E665, NMC) on a fixed target. Statistical and systematic errors added in quadrature are shown. The H1+ZEUS combined values are obtained from the measured reduced cross section and converted to F_2^p with a HERAPDF NLO fit, for all measured points where the predicted ratio of F_2^p to reduced cross-section was within 10% of unity. The data are plotted as a function of Q^2 in bins of fixed x. Some points have been slightly offset in Q^2 for clarity. The H1+ZEUS combined binning in x is used in this plot; all other data are rebinned to the x values of these data. For the purpose of plotting, F_2^p has been multiplied by 2^{ix}, where i_x is the number of the x bin, ranging from $i_x = 1$ ($x = 0.85$) to $i_x = 26$ ($x = 0.0000085$). Only data with $W^2 > 3.5$ GeV^2 is included. Plot from CJ collaboration (Shujie Li – private communication).

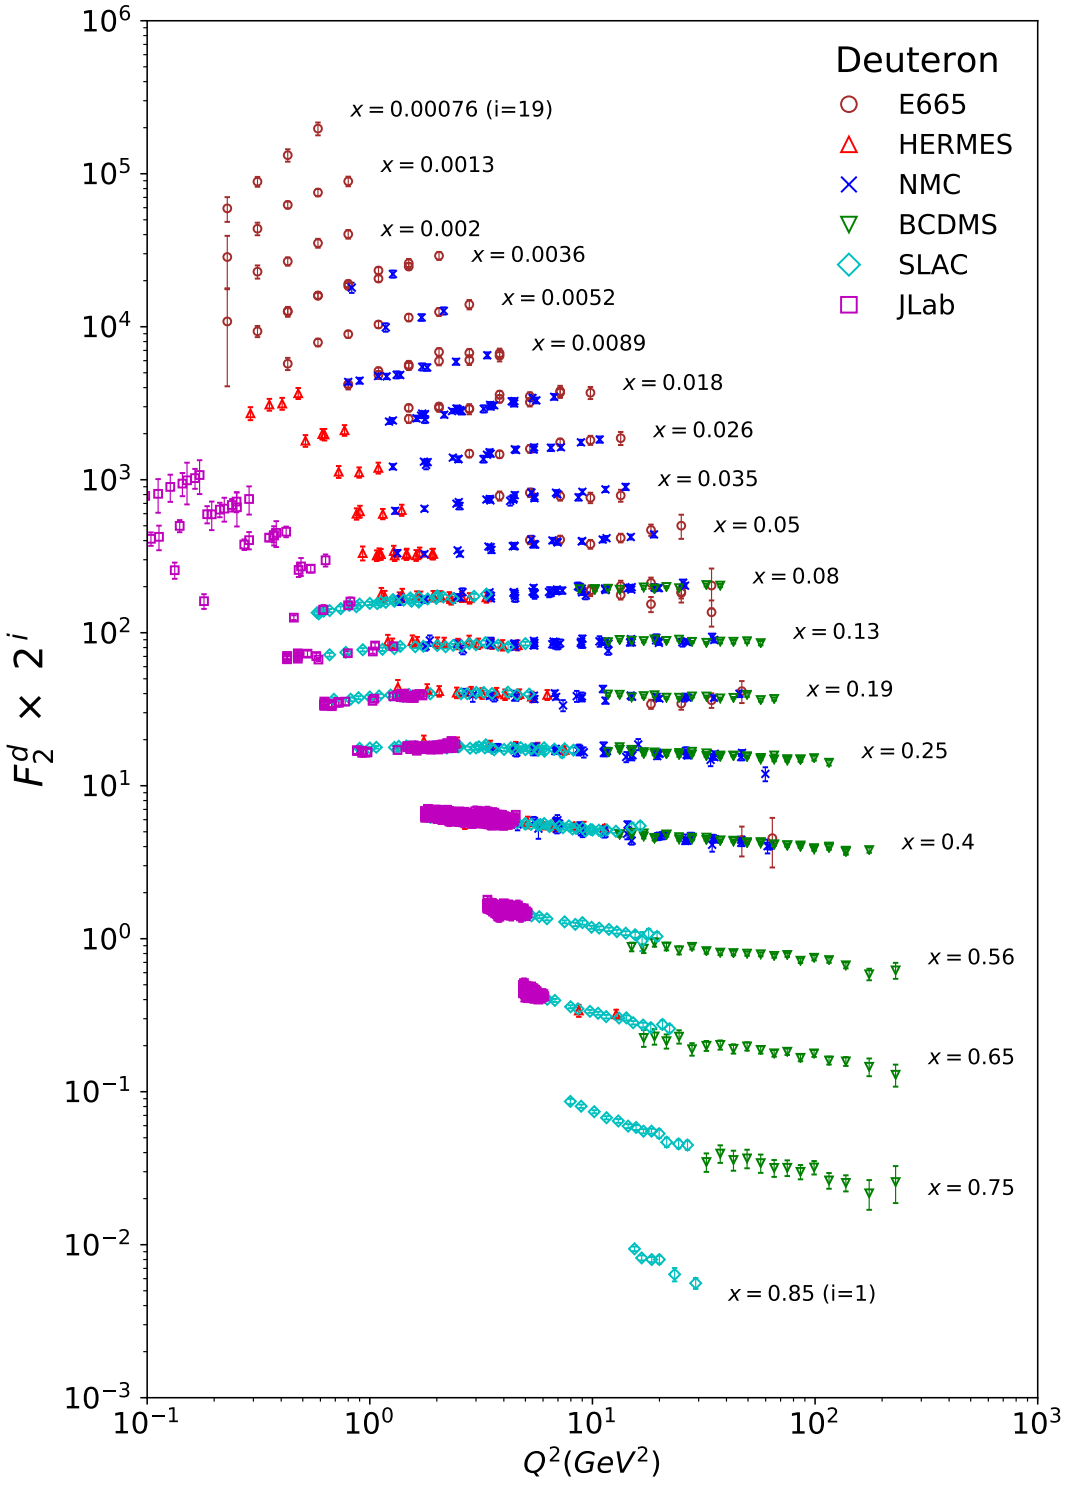

Figure 18.11: The deuteron structure function F_2^d measured in electromagnetic scattering of electrons/positrons (SLAC,HERMES,JLAB) and muons (BCDMS, E665, NMC) on a fixed target, shown as a function of Q^2 for bins of fixed x. Statistical and systematic errors added in quadrature are shown. For the purpose of plotting, F_2^d has been multiplied by 2^{ix}, where i_x is the number of the x bin, ranging from 1 ($x = 0.85$) to 29 ($x = 0.00076$). Only data with $W^2 > 3.5$ GeV^2 is included. Plot from CJ collaboration (Shujie Li – private communication) References: **BCDMS**—A.C. Benvenuti *et al.*, Phys. Lett. **B237**, 592 (1990). **E665, NMC, SLAC,HERMES**—same references as Fig. 18.10; **JLAB**—S. Malace *et al.*, Jefferson Lab Hall C E00-116 Collaboration, Phys. Rev. **C80**, 035207 (2009), V. Tvaskis *et al.*, Jefferson Lab Hall C E99-118 Collaboration, Phys. Rev. **C81**, 055207 (2010), J. Seely (MIT, LNS) *et al.*, Jefferson Lab Hall C E03-103 Collaboration, Phys. Rev. Figure 18.12: a) The deuteron structure function F_2 measured in deep inelastic scattering of muons on a fixed target (NMC) is compared to the structure function F_2 from neutrino-iron scattering (CCFR and NuTeV) using $F_2^\mu = (5/18)F_2^\nu - x(s+\overline{s})/6$, where heavy-target effects have been taken into account. The data are shown versus Q^2, for bins of fixed x. The NMC data have been rebinned to CCFR and NuTeV x values. For the purpose of plotting, a constant $c(x) = 0.05i_x$ is added to F_2, where i_x is the number of the x bin, ranging from 0 ($x = 0.75$) to 7 ($x = 0.175$). For $i_x = 8$ ($x = 0.125$) to 11 ($x = 0.015$), $2c(x)$ has been added. References: **NMC**—M. Arneodo *et al.*, Nucl. Phys. **B483**, 3 (1997); **CCFR/NuTeV**—U.K. Yang *et al.*, Phys. Rev. Lett. **86**, 2741 (2001); **NuTeV**—M. Tzanov *et al.*, Phys. Rev. **D74**, 012008 (2006).
b) The proton structure function F_2^p mostly at small x and Q^2, measured in electromagnetic scattering of electrons and positrons (H1, ZEUS), electrons (SLAC), and muons (BCDMS, NMC) on protons. Lines are ZEUS Regge and HERAPDF parameterizations for lower and higher Q^2, respectively. The width of the bins can be up to 10% of the stated Q^2. Some points have been slightly offset in x for clarity. The H1+ZEUS combined values for $Q^2 \geq 3.5$ GeV^2 are obtained from the measured reduced cross section and converted to F_2^p with a HERAPDF NLO fit, for all measured points where the predicted ratio of F_2^p to reduced cross-section was within 10% of unity. A turn-over is visible in the low-x points at medium Q^2 (3.5 GeV^2 and 6 GeV^2) for the H1+ZEUS combined values. In order to obtain F_2^p from the measured reduced cross-section, F_L must be estimated; for the points shown, this estimate is obtained from HERAPDF2.0. No F_L value consistent with the HERA data can eliminate the turn-over. This may indicate that at low x and Q^2 there are contributions to the structure functions that cannot be described in standard DGLAP evolution.
References: **H1 and ZEUS**—F.D. Aaron *et al.*, JHEP **1001**, 109 (2010) (data for $Q^2 < 3.5$ GeV^2), H. Abramowicz *et al.*, Eur. Phys. J. **C75**, 580 (2015) (data for $Q^2 \geq 3.5$ GeV^2 and HERAPDF parameterization); **ZEUS**—J. Breitweg *et al.*, Phys. Lett. **B487**, 53 (2000) (ZEUS Regge parameterization); **BCDMS, NMC, SLAC**—same references as Fig. 18.10.
Statistical and systematic errors added in quadrature are shown for both plots.

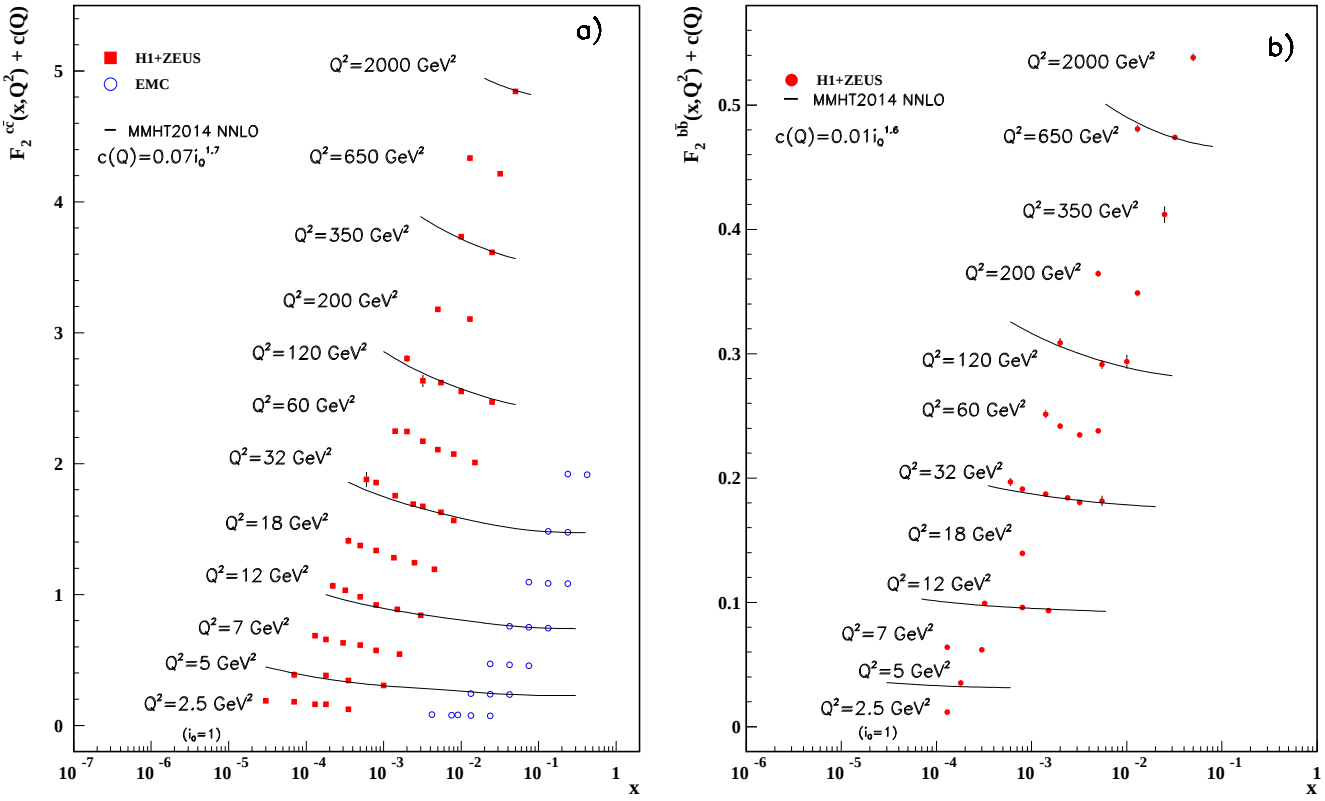

Figure 18.13: a) The charm-quark structure function $F_2^{c\bar{c}}(x)$, i.e. that part of the inclusive structure function F_2^p arising from the production of charm quarks, measured in electromagnetic scattering of positrons on protons (H1, ZEUS) (the values are obtained from the measured reduced cross section and converted to $F_2^{c\bar{c}}$ using the PDFs from the MMHT NNLO fit) and muons on iron (EMC). For the purpose of plotting, a constant $c(Q) = 0.07{i_Q}^{1.7}$ is added to $F_2^{c\bar{c}}$ where i_Q is the number of the Q^2 bin, ranging from 1 ($Q^2 = 2.5$ GeV^2) to 12 ($Q^2 = 2000$ GeV^2). References: **H1 and ZEUS run I +II combination**—H. Abramowicz *et al.*, Eur. Phys. J. **C78**, 473 (2018); **EMC**—J.J. Aubert *et al.*, Nucl. Phys. **B213**, 31 (1983).

b) The bottom-quark structure function $F_2^{b\bar{b}}(x)$. For the purpose of plotting, a constant $c(Q) = 0.01i_Q^{1.6}$ is added to $F_2^{b\bar{b}}$ where i_Q is the number of the Q^2 bin, ranging from 1 ($Q^2 = 2.5$ GeV^2) to 12 ($Q^2 = 2000$ GeV^2). References: **H1 and ZEUS run I combination**—H. Abramowicz *et al.*, Eur. Phys. J. **C78**, 473 (2018).

For both plots, statistical and systematic errors added in quadrature are shown. The data are given as a function of x in bins of Q^2. Points may have been slightly offset in x for clarity. Some data have been rebinned to common Q^2 values. Also shown is the MMHT2014 parameterization given at several Q^2 values (L. A. Harland-Lang *et al.*, Eur. Phys. J. **C75**, 204 (2015)).

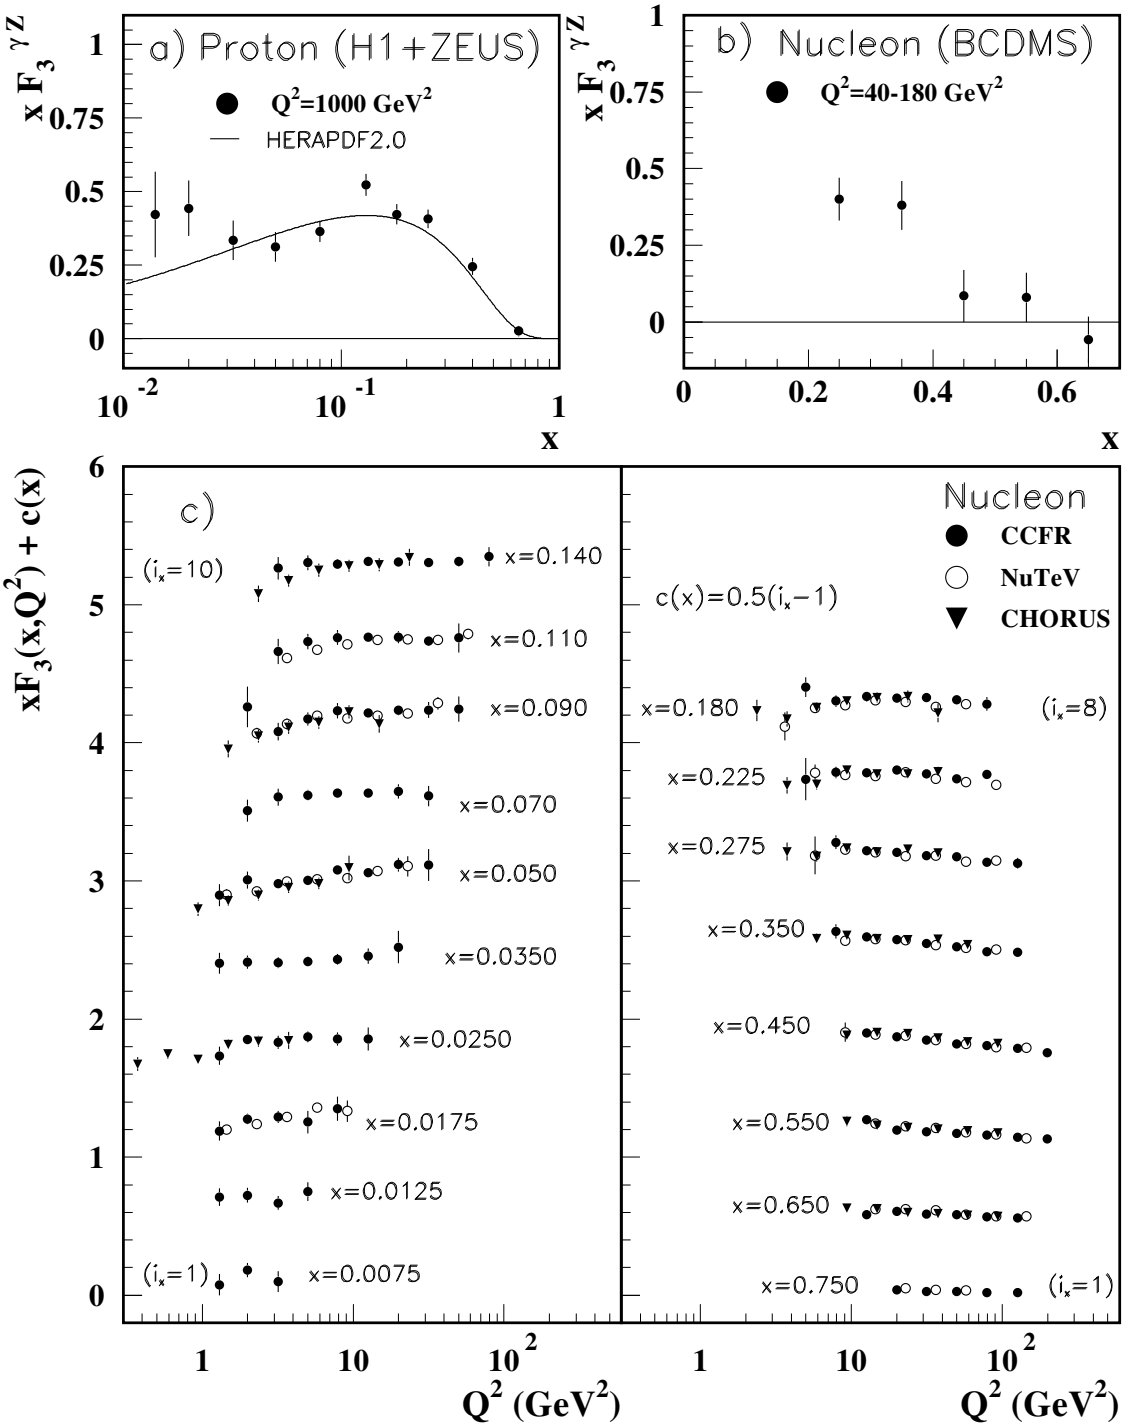

Figure 18.14: The structure function $xF_3^{\gamma Z}$ measured in electroweak scattering of **a)** electrons on protons (H1 and ZEUS) and **b)** muons on carbon (BCDMS). The line in **a)** is the HERAPDF parameterization. References: **H1 and ZEUS**—H. Abramowicz *et al.*, Eur. Phys. J. **C75**, 580 (2015) (for both data and HERAPDF parameterization); **BCDMS**—A. Argento *et al.*, Phys. Lett. **B140**, 142 (1984).
c) The structure function xF_3 of the nucleon measured in ν-Fe scattering. The data are plotted as a function of Q^2 in bins of fixed x. For the purpose of plotting, a constant $c(x) = 0.5(i_x - 1)$ is added to xF_3, where i_x is the number of the x bin as shown in the plot. The NuTeV and CHORUS points have been shifted to the nearest corresponding x bin as given in the plot and slightly offset in Q^2 for clarity. References: **CCFR**—W.G. Seligman *et al.*, Phys. Rev. Lett. **79**, 1213 (1997); **NuTeV**—M. Tzanov *et al.*, Phys. Rev. **D74**, 012008 (2006); **CHORUS**—G. Önengüt *et al.*, Phys. Lett. **B632**, 65 (2006).

Statistical and systematic errors added in quadrature are shown for all plots.

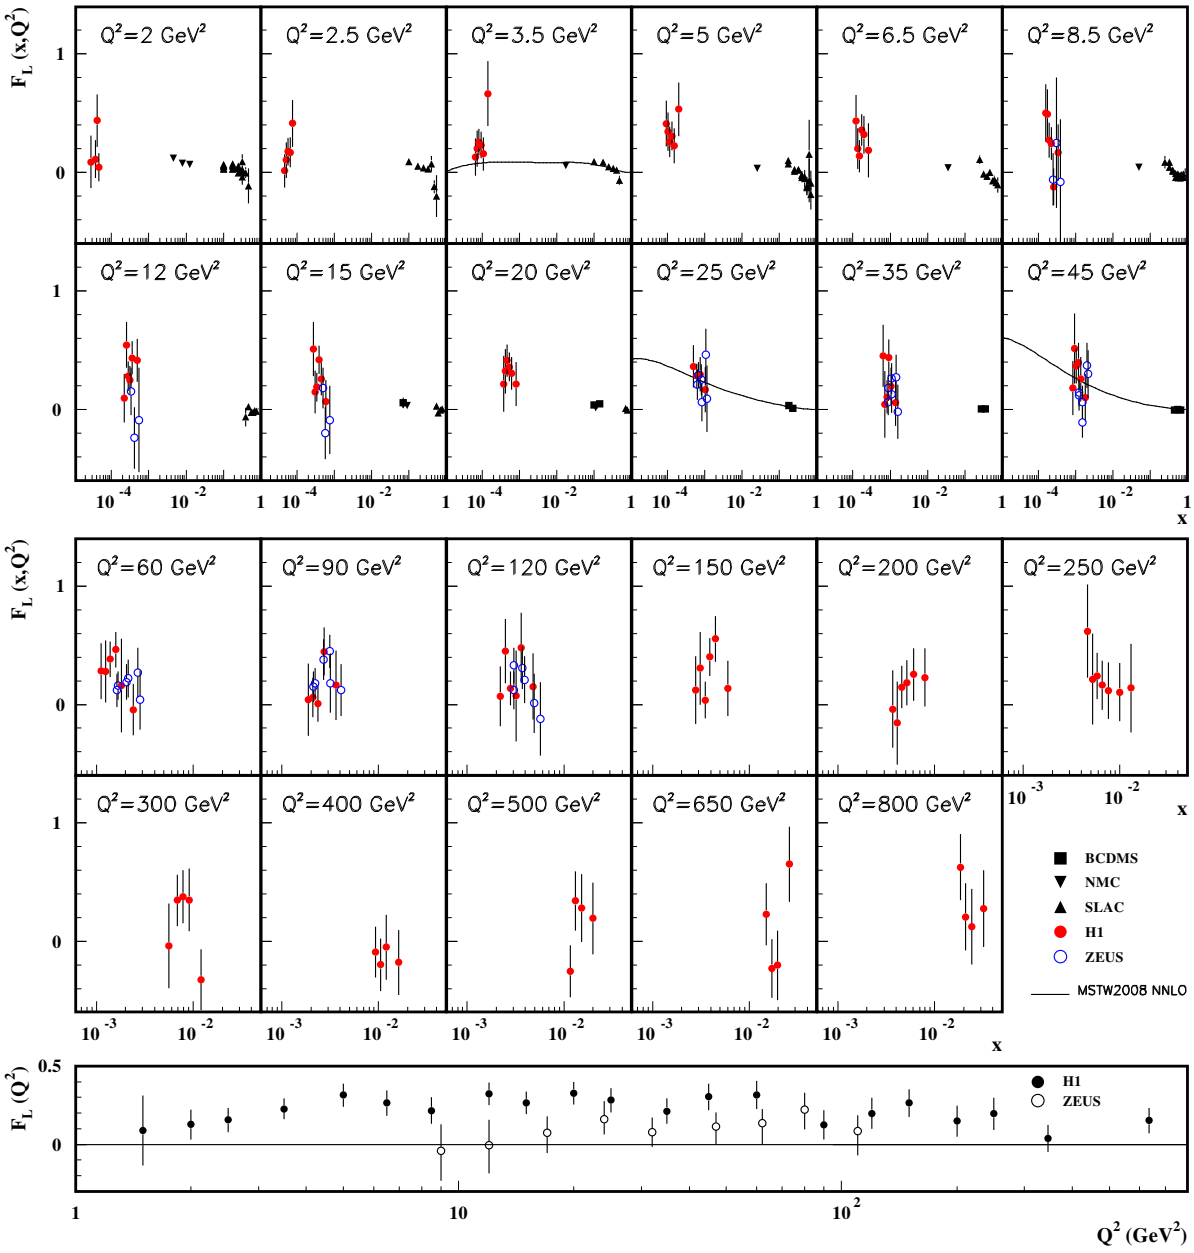

Figure 18.15: Top panels: The longitudinal structure function F_L as a function of x in bins of fixed Q^2 measured on the proton (except for the SLAC data which also contain deuterium data). BCDMS, NMC, and SLAC results are from measurements of R (the ratio of longitudinal to transverse photon absorption cross sections) which are converted to F_L by using the BDCMS parameterization of F_2 (A.C. Benvenuti *et al.*, Phys. Lett. **B223**, 485 (1989)). It is assumed that the Q^2 dependence of the fixed-target data is small within a given Q^2 bin. Some of the other data may have been rebinned to common Q^2 values. Some points have been slightly offset in x for clarity. Also shown is the MSTW2008 parameterization given at three Q^2 values (A.D. Martin *et al.*, Eur. Phys. J. **C63**, 189 (2009)). References: **H1**—V. Andreev *et al.*, Eur. Phys. J. **C74**, 2814 (2014); **ZEUS**—S. Chekanov *et al.*, Phys. Lett. **B682**, 8 (2009); H. Abramowicz et al., Phys. Rev. **D90**, 072002 (2014); **BCDMS**—A. Benvenuti *et al.*, Phys. Lett. **B223**, 485 (1989); **NMC**—M. Arneodo *et al.*, Nucl. Phys. **B483**, 3 (1997); **SLAC**—L.W. Whitlow *et al.*, Phys. Lett. **B250**, 193 (1990) and numerical values from the thesis of L.W. Whitlow (SLAC-357).
Bottom panel: The longitudinal structure function F_L as a function of Q^2. Some points have been slightly offset in Q^2 for clarity. References: **H1**—V. Andreev *et al.*, Eur. Phys. J. **C74**, 2814 (2014); **ZEUS**—H. Abramowicz et al., Phys. Rev. **D90**, 072002 (2014).
The results shown in the bottom plot require the assumption of the validity of the QCD form for the F_2 structure function in order to extract F_L. Statistical and systematic errors added in quadrature are shown for both plots.

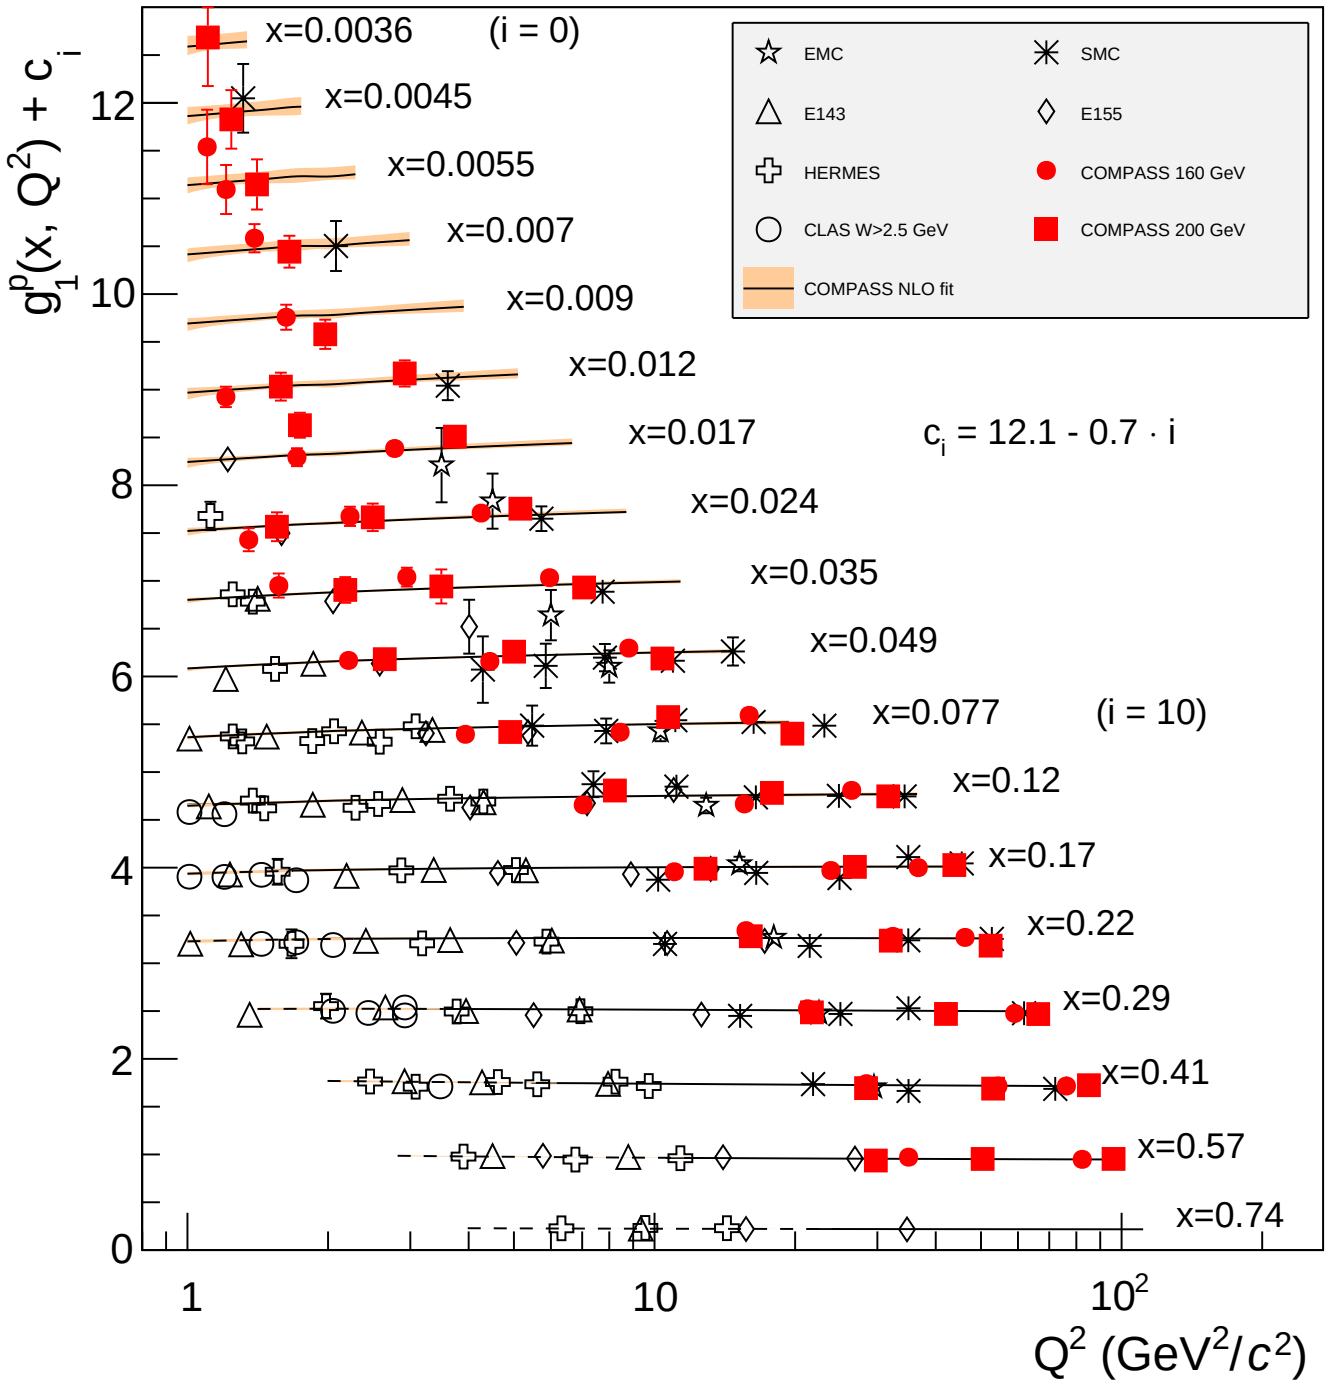

Figure 18.16: World data on the spin-dependent structure function g_1^p as a function of Q^2 for various values of x The lines represent the Q^2 dependence for each value of x, as determined from a NLO QCD fit. The dashed ranges represent the region with $W^2 < 10$ (GeV/c^2)^2. References: **EMC**—J. Ashman *et al.*, Phys. Lett. **B206**, 363 (1988); Nucl. Phys. **B328**, 1 (1989); **E143**—K. 19. Fragmentation Functions in e^+e^-, ep, and pp Collisions

Revised August 2023 by O. Biebel (Ludwig-Maximilians U.), D. de Florian (ICAS and ICIFI, UNSAM), D. Milstead (Stockholm U.) and W. Vogelsang (Tübingen U.).

19.1 Introduction to fragmentation

Quarks and gluons produced in hard-scattering reactions will ultimately give rise to the colorless hadronic bound states that may be observed in the detector. The associated hadronization process is described by fragmentation functions $D_i^h(x,\mu^2)$ $(i = q, \bar{q}, g)$ which are universal functions representing, in the simplest picture, a measure of the probability density that an outgoing parton produces a hadron h. Here, x is the fraction of the parton's momentum transferred to the hadron, and μ is a 'resolution' scale known as factorization scale. The $D_i^h(x,\mu^2)$ may be viewed as the final-state analogs of the initial-state parton distribution functions (PDFs) addressed in Section 18 of this *Review*. They are also sometimes referred to as *timelike* distributions since they are primarily accessed in e^+e^- annihilation via a timelike intermediate boson. (See Refs. [1,2] for introductory reviews, and Refs. [3–5] for summaries of experimental and theoretical research in this field).

The cleanest laboratory for the study of fragmentation functions is provided by semi-inclusive electron-positron annihilation, $e^+e^- \to \gamma/Z \to h+X$. The cross section for this reaction may be expressed in terms of 'fragmentation structure functions' $F_{T,L,A}$ that are directly related to the fragmentation functions. At center-of-mass (CM) energy $\sqrt{s} = q^2$ we have

$$\frac{1}{\sigma_0}\frac{d^2\sigma^h}{dx\,d\cos\theta} = \frac{3}{8}(1+\cos^2\theta)F_T^h(x,q^2) + \frac{3}{4}\sin^2\theta\,F_L^h(x,q^2) + \frac{3}{4}\cos\theta\,F_A^h(x,q^2)\,. \tag{19.1}$$

Here, q is the four-momentum of the intermediate photon or Z-boson, with $q^2 > 0$, and $x = 2P_h \cdot q/q^2$ with the hadron's four-momentum P_h is the fragmentation counterpart of the familiar DIS Bjorken variable. (Note that $x = 2E_h/\sqrt{s} \le 1$ in terms of the energy E_h of the produced hadron in the CM frame of the electron positron pair.) Furthermore, in the same frame, θ is the hadron's angle relative to the electron beam direction. Eq. (19.1) is the most general form for unpolarized inclusive single-particle production via vector bosons [6]. The fragmentation structure functions F_T and F_L represent the contributions from γ/Z polarizations transverse or longitudinal with respect to the direction of motion of the hadron. The parity-violating term with the asymmetric fragmentation function F_A arises from the interference between vector and axial-vector contributions. Various normalization factors σ_0 are used in the literature, ranging from the total cross section $\sigma_{\rm tot}$ for $e^+e^- \to$ hadrons, including all weak and QCD contributions, to $\sigma_0 = 4\pi\alpha^2 N_c/3s$ with $N_c = 3$, the lowest-order QED cross section for $e^+e^- \to \mu^+\mu^-$ times the number of colors N_c. LEP1 measurements of the three fragmentation structure functions are shown in Fig. 19.1.

Integration of Eq. (19.1) over all θ yields the total fragmentation structure function $F^h = F_T^h + F_L^h$:

$$\frac{1}{\sigma_0}\frac{d\sigma^h}{dx} = F^h(x,q^2) = \sum_i \int_x^1 \frac{dz}{z}\,C_i\left(z,\alpha_{\rm s}(\mu),\frac{q^2}{\mu^2}\right) D_i^h\left(\frac{x}{z},\mu^2\right)\,. \tag{19.2}$$

On the right we have written the factorized expression for the structure function in terms of a sum over convolutions of the fragmentation functions D_i^h for partons $i = u,\ \bar{u},\ d,\ \bar{d},\ \ldots,\ g$ with perturbative coefficient functions C_i. Since photons and Z bosons do not distinguish between quarks and antiquarks, e^+e^- annihilation primarily constrains the combinations $D_q^h + D_{\bar{q}}^h$. Gluon fragmentation contributes only at higher order in perturbation theory or by scaling violations. Corrections to the factorized expression in Eq. (19.2) are suppressed by inverse powers of q^2. They arise from quark and hadron mass terms and from non-perturbative effects.

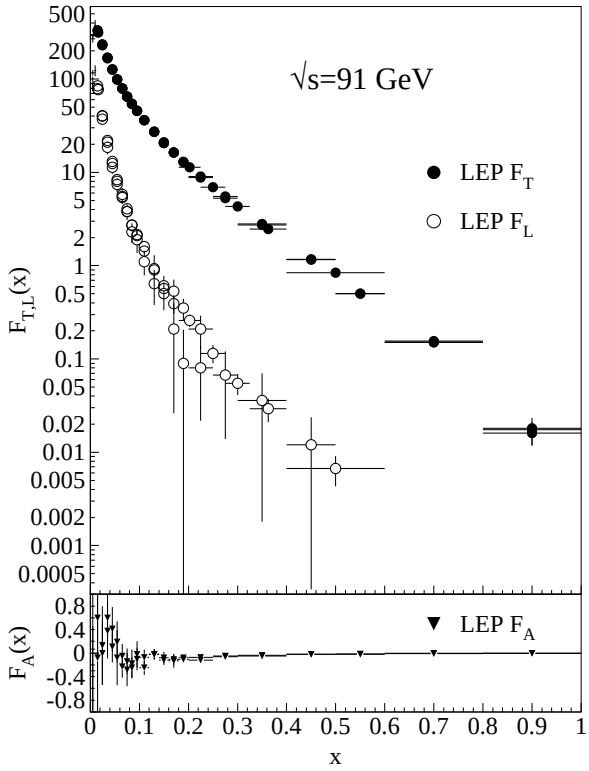

Figure 19.1: LEP1 measurements of total transverse (F_T), longitudinal (F_L), and asymmetric (F_A) fragmentation structure functions [7]. Data points with relative errors greater than 100% are omitted.

Analogous factorized expressions as in Eq. (19.2) may be written for each of the structure functions $F_{T,L,A}$ individually.

The fragmentation functions obey the momentum sum rule constraint

$$\sum_h \int_0^1 dx\,x\,D_i^h(x,\mu^2) = 1\,, \tag{19.3}$$

separately for each flavor i. Note that the sum rule involves a sum over all possible produced hadrons. The dependence of the functions D_i^h on the factorization scale μ^2 will be discussed in the next section.

Measurements of hadron production in deeply-inelastic lepton-proton scattering and hadron-hadron scattering are complementary to those in e^+e^- annihilation. The former process, $\ell p \to \ell' + h + X$, is known as *semi-inclusive deep-inelastic scattering (SIDIS)*. Here, in analogy with Eq. (19.2), the high virtuality of the photon in DIS also permits factorization of the cross section in terms of fragmentation functions, PDFs for the incoming proton, and perturbative hard-scattering cross sections. Likewise, factorization also occurs for $pp \to h + X$ at large transverse momentum of the produced hadron, and for $pp \to {\rm jet}(h) + X$, where the hadron is part of a fully reconstructed jet. The fragmentation functions contributing to $e^+e^- \to h + X$, $\ell p \to \ell' + h + X$, and $pp \to h + X$, $pp \to {\rm jet}(h) + X$ are universal in the sense that the same functions appear in the factorized expressions for the three reactions. Modern QCD analyses of fragmentation functions "globally" take into account experimental data sets for all three types of processes in order to obtain optimal sets of fragmentation functions.

Electron-positron annihilation has the advantage that there is no hadronic initial state and hence no beam remnant. This is in contrast to $\ell p \to \ell' + h + X$ or $pp \to h + X$, which are affected by hadron remnant contributions associated with the partons of the initial-state hadron(s) which are collaterally involved in the hard lepton-parton or parton-parton collision. On the other hand,

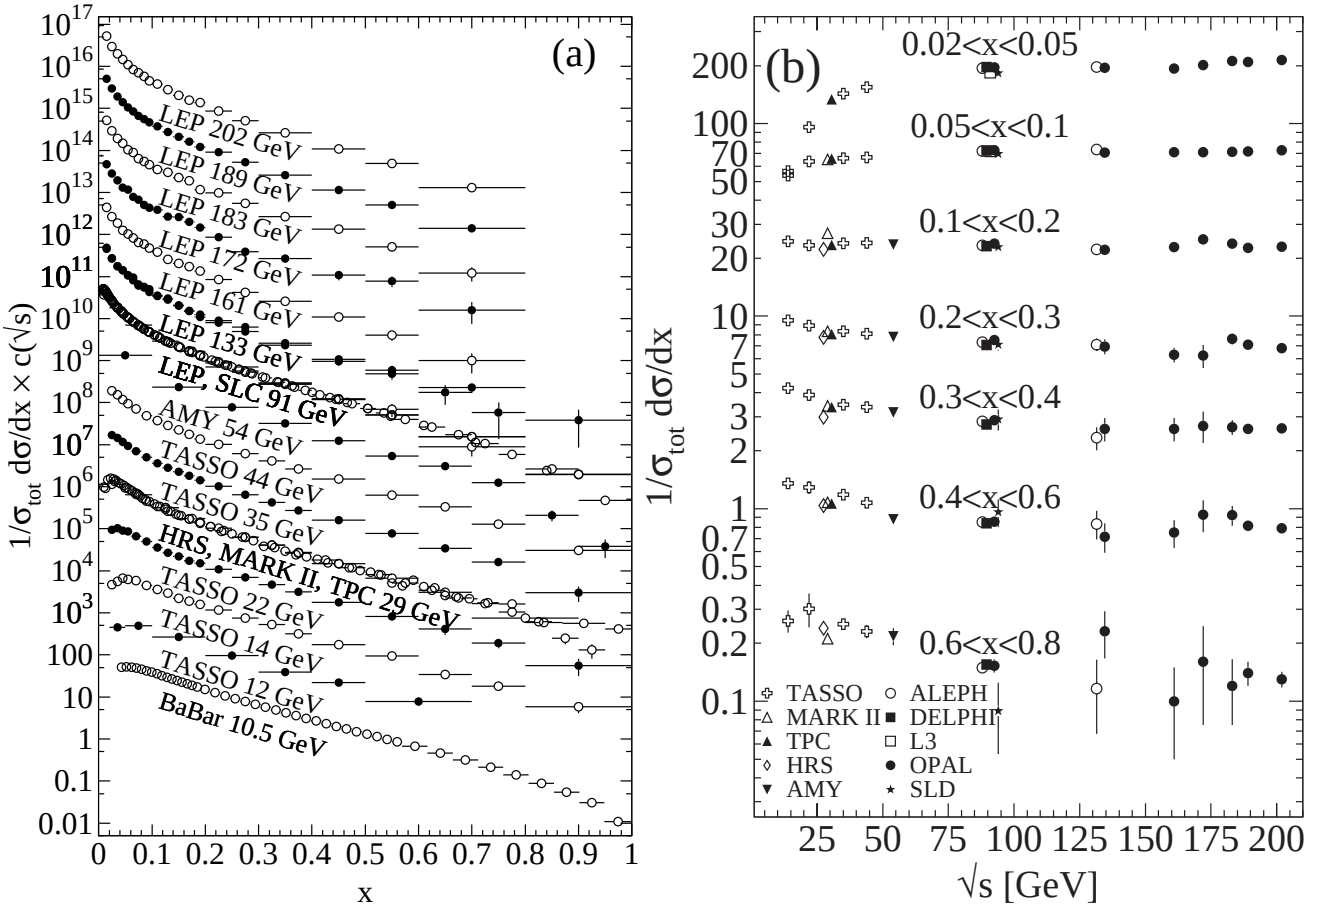

Figure 19.2: Cross section for $e^+e^- \to h + X$ for all charged hadrons [8–26], (a) for different CM energies $\sqrt{s}$ versus x, and (b) for various ranges of x versus $\sqrt{s}$. For (a) the distributions have been scaled by $c(\sqrt{s}) = 10^i$ with i ranging from $i = 0$ ($\sqrt{s} = 12$ GeV) to $i = 13$ ($\sqrt{s} = 202$ GeV).

$e^+e^- \to h + X$ has little sensitivity to D_g^h and is insensitive to the charge asymmetries $D_q^h - D_{\bar{q}}^h$. These quantities are best constrained in proton–(anti-)proton and electron-proton scattering, respectively. Especially the latter provides an environment that allows the study of the influence of initial-state QCD radiation on the fragmentation process, of the partonic and spin structure of the hadron target, and of the target remnant system. (See Ref. [27] for a comprehensive review of the measurements and models of fragmentation in lepton-hadron scattering).

Moreover, unlike e^+e^- annihilation where $q^2 = s$ is fixed by the collider energy, lepton-hadron scattering has two independent scales, $Q^2 = -q^2$ and the invariant mass squared, $W^2 \approx Q^2(1-x)/x$, of the hadronic final state, which both can vary by several orders of magnitudes for a given CM energy, thus allowing the study of fragmentation in different environments by a single experiment. For example, in photoproduction the exchanged photon is quasi-real ($Q^2 \approx 0$), leading to processes akin to hadron-hadron scattering. In DIS ($Q^2 \gg 1$ GeV^2), using factorization, the hadronic fragments of the struck quark can be directly compared with quark fragmentation in e^+e^- in a suitable frame. Results from lepton-hadron experiments quoted in this report primarily concern fragmentation in the DIS regime. Studies performed by lepton-hadron experiments of fragmentation with photoproduction data containing high transverse momentum jets or particles are also reported, when these are directly comparable to DIS and e^+e^- results.

Fragmentation studies in lepton-hadron collisions are usually performed in one of two frames in which the target hadron and the exchanged boson are collinear. The hadronic center-of-mass frame (HCMS) is defined as the rest system of the exchanged boson and incoming hadron, with the z^*-axis defined along the direction of the exchanged boson. The positive z^* direction defines the so-called current fragmentation region. Fragmentation measurements performed in the HCMS often use the Feynman-x variable $x_F = 2p_z^*/W$, where p_z^* is the longitudinal momentum of the particle in this frame. As W is the invariant mass of the hadronic final state, x_F ranges between -1 and 1.

The Breit system [28, 29] is related to the HCMS by a longitudinal boost such that the time component of q vanishes, i.e, $q = (0, 0, 0, -Q)$. In the parton model, the struck parton then has the longitudinal momentum $Q/2$ which becomes $-Q/2$ after the collision. As compared with the HCMS, the current fragmentation region of the Breit frame is more closely matched to the partonic scattering process, and is thus appropriate for direct comparisons of fragmentation functions in DIS with those from e^+e^- annihilation. The variable $x_p = 2p^*/Q$, where p^* is the particle's momentum in the current region of the Breit frame, is used at HERA for measurements in the Breit frame, enabling rather direct comparisons of DIS and e^+e^- results.

19.2 Scaling violations and QCD corrections

As mentioned, the coefficient functions for the fragmentation structure functions in $e^+e^- \to h + X$ are amenable to QCD perturbation theory. For each of the structure functions $F_{T,L,A}(x, q^2)$ in Eq. (19.1) (and hence for the total structure function F^h in Eq. (19.2)) the coefficient function has an expansion of the form

$$C_{a,i}\left(z, \alpha_s(\mu), \frac{q^2}{\mu^2}\right) = (1 - \delta_{aL})\,\delta_{iq}\,\delta(1-z) + \frac{\alpha_s(\mu)}{2\pi}\,c_{a,i}^{(1)}\left(z, \frac{q^2}{\mu^2}\right) + \left(\frac{\alpha_s(\mu)}{2\pi}\right)^2 c_{a,i}^{(2)}\left(z, \frac{q^2}{\mu^2}\right) + . \quad (19,4)$$

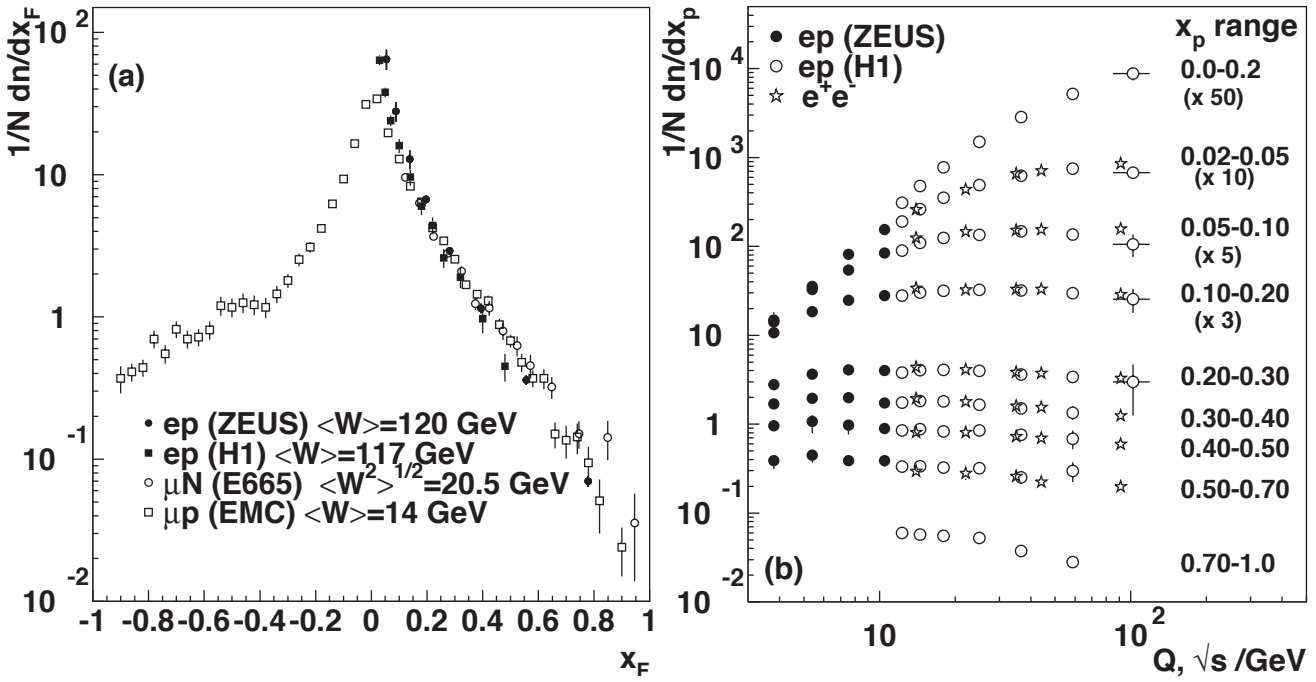

Figure 19.3: (a) The distribution $1/N \cdot dN/dx_F$ for all charged particles in DIS lepton-hadron experiments at different values of W, measured in the HCMS [30–33]. (b) Scaling violations of the fragmentation structure function for all charged particles in the current region of the Breit frame of DIS [34, 35] and in e^+e^- interactions [19, 36]. The data are shown as a function of $\sqrt{s}$ for e^+e^- results, and as a function of Q for the DIS results, each within the same indicated intervals of the scaled momentum x_p. The data for the four lowest intervals of x_p are multiplied by factors 50, 10, 5, and 3, respectively for better visibility.

where $a = T, L, A$. At the zeroth order in the strong coupling α_s the coefficient functions C_g for gluons vanish, while for (anti-) quarks $C_i = g_i(s)\,\delta(1-z)$ (except for F_L for which the leading contribution is of order α_s, as indicated in Eq. (19.4)). Here $g_i(s)$ is the appropriate electroweak coupling. In particular, $g_i(s)$ is proportional to the squared charge of the quark i at $s \ll M_Z^2$, when weak effects can be neglected. The full electroweak prefactors $g_i(s)$ can be found in Ref. [6]. The first-order QCD corrections to the coefficient functions have been calculated in Refs. [37,38], and the second-order terms in [39–41]. Thus, the coefficient functions are known to NNLO, except for F_L. We note that beyond the leading order the coefficient functions, and hence the fragmentation functions, start to depend on the choice of factorization scheme. The standard choice in the literature is the $\overline{\rm MS}$ scheme.

The simplest parton-model approach would predict scale-independent ('scaling') x-distributions for both the structure function F^h and the parton fragmentation functions D_i^h. Perturbative QCD corrections lead to logarithmic scaling violations via the evolution equations [42]

$$\frac{\partial}{\partial \ln \mu^2} D_i^h(x,\mu^2) \;=\; \sum_j \int_x^1 \frac{dz}{z}\, P_{ji}\Big(z, \alpha_s(\mu^2)\Big) D_j^h\left(\frac{x}{z}, \mu^2\right) \;, \tag{19.5}$$

where the functions $P_{ij}(z, \alpha_s(\mu^2))$ describe the splitting process $i \to j + X$, where parton j carries the longitudinal momentum fraction z of parton i. Note that for fragmentation the relevant splitting functions are P_{ji} (rather than P_{ij} as for the PDFs) since D_j^h represents the fragmentation of the final parton. Usually the system of evolution equations is decomposed into a 2×2 flavor-singlet sector comprising the gluon and the sum of all quark and antiquark fragmentation functions, and scalar ('non-singlet') equations for quark-antiquark and flavor differences.

The splitting functions in Eq. (19.5) have the perturbative expansion

$$P_{ji}(z,\alpha_s) \;=\; \frac{\alpha_s}{2\pi} P_{ji}^{(0)}(z) + \left(\frac{\alpha_s}{2\pi}\right)^2 P_{ji}^{(1)}(z) + \left(\frac{\alpha_s}{2\pi}\right)^3 P_{ji}^{(2)}(z) + \ldots \;, \tag{19.6}$$

where the leading-order (LO) functions $P^{(0)}(z)$ [42, 43] are the same as those for the initial-state parton distributions. The next-to-leading order (NLO) corrections $P^{(1)}(z)$ have been calculated in Refs. [44–48] (there are well-known misprints in the journal version of Ref. [45]). Ref. [48] also includes the spin-dependent case. The timelike functions are different from, but related to, their spacelike counterparts, see also Ref. [49]. The connections between the two sets of functions has facilitated recent calculations of the next-to-next-to-leading order (NNLO) quantities $P_{qq}^{(2)}(z)$ and $P_{gg}^{(2)}(z)$ in Eq. (19.6) [40,50]. In the same way, the corresponding off-diagonal quantities $P_{qg}^{(2)}$ and $P_{gq}^{(2)}$ were recently obtained in Ref. [51] with the help of constraints from the momentum sum rule Eq. (19.3) [50] and of the limit of $C_A = C_F = n_f$ for which QCD becomes supersymmetric. An uncertainty still remains for the $P_{qg}^{(2)}$ kernel, which however does not affect the logarithmic behavior at small and large momentum fractions. With the exception of Ref. [47], all these higher-order results refer to the standard $\overline{\rm MS}$ scheme with a fixed number n_f of light flavors. When the threshold for the production of a heavier quark flavor is crossed in the course of the scale evolution, fragmentation functions change. The NLO treatment of these flavor thresholds in the evolution has been addressed in Ref. [52].

The phenomenological effect of scale evolution is similar in the timelike and spacelike cases: As the scale increases, one observes a scaling violation in which the x-distribution is shifted towards lower values. This can be seen from Fig. 19.2 where a set of measurements of the total fragmentation structure function in e^+e^- annihilation are shown. In particular, the figure on the right exhibits the dependence on $\sqrt{q^2} = \sqrt{s}$ at fixed values of x. QCD analyses of these data are discussed in Section 19.5 below.

The NLO coefficient functions for SIDIS, $ep \to e + h + X$, have been presented in Refs. [37, 38] Corresponding results have also been obtained for the case that a non-vanishing hadron transverse momentum is required in the HCMS frame [53, 54].

Scaling violations in DIS are shown in Fig. 19.3 for both the HCMS and the Breit frames. In Fig. 1.3(a) the distribution in terms of $x_F = 2p_z^*/W$ shows a steeper slope in ep data than for the lower-energy μp data for $x_F > 0.15$, indicating the scaling

violations. At smaller values of x_F in the current jet region, the multiplicity of particles substantially increases with W, owing to the increased phase space available for the fragmentation process. The EMC data access both the current region and the region of the fragmenting target remnant system. At higher values of $|x_F|$, due to the extended nature of the remnant, the multiplicity in the target region far exceeds that in the current region. For acceptance reasons the remnant hemisphere of the HCMS is only accessible by the lower-energy fixed-target experiments.

Using hadrons from the current hemisphere in the Breit frame, measurements of fragmentation functions and the production properties of particles in ep scattering have been reported in Refs. [34, 35, 55–58]. Fig. 19.3(b) compares results from ep scattering and e^+e^- experiments; the latter results have been divided by two as they cover both event hemispheres. The agreement between the DIS and e^+e^- results is fairly good. However, processes in DIS which are not present in e^+e^- annihilation, such as boson-gluon fusion and initial-state QCD radiation, can depopulate the current region. These effects become most prominent at low values of Q and x_p. Hence, when compared with e^+e^- annihilation data at $\sqrt{s} = 5.2$, 6.5 GeV [59] not shown here, the DIS particle rates tend to lie below those observed in e^+e^- annihilation. A ZEUS study [60] finds that the direct comparability of the ep data to e^+e^- results at low scales is improved if twice the energy in the current hemisphere of the Breit frame, $2E_B^{\rm cr}$, is used instead of $Q/2$ as the fragmentation scale. Choosing $2E_B^{\rm cr}$ for the fragmentation scale approximates QCD radiation effects relevant at low scales, as detailed in Ref. [29].

19.3 Fragmentation functions for small particle momenta

The higher-order timelike splitting functions in Eq. (19.6) are singular at small values of x. They show a double-logarithmic enhancement, with leading terms of the form $\alpha_{\rm s}^k\left(\ln^{2k-2}x\right)/x$ at the kth order of perturbation theory, corresponding to poles $\alpha_{\rm s}^k\,(N-1)^{1-2k}$ for the Mellin moments

$$P^{(k)}(N) \;=\; \int_0^1 dx\; x^{N-1}\; P^{(k)}(x)\;. \qquad (19.7)$$

Despite large cancellations between leading and non-leading logarithms at non-asymptotic values of x, the resulting small-x rise in the timelike splitting functions dwarfs that of their spacelike counterparts for the evolution of the parton distributions in Section 18 of this *Review*, see Fig. 1 of Ref. [50]. Consequently, in fragmentation the fixed-order approximation to the evolution breaks down orders of magnitude earlier in x than in DIS.

The pattern of the known coefficients and other considerations suggest that the double-logarithmic terms sum to all-order expressions without any pole at $N = 1$, such as [61, 62]

$$P_{gg}^{\rm LL}(N) \;=\; -\frac{1}{4}\left(N - 1 - \sqrt{(N-1)^2 \cdot 24\,\alpha_{\rm s}/\pi}\right) \qquad (19.8)$$

for the gluon-to-gluon splitting function at leading logarithmic order. Keeping the first three terms in the resulting expansion of Eq. (19.5) around $N = 1$ and taking the Mellin inverse yields a Gaussian in the variable $\xi = \ln(1/x)$ for the small-x fragmentation functions,

$$xD(x, q^2 = s) \;\propto\; \exp\left[-\frac{1}{2\sigma^2}(\xi - \xi_p)^2\right]\;, \qquad (19.9)$$

with the peak position and width varying with the energy as [63] (see also Ref. [2])

$$\xi_p \;\simeq\; \frac{1}{4}\ln\left(\frac{s}{\Lambda^2}\right)\;,\quad \sigma \;\propto\; \left[\ln\left(\frac{s}{\Lambda^2}\right)\right]^{3/4}\;. \qquad (19.10)$$

Next-to-leading logarithmic corrections to the above predictions have been calculated [64]. In the method of Ref. [65], see also Refs. [66, 67], the corrections are included in an analytical form known as the 'modified leading logarithmic approximation' (MLLA). Alternatively they can be used to compute higher-moment corrections to the shape in Eq. (19.9) [68]. The small-x resummation of the coefficient functions for semi-inclusive e^+e^- annihilation and of the timelike spitting functions in the standard $\overline{\rm MS}$ scheme was extended in Refs. [69–73] and has reached full next-to-next-to-leading logarithmic accuracy. Applications of these results to gluon and quark jet multiplicities have been presented in Refs. [74].

Fig. 19.4 shows the ξ distribution for charged particles produced in the current region of the Breit frame in DIS and in e^+e^- annihilation. Consistently with Eq. (19.9) (the 'hump backed plateau') and Eq. (19.10) the distributions have a Gaussian shape, with the peak position and area increasing with CM energy (e^+e^-) and Q^2 (DIS).

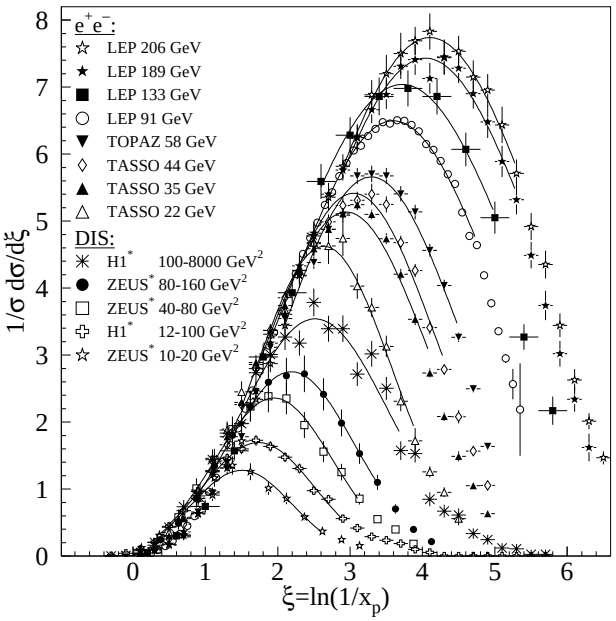

Figure 19.4: Distribution of the normalized fragmentation cross sections in $\xi = \ln(1/x_p)$ at several CM energies (e^+e^-) [10,11,16–19,57,58,75–78] and for intervals of Q^2 (DIS). At each energy only one representative measurement is displayed. For clarity some measurements at intermediate CM energies (e^+e^-) or Q^2 ranges (DIS) are not shown. The DIS measurements ($*$) have been scaled by a factor of 2 for direct comparability with the e^+e^- results. Fits of simple Gaussian functions are overlaid for illustration.

The predicted energy dependence of the peak in the ξ distribution (see Eq. (19.10)) is explained by soft gluon coherence (angular ordering), *i.e.*, the destructive interference of the color wavefunction of low energy gluon radiation, which correctly predicts the suppression of hadron production at small x. Of course, a decrease at very small x is expected on purely kinematical grounds, but this would occur at particle energies proportional to their masses, *i.e.*, at $x \propto m/\sqrt{s}$ and hence $\xi \sim \frac{1}{2}\ln s$. Thus, if the suppression were purely kinematic, the peak position ξ_p would vary twice as rapidly with the energy, which is ruled out by the data in Fig. 19.5. The e^+e^- and DIS data agree well with each other, demonstrating the universality of hadronization and the MLLA prediction. Measurements of the higher moments of the ξ distribution in e^+e^- [19, 78–80] and DIS [58] have also been performed and show consistency with each other.

The average charged-particle multiplicity is another observable sensitive to fragmentation functions for small particle momenta. Perturbative predictions using both NLO [89] and MLLA [90, 91] have been obtained by solving Eq. (19.5) yielding

$$\left\langle n_G(Q^2)\right\rangle \propto \alpha_{\rm s}^b(Q^2)\cdot\exp\left[\frac{c}{4\pi b_0\sqrt{\alpha_{\rm s}(Q^2)}}\cdot\left(1 + 6a_2\frac{\alpha_{\rm s}(Q^2)}{\pi}\right)\right], \qquad (19.11)$$

where $b = \frac{1}{4} + \frac{10}{27}\frac{n_f}{4\pi b_0}$, $c = \sqrt{96\pi}$, with $b_0 = (33 - 2n_f)/(12\pi)$,

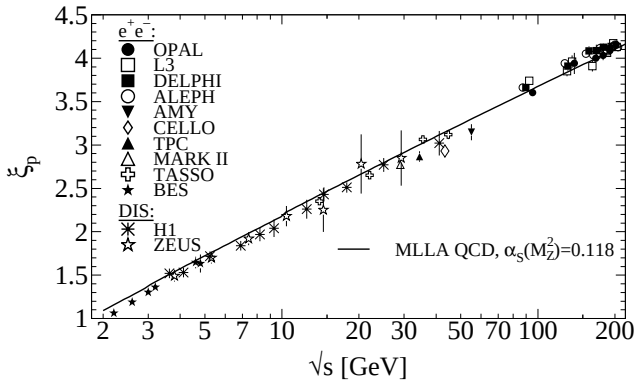

Figure 19.5: Evolution of the peak position, ξ_p, of the ξ distribution with the CM energy $\sqrt{s}$. The MLLA QCD prediction using $\alpha_s(s = M_Z^2) = 0.118$ is superimposed to the data of Refs. [10, 12, 15, 19, 56, 57, 76, 77, 80–88].

cf. Section 9 of this *Review*, for n_f contributing quark flavors. Higher-order corrections to Eq. (19.11) are known up to next-to-next-to-next-to-leading order (N^3LO), for details and references see [92]. The term proportional to $a_2 \approx -0.502 + 0.0421\, n_f - 0.00036\, n_f^2$ in Eq. (19.11) is the contribution due to NNLO corrections [93]. The quantity $\langle n_G(Q^2)\rangle$ refers to the average number of gluons, while for $\langle n_q(Q^2)\rangle$ for quarks a correction factor $1/r$ is required due to the different color factors in quark and gluon couplings, so that $\langle n_q(Q^2)\rangle = \langle n_G(Q^2)\rangle/r$. The correction factor depends only weakly on Q^2; higher-order corrections up to N^3LO on the asymptotic value $r = C_A/C_F = 9/4$ [94] are quoted in [92].

Employing the hypothesis of 'Local Parton-Hadron Duality' (LPHD) [90], *i.e.*, that the color charge of partons is balanced locally in phase space and, hence, their hadronization occurs locally such that (Mellin transformed) parton and hadron inclusive distributions directly correspond, Eq. (19.11) can be applied to describe average charged particle multiplicities obtained in e^+e^- annihilation. The equation can also be applied to $e^\pm p$ scattering if the current fragmentation region of the Breit frame is considered for measuring the average charged-particle multiplicity. Fig. 19.6 shows corresponding data and fits of Eq. (19.11) where apart from an LPHD normalization factor a constant offset has been allowed for, so that $\langle n_{\rm ch}(Q)\rangle = K_{\rm LHPD} \cdot \langle n_G(Q)\rangle/r + n_0$.

In hadron-hadron collisions beam remnants, e.g. from single-diffractive (SD) scattering where one colliding proton is negligibly deflected while hadrons related with the other colliding proton are well-separated in rapidity from the former proton, contribute to the measurement of the hadron multiplicity from a hard parton-parton scattering, making interpretation of the data more model dependent. Experimental results are usually given for inelastic processes or for non-single diffractive processes (NSD). Due to the large beam particle momenta at Tevatron and LHC, not all final state particles can be detected within the limited detector acceptance. Therefore, experiments at Tevatron and LHC quote particle multiplicities for limited ranges of pseudo-rapidity $\eta = -\ln\tan(\vartheta/2)$ or at central rapidity, i.e. $\eta = 0$, as shown in Fig. 19.6.

A universality of the average particle multiplicities in e^+e^- and $p^{(}\overline{p}^{)}$ processes has been reported in Ref. [124] when considering an effective collision energy $Q_{\rm eff} = \sqrt{s}/k$ in $p^{(}\overline{p}^{)}$ reduced by a factor of $k \approx 3$, plus a constant offset of $n_0 \approx 2$. A more detailed review is available in Ref. [125]. According to the investigations presented in Ref. [126] the universality of the energy dependence of average particle multiplicities also applies to hadron-hadron and nucleus-nucleus collisions for both full and central rapidity multiplicities. Evidence for this universality is given by the good agreement for the energy dependence of Eq. (19.11) when fit to the $p^{(}\overline{p}^{)}$ data as shown in Fig. 19.6.

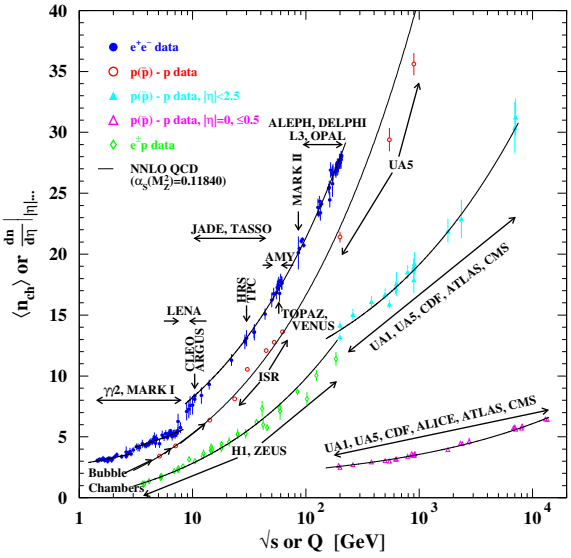

Figure 19.6: Average charged-particle multiplicity $\langle n_{\rm ch}\rangle$ as a function of $\sqrt{s}$ or Q for e^+e^- and $p\overline{p}$ annihilations, and pp and ep collisions. The indicated errors are statistical and systematic uncertainties added in quadrature, except when no systematic uncertainties are given. All NNLO QCD curves are from Eq. (19.11) with fitted normalization, $K_{\rm LHPD}$, and offset, n_0, using a fixed $\alpha_s(M_Z^2) = 0.1184$ [95] and for e^+e^- annihilation data $n_f = 3$, 4, or 5 depending on $\sqrt{s}$, else $n_f = 3$. $\mathbf{e^+e^-}$: Contributions from K_S^0 and Λ decays included. Data compiled from Refs. [8,10,16,16,22,77,83,96–106]; $\mathbf{e^\pm p}$: Multiplicities have been measured in the current fragmentation region of the Breit frame. Data compiled from Refs. [35, 57, 58, 60, 107]; $\mathbf{p^{(}\overline{p}^{)}}$: Measured values above 20 GeV refer to non-single diffractive (NSD) processes. Central pseudorapidity multiplicities $(\mathrm{d}n/\mathrm{d}\eta)|_{|\eta|...}$ refer to either $|\eta| < 2.5$ (CMS: $|\eta| < 2.4$) or $|\eta| = 0$ (UA5, CMS, ALICE: $|\eta| < 0.5$). Data compiled from Refs. [108–123].

19.4 Fragmentation models

Although the scaling violations can be calculated perturbatively, the actual form of the parton fragmentation functions is non-perturbative. Perturbative evolution gives rise to a shower of quarks and gluons (partons). Multi-parton final states from leading and higher order matrix element calculations are linked to these parton showers using factorization prescriptions, also called matching schemes, see Ref. [127] for an overview.

Phenomenological schemes are then used to model the carry-over of parton momenta and flavor to the hadrons. Implemented in Monte Carlo event generators (see Section 43 of this *Review*), these schemes have been tuned using e^+e^- data and provide good description of hadron collisions as well, thus providing evidence of the universality of fragmentation. However, e^+e^- mainly fix the quark jet fragmentation while it provides less constraints for modelling the gluon jet fragmentation.

19.5 Phenomenology of quark and gluon fragmentation functions

The fragmentation functions are solutions to the evolution equations Eq. (19.5), but need to be specified at some initial scale μ_0^2 (usually around 1 GeV^2 for light quarks and gluons, and at m_Q^2 for heavy quarks). A typical parameterization for a given light hadron is [128, 131–139]

$$D_i^h(x,\mu_0^2) = N_i\, x^{\alpha_i}(1-x)^{\beta_i}\left(1+\gamma_i(1-x)^{\delta_i}\right)\,, \qquad (19.12)$$

where as indicated the normalization N_i, and the parameters α_i, β_i, γ_i and δ_i depend on the type i of the fragmenting parton. Heavy flavor fragmentation into heavy mesons is discussed in Sec. 19.8 below. The parameters of Eq. (19.12) are obtained by

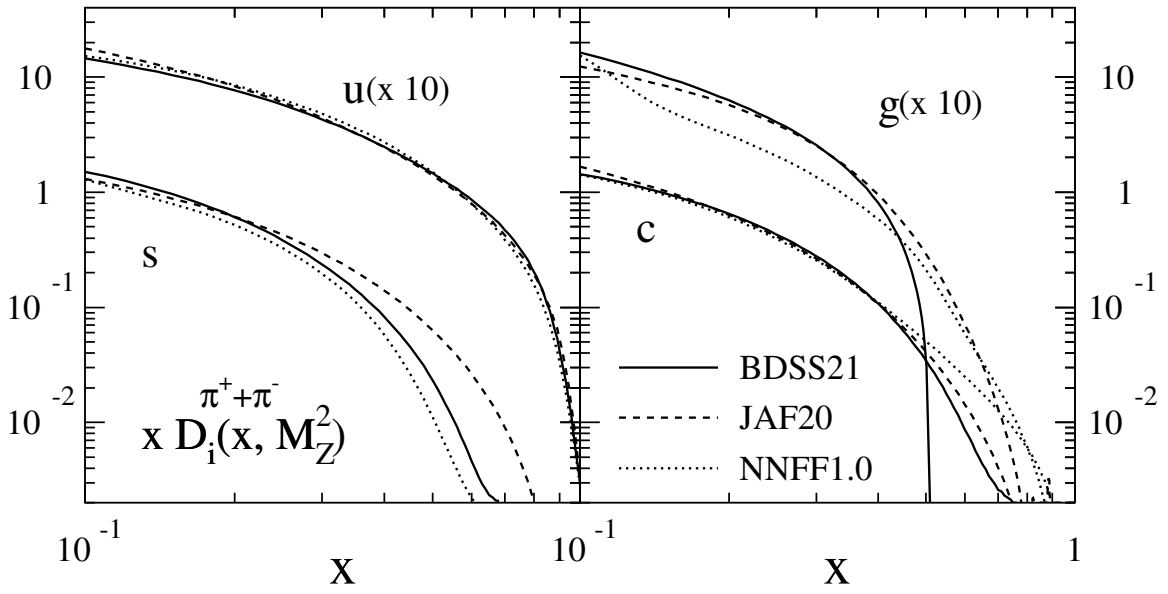

Figure 19.7: Comparison of up, strange, charm and gluon NLO fragmentation functions for $\pi^+ + \pi^-$ at the mass of the Z. The different lines correspond to the results of the analyses performed in Refs. [128–130].

performing global fits to data on various hadron types for different combinations of partons and hadrons in e^+e^-, lepton-hadron and hadron-hadron collisions. We note that the choice of parameterization of the fragmentation functions at the initial scale necessarily introduces a bias since it imposes a certain form of the functions. This bias is largely avoided in neural network approaches which offer a wide flexibility of the initial functions and have recently been applied to fragmentation functions as well [130]. Sets of fragmentation functions are now available for pions, kaons, protons, neutrons, η mesons, Λ baryons, and charged hadrons [129, 130, 132–144]. They are all at NLO level, except for Refs. [130, 141, 144] which have been performed at NNLO level. The latter sets are restricted to the analysis of e^+e^- annihilation data. Recently, data from hadron-hadron collisions have been added in the framework of the neural network approach at NLO accuracy for charged hadrons [145]. It is noteworthy that the NNLO effects lead to an improvement in the theoretical description of the data in e^+e^- annihilation.

Data from e^+e^- annihilation present the cleanest experimental source for the measurement of fragmentation functions, but cannot be used to disentangle quark from antiquark fragmentation. Since the bulk of the e^+e^- annihilation data is obtained at the mass of the Z-boson, where the electroweak couplings are roughly the same for the different partons, it provides the most precise determination of the flavor-singlet combination of quark and antiquark fragmentation functions. Flavor-tagged results [146], distinguishing between the light quark, charm and bottom contributions are of particular value for flavor decomposition, even though those measurements cannot be unambiguously interpreted in perturbative QCD.

The most relevant source for quark-antiquark (and also flavor) separation is provided by SIDIS data. Semi-inclusive measurements are usually performed at much lower scales than for e^+e^- annihilation. The inclusion of SIDIS data in global fits allows for a wider coverage in the evolution of the fragmentation functions, resulting at the same time in a stringent test of the universality of the distributions. Charged-hadron production data in hadronic collisions also have sensitivity to (anti-)quark fragmentation functions. A recent analysis [129] performs a simultaneous extraction of parton distributions and fragmentation functions based on SIDIS data.

The gluon fragmentation function $D_g^h(x)$ can be extracted, in

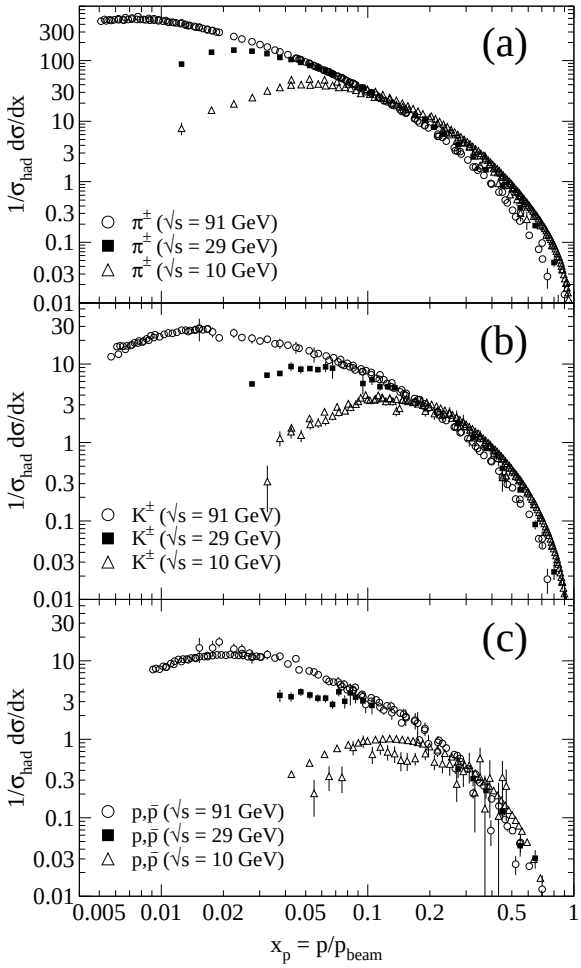

Figure 19.8: Scaled momentum spectra of (a) $\pi^\pm$, (b) $K^\pm$, and (c) $p, \overline{p}$ at $\sqrt{s} = 10$, 29, and 91 GeV [24, 26, 85, 147, 148].

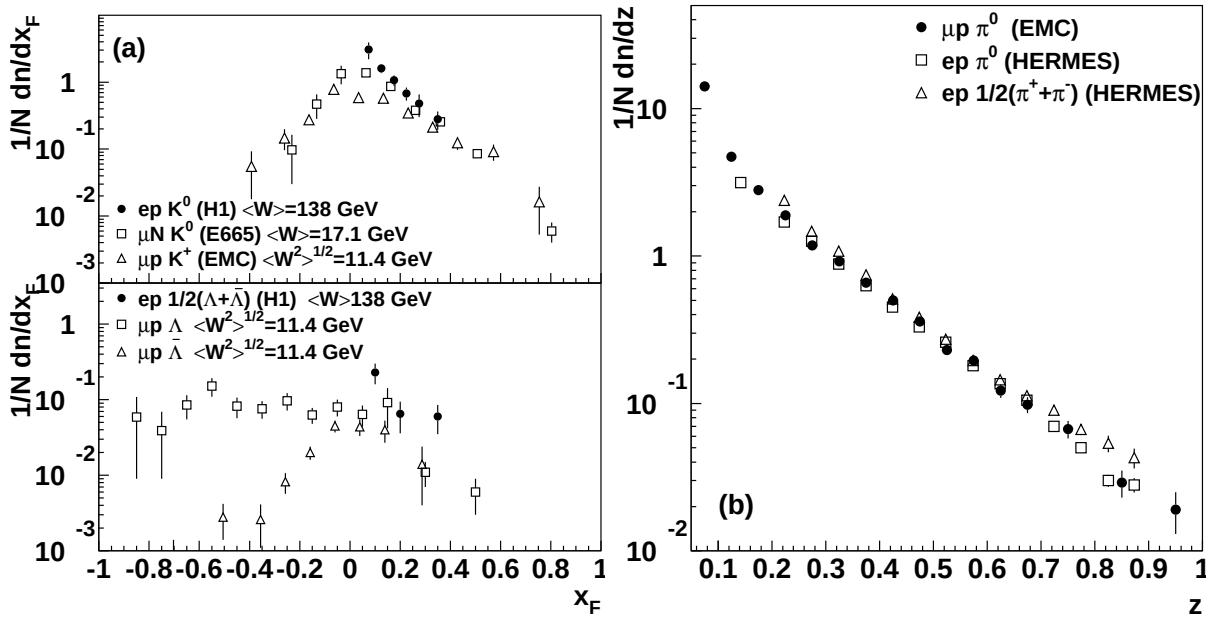

Figure 19.9: (a) $1/N \cdot dn/dx_F$ for identified strange particles in DIS at various values of W [149–151]. (b) $1/N \cdot dn/dz$ for measurements of pions in fixed-target DIS experiments [152–154].

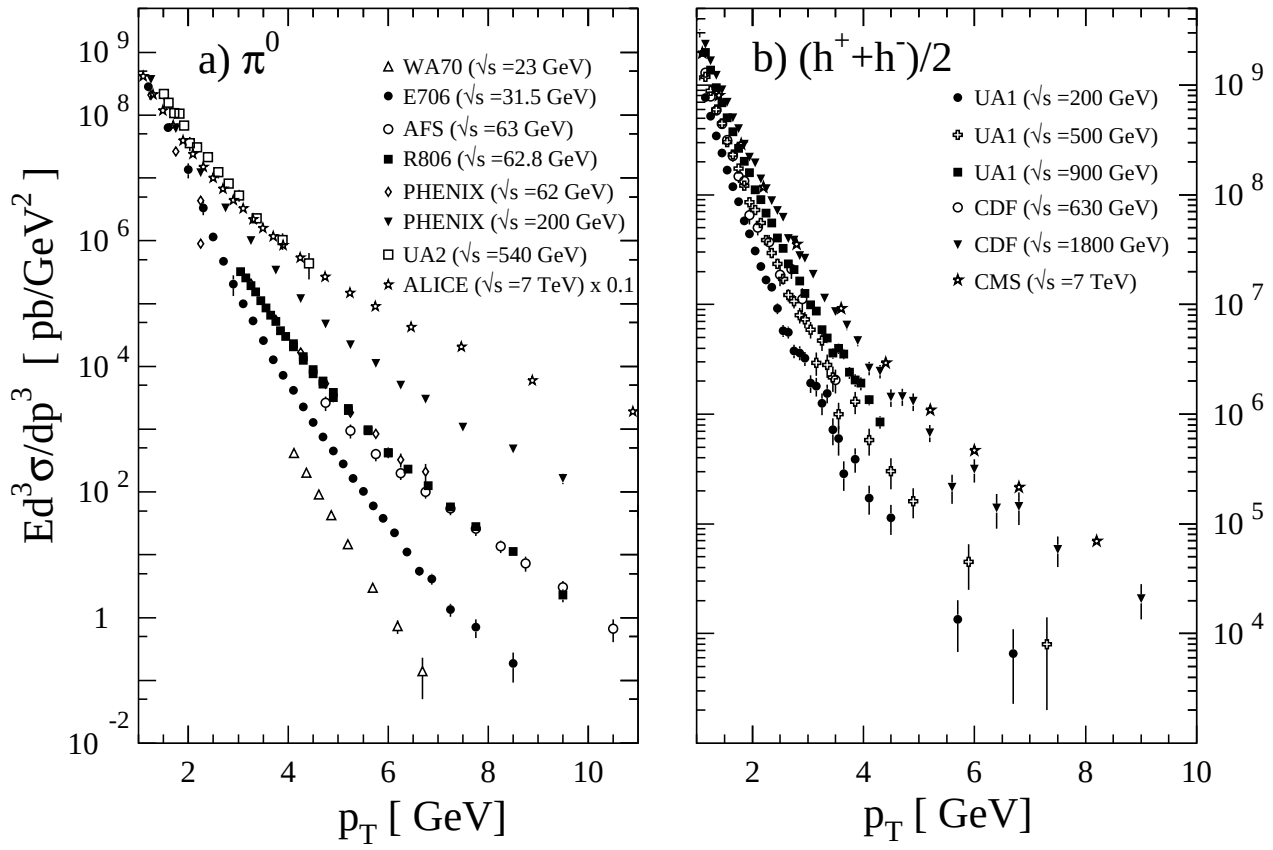

Figure 19.10: Selection of inclusive (a) π^0 and (b) charged-hadron production data from pp [118, 155–160] and $p\bar{p}$ [114, 161, 162] collisions.

principle, from the longitudinal fragmentation structure function F_L in Eq. (19.2), as the coefficient functions $C_{L,i}$ for quarks and gluons are comparable at order α_s. However at NLO, *i.e.*, including the $\mathcal{O}(\alpha_s^2)$ coefficient functions $C_{L,i}^{(2)}$ [39], quark fragmentation is dominant in F_L over a large part of the kinematic range, reducing the sensitivity to D_g^h. This distribution could be determined also by analyzing the scale evolution of the fragmentation functions. This possibility is limited by the lack of sufficiently precise data at energy scales away from the Z-resonance and the dominance of the quark contributions at medium and large values of x. In e^+e^- annihilation, D_g^h can also be deduced from the study of three-jet events in which the gluon jet is identified, for example, by tagging the other two jets with heavy quark decays. To leading order, the measured distributions of $x = E_{\rm had}/E_{\rm jet}$ for

Table 19.1: Classification of spin- and transverse-momentum dependent quark fragmentation functions. For simplicity we have left out the ubiquitous label for flavor i of the fragmenting quark and for hadron species h. Each of the functions carries the argument $(x, x^2k_T^2)$ (plus dependence on a factorization scale), where $xk_T = p_T^h$ is the hadron's transverse momentum. λ and Λ are the quark's and hadron's helicities, respectively, and $\vec{s}_T$ and $\vec{S}_T$ are their transverse spin vectors. We have defined $\left[\vec{a} \times \vec{b}\right] \equiv a^1 b^2 - a^2 b^1$. Finally, m_h is the mass of the produced hadron.

	quark polarization		
hadron pol.	unpolarized	long. polarized	transv. polarized
unpol.	D	–	$\frac{\left[\vec{k}_T \times \vec{s}_T\right]}{m_h} H^\perp$
long. pol.	–	$\lambda \Lambda G_L$	$\frac{\vec{k}_T \cdot \vec{s}_T}{m_h} \Lambda H_L^\perp$
transv. pol.	$\frac{\left[\vec{k}_T \times \vec{S}_T\right]}{m_h} D_T^\perp$	$\frac{\vec{k}_T \cdot \vec{S}_T}{m_h} \lambda G_T^\perp$	$(\vec{s}_T \cdot \vec{S}_T) H_T + \frac{\vec{k}_T \cdot \vec{S}_T}{m_h} \frac{\vec{k}_T \cdot \vec{s}_T}{m_h} H_T^\perp$

particles in gluon jets can be identified directly with the gluon fragmentation function $D_g^h(x)$.

Data for $p^{(\overline{p})} \to h + X$ provide much more direct constraint on D_g^h. At variance with e^+e^- annihilation and SIDIS, here gluon fragmentation contributes already at the lowest order in the coupling constant. At large $x \gtrsim 0.5$, where information from e^+e^- is sparse, data from hadronic colliders significantly improve extractions of D_g^h [131, 132, 138, 140]. Recent LHC data has been included in the NLO analyses [128,138,139] of pion-fragmentation functions; see Sec.(17.7) for more details. Note that these analyses are currently the only ones that 'globally' incorporate available data from all sources, $e^+e^- \to h + X$, $ep \to e'h + X$ and $pp \to h + X$.

We note that recently a 'hybrid' type of high-p_T jet/hadron observable has also been considered both theoretically [163–169] and experimentally [170–177]. It is defined by an identified specific hadron found inside a fully reconstructed jet. This gives rise to a *same-side* hadron-jet momentum correlation that may be addressed using perturbative methods. One of several relevant kinematical variables (see [168] for an overview) is $z_h \equiv (\vec{p}_T^{\,h} \cdot \vec{p}_T^{\,\rm jet})/(p_T^{\rm jet})^2$, where $\vec{p}_T^{\,h}$ and $\vec{p}_T^{\,\rm jet}$ are the transverse momenta of the hadron and the jet, respectively. The observable provides an alternative window on fragmentation functions in a more exclusive setting, enabling novel tests of the universality of fragmentation functions. Varying z_h and/or the hadron species, one can map out the fragmentation functions 'locally' as functions of x. This is in contrast to the single-inclusive observable $pp \to h + X$, which inevitably samples over a broad range of x. Although hadron-in-jet data are not yet routinely included in analyse of fragmentation functions, a 'proof-of-principle' analysis does exist [178] that shows the potential of the observable in providing constraint on fragmentation functions.

A comparison of recent NLO fits of fragmentation functions for $\pi^+ + \pi^-$ obtained by the updated version of BDSS21 [128], JAF20 [129] and NNPDF1.0 [130] is shown in Fig. 19.7. Differences among the functions for these sets are visible, especially for the gluon fragmentation function over the full range of x and for the quark functions at large momentum fractions. The differences are even larger for other species of hadrons like kaons and protons [131,132,136,140]. Recent analyses [128–130,136,138,139,179,180] estimate the uncertainties involved in the extraction of fragmentation functions.

Photonic fragmentation functions play a relevant role in the theoretical understanding of inclusive photon production in (leptonic and hadronic) high energy processes. In the sprit of the analogy between parton fragmentation functions and parton distribution functions, also photonic fragmentation functions are analogous to the photon structure function F_2^γ and to the proton's photonic parton distributions (see review on structure functions in Section 18 of this *Review*). Since photons have a pointlike coupling to quarks [181], the corresponding fragmentation functions obey inhomogeneous evolution equations and are generally decomposed into a perturbative and a non-perturbative component [135, 182, 183]. The hadronic part, sometimes approximated by the Vector Meson Dominance Model, can in principle be obtained by performing a global analysis to the available prompt photon production data [7,12,15,19–21,85,147,184,185], although in practice this has not been done. We note that also the cross section for photons produced in fully reconstructed jets has been proposed [186] as a new tool for obtaining access to photon fragmentation functions, in analogy to the hadron-in-jet cross section discussed above.

19.6 Identified particles in e^+e^- and semi-inclusive DIS

There is a great wealth of measurements of e^+e^- fragmentation into identified particles. A collection of references for data on fragmentation into identified particles is provided in Table 53.1 of this *Review*. As a representative example, Figure 19.8 shows differential charged-hadron spectra as functions of the scaled hadron momentum at several CM energies.

Quantitative results of studies of scaling violations in e^+e^- fragmentation have been reported in [7,21,187,188]. Scaling violations may be used to extract a value of α_s; the values obtained are consistent with the world average (see review on QCD in Section 9 of this *Review*).

Many studies have been made of production of identified particles in lepton-hadron scattering, although fewer particle species have been measured than in e^+e^- collisions. References [149, 150, 152–154, 189–191] and [151, 192–197] are representative of the data from fixed target and ep collider experiments, respectively. QCD calculations performed at NLO provide an overall good description of the HERA data [33, 34, 58, 197–199], both for SIDIS [200] and for the hadron transverse momentum distribution [53, 201] in the kinematic regions in which the calculations are predictive. Threshold corrections to SIDIS have been computed at NNLO [202] and even at one order higher [203]. Very recently, the full set of NNLO QCD corrections to the corresponding coefficient functions were obtained in [204, 205].

Fig. 19.9(a) compares lower-energy fixed-target and HERA data on strangeness production, showing that the HERA spectra have substantially increased multiplicities, albeit with statistical precision that is insufficient to study scaling violations. The fixed-target data show that the Λ rate substantially exceeds the $\overline{\Lambda}$ rate in the remnant region, owing to the conserved baryon number from the baryon target. Fig. 19.9(b) shows $1/N \cdot dn/dz$ for neutral and charged pion production, where z is defined as the ratio of the pion energy to that of the exchanged boson, both measured in the laboratory frame. Results are shown from the HERMES and the EMC experiments, where the HERMES data have been evolved to $\langle Q^2 \rangle = 25$ GeV^2 at NLO QCD, in order to be comparable with the EMC data. Each of the experiments uses various kinematic cuts to ensure that the measured particles lie in the region that is expected to be associated with the struck quark. In the DIS kinematic regime accessed at these experiments, and over the range in z shown in Fig. 19.9, the z and x_F variables

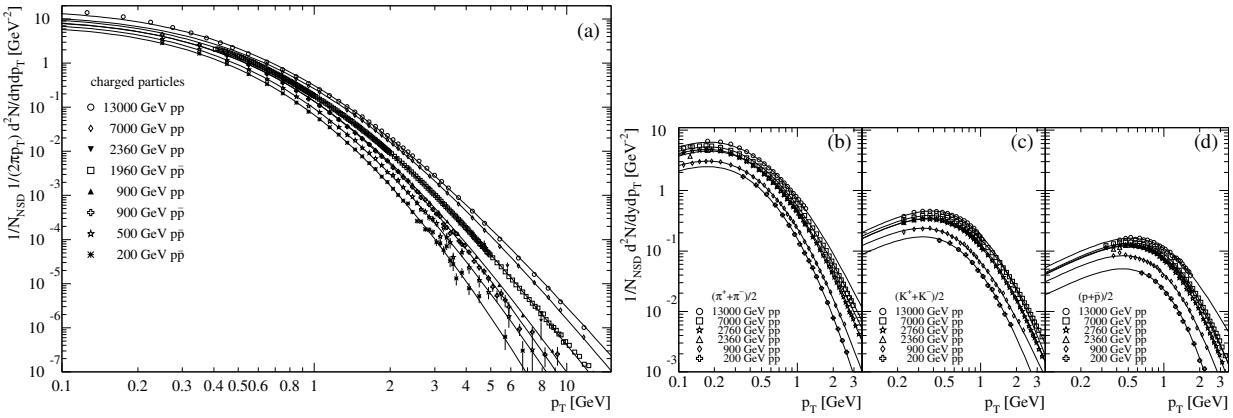

Figure 19.11: (a) Selection of inclusive charged-particle transverse momentum spectra [114, 117, 119, 121, 161, 206, 207], normalized to the non-single diffractive cross section (NSD). (b)-(d) Selection of identified charged-particle transverse momentum spectra [208–213] normalized to the NSD cross section. All spectra are scaled to the NSD cross-section using measurements of total, inelastic, elastic, single, or non-single diffractive cross sections from [214–218, 218–220]. The overall normalization uncertainty of about 3% is not shown. Superimposed are fits of the Tsallis distribution in Eq. (19.13).

have similar values [30]. The precision data on identified particles can be used in the study of the quark flavor content of the proton [179, 221, 222].

Data on identified particle production can aid the investigation of the universality of jet fragmentation in e^+e^- and DIS. The strangeness suppression factor γ_s, as derived principally from tuning the Lund string model [223] within JETSET [224], is typically found to be around 0.3 in e^+e^- experiments [75], although values closer to 0.2 [225] have also been obtained. A number of measurements of so-called V^0-particles (K^0, Λ^0) and the relative rates of V^0's and inclusively produced charged particles have been performed at HERA [151,192,226] and fixed target experiments [149]. These typically favour a stronger suppression ($\gamma_s \approx 0.2$) than usually obtained from e^+e^- data, although values close to 0.3 have also been obtained [227, 228].

However, when comparing the description of QCD-based models for lepton-hadron interactions and e^+e^- collisions, it is important to note that the overall description by event generators of inclusively produced hadronic final states is more accurate in e^+e^- collisions than in lepton-hadron interactions [229]. Predictions of particle rates in lepton-hadron scattering are affected by uncertainties in the modelling of the parton composition of the proton and photon, the extended target remnant, and initial and final-state QCD radiation. Furthermore, the tuning of event generators for e^+e^- collisions is typically based on a larger set of parameters and uses more observables [75] than are used when optimizing models for lepton-hadron data [230].

19.7 Fragmentation in hadron-hadron collisions

An extensive set on high-transverse momentum (p_T) single-inclusive hadron data has been collected in $h_1h_2 \to hX$ scattering processes, both at high energy colliders and fixed-target experiments [155–162,185,231–253]. Fig. 19.10 shows the invariant cross sections $E\mathrm{d}^3\sigma/\mathrm{d}p^3$ for a compilation of neutral-pion and charged-hadron production data for energies in the range $\sqrt{s} \approx 23$ - 7000 GeV.

The differential cross section for high-transverse momentum hadron production has been computed to NLO accuracy in perturbative QCD [254]. The NLO corrections are typically large and can even double the prediction for the cross section at fixed-target energies. Nevertheless, the NLO calculations significantly under-predict the cross-section for several fixed-target energy data sets [249, 255, 256]. Different strategies have been developed to ameliorate the theoretical description at fixed-target energies. A possible phenomenological approach involves the introduction of a non-perturbative intrinsic partonic transverse momentum [160, 249, 257, 258]. Furthermore, the resummation of the dominant higher order corrections at threshold produces an enhancement of the theoretical calculation that significantly improves the description of the data [259, 260].

Data collected at high energy colliders are either included in global fit analyses or used as a test for the universality of fragmentation functions. A certain tension has been observed between data sets from RHIC and the LHC [261]. The tension can be largely resolved [128] by taking properly into account the theoretical scale dependence in the global analysis, allowing factorization and renormalization scales to variate according to the kinematics of each experiment within a conventional range.

Transverse momentum distributions can usually be fit by power laws [262]. An approach to describe the low p_T particle spectra is the Tsallis distribution [263–265], which is based on a non-extensive generalization of the Boltzmann-Gibbs statistics. The functional form [266]

$$\frac{\mathrm{d}^2N}{\mathrm{d}p_T\mathrm{d}y} = p_T\frac{\mathrm{d}N}{\mathrm{d}y}\frac{(n-1)(n-2)}{nT(nT+m_0(n-2))}\left[1+\frac{m_T-m_0}{nT}\right]^{-n} \quad (19.13)$$

is frequently used to fit the transverse momentum spectra, where $\mathrm{d}N/\mathrm{d}y$ is the particle's multiplicity, T and n are fit parameters of the Tsallis distribution, m_0 is the either the mass of the most abundant particle, i.e. the pion for inclusive spectra, or the mass of an identified particle, and $m_T = \sqrt{p_T^2 + m_0^2}$. The parameter n is related to the non-extensive parameter $q = n/(n-1)$ of the original Tsallis formula [267], and T is connected to the temperature in the Boltzmann-Gibbs statistics. The Tsallis distribution has been very successfully fit to measured transverse momentum distributions of both inclusive charged particles and identified particle spectra for hadron-hadron collisions, see for example [268–270], for collisions of heavy nuclei, see for example [271], and also for e^+e^- collisions, see for example [272]. The energy dependence of the fitted Tsallis parameters has also been investigated in detail, see [266, 273]. Fig. 19.11 shows examples of hadron production data in pp and $p\bar{p}$ collisions compared to Tsallis distributions.

Hadron production provides a critical observable for probing the high energy-density matter produced in heavy-ion collisions. Measurements at colliders show a suppression of inclusive hadron yields at high transverse momentum for AA collisions compared to pp scattering, indicating the formation of a dense medium opaque to quark and gluons, see e.g. [274].

19.8 Heavy quark fragmentation

It was recognized very early [275] that a heavy flavored meson should retain a large fraction of the momentum of the primordial heavy quark, and therefore its fragmentation function should be much harder than that of a light hadron. In the limit of a very heavy quark, one expects the fragmentation function for a heavy quark to go into any heavy hadron to be peaked near $x = 1$.

When the heavy quark is produced at a momentum much larger than its mass, one expects important perturbative effects, enhanced by powers of the logarithm of the transverse momentum

over the heavy quark mass, to intervene and modify the shape of the fragmentation function. In leading logarithmic order (*i.e.*, including all powers of $\alpha_s \log(m_Q/p_T)$), the total (*i.e.*, summed over all hadron types) perturbative fragmentation function is simply obtained by solving the leading evolution equation for fragmentation functions, Eq. (19.5), with the initial condition due to the finite mass of the heavy quark given by $D_Q(x,\mu^2)\big|_{\mu^2=m_Q^2} = \delta(1-x)$ and $D_i(x,\mu^2)\big|_{\mu^2=m_Q^2} = 0$ for $i \neq Q$ (here $D_i(x,\mu^2)$, stands for the probability to produce a heavy quark Q from parton i with a fraction x of the parton momentum).

Several extensions of the leading logarithmic result have appeared in the literature. Next-to-leading-log (NLL) order results for the perturbative heavy quark fragmentation function have been obtained in [279]. The resummation of the dominant logarithmic contributions at large x was performed in [280] to next-to-leading-log accuracy. Fixed-order calculations of the fragmentation function at order α_s^2 in e^+e^- annihilation have appeared in [281] while the initial condition for the perturbative heavy quark fragmentation function has been extended to NNLO in [282].

Inclusion of non-perturbative effects in the calculation of the heavy-quark fragmentation function is done by convoluting the perturbative result with a phenomenological non-perturbative form. This form follows from the simple kinematical consideration that the formation of a hadron by attaching light quarks/antiquarks to the heavy quark will slightly decelerate the heavy quark. Thus, its shape will show a peak that becomes increasingly centered next to $x = 1$ the higher the quark mass. Among the most popular parameterizations we have the following:

$$\text{Peterson } \textit{et al.}\ [283]: \quad D_{\rm np}(x) \propto \frac{1}{x}\left(1-\frac{1}{x}-\frac{\epsilon}{1-x}\right)^{-2}, \tag{19.14}$$

$$\text{Kartvelishvili } \textit{et al.}\ [284]: \quad D_{\rm np}(x) \propto x^{\alpha}(1-x), \tag{19.15}$$

where ϵ, ϵ_C, a, $bm_{h,\perp}^2$, α, and β are non-perturbative parameters that depend on the heavy hadron considered. The parameters entering the non-perturbative forms are fitted together with some model of hard radiation, which can be either a shower Monte Carlo, a leading-log or NLL calculation (which may or may not include Sudakov resummation), or a fixed order calculation. In [281], for example, the Peterson *et al.* [283] ϵ parameter for charm and bottom production is fitted from the measured distributions of Refs. [289, 290] for charm, and of [291] for bottom. If the leading-logarithmic approximation (LLA) is used for the perturbative part, one finds $\epsilon_c \approx 0.05$ and $\epsilon_b \approx 0.006$; if a second order calculation is used one finds $\epsilon_c \approx 0.035$ and $\epsilon_b \approx 0.0033$; if a NLL improved fixed order $\mathcal{O}(\alpha_s^2)$ calculation is used instead of NLO $\mathcal{O}(\alpha_s)$ one finds $\epsilon_c \approx 0.022$ and $\epsilon_b \approx 0.0023$. The larger values found in the LL approximation are consistent with what is obtained in the context of parton shower models [292], as expected. The ϵ parameter for charm and bottom scales roughly with the inverse square of the heavy flavor mass. This behavior can be justified by several arguments [275, 293, 294]. It can be used to relate the non-perturbative parts of the fragmentation functions of charm and bottom quarks [281, 286, 295].

A more conventional approach [296] involves the introduction of a unique set of heavy quark fragmentation functions of non-perturbative nature that obey the usual massless evolution equations in Eq. (19.5). Finite mass terms of the form $(m_Q/p_T)^n$ are kept in the corresponding short distance coefficient function for each scattering process. Within this approach, the initial condition for the perturbative fragmentation function provides the term needed to define the correct subtraction scheme to match the massless limit for the coefficient function (see e.g. [297]). Such an implementation is in line with the variable flavor number scheme introduced for parton distributions functions, as described in Section 18 of this *Review*.

High statistics data for charmed-meson production near the Υ resonance (excluding decay products of B mesons) have been published [276, 277]. They include results for D and D^*, D_s (see also [298, 299]) and Λ_c. Shown in Fig. 19.12(a) are the CLEO and BELLE inclusive cross-sections times branching ratio $\mathcal{B}$, $s\mathcal{B}d\sigma/dx_p$, for the production of D^0 and D^{*+}. The variable x_p approximates the light-cone momentum fraction x, but is not identical to it. The two measurements are consistent with each other.

The branching ratio $\mathcal{B}$ represents $D^0 \to K^-\pi^+$ for the D^0 results and for the D^{*+} the product of the branching fractions for $D^{*+} \to D^0\pi^+$ and $D^0 \to K^-\pi^+$. Given the high precision of CLEO's and BELLE's data, a superposition of different parametric forms for the non-perturbative contribution is needed to obtain a good fit [52]. Older studies are reported in Refs. [290, 300, 301]. Charmed meson spectra on the Z peak have been published by OPAL and ALEPH [302, 303].

Charm quark production has also been extensively studied at HERA by the H1 and ZEUS collaborations. Measurements have been made of $D^{*\pm}$, $D^{\pm}$, and $D_s^{\pm}$ mesons and the Λ_c baryon. See, for example, Refs. [304, 305].

Experimental studies of the fragmentation function for b quarks, shown in Fig. 19.12(b), have been performed at LEP and SLD [278, 291, 306]. Commonly used methods identify the B meson through its semileptonic decay or based upon tracks emerging from the B secondary vertex. Heavy flavor contributions from gluon splitting are usually explicitly removed before fitting for the fragmentation functions. The studies in [278] fit the B spectrum using a Monte Carlo shower model supplemented with non-perturbative fragmentation functions yielding consistent results.

The experiments measure primarily the spectrum of B mesons. This defines a fragmentation function that includes the effect of the decay of higher mass excitations, like the B^* and B^{**}. In the literature (cf. details in Ref. [307]), there is sometimes ambiguity in what is defined to be the bottom fragmentation function. Instead of using what is directly measured (*i.e.*, the B meson spectrum), in some cases corrections are applied to account for B^* or B^{**} production.

Heavy-flavor production in e^+e^- collisions is the primary source of information for the role of fragmentation effects in heavy-flavor production in hadron-hadron and lepton-hadron collisions. The QCD calculations tend to underestimate the data in certain regions of phase space. Some experimental results from LHC summarized in [308] show such deviations e.g. at high transverse jet momentum and also at low di-jet separation angles, see [309] for details, and were already theoretically investigated in [310].

Both bottomed- and charmed-meson spectra have been measured at the Tevatron with unprecedented accuracy [311]. The measured spectra are in good agreement with QCD calculations (including non-perturbative fragmentation effects inferred from e^+e^- data [312]).

The HERA collaborations have produced a number of measurements of beauty production; see, for example, Refs. [304, 313–316]. As for the Tevatron data, the HERA results are described well by QCD-based calculations using fragmentation models optimized with e^+e^- data.

Besides degrading the fragmentation function by gluon radiation, QCD evolution can also generate soft heavy quarks, increasing in the small x region as $\sqrt{s}$ increases. Several theoretical studies are available on the issue of how often $b\bar{b}$ or $c\bar{c}$ pairs are

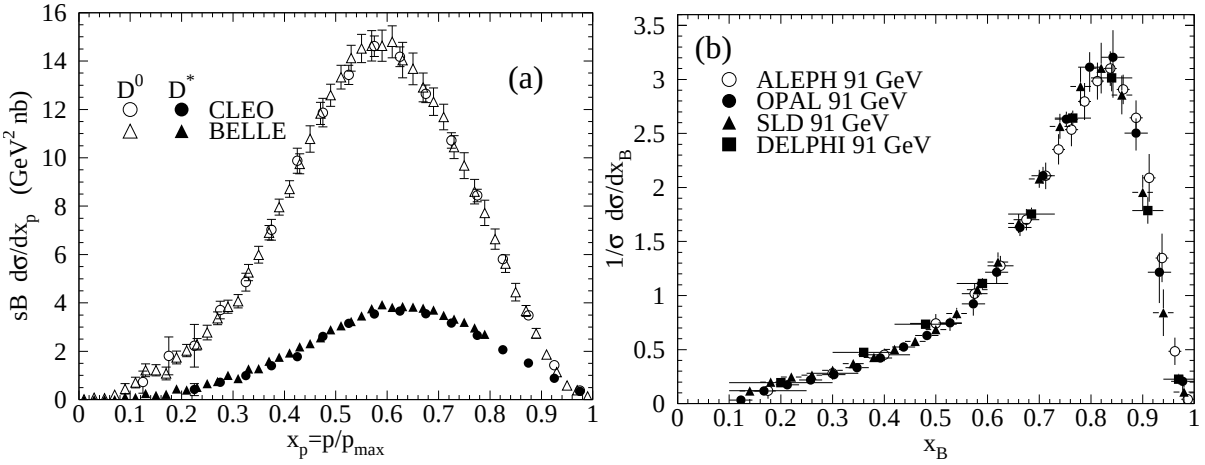

Figure 19.12: (a) Efficiency-corrected inclusive cross-section measurements for the production of D^0 and D^{*+} in e^+e^- measurements at $\sqrt{s} \approx 10.6$ GeV, excluding B decay products [276] [277]. (b) Measured e^+e^- fragmentation function of b quarks into B hadrons at $\sqrt{s} \approx 91$ GeV [278].

produced indirectly via a gluon splitting mechanism [317–319]. Experimental results from studies on charm and bottom production via gluon splitting, given in [303, 320–324], yield weighted averages of $\overline{n}_{g\to c\bar{c}} = 3.05 \pm 0.45\%$ and $\overline{n}_{g\to b\bar{b}} = 0.277 \pm 0.072\%$, respectively. The production of bottom-antibottom quark pairs via gluon splitting has also been investigated at hadron colliders, see for example [325–327].

19.9 Spin-dependent and transverse-momentum dependent fragmentation functions

The fragmentation functions we have considered so far apply to the spin-averaged case in which the polarization of the produced hadron is not observed, or the hadron has spin-0. We have also only considered 'collinear' fragmentation functions $D_i^h(x,\mu^2)$ which carry only one kinematical variable, the momentum fraction x. New insights into fragmentation and hadronization become available when also the dependence of fragmentation functions on the spin of the produced hadron and/or its relative transverse momentum with respect to the fragmenting parton are considered. In the latter case, one refers to the fragmentation functions as 'transverse-momentum dependent (TMD)' fragmentation functions.

Staying first with collinear fragmentation functions, two types of spin-dependent fragmentation functions to spin-1/2 hadrons can be considered. The helicity-dependent fragmentation function measures the transfer of longitudinal spin from the fragmenting parton to the hadron [38, 328–331]. It is given by

$$\Delta D_i^h(x,\mu^2) \equiv D_{i+}^{h+}(x,\mu^2) - D_{i+}^{h-}(x,\mu^2)\,, \qquad (19.20)$$

where the superscripts $\pm$ refer to the helicities of the parton and hadron. Λ hyperons are ideally suited for measurements of the ΔD_i^h, thanks to their self-analyzing weak decay $\Lambda \to \pi p$. Measurements of the longitudinal spin transfer to Lambda hyperons have been presented in e^+e^- (on the Z resonance), ℓp, and pp scattering in Refs. [332–338]. One may readily extend Eq. (19.20) to the case of transverse polarization of hadrons and quarks [339], where the corresponding fragmentation functions are known as 'transversity' fragmentation functions. There are also measurements constraining these fragmentation functions [333, 340, 341]. A recent phenomenological analysis was presented in [342].

If the transverse-momentum (k_T) dependence of fragmentation functions is considered, there are eight types of leading-twist functions, defined by the correlations among the hadronic and partonic spin vectors and transverse-momentum vectors they represent. (For review, see [5]). We note that the eight fragmentation functions given in the table below exist separately for each quark and antiquark flavor, and a similar set may be introduced for gluons. Upon integration over the transverse momentum k_T the collinear unpolarized, helicity, and transversity fragmentation functions are reproduced.

The various fragmentation functions may be obtained from spin asymmetries and angular distributions in hadron production processes. There is a large body of precision data by now on transverse-momentum distributions in e^+e^- annihilation [343] and SIDIS [190, 344] that provide constraints on the unpolarized TMD fragmentation functions D_i^h, which have been analyzed theoretically, partly also including TMD evolution effects and high orders of perturbation theory [345–352].

Besides the unpolarized functions D most of the attention in experiment and theory has been on the function $H^\perp$ which describes the production of unpolarized (or spin-0) hadrons by transversely polarized quarks. This function is known as the 'Collins function' [353]. Its importance also derives from the fact that it may be used to probe the quark transversity PDF of the nucleon [354] which gives the probability of finding a transversely polarized quark with its spin aligned or anti-aligned with the spin of a transversely polarized nucleon. The transversity function is chiral-odd, and therefore not accessible through measurements of inclusive lepton-hadron scattering. The Collins effect in semi-inclusive DIS, on the other hand, provides an avenue for accessing transversity. The Collins fragmentation function is chiral-odd and T-odd, leading to a characteristic single-spin asymmetry in the azimuthal angular distribution of the produced hadron in the hadron scattering plane. A number of SIDIS [355–366] and e^+e^- experiments [367–371] have performed measurements of the Collins effect, for charged pions and kaons. These have been analyzed theoretically [372, 373], leading to an extraction of the nucleon's transversity distributions [373]. The Collins effect has also been studied in pp scattering, where one considers azimuthal transverse single-spin asymmetries for distributions of hadrons inside jets [177, 374, 375].

In the context of extractions of transversity PDFs also fragmentation functions for same-side pairs of hadrons with small invariant mass, *dihadrons*, have been introduced and studied [376–384]. Compared to the Collins effect, dihadron fragmentation functions have the advantage that they may be defined purely in collinear factorization. The relevant spin-dependent dihadron fragmentation function exploits a correlation between the transverse polarization of the fragmenting quark and the relative momentum of the two hadrons. In SIDIS with a transversely polarized hadron beam, the dihadron cross section then contains a specific modulation in the azimuthal orientation of the plane containing the momenta of the two hadrons. The coefficient of this modulation is a product of the spin-dependent dihadron fragmentation function and the target's transversity PDF. The dihadron fragmentation functions may be separately extracted from measurements in e^+e^- annihilation, and the Belle experiment has presented data [385] that have been analyzed theoretically [386, 387].

In lepton scattering, HERMES [388] and COMPASS [389, 390] have reported data sensitive to the spin-dependent dihadron fragmentation functions, and recently the STAR experiment at RHIC has presented data in the azimuthal distribution of $\pi^+\pi^-$ pairs produced in pp scattering with one transversely polarized proton [391]. The results have been successfully used for the extraction of transversity PDFs [387, 392–394].

20. High Energy Soft QCD and Diffraction

Revised August 2023 by V.A. Khoze (Durham U.), M.G. Ryskin (Petersburg Nuclear Phys. Inst.) and M. Taševský (Prague, Inst. Phys.).

20.1 Introduction

Despite the enormous successes of Quantum Chromodynamics (QCD) (see Section 9 in [1] and [2]) there remain a number of deep questions to be answered in the domain of strong interaction physics. These concern first of all small momentum transfer processes which are generically called soft interactions.

One of the most challenging problems is the high-energy behaviour of hadronic scattering processes. At high collision energies, $\sqrt{s}$, soft interactions play a dominant role. Unfortunately, soft interactions cannot be described in terms of perturbative QCD. These are non-perturbative phenomena related to confinement which are generally considered in the context of the analytic S-matrix, based on *first principles*, such as analyticity, crossing symmetry and unitarity of partial waves, see e.g. [3, 4]. At high energies the most self-consistent way to perform the calculations and to describe the data is the Regge approach (see for example [5–7]), which will be considered below. As discussed in Section 20.5, this formalism could be smoothly matched with perturbative QCD calculations at larger transverse momenta. Therefore, here we will concentrate on the properties of high energy soft interactions that can be expected from the extension of the perturbative QCD domain.

The main aim of this review is to present the well-established theoretical framework, based on Regge theory and QCD, used for describing high-energy collisions. A limited number of some new experimental results, mainly from the LHC, are shown in order to demonstrate that the gross features of the data are in agreement with this approach. We are not focussing on any particular phenomenological or Monte Carlo model, which are covered in the dedicated reviews and books, see e.g. Section 43 in [1], [2, 8–14] and Chapter 2 in [15].

Typically, in multiparticle production, the secondaries[1] fill the whole available rapidity interval.[2] However, there exists an important class of events in which a large interval of rapidity (typically at least 4 units) is devoid of any hadronic activity. Such an interval is called a Large Rapidity Gap (LRG). The most frequent case with a LRG is elastic scattering. There are also events in which one of the incoming protons (or both) is transformed (dissociates) into a set of two or more final state particles with the mass $M \ll \sqrt{s}$ and proton quantum number. All these events have properties similar to those of the well-known from optics pattern of diffraction of a beam of light on an obstacle. By analogy, in high-energy physics, the corresponding processes are usually called diffractive. The classic example is the elastic scattering of hadrons on nuclei (see e.g. [16]), which manifests an angular distribution with a series of minima and maxima, analogous to the diffraction of light on a black disk. At LHC energies diffractive processes constitute up to 40% of the total (pp) cross section, $\sigma_{\rm tot}$. Therefore, we will pay special attention to the description of the elastic scattering amplitude and proton diffractive dissociation. Diffraction dissociation can be considered as a quantum mechanical process caused by the fact that different components of the incoming hadron wave function have different probabilities for interaction with a target [17]. This feature allows us to probe the transverse size of the interaction region.

Note that besides being of a fundamental interest in their own right for understanding the high energy behaviour of the QCD amplitude, there are several reasons why it is important to study soft and diffractive processes. Firstly, soft interactions unavoidably give an underlying component to rare 'hard' events, from which we hope to extract signals for New Physics. Secondly, we should be able to estimate the probability that rapidity gaps, which occur in 'hard' diffractive events, survive rescattering effects, that is, survive the population of the gaps by the secondary particles from the underlying event. Thirdly, an understanding of diffractive processes is very important for evaluation of pile-up backgrounds in high-luminosity pp collisions, which have a direct impact on various experimental measurements. Pile-up corresponds to soft independent interactions in the same bunch crossing whose number rises with increasing instantaneous luminosity. And, finally, studies of diffractive processes should help in the understanding of the structure of high-energy cosmic ray cascades, which requires a very detailed knowledge of the spectra of particles carrying a large fraction x of the incoming momentum in proton-air and nucleus-air interactions, see for instance [18].

Experimentally, diffractive processes are selected using two distinct features:

1. large regions (typically at least $\Delta\eta > 4$) in the detector are devoid of hadronic activity (LRG) and/or
2. one or both incoming particles stay intact after collision and are registered by the dedicated forward detectors placed a few hundred meters from the interaction point. The momentum loss of the initial particle, $\xi = 1 - x$, is typically smaller than 0.15.

Thus, in the case of proton-proton collisions, diffractive events correspond to elastic $pp \to pp$ scattering and to $pp \to p + X$ (Single Dissociation, SD) and $pp \to X + Y$ (Double Dissociation, DD) processes, where the + sign denotes a large rapidity gap. Note that strictly speaking in high energy physics it is impossible to define (and select) rigorously purely diffractive events. We can always have some admixture of events of different origin. As a rule we call 'diffractive' the events with sufficiently large gap (with say $\Delta y > 4$, see above) and the vacuum quantum numbers transferred across the gap. Typically at the LHC the integrated cross sections of diffractive dissociation, $\sigma_{\rm SD}$, $\sigma_{\rm DD}$, are of the order of 5–10 mb depending on the gap size. Schematic diagrams of all discussed processes are shown in Fig. 20.1.

20.2 Regge pole approach

In pre-QCD times, in order to describe the behaviour of scattering amplitudes at high energy, $\sqrt{s}$, and small momentum-transfer squared, $-t$, Regge theory was developed and successfully applied in a wide range of energies. The Regge approach [5–7] is based on the singularities of amplitudes in the complex angular momentum, j, plane.

For instance, the measured $\pi^- p \to \pi^0 n$ amplitude behaves as

$$T_{\pi p}(s,t) \propto s^{\alpha_\rho(t)}, \tag{20.1}$$

where the process is described by the exchange of the ρ-trajectory, $j = \alpha_\rho(t) \simeq 0.5 + 0.9t$ (with $t = (p_{\pi^-} - p_{\pi^0})^2$ in GeV^2). This trajectory passes through the spin-1 ρ-meson resonance in the 'crossed' t-channel $\pi^-\pi^0 \to \bar{p}n$; that is, $\alpha_\rho(t = m_\rho^2) = 1$. The corresponding cross section decreases with increasing s.

On the other hand, high-energy total and elastic pp cross sections are observed to grow slowly with energy (see e.g. Section 53 in [1]) and in terms of Regge theory are dominated by the exchange of a trajectory with vacuum quantum numbers, $\sigma_{\rm tot} \propto s^{j-1}$. The simplest possibility is to assume that the rightmost singularity in the j-plane, which drives the high-energy behaviour of the cross section, is the leading (at $t \le 0$) Regge pole at $j = \alpha(t)$. Then the pp elastic amplitude reads

$$T_{\rm el}(s,t) \propto s^{\alpha_{\rm I\!P}(t)} \ . \tag{20.2}$$

The total cross section can then be conveniently expressed using the so called optical theorem which states that

$$s\sigma_{\rm tot} = {\rm Im}T_{\rm el}(s, t = 0), \tag{20.3}$$

as illustrated in the upper part of Fig. 20.2, and thus

$$\sigma_{\rm tot} \propto s^{\alpha_{\rm I\!P}(0)-1}. \tag{20.4}$$

[1] Here and in what follows, we call secondaries the new particles produced in the course of the interaction.

[2] For definition of particle rapidity (pseudorapidity), see Section 49.5.2 in [1]; $y = \frac{1}{2} \ln \frac{E+p_z}{E-p_z}$ ($\eta = -\ln(\tan(\theta/2))$; the correct variable is the rapidity y, however, experimentally it is simpler to use the pseudorapidity η which does not require identifying the particles, setting $m = 0$. For $p_T \gg m$, $\eta \simeq y$.

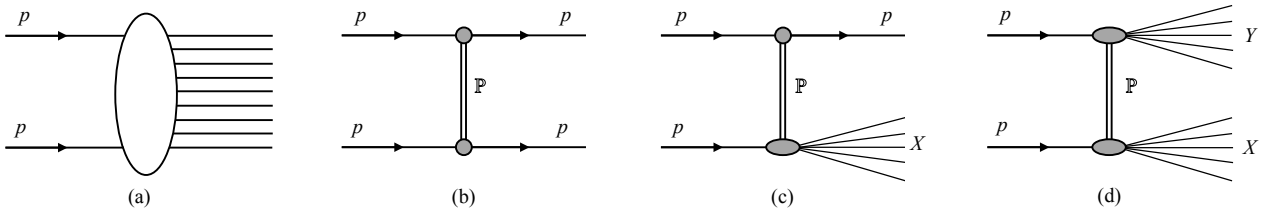

Figure 20.1: Schematic diagrams of soft pp processes. (a) non-diffractive processes, (b) elastic scattering, (c) single dissociation and (d) double dissociation. The double line corresponds to the Pomeron exchange.

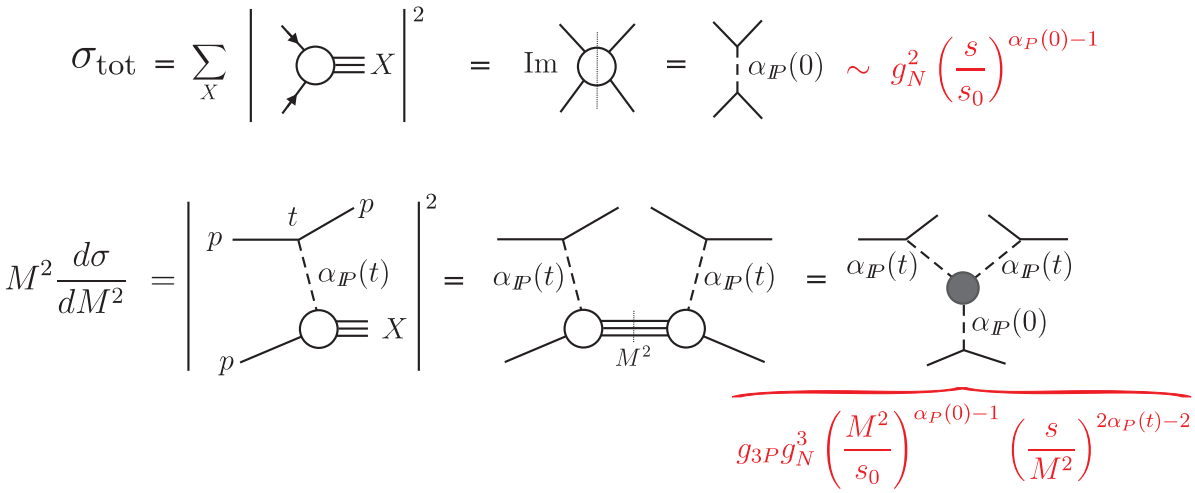

Figure 20.2: Illustration of the optical theorem for the total cross section and for high-mass diffractive dissociation in the absence of absorptive corrections.

The pole with the largest intercept, originally assumed to be $\alpha_{I\!P}(0) = 1$ since high-energy total cross sections were thought to have a constant asymptotic behaviour, is called the *Pomeron*[3]

Prior to the LHC, the energy behaviour of $pp, p\bar{p}, \pi p, Kp$ cross sections was satisfactorily reproduced by the sum of the Pomeron and secondary Reggeons (the poles at lower values of j, typically with $\alpha_\rho(0) \simeq 0.5$, see [22, 23] and Section 51 in [24]). However, above Tevatron energies the secondary Reggeon contributions (which all have intercepts $\alpha(0) \simeq 0.5$) are highly suppressed, which enables us to study the properties of the Pomeron only.

A popular parameterization of the elastic pp-scattering amplitude by Donnachie-Landshoff (DL) is the Regge form [25]

$$T_{\rm el}(s,t) = \eta_P \sigma_0 F_1^2(t) s^{\alpha_{I\!P}(t)}, \tag{20.5}$$

where $\sigma_0 = 21.7$ mb [26] and η_P is the signature factor

$$\eta_P = \frac{1 + \exp(-i\pi\alpha_{I\!P}(t))}{\sin(-\pi\alpha_{I\!P}(t))}, \tag{20.6}$$

F_1 is the Dirac electromagnetic form factor of the proton and the *effective* Pomeron trajectory

$$\alpha_{I\!P}(t) = 1 + \Delta + \alpha' t \;\simeq\; 1 + 0.0808 + 0.25t, \tag{20.7}$$

with t given in GeV^2. The intercept $\alpha_{I\!P}(0)$ just above 1 reproduces the observed slow growth of the total hadron-hadron cross sections at high energies.

However, this simple parameterization is becoming increasingly deficient at higher energies. This is because due to unitarity we have to take into account not only Regge poles, but also the cuts in the j-plane [27, 28], which correspond to the multiple exchange of Regge poles in the t-channel, see for instance [29–31]. A powerful technique to evaluate Reggeon diagrams was developed by Gribov [7, 32] (Reggeon calculus or Reggeon Field Theory (RFT)), which allows us to calculate the multi-Pomeron contributions.

[3] Pomeron pole was named after I. Y. Pomeranchuk. The history of the Pomeron is discussed in [19–21].

20.3 Theoretical description of high-energy diffraction

Diffractive processes (see e.g. reviews [33–37]) represent a rich testing ground for the dynamics of soft interactions as well as Monte Carlo models for soft hadron-hadron physics (see for reviews e.g. [8], Section 43 in [1] and Chapter 2 in [15]).

There is no universally agreed definition of diffractive processes. Theoretically, diffraction is the effect caused by the absorption of the incoming plane-wave in some region of impact parameter, b. After a decomposition of the distorted plane-wave over the outgoing momentum, q, due to absorption we arrive at some set of plane-waves with non-zero transverse momentum, $q_t \neq 0$. Experimentally, we call diffractive the events with large rapidity gaps (LRG) in the distribution of the final state particles. However, this definition is appropriate only for the events with very large gap sizes ($\Delta\eta > 4 - 5$); otherwise gaps can also be caused by fluctuations in the hadronization process [38].

In the case of proton-proton collisions, diffraction corresponds to elastic $pp \to pp$ scattering and to the $pp \to p + X$ and $pp \to X_1 + X_2$ processes where one or both protons are allowed to dissociate into a system X with the quantum numbers of the proton. The $p \to X$ dissociation is caused by the fact that the individual components of the incoming proton wave function interact differently with the target (see Section 20.3.1).

Theoretically, high-energy diffraction may be studied from either the s-channel or the t-channel viewpoint.

20.3.1 *Diffraction from the s-channel viewpoint*

Unitarity plays a central role in diffractive processes. To discuss unitarity effects it is convenient to work in terms of impact parameter, b. The total cross section is closely related to the elastic scattering amplitude and the scattering into inelastic final states via the s-channel unitarity of the S-matrix (see Sections 50 and 53 in [1]), $SS^\dagger = I$, or

$$disc\; T \equiv T - T^\dagger = iT^\dagger T \tag{20.8}$$

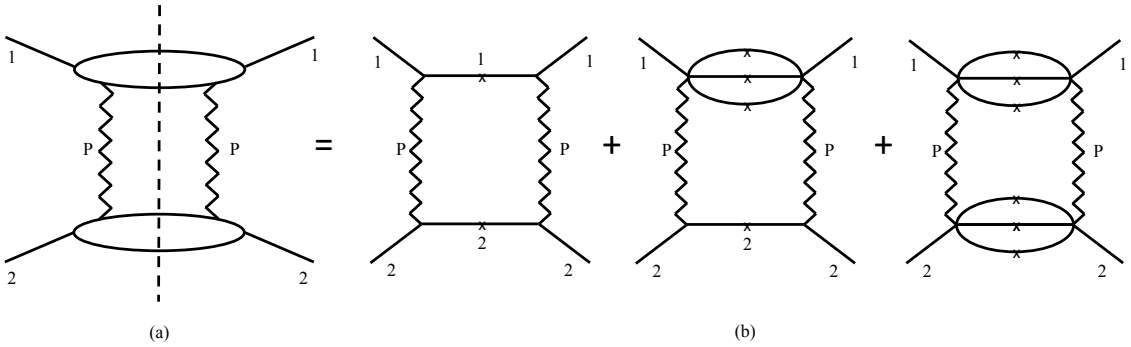

Figure 20.3: Two-Pomeron exchange in the t channel expressed as a sum over all diffractive intermediate states in the s-channel. The crosses indicate that the particles are on the mass shell.

with $S = I + iT$. If we were to focus, for example, on the unitarity for elastic and quasielastic processes, then *disc* T would simply denote a cut in s-channel between incoming and outgoing particles as visualized by crosses in Fig. 20.3.

At high energies, the s-channel unitarity relation is diagonal in the b basis such that

$$2\mathrm{Im}\, T_{\rm el}(s,b) = |T_{\rm el}(s,b)|^2 + G_{\rm inel}(s,b) \tag{20.9}$$

with

$$\sigma_{\rm tot} = 2\int d^2b\, \mathrm{Im}\, T_{\rm el}(s,b) \tag{20.10}$$

$$\sigma_{\rm el} = \int d^2b\, |T_{\rm el}(s,b)|^2 \tag{20.11}$$

$$\sigma_{\rm inel} = \int d^2b\, \left[2\mathrm{Im}\, T_{\rm el}(s,b) - |T_{\rm el}(s,b)|^2\right]. \tag{20.12}$$

The general solution of Eq. (20.9) is

$$T_{\rm el}(b) \;=\; i(1 - e^{-\Omega(b)/2}) \tag{20.13}$$

and

$$G_{\rm inel}(s,b) = 1 - \mathrm{e}^{-\mathrm{Re}\Omega(b)} = 1 - P_{\rm nointer}(s,b), \tag{20.14}$$

where $G_{\rm inel}$ is the sum over all inelastic intermediate states and $P_{\rm nointer}$ is a probability to have no inelastic interactions. $G_{\rm inel}(s,b)$ describes the b-profile of inelastic particle collisions. It satisfies the condition $0 \le G_{\rm inel} \le 1$ and determines how absorptive the interaction region is at a given impact parameter (with $G_{\rm inel}$= 1 for full absorption and $G_{\rm inel}$= 0 for the complete dominance of elastic scattering). As seen from Eq. (20.14), $\exp(-\mathrm{Re}\Omega(s,b))$ is the probability that no inelastic interactions occur at impact parameter b. Ω ($\mathrm{Re}\Omega \ge 0$) is called the opacity (optical density) or eikonal. The quantity

$$S^2(b) \equiv e^{-\mathrm{Re}\Omega(b)} \;=\; P_{\rm nointer}(b) \tag{20.15}$$

is the so-called survival factor, which enables us to calculate the probability that the LRG survives soft rescattering.

In terms of the opacity the elastic cross section takes the form

$$\frac{\mathrm{d}\sigma_{\rm el}}{\mathrm{d}t} = \frac{1}{16\pi s^2}\,|T_{\rm el}(s,t)|^2 = \frac{1}{4\pi}\left|\int \mathrm{d}^2b\; e^{i\vec{q}_t\cdot\vec{b}}(1 - e^{-\Omega(b)/2})\right|^2$$
$$= \pi\left|\int b\mathrm{d}b\; J_0(q_t b)(1 - e^{-\Omega(b)/2})\right|^2, \tag{20.16}$$

where $q_t = \sqrt{|t|}$ and J_0 is the zeroth-order Bessel function.

To describe the elastic scattering at one fixed energy we can always find an appropriate parameterization for the opacity $\Omega(b)$ and tune the parameters to reproduce the observed $\mathrm{d}\sigma_{\rm el}/\mathrm{d}t$ cross section. Moreover, we can fix the form of the parameterization, but choose, at each particular energy, the corresponding values of parameters; see, e.g. [39]. Alternatively, we may simply take the Fourier-Bessel transform from the experimental data [33, 40, 41]

$$\mathrm{Im}T_{\rm el}(b) \;=\; \int \frac{q_t \mathrm{d}q_t}{4\pi}\sqrt{\frac{\mathrm{d}\sigma_{\rm el}}{\mathrm{d}t}\frac{16\pi}{1+\rho^2}}\; J_0(q_t b), \tag{20.17}$$

where the square root represents $\mathrm{Im}T_{\rm el}(q_t)$, with $\rho \equiv \mathrm{Re}T_{\rm el}/\mathrm{Im}T_{\rm el}$. In this way, we first determine $T_{\rm el}$ from the data for $\mathrm{d}\sigma_{\rm el}/\mathrm{d}t$, and then calculate $\Omega(b)$ using Eq. (20.13), assuming in accordance with data that ρ is small (or $\rho(t)$ = constant).

At high energies $\rho^2 \ll 1$, which is usually well justified except in the diffractive dip region (see Section 20.3.3.1 for discussion of the dip region).

The value of ρ can be derived via the dispersion relation, see [3]:

$$\frac{1}{s}\mathrm{Re}T_{\rm el}(s) \;=\; \frac{1}{\pi}\int_{-\infty}^{+\infty}\frac{\mathrm{d}s'}{s'-s}\sigma_{\rm tot}(|s'|) \;=\; \frac{1}{\pi}\int_0^{\infty}\sigma_{\rm tot}(s')\frac{2s\mathrm{d}s'}{s'^2 - s^2}. \tag{20.18}$$

Since we consider just the charge-parity C-even amplitude, here for negative s' we put $\sigma_{p\bar{p}} = \sigma_{pp}$. That is, for negative s', which corresponds to the interaction with an *anti*particle, we use the same $\sigma_{pp}(|s'|)$. The major contribution comes from $s' \simeq s$. Thus, with a good accuracy we can evaluate $\rho(t=0)$ as

$$\rho \;\simeq\; \frac{\pi}{2}\,\frac{\partial \ln \sigma_{\rm tot}(s)}{\partial \ln s}. \tag{20.19}$$

20.3.2 *Diffractive dissociation*

The elastic cross section probes the optical density of the proton. The well known example of scattering on a black disk, with $G_{\rm inel} = 1$ for $b < R$, gives $\sigma_{\rm el} = \sigma_{\rm inel} = \pi R^2$ and $\sigma_{\rm tot} = 2\pi R^2$. In general, the absorption of the initial wave (due to inelastic channels) leads, via s-channel unitarity, to elastic scattering.

Inelastic diffraction (i.e. proton dissociation) is a consequence of the *internal structure* of hadrons. This can be conveniently described at high energies, where the lifetimes of each particular Fock component of the incoming hadron/proton wave function (the hadronic fluctuations) are large, $\tau \sim E/m^2$, and during these time intervals the corresponding Fock states can be considered as 'frozen'. Each hadronic constituent can undergo a scattering with its own probability and thus destroys coherence of the fluctuations[4]. As a result, the outgoing superposition of states will be different from the incident particle, and will most likely contain multiparticle states, so we will have *inelastic*, as well as elastic scattering.

To calculate diffractive dissociation we can enlarge the set of intermediate states (p, N_a^*), from just the single elastic channel, and introduce a multichannel eikonal. However, it is more convenient

[4] At high energies the configurations with different transverse separation, r, between the quarks (valence partons) can serve as an example of such Fock states. An interaction with the QCD Pomeron does not change the value of r, while the cross section $\sigma \propto \alpha_s^2 \cdot r^2$ (see Section 20.4.2 and [42–44]).

to follow Good and Walker [45], and to introduce states ϕ_k diagonalising the T matrix (which e.g. in the proton case describes different $p \to N^*$, $N_a^* \to N_b^*$ transitions). Such eigenstates only undergo elastic scattering. Since there are no off-diagonal transitions,

$$\langle \phi_i | T | \phi_k \rangle = 0 \qquad \text{for } i \neq k, \tag{20.20}$$

a state k cannot diffractively dissociate into a state $j \neq k$. Working in terms of the Good-Walker eigenstates ϕ_i, we have a simple one-channel eikonal for each state. We denote the orthogonal matrix which diagonalizes T by a, so that

$$T \;=\; aFa^T \qquad \text{with} \qquad \langle \phi_i | F | \phi_k \rangle \;=\; F_k \, \delta_{ik}, \tag{20.21}$$

where F_k is the probability amplitude of the hadronic process proceeding via the diffractive eigenstate ϕ_k.

Now consider the diffractive dissociation of an incoming state $|h\rangle$. We can write

$$|h\rangle \;=\; \sum_k a_{hk} \, |\phi_k\rangle. \tag{20.22}$$

The elastic scattering amplitude satisfies

$$\langle h|T|h\rangle \;=\; \sum_k |a_{hk}|^2 \, F_k \;=\; \langle F \rangle, \tag{20.23}$$

where $F_k \equiv \langle \phi_k | F | \phi_k \rangle$ and where the brackets of $\langle F \rangle$ mean that we take the average of F over the initial probability distribution of diffractive eigenstates. After the diffractive scattering described by T_{fh}, the final state $|f\rangle$ will, in general, be a different superposition of eigenstates from that of $|h\rangle$, which was shown in Eq. (20.22). Neglecting the real parts, for the cross sections at a given impact parameter b, we have

$$\begin{aligned}
\frac{\mathrm{d}\sigma_{\rm tot}}{\mathrm{d}^2 b} &= 2\,\mathrm{Im}\langle h|T|h\rangle \;=\; 2\sum_k |a_{hk}|^2 \,\mathrm{Im} F_k \;=\; 2\langle \mathrm{Im} F\rangle \\
\frac{\mathrm{d}\sigma_{\rm el}}{\mathrm{d}^2 b} &= |\langle h|T|h\rangle|^2 \;=\; \left| \sum_k |a_{hk}|^2 \, F_k \right|^2 \;=\; \langle |F| \rangle^2 \\
\frac{\mathrm{d}\sigma_{\rm el\,+\,SD}}{\mathrm{d}^2 b} &= \sum_k |\langle \phi_k | T | h \rangle|^2 \;=\; \sum_k |a_{hk}|^2 \, |F_k^2| \;=\; \langle |F^2| \rangle.
\end{aligned} \tag{20.24}$$

It follows that the cross section for the single diffractive dissociation of a proton,

$$\frac{\mathrm{d}\sigma_{\rm SD}}{\mathrm{d}^2 b} \;=\; \langle |F^2| \rangle \;-\; \langle |F| \rangle^2, \tag{20.25}$$

is given by the statistical dispersion in the absorption probabilities of the diffractive eigenstates. Here the average is taken over the components k of the incoming proton which dissociates. If the averages are taken over the components of both of the incoming particles, then Eq. (20.25) is the sum of the cross sections for single and double dissociation, see Fig. 20.3.

Note that if all the components ϕ_k of the incoming proton $|h\rangle$ were absorbed equally, then the diffracted superposition would be proportional to the incident one and the probability of the inelastic diffraction would be zero. Thus if, at very high energies, the amplitudes F_k at small impact parameters are equal to the black disk limit, $F_k = i$, then diffractive production will be equal to zero in this impact parameter domain, and so will only occur in the peripheral b region where the edge of the disk becomes not completely black. Hence the impact parameter structure of diffractive dissociation and elastic scattering is drastically different in the presence of absorptive s-channel unitarity effects (see the $G_{\rm inel}$ term in Eq. (20.9)). Under the assumption that amplitudes F_k at high energies cannot exceed the black disk limit, Im $F_k \leq 1$, equations 20.24 lead to the following bound

$$\frac{\mathrm{d}\sigma_{\rm el\,+\,SD_1+SD_2+DD}}{\mathrm{d}^2 b} \leq \frac{1}{2} \frac{\mathrm{d}\sigma_{\rm tot}}{\mathrm{d}^2 b} \,. \tag{20.26}$$

known as the Pumplin bound [46] [5].

20.3.3 *Diffraction from the t-channel viewpoint*

The t-channel approach is based on the Regge model (see Section 20.2), where high-energy diffractive processes are mediated by the exchange of a Pomeron ($\mathbb{P}$). In the case of the elastic pp-scattering amplitude in the eikonal model (see Eq. (20.13)), the opacity corresponding to the exchange of one Pomeron is

$$\Omega(s,b) = \int \frac{\mathrm{d}^2 q_t}{4\pi^2} \; \Omega(s,q_t) \; e^{i\vec{q}_t \cdot \vec{b}} \tag{20.27}$$

with

$$\Omega(s,q_t) = \frac{1}{s} T'_{\rm el} = -i\eta_P(t) g_N(t) g_N(t) \left(\frac{s}{s_0} \right)^{\alpha_{\mathbb{P}}(t)-1}, \tag{20.28}$$

where $T'_{\rm el}$ is the two-particle s-channel irreducible elastic amplitude, cf. Eq. (20.5), and $g_N(t)$ is the proton-Pomeron coupling.

If we assume an exponential t-dependence of the coupling, $g_N(t) = g_N(0) \exp(B_0 t)$, and neglect the Pomeron phase, then the opacity is

$$\Omega(s,q_t) = g_N(0) g_N(0) \left(\frac{s}{s_0} \right)^{\alpha_{\mathbb{P}}(0)-1} e^{Bt}, \tag{20.29}$$

with the t-slope given by

$$B \;=\; 2B_0 + \alpha'_{\mathbb{P}} \ln\left(\frac{s}{s_0} \right). \tag{20.30}$$

At high energies the opacity has a Gaussian form in the b-space:

$$\Omega(s,b) = \frac{g_N^2(0)}{4\pi B} \left(\frac{s}{s_0} \right)^{\alpha_{\mathbb{P}}(0)-1} e^{-b^2/4B} \,. \tag{20.31}$$

In terms of opacity the effective radius of interaction increases at high energies as $\sqrt{\alpha'_{\mathbb{P}} \ln(s/s_0)}$. This means that with energy increasing the differential cross section becomes steeper (the so called *shrinkage* of the diffractive peak).

If we were to take for the Pomeron the DL parametrisation [25, 26], that is to keep just the first, $T(b) = \Omega(b)/2$, term in the elastic amplitude (Eq. (20.13)) then, at LHC energies, the Gaussian would exceed the black disk limit at small b. However, the eikonal unitarization reduces the power growth of the one-Pomeron exchange cross section. Thus, in Eq. (20.31) $\Omega(s,b) \propto (s/s_0)^{\alpha_{\mathbb{P}}-1}$ gives an amplitude Im $T_{\rm el}(s,b) = 1 - e^{-\Omega/2} < 1$. Hence the total cross section is limited by the size of the effective interaction area $\sigma_{\rm tot} < 2\pi R^2$, where the interaction radius R can be estimated from Eq. (20.31) as the value of b where Re$\Omega(b)$ becomes ~ 1.

For the parameterization of Eq. (20.31) the corresponding radius grows at very large energies as

$$b^2 = R^2 = 4B \ln\left[\frac{g_N^2(0)}{4\pi B} \left(\frac{s}{s_0} \right)^{\alpha_{\mathbb{P}}(0)-1} \right] \simeq 4\Delta \alpha'_{\mathbb{P}} \ln^2(s/s_0) \,. \tag{20.32}$$

That is for $\Delta = 0.1$ and $\alpha'_{\mathbb{P}}$=0.25 GeV^{-2} we may expect that the cross section increases as

$$\sigma_{\rm tot} = 2\pi R^2 \simeq c \cdot \ln^2 s \,, \tag{20.33}$$

with $c = 8\pi\Delta\alpha'_{\mathbb{P}} = 0.24$ mb. This value is close to that obtained by the COMPETE parameterization ($c = 0.27$ mb [22, 24]) but much smaller than the Froissart-Lukaszuk-Martin (FLM) bound [47–49]. With $c^{\rm FLM} = \pi/m_\pi^2 \simeq 60$ mb, see Section 20.7,

$$\sigma_{\rm tot} \leq \frac{\pi}{m_\pi^2} \ln^2\left(\frac{s}{s_0} \right). \tag{20.34}$$

[5] Strictly speaking the proof of the Pumplin bound is justified only for low mass dissociation. When the masses $M_{1,2}$ become so large (say, $M_i^2 > \sqrt{s s_0}$) that the Good-Walker states $|\phi_i\rangle$, corresponding to two incoming protons overlap, we may face double counting. Therefore, the high mass dissociation will be considered in the next Section, in terms of the multi-Pomeron diagram. Here and in what follows s_0 is a constant which should be defined for a particular theoretical model or fitted from experiment.

The fact that $c = (0.24\text{–}0.27)$ mb $\ll c^{\rm FLM} = 60$ mb demonstrates that even at the LHC we are very far from true high-energy asymptotics [6], and the observed growth of the cross section is driven by the interactions at relatively large transverse momenta $k_t \gg m_\pi$ rather than the smallest hadron mass m_π in the denominator of Eq. (20.34).

20.3.3.1 *The t-slope and dip in the elastic cross section*

We first start with a relatively small one-Pomeron amplitude and consider the two-Pomeron contribution corresponding to the Ω^2 term in the expansion of the eikonal $1 - \exp(-\Omega/2)$. In this term the momentum transferred, $q_t = \sqrt{|t|}$, is divided between the two Pomerons so that each Pomeron carries about a momentum $q_t/2$. Correspondingly, the t dependence of the whole 'two-Pomeron' amplitude will be $\exp(2B(t/4)) = \exp(Bt/2)$ [7].

Since the two-Pomeron contribution has an opposite sign in comparison with the one-Pomeron exchange, their interference will result in the appearance of the first diffractive minimum which moves to smaller $|t|$ with energy increasing. Such interference effects are largely responsible for the zero in the imaginary part of the amplitude (with the minimum filled by the real part).

It is worth mentioning that the one-channel eikonal discussed so far is a rather oversimplified approximation. It provides some indications about the behaviour we may expect for the elastic cross section, but clearly it does not give the whole story. Moreover, even within the framework of the one-channel eikonal, the expectation for the elastic slope t-dependence could be masked by other effects. Firstly, there is no reason why the t-dependence of the proton-Pomeron coupling $g_N(t)$ has to be a pure exponent. Next, there exists a two-pion singularity at $t = 4m_\pi^2$ (close to the physical region) in the Pomeron trajectory which generates some curvature in the behaviour of $\mathrm{d}\sigma_{\rm el}/\mathrm{d}t$ [50–52]. So there may be some compensation between the effects caused by the eikonal (arising from the interference between the different multi-Pomeron contributions), and the curvatures coming from the form of the proton-Pomeron coupling and the two-pion singularity of the Pomeron trajectory. However, an exact compensation looks quite non-trivial and a *pure* exponential behaviour of $\mathrm{d}\sigma_{\rm el}/\mathrm{d}t$ looks highly unlikely.

Indeed, the measurements by the TOTEM collaboration at 8 TeV [53] and at 13 TeV [54] clearly demonstrate that the local slope of the elastic pp cross section,

$$B = \mathrm{d}[\ln(\mathrm{d}\sigma_{\rm el}/\mathrm{d}t)]/\mathrm{d}t, \tag{20.35}$$

at $-t \lesssim 0.3$ GeV^2 varies with t.

20.3.3.2 *High mass dissociation*

Let us turn to inelastic diffractive processes that is, to single and double proton dissociations, $pp \to X+p$ and $pp \to X_1+X_2$, where the $+$ sign denotes the presence of a LRG in the distribution of final state particles. For example, for the diffractive dissociation of a proton into a system of mass M, the rapidity gap between the incoming proton and the remaining hadrons is

$$\Delta y = \ln\left(\frac{s}{M^2}\right) = \ln\left(\frac{1}{\xi}\right), \tag{20.36}$$

where $\xi = 1 - x$ and x is the initial momentum fraction (Feynman variable) carried by the outgoing proton. The masses, M, of the diffractively excited states, produced in high $\sqrt{s}$ collisions, can be large. To separate dissociation from the common inelastic process, usually the condition $M^2 \ll s$ is imposed.

The simplest multi-Pomeron diagram used to describe the diffractive dissociation is the so-called triple-Pomeron graph, shown at the end of Fig. 20.2.

In the Regge pole model, the cross section for the inclusive single diffractive (SD) dissociation process [55–57] can be written in the form (see Fig. 20.2)

$$\frac{\xi \mathrm{d}\sigma_{\rm SD}}{\mathrm{d}t\mathrm{d}\xi} = \frac{M^2 \mathrm{d}\sigma_{\rm SD}}{\mathrm{d}t\mathrm{d}M^2} = \frac{g_{3\mathbb{P}}(t) g_N(0) g_N^2(t)}{16\pi^2} \left(\frac{s}{M^2}\right)^{2\alpha_{\mathbb{P}}(t)-2} \left(\frac{M^2}{s_0}\right)^{\alpha_{\mathbb{P}}(0)-1}, \tag{20.37}$$

where $g_{3\mathbb{P}}(t)$ is the triple-Pomeron coupling. The value of the coupling $g_{3\mathbb{P}}$ is usually obtained from a triple-Regge analysis of lower energy data (see e.g. [34]) .

In an analogous way the cross section for double dissociation reads

$$\frac{\xi_1\xi_2 \mathrm{d}\sigma_{\rm DD}}{\mathrm{d}t\mathrm{d}\xi_1\xi_2} = \frac{M_1^2 M_2^2 \mathrm{d}\sigma_{\rm DD}}{\mathrm{d}t\mathrm{d}M_1^2\mathrm{d}M_2^2} = \frac{g_{3\mathbb{P}}^2(t) g_N^2(0)}{16\pi^3} \left(\frac{s s_0}{M_1^2 M_2^2}\right)^{2\alpha_{\mathbb{P}}(t)-2} \left(\frac{M_1^2 M_2^2}{s_0^2}\right)^{\alpha_{\mathbb{P}}(0)-1}, \tag{20.38}$$

where t is the momentum squared transferred through the LRG. As discussed in Section 20.5, from a microscopic point of view the

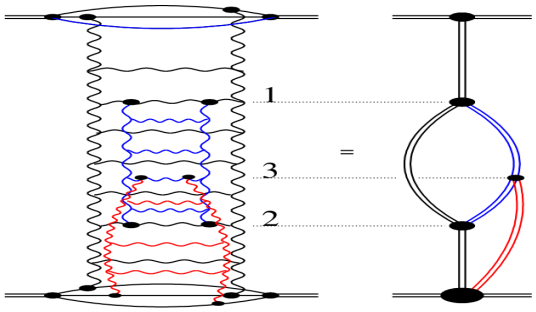

Figure 20.4: Pomeron exchange with schematic diagrams for the enhanced and semi-enhanced exchanges.

Pomeron exchange is described by a set of ladder-type diagrams (see [58–60]), which can lead to a rescattering of the intermediate partons (produced inside this ladder during the evolution), see Fig. 20.4. The left plot shows the Pomeron exchange complemented with the rescattering of partons 1 and 2 and the scattering of a parton 3 on the target. In terms of multi-Pomeron exchanges this corresponds to the diagram on the right hand side, where the Pomeron exchange is shown by the double line of a corresponding colour. The blue one is called "enhanced" (its contribution is integrated over the rapidities of both upper and lower vertices, i.e. of partons 1 and 2). The loop formed by the Pomerons shown in red is called "semi-enhanced" (it is integrated over the rapidity of one intermediate parton).

While the rescattering of the incoming hadron (proton) is already embedded in the eikonal formula (Eq. (20.13)), the rescattering of the intermediate partons in RFT is accounted for by the so-called enhanced diagrams [8] with multi-Pomeron vertices, g_m^n, which couple m to n Pomerons. It is quite a challenging task to resum all the enhanced diagrams, however this was successfully performed within the framework of the QGSJET Monte Carlo [61]. An elegant approach to sum up all enhanced diagrams in the case when each extra effective Pomeron contribution is very large was proposed in [62], assuming the analyticity of the g_m^n vertices in n and m in the right half of the complex n- and m-planes. The resulting amplitude becomes a black disk.

The simplest triple-Pomeron vertex $g_2^1 = g_{3\mathbb{P}}$ produces the first multi-Pomeron graph considered above (see the end of Fig. 20.2). However, numerically the multi-Pomeron vertices are relatively small. Note also that the value of $g_{3\mathbb{P}}$, determined from the fit to

[6] As usual, we assume $s_0 = 1$ GeV^2, but the qualitative conclusion does not depend on any realistic choice of s_0.

[7] The two-Pomeron contribution has a factor of two smaller t-slope, and in terms of the impact parameter, the $\Omega^2(b)$ term is concentrated in the domain of a smaller radius. In such a simplified picture, the impact parameters corresponding to an exchange of n Pomerons will rapidly decrease with n increasing.

[8] This contribution is *enhanced* due to the large parton multiplicity.

experimental data (e.g. [63]), is actually an effective vertex with coupling

$$g_{\rm eff} \;=\; g_{3\mathbb{P}}\,\langle S^2\rangle, \tag{20.39}$$

which already includes the survival factor $S^2(b)$, see Eq. (20.15).

Since the opacity Ω increases with energy, at large Ω the number of multiple interactions grows as $N \propto \Omega$, leading to a smaller S^2. An explicit analysis [64] accounting for the survival effects gives a coupling $g_{3\mathbb{P}}$ about a factor of 3 larger than $g_{\rm eff}$, namely $g_{3\mathbb{P}} \simeq 0.2 g_N$.

Recall that the Pomeron exchange simultaneously describes both the elastic scattering amplitude, $T_{\rm el}$, and the multiparticle production cross section, $G_{\rm inel}$. The discontinuity (*disc* $T_{\rm el}$) of the ladder diagram corresponds to the production of secondary particles, practically homogeneously distributed over the whole available rapidity interval covered by the Pomeron, as illustrated by the right-hand diagram in Fig. 20.5.

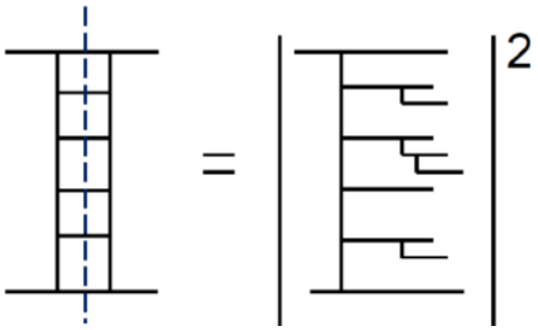

Figure 20.5: Cut Pomeron contribution to the inelastic cross section.

For the one-Pomeron case this discontinuity is called the "cut Pomeron". Correspondingly each multi-Pomeron diagram describes a series of different processes. Cutting k Pomerons in the diagram with n Pomerons we get the inelastic interaction with the multiplicity (density of secondaries) k times larger than that, N_0, produced by one cut Pomeron, $\mathrm{d}N/\mathrm{d}y = k \cdot N_0$. The remaining $n-k$ (elastic) Pomerons account for the absorptive corrections to the subprocess with k cut Pomerons. Indeed, the contribution of the diagram with n Pomerons includes also the processes with larger, $(k+i)\cdot N_0$ multiplicities (cut Pomerons), where $(i = 1, 2, ..., n-k)$. Absorptive corrections, described by the remaining elastic Pomerons, play a role of the survival factor S^2 for the process with the fixed particle density $k \cdot N_0$. They ensure probability conservation (the sum of the probabilities of all possible different channels is equal to one) and restore unitarity. Note that the multi-Pomeron diagrams represent all possible interactions between partons from the protons and partons from the Pomerons. In the case of Monte Carlo generators, the non-enhanced multi-Pomeron contributions are included in terms of the multiple parton interaction (MPI) option, see [13,65] and Section 7.2 in [2]. However, as a rule, this option accounts mainly for the multiple interactions between the partons from the protons (incoming hadrons). The energy-momentum sharing between the various inelastic rescattering processes (including the cut and uncut Pomerons) was performed at the amplitude level within the EPOS Monte Carlo [66].

20.3.3.3 *AGK cutting rules*

The relation between the cross sections of subprocesses with a different number of cut Pomerons within a given diagram with n Pomerons) is given by the AGK (Abramovsky-Gribov-Kancheli [67]) cutting rules. These rules include also the cut *between* the Pomerons with $k = 0$ which corresponds to the contribution of the particular diagram to the elastic cross section. By applying these rules, it is possible to show the self-consistency of the approach, which was lacking in the pure Regge-pole model.

Consider a diagram where the elastic scattering amplitude is mediated by an exchange of n Pomerons. The AGK cutting rules specify the coefficients c_n^k arising when k of these Pomerons are cut. Recall that the Pomeron cut discontinuities give the corresponding inelastic contributions to $\sigma_{\rm tot}$. The terms with $k = 0$ correspond to the diffractive cutting of the diagram (that is, the cut is between the Pomeron exchanges, and not through the Pomerons themselves), while the terms with $k = 1, 2, ...$ describe the processes with k cut Pomerons. The coefficients $c_n^k = \sigma_n^k/|\sigma_{\rm tot}^{(n)}|$ are [9]

$$c_n^{k=0} = (-1)^n(2^{n-1}-1), \qquad c_n^{k\neq 0} \;=\; (-2)^{n-1}\frac{(-1)^{k-1}n!}{k!(n-k)!} \tag{20.40}$$

where $\sigma_{\rm tot}^{(n)}$ denotes the contribution of the n-Pomeron diagram to the total cross section. Note the alternating sign of $\sigma_{\rm tot}^{(n)}$ expressed as $(-1)^{n-1}$.

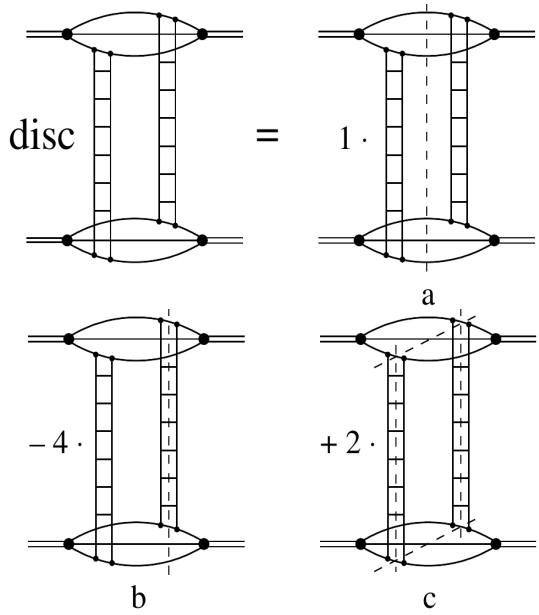

Figure 20.6: Two-Pomeron exchange diagram as a sum of different AGK cuts shown by the dashed lines.

For the two-Pomeron exchange, $n = 2$, the coefficients are $+1$, -4, or $+2$ according to whether $k = 0$, 1 or 2 Pomerons are cut, respectively. As shown in Fig. 20.6, the amplitude of the two-Pomeron exchange corresponds to a sum of three processes: i) inelastic interaction with particle density twice that caused by one Pomeron (see Fig. 20.6(c)) which enters with the coefficient '2', ii) shadowing (absorptive) correction to the one-Pomeron exchange contribution, which corresponds to events with a single Pomeron density (only one Pomeron is cut), see Fig. 20.6 (b), which enters with a factor '-4', and iii) diffractive elastic scattering or proton dissociation (when different components of the proton wave function correspond to different interaction cross sections), caused by the distortion of the incoming plane wave, see Fig. 20.6(a).

Note that the inclusive cross section is not affected by the multi-Pomeron contribution: $2 \times (2) + 1 \times (-4) = 0$. This is a general property of the AGK rules valid for any number of Pomerons n. Thus in order to calculate the inclusive single-particle cross section, it is sufficient to consider just the *one*-Pomeron exchange diagram.

Let us emphasize that the AGK rules provide a framework to consistently work with multi-Pomeron diagrams, that is, with the Regge cuts, accounting for their contributions to different processes (elastic scattering and diffractive dissociation, inelastic events with different densities, $\mathrm{d}N/\mathrm{d}y$, of secondaries, etc.).

Measurements of diffractive dissociation cross sections have been made in a wide range of pre-LHC energies, see e.g. [68–73]. At the LHC, cross sections of events with a LRG were measured by the ATLAS, CMS and ALICE collaborations at 7 and 8 TeV,

[9] In their complete form the AGK cutting rules were implemented in the QGSJET Monte Carlo [61].

see [74–77]. ATLAS [78] and CMS and TOTEM [79] presented first measurements of SD cross sections at 8 TeV with a tagged forward proton. While ATLAS measured inclusive SD cross section, CMS and TOTEM studied SD dijet production. Note that in [78] the measured slope $B = 7.65 \pm 0.34$ GeV^{-2} of the inclusive SD cross section as well as the differential distributions $\frac{\xi \mathrm{d}\sigma_{\mathrm{SD}}}{\mathrm{d}t\mathrm{d}\xi}$ for $0.0001 \leq \xi \leq 0.025$ are (within the experimental uncertainties) in a good agreement with the theoretical expectations [29,80]. Moreover a relatively small (in comparison with the $\mathrm{d}\sigma_{\mathrm{el}}/\mathrm{d}t$) slope B indicates that the size of the triple-Pomeron vertex is much smaller than the proton size.

20.3.4 *Central Diffractive processes*

Processes $pp \to p + X + p$, where an object X, produced in the central rapidity region, is separated from the outgoing protons by a LRG on each side, are called Central Exclusive Production (CEP). They are described by the double Pomeron exchange (DPE) diagrams. When the mass of the central system, M_X, is large and the interaction in the M_X region can be described by Pomeron exchange, the corresponding cross section reads

$$\frac{\xi_1\xi_2 \mathrm{d}\sigma^{\mathrm{CEP}}}{\mathrm{d}\xi_1 \mathrm{d}t_1 \mathrm{d}\xi_2 \mathrm{d}t_2} = \frac{g_N^2(t_1) g_N^2(t_2)}{(16\pi^2)^2} \left(\frac{1}{\xi_1}\right)^{2\alpha_{\mathbb{P}}(t_1)-2} \left(\frac{1}{\xi_2}\right)^{2\alpha_{\mathbb{P}}(t_2)-2} \times g_{3\mathbb{P}}^2(0) \left(\frac{M_X^2}{s_0}\right)^{\alpha_{\mathbb{P}}(0)-1} . \tag{20.41}$$

If the mass M_X is not too large or for the cases (such as exclusive Higgs boson or dijet production) where the mass M_X is comparable with the corresponding hard scale, the last factor $g_{3\mathbb{P}}^2(0)(M_X^2/s_0)^{\alpha_{\mathbb{P}}(0)-1}$ should be replaced by the corresponding 'Pomeron-Pomeron cross section', see for instance [81,82].

Note that equations (20.37), (20.38) and (20.41) are written in a simplified way without accounting for absorptive corrections. That is, the cross sections in equations (20.37) (20.38) and (20.41) should be multiplied by the gap survival factor S^2 (see Eq. (20.15)).

Since the QCD Pomeron is built mainly from gluons it is natural to search for glueballs in double Pomeron exchange processes, and in particular, in CEP.

Resonance production in the Pomeron-Pomeron fusion was extensively studied at the CERN ISR at $\sqrt{s}$ from 22 GeV to 63 GeV (see for reviews [82–84]) and, after the ISR closure in 1983, in fixed target experiments at the CERN SPS [85] and E690 at the Tevatron [86, 87]. Glueballs were actively searched for and the properties of the f_0 and f_2 production studied in detail using multiparticle spectrometers, such as the Omega facility at the CERN SPS experiments (WA76, WA91 and WA102), see for a review [85].

An important property of CEP processes, which can be expected from matching with the perturbative QCD LO (leading order) calculation, is the $J_z = 0$ dominance. Perturbatively, for the CEP of a heavy object, the leading contribution comes from a configuration with the projection of this object spin onto the beam axis $J_z = 0$ [81]. Note that the CEP cross section is suppressed at large M_X by a strong bremsstrahlung off the incoming gluons (from the Pomeron) which would violate the 'exclusivity'. The small probability of not having such radiation is described by the Sudakov suppression factor, T_{Sud}, [88], see [81] for details.

20.3.5 *Diffractive parton distributions*

Selecting in Deep Inelastic Scattering (DIS) events with a LRG (see e.g. [89,90]) or detecting the leading proton (see Section V.C. in the review [91]) we can study the parton (quark and gluon) distributions of the Pomeron [10]. In other words, such events can be treated as DIS on the Pomeron target with the incoming Pomeron flux given by

$$f_{\mathbb{P}}(x_{\mathbb{P}}) = \int \mathrm{d}t \frac{g_N^2(t)}{16\pi^2} x_{\mathbb{P}}^{2(1-\alpha_{\mathbb{P}}(t))} , \tag{20.42}$$

where the proton momentum fraction transferred through the Pomeron $x_{\mathbb{P}} = \xi = M^2/s$.

These Pomeron PDFs were extracted from the HERA measurements of ep scattering with leading protons or a LRG and can be used to describe the inclusive production of high E_T dijets or another hard process based on the collinear factorization theorem in the same way as that in non-diffractive collisions (see [91]). The inclusive measurements of these PDFs are described in [92–94], with the combined H1 and ZEUS data using tagged protons analyzed in [95]. The impact of diffractive jet measurements is addressed e.g. in [96] and the measured charm contribution is presented in [97, 98]. As far as the parton distributions are known, we can calculate the corresponding inelastic cross section of the Pomeron-proton interaction using one of the 'general purpose' Monte Carlo generators (see e.g. [13]), multiply it by the Pomeron flux and compare the obtained result with the Regge formula in Eq. (20.37). This approach provides another way to evaluate the triple-Pomeron vertex $g_{3\mathbb{P}}$. The corresponding analysis was performed in [99] and leads to practically the same (within the error bars) value of $g_{3\mathbb{P}} = 0.2 g_N(0)$.

It is worth mentioning that in DIS at large Q^2 we are dealing with small-size objects and the rescattering effects are small. Therefore, the survival factor $S^2 \simeq 1$ and does not affect the results.

20.4 Experimental data on diffraction at high energies

20.4.1 *Total and elastic cross sections*

The elastic scattering of protons is a process with a special and rather simple experimental signature: the central detector is empty while the incoming protons after the collisions are detected in the dedicated forward proton detectors (FPD) placed far from the interaction point (IP). Elastic scattering data are taken in special runs in order to be able to reach different ranges of t-values and thanks to the very large value of the cross section the data can be collected with a relatively low instantaneous luminosity and hence a negligible pile-up.[11]

These special runs usually have very few proton bunches and differ in the t range covered, which is governed roughly by the relation $t_{\mathrm{min}} \propto d^2/\beta^*$. Here d is the distance, expressed in multiples of the beam size at the detector, from the centre of the LHC beam and β^* is defined as the distance from the IP to the point where the transverse area of the beam is twice as wide as that at the IP (see Section 31 in [1]). Note that if we work at large β^*, the incoming protons have very small angular divergence leading to small average transverse momentum, which allows us to measure very small $|t|$ values. The lowest $|t|$ values measured so far at the LHC are 4×10^{-4} GeV^2 (ALFA) and 6×10^{-4} GeV^2 (TOTEM) reached with the 8 TeV LHC beam configured with β^*=1 km optics. The largest t values of about 4 GeV^2 were measured by TOTEM at 8 and 13 TeV with $\beta^* = 90$ m thanks to special triggers. Other β^* values used in special runs are 3.5 m, 11 m and 2.5 km.

There are four ways to determine the σ_{tot} value:

1. **Elastic and Inelastic.** This method does not require the optical theorem and hence no extrapolation of $\mathrm{d}\sigma_{\mathrm{el}}/\mathrm{d}t$ to $t = 0$ and no ρ (defined below Eq. (20.17)) but rather the luminosity and measuring rates N_{el} (elastic) and N_{inel} (inelastic). The total cross section is then simply:
$$\sigma_{\mathrm{tot}} = \frac{1}{\mathcal{L}}(N_{\mathrm{el}} + N_{\mathrm{inel}}). \tag{20.43}$$
Of course, both N_{el} and N_{inel} should be corrected for the detector acceptance and efficiency. This is especially important for N_{inel} since the detectors never cover the whole rapidity region (i.e. the whole 4π).
2. **Elastic only.** This approach necessitates measuring $\mathrm{d}\sigma_{\mathrm{el}}/\mathrm{d}t$ and using the optical theorem with a known value of ρ. As explained in Section 20.2, the optical theorem states that

[10] see also Section 18.5 in [1]

[11] The pile-up is formed by additional pp collisions which typically produce low-p_T particles. These may affect the signal sample and worsen various reconstruction and identification efficiencies.

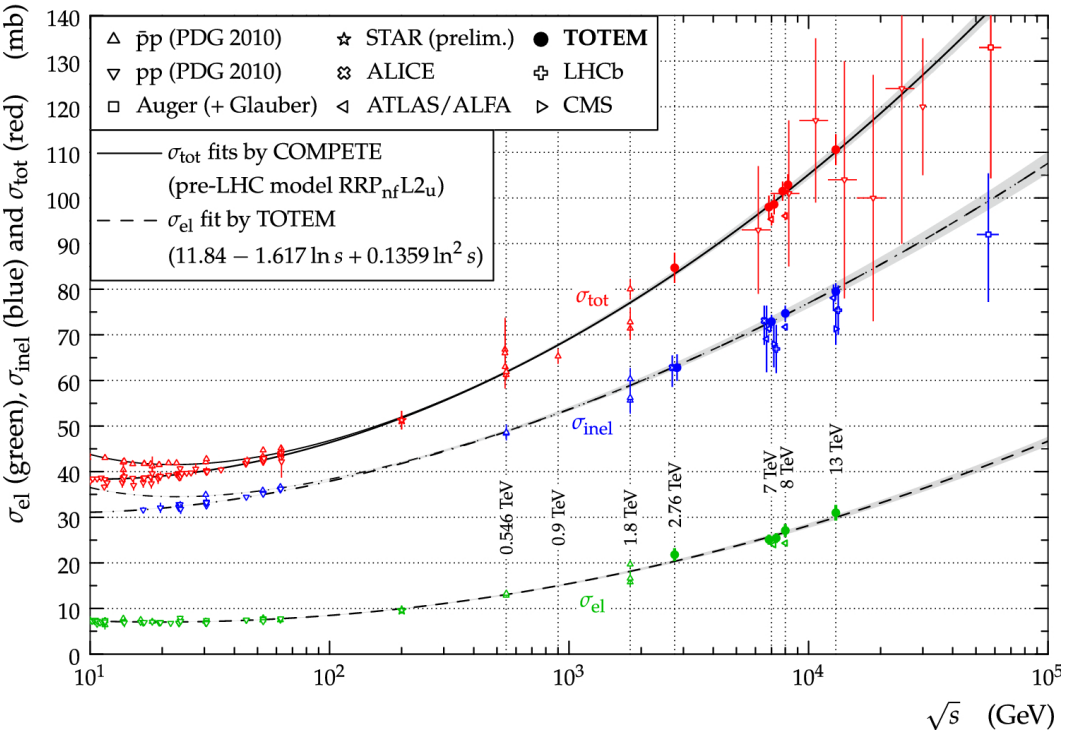

Figure 20.7: Overview of elastic ($\sigma_{\rm el}$), inelastic ($\sigma_{\rm inel}$) and total ($\sigma_{\rm tot}$) cross section data for pp and $p\bar{p}$ collisions as a function of $\sqrt{s}$. The continuous black lines (lower for pp, upper for $p\bar{p}$) represent the best fits of the total cross section data by the COMPETE collaboration [22]. The dashed line is a fit of the elastic cross section data. The dashed-dotted lines refer to the inelastic cross section and are obtained from the difference between the continuous and dashed lines. Figure from Ref. [100].

$\sigma_{\rm tot} \propto {\rm Im}[T_{\rm el}(t \to 0)]$, see Eq. (20.3). Since in practice it is not possible to measure down to $t = 0$, we need to extrapolate. To minimize the model dependence when extrapolating, it is vital to measure down to as low $|t|$ values as possible (i.e. high β^*). This method requires an independent luminosity measurement. Once the luminosity is known, $\mathrm{d}\sigma_{\rm el}/\mathrm{d}t$ can be normalized and used to extract $\sigma_{\rm tot}$ using the formula:

$$\sigma_{\rm tot}^2 = \frac{16\pi}{1+\rho^2} \left.\frac{\mathrm{d}\sigma_{\rm el}}{\mathrm{d}t}\right|_{t\to 0} . \qquad (20.44)$$

3. **Coulomb normalization.** Similarly to the previous method, this approach relies on the elastic observables only and requires a measurement of the elastic cross section at very low values of $|t|$, where it is sensitive to the theoretically well known Coulomb QED contribution $4\pi\alpha^2_{\rm QED}/t^2$. The normalization of $\mathrm{d}\sigma_{\rm el}/\mathrm{d}t$ is then determined by fitting the experimental data at very low $|t|$ using a formula including the Coulomb amplitude and its interference with the strongly interacting (the so-called nuclear) term. This method has been successfully used by UA4/2 [101] and TOTEM [102].
4. **Luminosity-independent.** This method does not rely on the knowledge of luminosity but rather on the knowledge of $N_{\rm el}$ and $N_{\rm inel}$ and on the optical theorem: combining equations (20.43) and (20.44) with $\frac{\mathrm{d}\sigma_{\rm el}}{\mathrm{d}t} = \frac{1}{\mathcal{L}}\frac{\mathrm{d}N_{\rm el}}{\mathrm{d}t}$ we get

$$\sigma_{\rm tot} = \frac{16\pi}{1+\rho^2} \frac{\left.\mathrm{d}N_{\rm el}/\mathrm{d}t\right|_{t=0}}{N_{\rm el}+N_{\rm inel}}, \qquad (20.45)$$

where $\left.\mathrm{d}N_{\rm el}/\mathrm{d}t\right|_{t=0}$ corresponds to the extrapolation to $t = 0$ of the nuclear term only. By independently and simultaneously measuring $N_{\rm el}$ and $N_{\rm inel}$, and applying the optical theorem, we can also determine the luminosity.

The TOTEM [100, 103–105] and ATLAS [106, 107] collaborations at CERN have covered an energy range from $\sqrt{s}$=2.76 TeV to 13 TeV. A compilation of high energy total pp and $p\bar{p}$ cross section measurements is shown in Fig. 20.7 (for discussion of the pre-LHC elastic scattering data see review [108]).

Despite some tension between the Tevatron CDF [109] and E811 [110] data [12] and to a lesser extent between the TOTEM [104, 105] and ATLAS [106, 107] measurements, the data clearly indicate that in the Tevatron – LHC energy interval the total cross section starts to grow *faster* than the power-law parametrization [26] describing the data below the Tevatron energy. In particular, while the DL fit [26] predicts $\sigma_{\rm tot} = 90.7$ mb at $\sqrt{s} = 7$ TeV, the TOTEM experiment observes 98.6±2.2 mb [104].

A compilation of the high-energy data on the elastic slope is shown in Fig. 20.8. It is clearly seen that in the TeV energy range the slope increases with $\sqrt{s}$ more rapidly than the logarithmic behaviour expected in the case of one-Pomeron exchange, see Eq. (20.30). Such an acceleration of the t-slope derivative, $\mathrm{d}B/\mathrm{d}\ln s$, is a clear manifestation of the increasing role of the multi-Pomeron exchanges, where asymptotically the slope should rise as $\ln^2 s$, see [117]. Finally, Fig. 20.9 illustrates the energy dependence of the differential elastic pp cross section. As expected (see Section 20.3.3.1), the diffractive dip moves to smaller $|t|$ with increasing energy.

20.4.2 *Diffractive vector meson production*

The exclusive production of vector mesons was studied in detail at HERA (see for a review [91]). It is well described within the 'dipole model' (see for review and references [120]), where the incoming photon first fluctuates into a quark-antiquark, which then interacts with the target proton and, finally, with the probability given by the overlap integral between the vector meson wave function and the outgoing $q\bar{q}$-pair, the vector meson is produced. The crucial quantity is the value of cross section, $\sigma(q\bar{q} - p)$, of elastic scattering of the $q\bar{q}$-pair on the proton. The energy behaviour of $\sigma(q\bar{q} - p)$ is driven by the intercept, $\alpha_{\rm eff}(0)$, of the effective Pomeron [13] (rightmost singularity in the j-plane), while

[12] The CDF 1.8 TeV point [109] is 2.8 σ higher than the corresponding E811 result [110].

[13] Effective Pomeron means that this is not an original pole in the j-plane, but it includes the corrections (renormalizations) caused by the enhanced diagrams (see e.g. [121]).

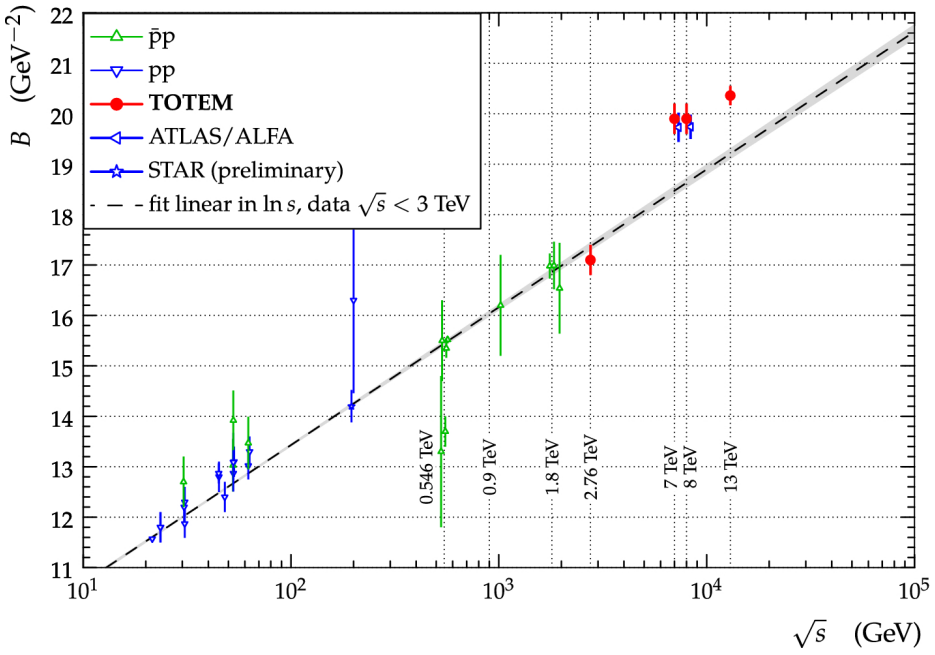

Figure 20.8: The diffractive slope B for pp and $p\bar{p}$ elastic scattering as a function of $\sqrt{s}$. The experimental uncertainties represent the quadratic sum of statistical and systematic uncertainties. The dashed line is a result of a linear fit to data at $\sqrt{s} < 3$ TeV. The data points come from [103–107, 111–113]. Figure from Ref. [100].

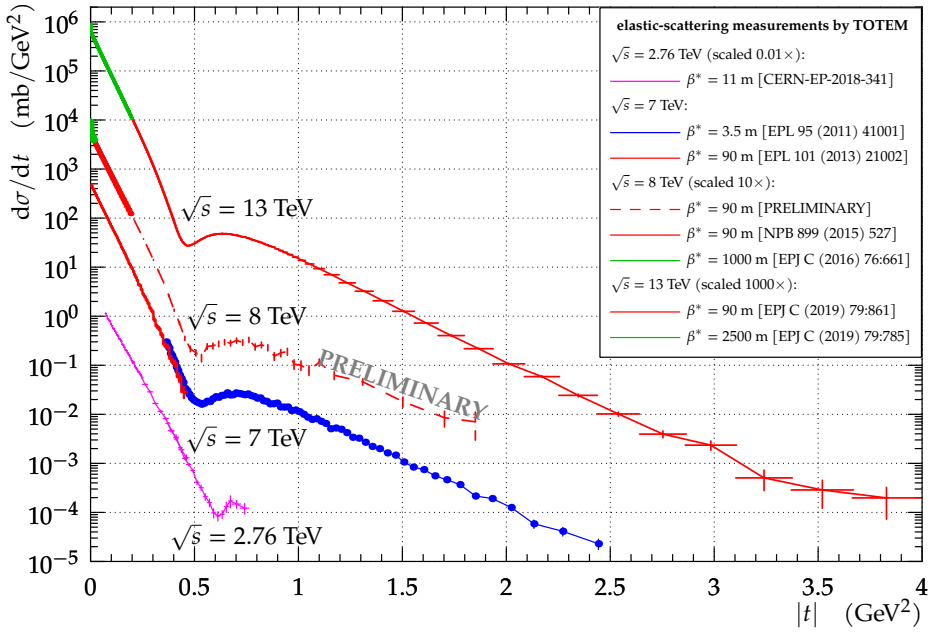

Figure 20.9: The t-dependence of the pp elastic cross section for collision energies $\sqrt{s} = 2.76$ TeV [103], 7 TeV [104, 114], 8 TeV [53,115,116] and 13 TeV [54,102]. The experimental uncertainties represent the quadratic sum of statistical and systematic uncertainties. Figure from Ref. [116].

the value of the cross section depends on the quark separation, r, in the transverse plane, $\sigma(q\bar{q}-p) \propto \alpha_s^2\langle r^2\rangle$ [43, 44]. Thus different processes with the same $\langle r^2\rangle$ are driven by the same $\sigma(q\bar{q}-p)$ cross section.

In the DIS case this separation in turn is controlled by the photon virtuality, Q^2, and the quark mass, m_q: $\langle r^2\rangle \simeq 1/(z(1-z)Q^2 + m_q^2)$ (z is the photon momentum fraction carried by the quark). Indeed, the cross section of the ρ meson diffractive production in DIS at $Q^2 = M_{J/\psi}^2$ is close (up to the difference in the quark electric charges) to that for the J/ψ photoproduction, see Fig. 20.10 (Left).

The production cross section depends non-trivially on W, the energy of the $\gamma^* p$ center of mass system. It increases with W as W^n, where $n = 0.2$ for ρ, ω and ϕ (light quark)-mesons but $n = 0.8$ for J/ψ. Note that in the J/ψ case the energy dependence is close to that of the BFKL (Balitsky-Fadin-Kuraev-Lipatov) Pomeron [59, 122, 123], that is, the singularity calculated within the leading (and next-to-leading) approximation in perturbative QCD. But at lower scales the absorptive (multi-Pomeron) corrections tame the growth which leads to smaller values of n ([124–127]), see Fig. 20.10 (Right).

A similar situation reveals in the dependence of $\alpha_{\rm eff}$ on Q^2, as can be seen in Fig. 47 of [91]. At a large scale $\mu^2 = (Q^2 + M_V^2)/4$ the value of $\alpha_{\rm eff} \simeq 1.3$ is close to the prediction for the QCD

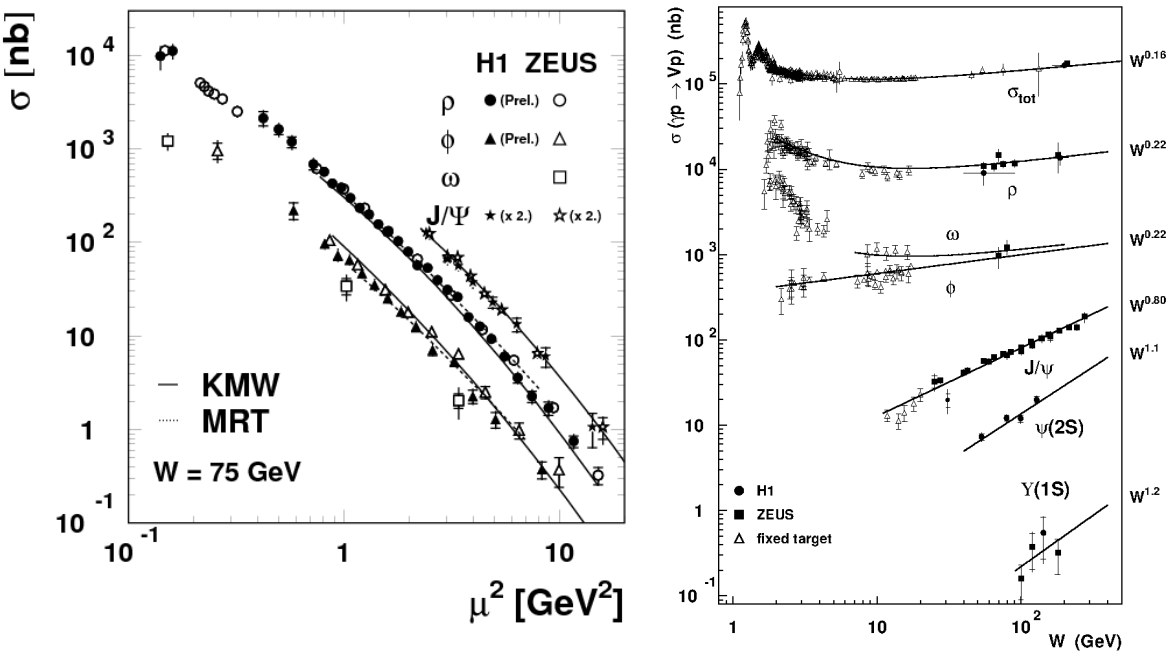

Figure 20.10: (Left) The ρ, ω, ϕ and J/ψ elastic production cross sections as a function of the scale $\mu^2 = (Q^2 + M_V^2)/4$. For readability of the figure, the J/ψ cross sections are multiplied by a factor 2. Figure from Ref. [118]. (Right) Compilation of photoproduction cross section measurements as a function of the γp centre-of-mass energy, W. The total cross section and various vector meson production cross sections are included, with the approximate power law dependences $\sigma \propto W^\delta$ indicated for each process. Figure from Ref. [119].

Pomeron, while for a smaller scale, the absorptive corrections described by the multi-Pomeron diagrams start to reduce the cross section, and $\alpha_{\rm eff}$ decreases.

20.5 Pomeron in QCD

All features described in the previous Sections were based on *first principles*, such as analyticity (based on causality), unitarity, crossing symmetry, etc. Since QCD theory satisfies all these principles it should reveal a corresponding "Regge" behaviour. Indeed, within perturbative QCD there is a Pomeron: an even-signature singularity in the j-plane with vacuum quantum numbers. While in the old Regge theory the Regge trajectories and their couplings were phenomenological numbers fitted from experiment, perturbative QCD allows one to calculate the positions of the singularities and the corresponding couplings with $O(\alpha_s)$ and even with $O(\alpha_s^2)$ accuracy [59, 122, 123, 128–131].

In terms of Feynman diagrams, the QCD Pomeron may be viewed as a sum of multi-particle ladders built by the exchange of two t-channel (reggeized [14]) gluons, see the left-hand side of Fig. 20.5.

The sum of ladder diagrams of the type of Fig. 20.5 is the simplest multiparticle structure which reproduces the power-like s^α behaviour of the Pomeron pole. In other words it corresponds to a sum of completely inelastic $2 \to n$ processes, that is, to the last term $G_{\rm inel} = 1 - \exp(-\Omega)$ in the unitarity equation (20.9). This set of diagrams was resummed in the limit of a small QCD coupling, $\alpha_s \ll 1$, but large energy, such that $\alpha_s \ln(s/s_0) \sim O(1)$ [59]. The summation results in the rightmost singularity at $j = 1 + \omega_0 > 1$. After accounting for the next-to-leading logarithmic (NLL) corrections, the position of the singularity (Pomeron intercept) corresponds to $\omega_0 = 0.25$–0.3 depending only weakly on the scale [122, 123, 132–136], whose value is characterized by the transverse momentum, k_t, of gluons in the ladder.

It was demonstrated (see e.g. [137]) that the resummation of the $(\alpha_s \ln(1/x))^n$ terms based on the QCD Pomeron results essentially improves the description of low-x inclusive HERA data within the framework of the NNLO DGLAP evolution.

At this stage the singularity is the cut in the j-plane. However we have to account for the boundary conditions at relatively small k_t. Imposing a reasonable boundary, we arrive at a series of Regge poles in the interval from $j = 1$ to $j = 1 + \omega_0$ instead of the cut [134]. Note that the first (corresponding to the rightmost pole in the j-plane, i.e. to the pole with the largest Re j) eigenfunction consists of gluons with relatively small k_t, while for the next poles the k_t increases. DIS inclusive $\gamma^* p$ cross sections were fitted in [135] using the QCD based approach in which Pomeron is represented by series of Regge poles obtained within the perturbative QCD BFKL approach. It was concluded that the first pole has a small coupling to the proton. It is possible that this small value of the coupling to the proton is related to the fact that the enhanced multi-Pomeron diagrams (i.e. the rescattering of intermediate partons) were neglected in the fit. The main effect of this enhanced contribution is the "renormalization" of the intercept which diminishes the effective value of ω_0. Besides this, the enhanced diagrams provide a saturation by reducing the rise of the parton densities in the $(b,\ k_t,\ y)$-space (see e.g. [138, 139]).

Note that perturbative QCD allows us to understand why the values of the phenomenological multi-Pomeron vertices and the shift, ω_0, of the intercept, are small (due to $\alpha_s \ll 1$ and some numerical factors such as N_c and π). Indeed, at the lowest α_s orders we get for the ω_0 value and the simplest multi-Pomeron vertices (see e.g. [59, 139, 140]):

$$\omega_0 \propto \frac{N_c \alpha_s}{\pi}, \quad g_{3\mathbb{P}} \propto \frac{N_c \alpha_s^2}{(N_c^2-1)\pi^2} \quad \text{and} \quad g_2^2 \propto \frac{N_c \alpha_s}{(N_c^2-1)^2}\ , \tag{20.46}$$

where g_2^2 is the coupling corresponding to the transition of 2 into 2 Pomerons.

20.5.1 *BFKL evolution in the 'dipole' representation*

It was shown in [141–144] that the LO BFKL Pomeron equation [59] can be written in terms of the evolution of the dipole

[14] That is, the virtual loop corrections to the one-gluon exchanges are included. These corrections are important in order to provide infrared stability of the results.

density, $N(x_d, y_d; y)$, in rapidity y (here x_d and y_d are the transverse coordinates of two t-channel gluons which form the colour singlet dipole). Indeed, after the emission of a new gluon at point z_d, the initial colour dipole with coordinates (x_d, y_d) turns into a pair of dipoles (x_d, z_d) and (z_d, y_d). This can be considered as a development of a 'dipole cascade'. Moreover in this formalism it is easy to include the non-linear absorptive corrections (last term in the square brackets in Eq. (20.47)), which accounts for the rescattering of the intermediate partons (gluons) on the target proton. The corresponding contribution is described by the so-called "fan" diagrams and these are the most important corrections to the linear DGLAP (Dokshitzer-Gribov-Lipatov-Altarelli-Parisi) evolution [145] in the case of DIS at not large scales but at very small momentum fraction [139].

The resulting non-linear evolution (Balitsky-Kovchegov equation [146–148]) reads

$$\frac{\mathrm{d}}{\mathrm{d}y}N(x_d, y_d; y) = \frac{\alpha_s N_c}{2\pi^2}\int \mathrm{d}^2 z_d \frac{(x_d - y_d)^2}{(x_d - z_d)^2(y_d - z_d)^2} \times [N(x_d, z_d; y) + N(y_d, z_d; y) - N(x_d, y_d; y) - N(x_d, z_d; y)N(y_d, z_d; y)] \ . \tag{20.47}$$

For a small density N the last term in the square brackets can be neglected, and the first three terms in Eq. (20.47) reproduce the conventional BFKL equation in the coordinate representation. However, for large $N \to 1$ the right-hand side of Eq. (20.47) vanishes and we reach the saturation $N = 1$. It is worth mentioning that, as shown in [149], in terms of 'dipole' formalism, with the triple-Pomeron vertex generated by the 'one dipole to two dipoles' transition, it is possible to relate the Good-Walker approach to high mass diffraction with the triple-Pomeron diagram.

20.5.2 *Distribution of secondaries: theory versus experiment*

As already discussed, in terms of Feynman diagrams the cut Pomeron can be viewed as a set of ladder diagrams corresponding to a sum of completely inelastic $2 \to n$ processes, that is, to the last term $G_{\mathrm{inel}} = 1 - \exp(-\Omega)$ in the unitarity equation (20.9). Here $n > 2$ means the production of additional $(n-2)$ gluons which, after hadronization, form minijets. [15] Therefore, in the final state driven by one Pomeron, we expect to observe gluon minijets with a flat rapidity distribution in the central (plateau) rapidity region. This would correspond to a flat pseudorapidity distribution of produced particles if they were massless. A typical pseudorapidity distribution of charged particles in inclusive events (up to $|\eta| = 7$) is shown in Fig. 20.11 (left) [150] (see also Fig. 53.1 in [1]). The central part ($|\eta| < 2.5$) was measured by CMS, while the forward region was covered by TOTEM. The dip observed at $\eta = 0$ is explained by the presence of massive particles (the Jacobian $J(p_T, m, \eta) = p_T/E \to p_T/\sqrt{p_T^2 + m^2}$ at $\eta = 0$). A photon energy spectrum is shown in Fig. 20.11 (right) [151], measured by LHCf inclusively and in events with a diffraction topology, i.e. no charged particles with $p_T > 100$ MeV and $|\eta| < 2.5$ observed by ATLAS. As expected in diffractive events the energy flow decreases with E_γ more slowly than that in the inclusive case.

The energy dependence of the particle density $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta$ at $\eta = 0$ is shown in Fig. 20.12 (left). Neglecting absorptive corrections given by the enhanced diagrams (which mainly change ('renormalize') the effective Pomeron intercept $\alpha_{\mathrm{eff}}(0) = 1 + \Delta$ [121]), we conclude that according to the AGK rules the plateau height $\mathrm{d}\sigma/\mathrm{d}\eta \propto s^{\Delta}$ is driven just by the one-Pomeron exchange with effective $\Delta \sim 0.2$ (see Section 20.3.3.3). That is, the density of secondaries observed in the inclusive process increases with increasing energy faster than the total cross section, whose growth is tamed by the multi-Pomeron diagrams. Indeed, as is seen from Fig. 20.12 (left), in the interval of collider energies $\mathrm{d}N_{\mathrm{ch}}/\mathrm{d}\eta = (1/\sigma_{\mathrm{inel}})\mathrm{d}\sigma/\mathrm{d}\eta \propto s^{0.115}$ (i.e. $\mathrm{d}\sigma/\mathrm{d}\eta \propto s^{0.215}$), while $\sigma_{\mathrm{inel}} \propto s^{0.1}$.

[15] Minijets result from hadronization of partons emitted from the cut QCD Pomeron. Typically these are groups of hadrons with comparatively low overall $E_T \lesssim$ 5–10 GeV.

Contrary to the 'old' Regge theory where it was *assumed* (based on the experimental data existing in the 1950s and 1960s) that all transverse momenta are limited, in QCD the k_t distributions of jets (charged particles) have a long k_t tail ($\mathrm{d}\sigma/\mathrm{d}k_t^2 \propto \alpha_s^2(k_t^2)/k_t^4$ at large k_t and very large energy $s \gg k_t^2$). An example of the p_T distribution of charged secondaries is shown in Fig. 20.12 (right).

Note that the mean transverse momentum of secondaries, produced via jet fragmentation, slowly increases with collision energy, see Fig. 20.13 (right). This is caused by the stronger absorption (at larger $\sqrt{s}$) of the gluons with a smaller k_t ($\sigma^{\mathrm{abs}} \propto 1/k_t^2$). The growth of $\langle p_T \rangle$ with multiplicity (see Fig. 20.13 (left)) can be explained by the fact that events with larger N_{ch} correspond to a smaller impact parameter, b, where the absorption of a low k_t component is stronger and, next, larger multiplicity can be originated by the events with jets/minijets with higher p_T. Since the mean p_T of secondaries grows with $\sqrt{s}$, the increase with $\sqrt{s}$ of transverse energy flow is a bit faster than that of particle density.

The model [162] based on a modification of the classic RFT allows one to trace the smooth transition from the pure perturbative, large k_t, region into the *soft* domain. A strong absorption of the low k_t partons plays a crucial role here since it produces an effective infrared cutoff, k_{sat}, and provides the possibility of extending the parton approach, used for 'hard' processes, to also describe high-energy soft and semihard interactions. This approach combines a description of soft physics and diffraction with jet physics in a coherent self-consistent way.

Another way is to include the soft and hard components independently [37, 66, 163, 164]. In this approach the soft part is described in terms of RFT with the phenomenological "soft" Pomeron pole while the hard part is calculated in terms of the parton model for minijet production with the energy dependent cutoff $k_t > k_0(s)$. A combined description of soft and hard processes in hadronic collisions is reached within the QGSJET Monte Carlo model (e.g. [61]) in the framework of the so-called "semihard Pomeron" approach (see e.g. [165]).

In [166] a model was constructed, which incorporated the attractive features of the two successful theoretical approaches to high energy QCD: BFKL Pomeron calculus [59,60] and the Colour Glass Condensate/saturation [167].

20.5.2.1 *Correlations*

All LHC experiments routinely measure tracks with $p_T > p_{\mathrm{min}}$, where p_{min} can vary in different studies. Typically, $p_{\mathrm{min}} =$ 200 MeV, where tracking reconstruction efficiencies are larger than 70%. In order to identify particle species, each experiment has sophisticated identification procedures usually based on the ionization energy loss, $\mathrm{d}E/\mathrm{d}x$, or other techniques, with different regions of applicability for different particle species. Thanks to usually relatively large cross sections of soft QCD processes, most of the results below come from event samples with very low or negligible pile-up.

Following the notation in [168], symmetrized inclusive particle number densities for q points at $y_1, ..., y_q$ (where y_i represents the 4-momentum of the ith particle), $\rho_q(y_1, ..., y_q)$, are related to the inclusive differential cross section by

$$\frac{1}{\sigma_{\mathrm{inel}}}\mathrm{d}\sigma = \rho_1(y)\mathrm{d}y, \quad \frac{1}{\sigma_{\mathrm{inel}}}\mathrm{d}^2\sigma = \rho_2(y_1, y_2)\mathrm{d}y_1\mathrm{d}y_2 \quad \text{etc.} \tag{20.48}$$

By integrating we get

$$\int \rho_1(y)\mathrm{d}y = \langle n \rangle, \quad \int\int \rho_2(y_1, y_2)\mathrm{d}y_1\mathrm{d}y_2 = \langle n(n-1) \rangle \quad \text{etc.}, \tag{20.49}$$

where the angular brackets denote averaging over the event sample and n is the particle multiplicity.

Since the inclusive q-particle densities in general contain trivial contributions from lower-order densities, it is convenient to consider quantities C_q which vanish when one of their arguments becomes statistically independent of (uncorrelated with) the others. These quantities C_q, called correlation functions (or cumulant

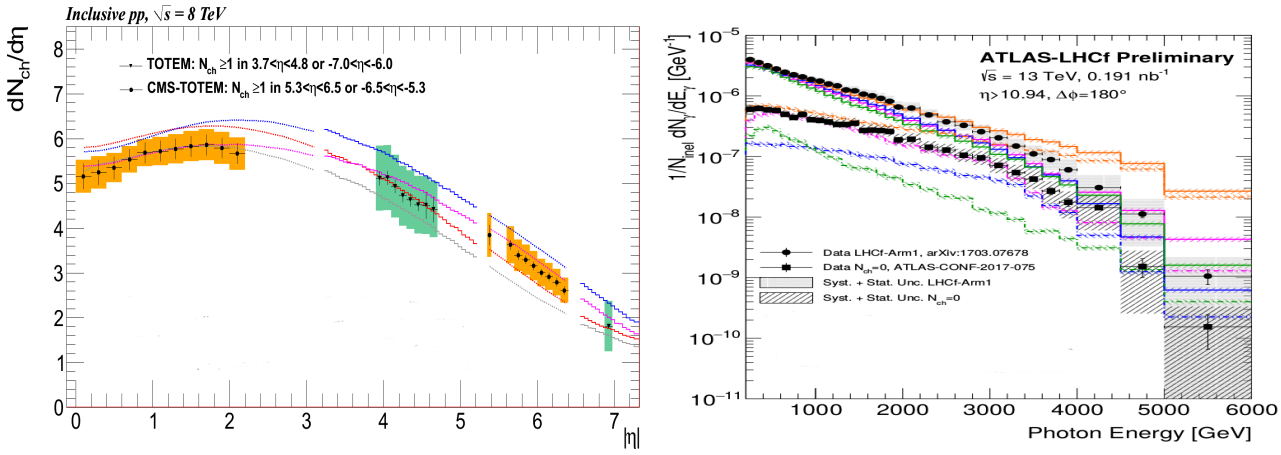

Figure 20.11: (Left) Charged-particle pseudorapidity distribution for inclusive events measured by CMS and TOTEM [150]. The error bars represent the statistical and uncorrelated systematic uncertainties between neighboring bins, while the shaded areas denote the combined statistical and full systematic uncertainties. The coloured lines indicate model predictions. (Right) Photon energy spectrum measured by LHCf at $|\eta|$ >10.94. The filled circles show the inclusive photon spectrum measured by LHCf [152] and filled squares the spectrum for $N_{\rm ch} = 0$ events where no charged particles with $p_T > 100$ MeV and $|\eta|$ <2.5 are observed by ATLAS [153]. The coloured lines indicate model predictions. The error bars correspond to the statistical uncertainties and the shaded areas denote the combined statistical and systematic uncertainties. Figure from Ref. [151].

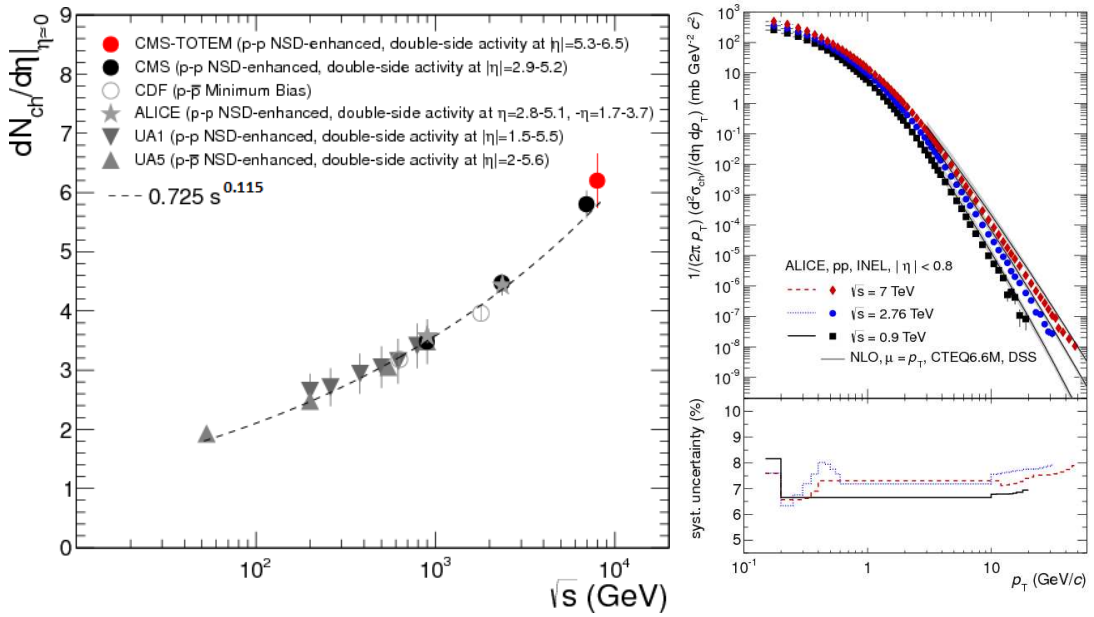

Figure 20.12: (Left) Energy dependence of the charged particle density $\mathrm{d}N_{\rm ch}/\mathrm{d}\eta$ at $\eta \approx 0$ for pp and $p\bar{p}$ collisions. Shown are measurements performed with different Non-SD event selections from UA1 [154], UA5 [155], CDF [156,157], ALICE [158] and CMS [159]. The dashed line is a power-law fit to the data. Figure from Ref. [150]. (Right) Differential cross section of charged particles with $|\eta| < 0.8$ in inelastic pp collisions at $\sqrt{s} = 0.9, 2.76$ and 7 TeV as a function of p_T. Only statistical uncertainties are shown. Figure from Ref. [160].

functions), are defined as:

$$
\begin{aligned}
C_2(1,2) &= \rho_2(1,2) - \rho_1(1)\rho_1(2), \quad C_3(1,2,3) \\
&= \rho_3(1,2,3) - \sum_{(3)} \rho_1(1)\rho_2(2,3) + 2\rho_1(1)\rho_1(2)\rho_1(3), \\
C_4(1,2,3,4) &= \rho_4(1,2,3,4) - \sum_{(4)} \rho_1(1)\rho_3(1,2,3) \\
&\quad - \sum_{(3)} \rho_2(1,2)\rho_2(3,4) + 2\sum_{(6)} \rho_1(1)\rho_1(2)\rho_2(3,4) \\
&\quad - 6\rho_1(1)\rho_1(2)\rho_1(3)\rho_1(4).
\end{aligned}
\tag{20.50}
$$

The 2D two-particle correlation function is defined as

$$
C(\Delta\eta, \Delta\phi) = \frac{\rho_2(\Delta\eta, \Delta\phi)}{\rho_1(\eta_a, \phi_a)\rho_1(\eta_b, \phi_b)}. \tag{20.51}
$$

The distribution $\rho_2(\Delta\eta, \Delta\phi)$ is usually interpreted as a conditional probability to observe a particle a at the phase-space point (η_a, ϕ_a) if a particle b at (η_b, ϕ_b) is observed as well, and $\Delta\eta = \eta_a - \eta_b$ and $\Delta\phi = \phi_a - \phi_b$. The distributions $\rho_1(\eta_a, \phi_a)$ and $\rho_1(\eta_b, \phi_b)$ are probabilities to observe a single particle at (η_a, ϕ_a) and (η_b, ϕ_b), respectively. The denominator of Eq. (20.51) is constructed as a product of two single-particle distributions using an event mixing technique, where each particle in the pair comes from a different event. Experimentally, each reconstructed track is weighted by the inverse of an efficiency factor which accounts

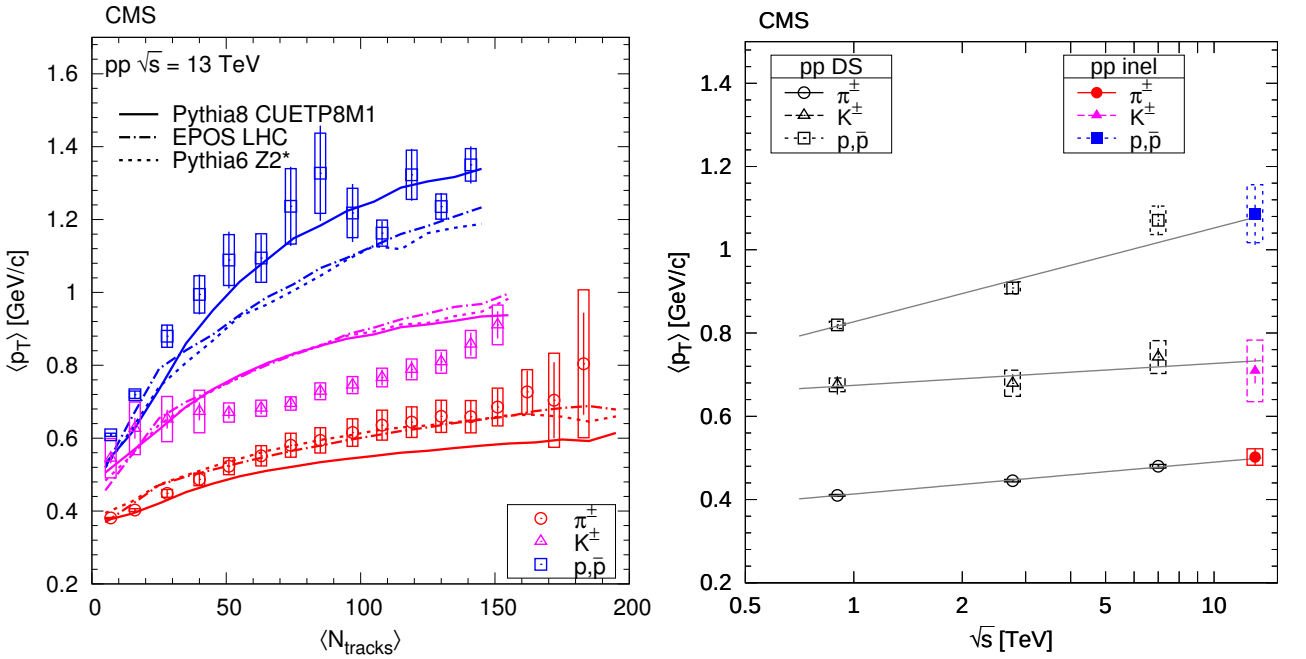

Figure 20.13: Average p_T of pions, kaons and protons in the range $|\eta| < 1.0$ as a function of (left) track multiplicity at $|\eta| < 2.4$ and (right) of center-of-mass energy where the curves show linear fits using lns. The error bars indicate the uncorrelated combined uncertainties, while the boxes show the uncorrelated systematic uncertainties. Figures from Ref. [161].

for the detector acceptance, the reconstruction and particle identification efficiencies, the contamination by secondary particles and the fraction of misreconstructed tracks.

An example of two-particle correlation functions measured in *pp* collisions at 7 TeV is shown in Fig. 20.14 for identical-particle pairs (right panel) and for particle–anti-particle pairs (left panel) [169].

We observe two distinct features which can be explained by short-range (in rapidity) correlations: 1) a near-side peak at $\Delta\phi \approx 0$ and 2) an away-side peak or rather a ridge at $\Delta\phi \approx \pi$. The near-side peak is considered to be caused by at least three effects:

- *fragmentation of partons scattered at a hard scale.* These relatively high p_T partons produce showers which after the hadronization form the mini-jets which create a broad structure extending over at least one unit in $\Delta\eta$ and $\Delta\phi$.
- *resonance decays.* The decay of resonances contributes to the near-side peak at $\Delta\eta \sim 0$ and extended in $\Delta\phi$ [170–172], depending on the released kinetic energy of the given resonance. This effect is mostly visible for unlike-sign particle pairs.
- *femtoscopic correlations.* The term "femtoscopic" refers to a length scale of the order of 10^{-15} m. These correlations are present at low relative momenta of the particles in a pair (representing a very small phase-space corner, so they are practically invisible in terms of $(\Delta\eta, \Delta\phi)$) and give rise to an enhancement of the correlation function (due to Bose-Einstein quantum statistics for identical bosons) or its suppression (due to Fermi-Dirac quantum statistics for identical fermions). Besides this, at low relative momenta there are correlations caused by Coulomb and/or other final state interactions. The shape of all these effects in $(\Delta\eta, \Delta\phi)$ space depend strongly on the mass of the particle type as well as on the size of the particle-emitting system. The latter is traditionally measured in Bose-Einstein correlation (BEC) analyses and is not part of this review.

The away-side peak originates from energy-momentum conservation which manifests itself by the quark and the anti-quark going back-to-back in ϕ. In this case the rapidity width of the away-side peak is much larger than the near-side peak since in the original matrix element the quark and the antiquark can be separated by some $\Delta\eta$ interval.

As discussed in Sections 20.3.3.2 and 20.3.3.3, there may be several cut Pomerons in the same event, each giving rise to particle sets which are, in general, independent of each other (except for small Bose-Einstein correlations). This leads to long-range (in rapidity) correlations. Since the density of secondaries, $\mathrm{d}N/\mathrm{d}y$, is proportional to the number of cut Pomerons, k, the probability to observe at least one particle is proportional to $\langle k \rangle$, while the probability to observe simultaneously two particles separated by some (rather large) rapidity interval is proportional to $\langle k^2 \rangle$. Thus the long-range correlations are pedicted to be $C_2 = \langle k^2 \rangle / \langle k \rangle^2 - 1 > 0$ which depends weakly on the separation $\Delta\eta$ between the two particles [173, 174]. In the case of the pure eikonal approach, neglecting the enhanced diagrams and the conservation law effects in the proton fragmentation region, we expect that these long-range correlations,

$$C_2(\Delta y) = \frac{\sigma_{\mathrm{inel}} \mathrm{d}^2\sigma/\mathrm{d}y_1 \mathrm{d}y_2}{\mathrm{d}\sigma/\mathrm{d}y_1 \; \mathrm{d}\sigma/\mathrm{d}y_2} - 1 \sim \mathrm{const}, \qquad (20.52)$$

do not depend on the rapidity separation, $\Delta y = |y_1 - y_2|$, between the two particles. The contribution of the processes with more cut Pomerons also results in a much wider multiplicity distribution and in a larger density of soft particles coming from the 'underlying event'.

20.5.2.2 *Color reconnection*

In this context, we have to mention also the so-called 'colour reconnection' phenomenon. This is a pure 'soft QCD' effect. The point is that after a number of coloured secondary partons are produced, there are different possibilities to form the colour flow between these partons and to group the partons into colourless clusters. In the process of reconnection, one rearranges the colour flow in such a way as to minimize the size of the clusters. This is especially important when dealing with MPI contributions. The reconnection between the different cut Pomerons diminishes the final multiplicity and can change the form of the N_{ch} distributions (see e.g. Section 43.3.2 of [1] and [2, 13, 177, 178]).

20.5.2.3 *Double parton scattering*

The probability of MPI depends on the spatial distribution of partons in the incoming protons. The effects of MPI are suppressed if the density of partons is low and the partons from the incoming beam particles are separated from each other by a large

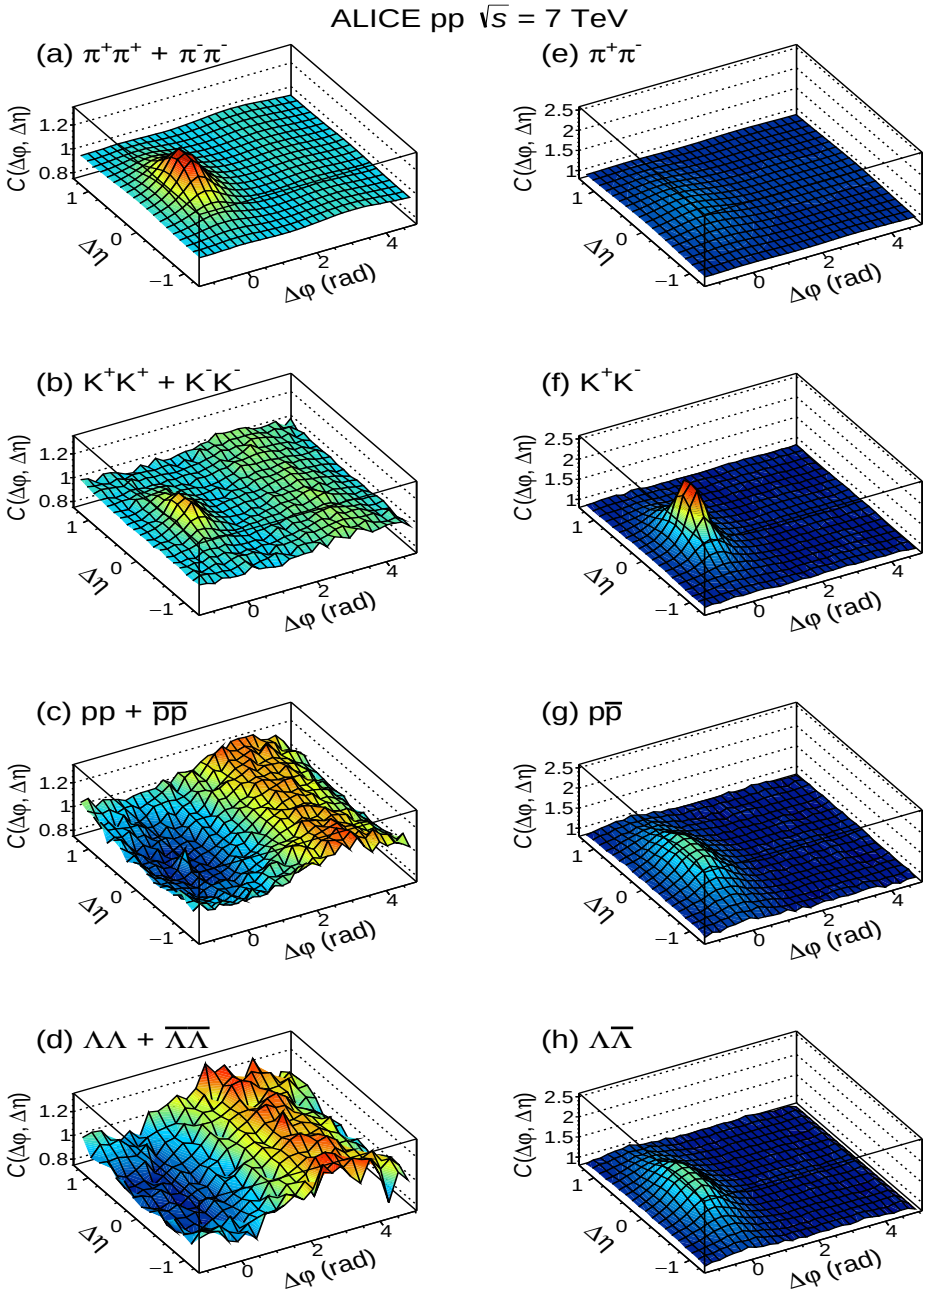

Figure 20.14: Two-particle correlation functions for identical-particle pairs: $\pi^+\pi^+ + \pi^-\pi^-$, $K^+K^+ + K^-K^-$, $pp + \bar{p}\bar{p}$, and $\Lambda\Lambda + \bar{\Lambda}\bar{\Lambda}$ (left panel) and particle–anti-particle pairs: $\pi^+\pi^-$, K^+K^-, $p\bar{p}$ and $\Lambda\bar{\Lambda}$ (right panel). Figure from Ref. [169].

interval in transverse coordinate space $\vec{x}_t$. Events in which two hard subprocesses, caused by interactions of two different parton pairs (say, (a_1b_1) and (a_2b_2)), take place simultaneously, are called Double Parton Scattering (DPS). The DPS cross section is driven by the 'double parton distributions', $D(y_{a_1}, y_{a_2}, ...)$, where y_{a_1} and y_{a_2} are momentum fractions carried by the partons from the proton a and the dots denote all other coordinates. As a rule, experiments study DPS processes at relatively small momentum fractions y_i. Here, correlations due to momentum conservation (like $y_{a_1} + y_{a_2} < 1$) are not so important, and with a reasonable accuracy we can assume a factorization

$$D(y_{a_1}, y_{a_2}, ...) \propto F(y_{a_1}) \cdot F(y_{a_2}) \ , \tag{20.53}$$

where $F(y_{a_i})$ are the single parton distributions. In such a case the DPS cross section takes the form

$$\sigma^{\rm DPS} \ = \ c \cdot \frac{\sigma_{a_1b_1}\sigma_{a_2b_2}}{\sigma_{\rm eff}} \ , \tag{20.54}$$

where $\sigma_{a_1b_1}$ and $\sigma_{a_2b_2}$ are cross sections for the two *independent* hard processes, while $\sigma_{\rm eff}$ characterizes the mean area occupied by the partons a_1 and b_1; the constant factor $c = 1/2$ if both hard processes (a_1b_1) and (a_2b_2) are identical, otherwise $c = 1$. Thus the DPS cross section is sensitive to the spatial separations between partons in the proton (see Section 7.2.3 in [2] and [179, 180] for more explanations and reviews).

One problem is that within this approach we *assume* that the partons a_1 and a_2 are produced by two independent parton showers (and similarly for the other incoming proton). On the other hand, there is a probability that from the beginning we start with the evolution of a single shower which further splits into two different branches. In this case the separation between the two partons (two shower branches) becomes very small – of the order of the inverse scale ($\sim 1/\sqrt{q^2}$) at which the splitting occurs. The exact value of this 'splitting' scale q^2 depends on the particular kinematics of the DPS process. So, different experiments (with

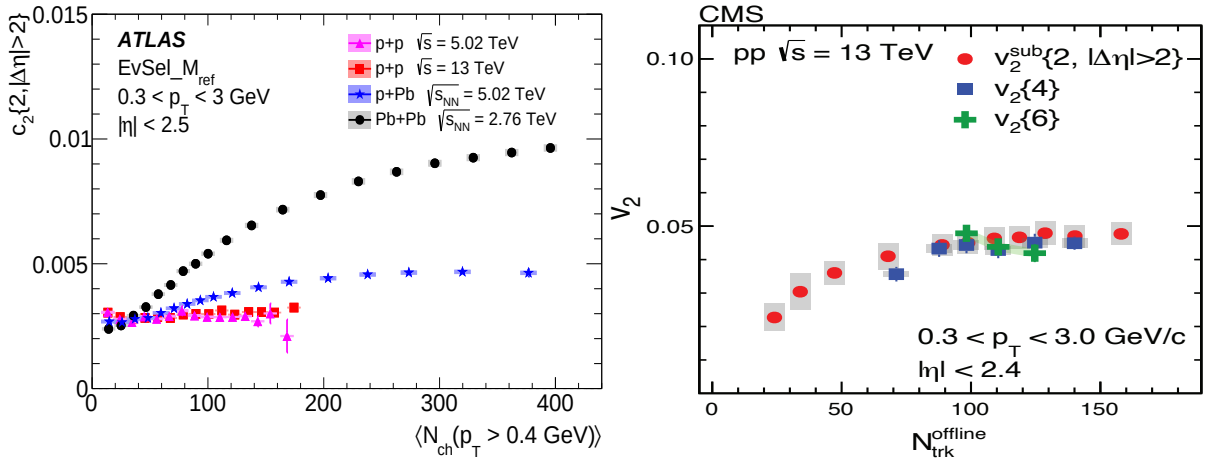

Figure 20.15: (Left) The two-particle cumulant, $c_2\{2, |\Delta\eta| > 2\}$, as a function of $\langle N_{\rm ch}(p_T > 0.4\ {\rm GeV})\rangle$ for pp collisions at $\sqrt{s} = 5.02$ and 13 TeV, pPb collisions at $\sqrt{s_{NN}} = 5.02$ TeV and low-multiplicity $PbPb$ collisions at $\sqrt{s_{NN}} = 2.76$ TeV. The data are constructed from particles with $0.3 < p_T < 3.0$ GeV. Figure from Ref. [175]. (Right) The $v_2\{2, |\Delta\eta| > 2\}$, $v_2\{4\}$ and $v_2\{6\}$ values as a function of number of charged particles, averaged over $0.3 < p_T < 3.0$ GeV and $|\eta| < 2.4$, in pp collisions at $\sqrt{s} = 13$ TeV. Figure from Ref. [176]. The error bars correspond to the statistical uncertainties, while the shaded areas denote the systematic uncertainties.

different kinematical conditions) can give somewhat different values of $\sigma_{\rm eff}$. In general, the value of $\sigma_{\rm eff}$ depends on the following features: a) on the measured process since the spatial (b_t) distributions of different incoming partons (light quarks, heavy quarks, gluons) can be different; b) on the splitting scale, $\sqrt{q^2}$, of one parton cascade into two branches. The typically high value of the splitting scale then explains the fact that the experimentally measured values of $\sigma_{\rm eff} \sim 7$–25 mb (see Fig. 4 of [181]) are smaller than $\sigma_{\rm tot}$ or mostly even lower than the proton area $\pi R_p^2 \sim 22$–24 mb (see e.g. [182]); c) on the p_T balance, k_T, in the individual hard process (e.g. for two dijet productions $k_T = |\overrightarrow{pT1} + \overrightarrow{pT2}|$ where p_{T1} and p_{T2} are jet p_T's of the first hard process (similarly for the second hard process). A small value of k_T indicates that there were no splittings or the splitting scale $\sqrt{q^2}$ was small and, therefore, we expect larger $\sigma_{\rm eff}$; d) on the contribution of single parton scatterings misidentified as DPS. For a lower scale of the hard process this contribution is larger (see [183] for more detailed discussion).

20.5.2.4 *Final state interactions*

The formalism of the RFT does not include 'final state interactions' [16]. Therefore, besides the correlations considered in the previous Section 20.5.2.1 we have to expect the correlation caused by partons and hadrons rescattering in the final state. These effects are not crucial at lower energies, but become more important at high LHC energies, in particular in heavy-ion collisions where the particle density is large. For example, the final state interactions (FSI) lead to the formation of the collective flow of secondaries (see e.g. [185] for a review), especially in high-multiplicity events. To study the collective flow experimentally, one has to subtract correlations coming from few-particle sources such as resonance decays, mini-jets, multi-jets and BEC (so called "non-flow"). The non-flow can efficiently be suppressed using the sub-event method, that is by studying the azimuthal correlations between particles separated in η [186], or subtracted using the multi-particle correlation (or cumulant) techniques.

The cumulant method is based on calculating $2k$-particle azimuthal correlations, ${\rm corr}_n\{2k\}$, and cumulants $c_n\{2k\}$ (where $k = 1, 2, ...$), for nth Fourier harmonics. The ${\rm corr}_n\{2k\}$ are defined as [187, 188]:

$$\langle\langle {\rm corr}_n\{2\}\rangle\rangle = \langle\langle e^{in(\phi_1-\phi_2)}\rangle\rangle, \quad \langle\langle {\rm corr}_n\{4\}\rangle\rangle = \langle\langle e^{in(\phi_1+\phi_2-\phi_3-\phi_4)}\rangle\rangle,$$

$$\langle\langle {\rm corr}_n\{6\}\rangle\rangle = \langle\langle e^{in(\phi_1+\phi_2+\phi_3-\phi_4-\phi_5-\phi_6}\rangle\rangle$$

and similarly for higher numbers of correlated particles. The double-brackets $\langle\langle\rangle\rangle$ denote averaging first over particles in an event and then over events within a given event class. For every event, the average is taken over all possible combinations of azimuthal angles ϕ_l ($l = 1, ..., 2k$) of the $2k$ particles. The cumulants are then obtained from multi-particle azimuthal correlations after subtracting correlations between $2(k-1)$ particles according to the following formulae [187, 188]:

$$c_n\{2\} = \langle\langle {\rm corr}_n\{2\}\rangle\rangle,\ c_n\{4\} = \langle\langle {\rm corr}_n\{4\}\rangle\rangle - 2\langle\langle {\rm corr}_n\{2\}\rangle\rangle^2,$$
$$c_n\{6\} = \langle\langle {\rm corr}_n\{6\}\rangle\rangle - 9\langle\langle {\rm corr}_n\{2\}\rangle\rangle \times \langle\langle {\rm corr}_n\{4\}\rangle\rangle + 12\langle\langle {\rm corr}_n\{2\}\rangle\rangle^3.$$

The cumulants for higher particle multiplicities are calculated in [187, 188]. The cumulants then serve to estimate the Fourier harmonics v_n as follows [187]:

$$v_n\{2\} = \sqrt{c_n\{2\}},\ v_n\{4\} = \sqrt[4]{-c_n\{4\}},\ v_n\{6\} = \sqrt[6]{c_n\{6\}/4}.$$

Some of the long-range correlation ($|\Delta\eta| > 2$) results obtained on a sample of charged particles with $0.3 < p_T < 3.0$ GeV and $|\eta| < 2.4$ are summarized in Fig. 20.15. The left plot shows the cumulant c_2 measured for pp, pPb and $PbPb$ collisions [175], while the right plot shows the elliptical harmonics v_2 measured for pp collisions [176], both as functions of multiplicities of charged particles. The two-particle correlations are observed to be strongest and rising with $N_{\rm ch}$ for $PbPb$ collisions, and weakest and rather flat for pp collisions. The elliptical-flow harmonics for 4- and 6-particle correlations show again a rather flat multiplicity dependence (at least for large multiplicities). Within experimental uncertainties, the values of $v_2\{2\}, v_2\{4\}$ and $v_2\{6\}$ measured in pp collisions at 13 TeV are consistent with each other. The similarity between $v_2\{4\}$ and $v_2\{6\}$ suggests that some collective effects are occurring in pp collisions at high multiplicity and the observations are similar to those in $PbPb$ collisions, where the $v_2\{4\}$ values were measured to be close to $v_2\{6\}$ but they are both lower than $v_2\{2\}$ (not shown here)).

Another example of long-range correlations is the so-called "ridge effect". Here not only the 'back-to-back' jet correlations are registered, but also an excess of particles going in the same (in the azimuthal plane) direction as the leading (relatively high p_T) hadron. Moreover, this excess is seen at the rapidities separated from the leading hadron by a rather large interval (see e.g. [189] for a review).

It is popular to describe such FSI effects within the hydrodynamic model [190], which operates with collective (thermodynamic) variables. In terms of microscopic interactions, the collec-

[16] In general, final state interactions can be included into the detailed structure of the multi-Pomeron vertices. However these vertices are phenomenological objects which are not well known experimentally.

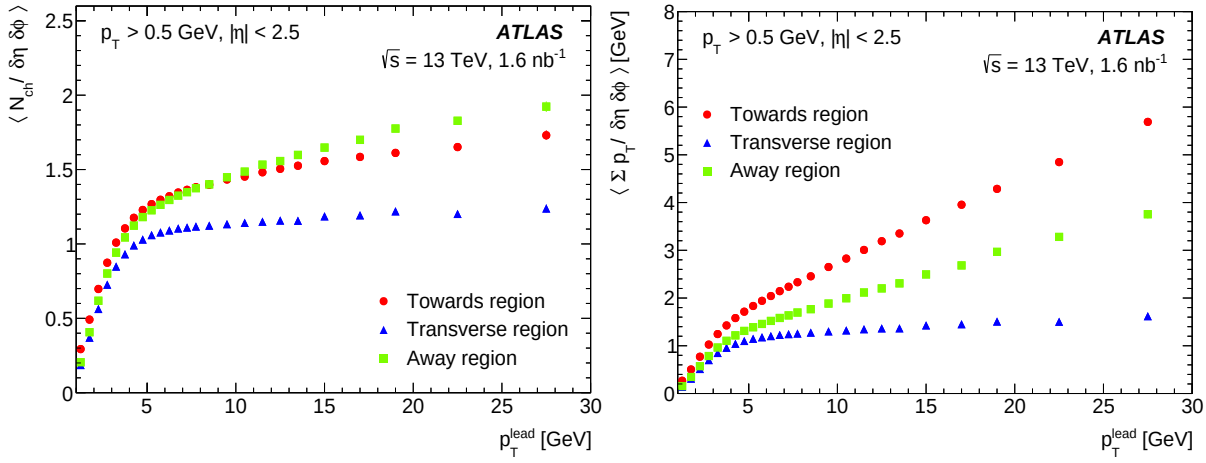

Figure 20.16: Mean charged particle density (left) and the sum of transverse momenta of secondaries (right) in events with the 'leading' high p_T particle as a function of $p_T^{\rm lead}$ in the transverse, towards and away azimuthal regions. Secondaries with $p_T > 0.5$ GeV and $|\eta| < 2.5$ are registered. The error bars (mostly hidden by the data markers) represent combined statistical and systematic uncertainties. Figures from [184].

tive flow can be caused by the geometry of a particular collision (the absorption is smaller for the secondaries flying in the direction orthogonal to the impact parameter vector $\vec{b}$ [191, 192]), or by the colour reconnection at the hadronization stage [193], or accounting for the rescattering of secondaries directly, as was done, for example, in the AMPT model [194].

20.5.3 *The underlying event*

Except for the exclusive case, any 'hard' subprocess is accompanied by soft secondaries coming from initial state radiation (ISR), final state radiation (FSR) and multiple parton interaction (MPI), see Subsection 7.2.2 in [2]. These extra particles distort the signal we are looking for. In particular, they affect the isolation criteria applied to photons and charged leptons and the vertex reconstruction efficiency. In general, also the effects of colour reconnection (discussed in Section 20.5.2.2) contribute to the underlying event.

The usual procedure of estimating the amount of underlying event (UE) is to spatially divide tracks in each event according to their azimuthal angle into the Toward region (where the highest p_T jet points), the Away region (opposite to the Toward region) and to two Transverse regions. The standard observables are the average track multiplicity per unit area and the average scalar sum of track p_T per unit area. Figure 20.16 shows the particle density and the sum of p_T for the UE in ATLAS events containing at least one charged particle with $p_T > 0.5$ GeV and $|\eta| < 2.5$ [184].

Note that by construction the largest values of $\langle p_T \rangle$ are observed in the 'Toward' region, while in the 'Away' region we observe a slightly larger density than in the Toward region. These are results of the 'leading' and 'backward' jet fragmentation. In the transverse region, mostly filled by particles from the UE, the particle density and sum of p_T per unit $(\Delta\eta, \Delta\phi)$ area practically do not depend on the $p_T^{\rm lead}$ since these secondaries come from the other cut Pomeron(s), that is, from other 'multiple interactions'. For low $p_T^{\rm lead} < 2$ GeV the distributions in all three regions are close to each other. These events actually do not contain a 'hard' subprocess. Moreover, for a very small $p_T^{\rm lead} \to 1$ GeV we start to select soft events with abnormally low $p_T < p_T^{\rm lead}$ particles. Since only particles with $p_T > 0.5$ GeV are registered, the signal drops fast for $p_T^{\rm lead} \to 1$ GeV. As a function of collision energy $\sqrt{s}$, the energy flow in the transverse region increases as $\sum p_T \sim s^{0.2}$ (as follows from Fig. 7 (right) in [184]) due to the larger number of MPI collisions and larger $\langle p_T \rangle$ in each collision [17]. As follows from this and other UE-dedicated LHC studies [195], from the comparisons of the data to the models with and without MPI, the necessity of MPI is convincingly demonstrated.

[17] Recall the stronger absorption of the low k_t partons.

20.6 The Odderon

Apart from the even-signature singularity (Pomeron), in QCD with $N_c = 3$ there exists its counterpart, the odd-signature singularity placed at $j \simeq 1$ and formed by three t-channel reggeized gluons connected in colour space by the symmetric d^{abc} tensor of the colour $SU(3)$ group [200, 201]. This object is called the Odderon. The Odderon exchange amplitude has opposite sign for pp and $p\bar{p}$ scatterings. Its intercept is predicted to be very close to $j = 1$ [202–204], while according to perturbative estimates the coupling to the nucleon is rather small [205,206]. The corresponding amplitude is mainly real and is about 100 times smaller than the imaginary part of the Pomeron exchange amplitude. Calculating the elastic amplitude via the eikonal formula (20.13) we have to replace the opacity $\Omega(b)$ by the sum $\Omega = \Omega_{\rm even} + \Omega_{\rm odd}$, where $\Omega_{\rm even}$ is mainly real and $\Omega_{\rm odd}$ is imaginary. Note that at $t = 0$ this QCD Odderon does not couple to mesons, and the t-slope of the Odderon amplitude is expected to be smaller than that for the Pomeron; instead of the singularity at $t = 4m_\pi^2$ in the Pomeron case, the nearest singularity in the Odderon channel is at $t = 9m_\pi^2$, see for instance [204]. Thus, in the impact parameter b space the QCD Odderon occupies an area of a smaller radius, see e.g. [207].

Experimentally an indication in favour of a manifestation of the high energy C-odd amplitude was observed by comparing the elastic pp and $p\bar{p}$ cross sections in the dip region (where the contribution from the C-even amplitude has a minimum) at the CERN-ISR [197], see Fig. 20.17 (left) [18].

To get a better understanding of the Odderon effects it would be very instructive to have the $d\sigma_{el}/dt$ data for both pp and $p\bar{p}$ reactions at the same but higher energy ~ 1 TeV (ideally in the same apparatus) and, in the ideal case, to study the energy dependence.

At the moment we can only compare the pp cross section measured by TOTEM at $\sqrt{s} = 2.76$ TeV [103] with the $d\sigma/dt$ values measured by the D0 collaboration at 1.96 TeV in $p\bar{p}$ collisions [199], see Fig. 20.17 (right).

The situation looks quite intriguing, but needs further investigation. Note that in the TeV energy range the ω, ρ and ωP, ρP exchange contributions, which may be responsible for the difference between the pp and $p\bar{p}$ cross sections in the dip region at the ISR energies, are practically negligible.

Another way to search for the Odderon is to measure the real part of the elastic pp scattering amplitude via the interference with the pure QED one-photon exchange. Since the one-photon

[18] Note that a qualitatively similar behaviour to the $p\bar{p}$ ISR data, namely a filling in of the dip in the t-distribution, was observed by the UA4 collaboration at the CERN S$p\bar{p}$S collider at $\sqrt{s}$=546 and 630 GeV(see [208,209] and in particular Fig. 2 in [209]) and by the $D0$ collaboration at the Tevatron at 1.96 TeV [199].

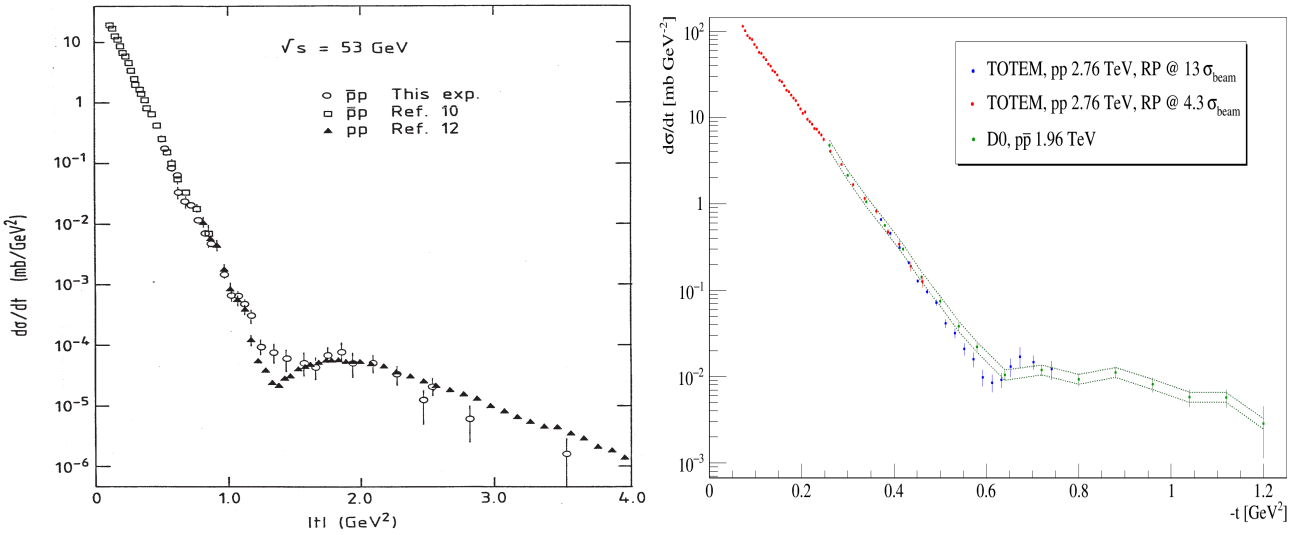

Figure 20.17: Comparison of the t-dependence of the elastic cross sections from pp and $p\bar{p}$ collisions. (Left) Data from the ISR energy of 53 GeV are shown by closed triangles [196] for pp collisions and by open circles [197] and open squares [198] for $p\bar{p}$ collisions. Only t-dependent uncertainties are shown and the systematic scale uncertainty is estimated to be ±30%. Figure from Ref. [197]. (Right) Data from the D0 experiment at 1.96 TeV [199] are compared with data from the TOTEM experiment [103]. The green dashed line indicates the normalization uncertainty of the D0 measurement. Figure from Ref. [103].

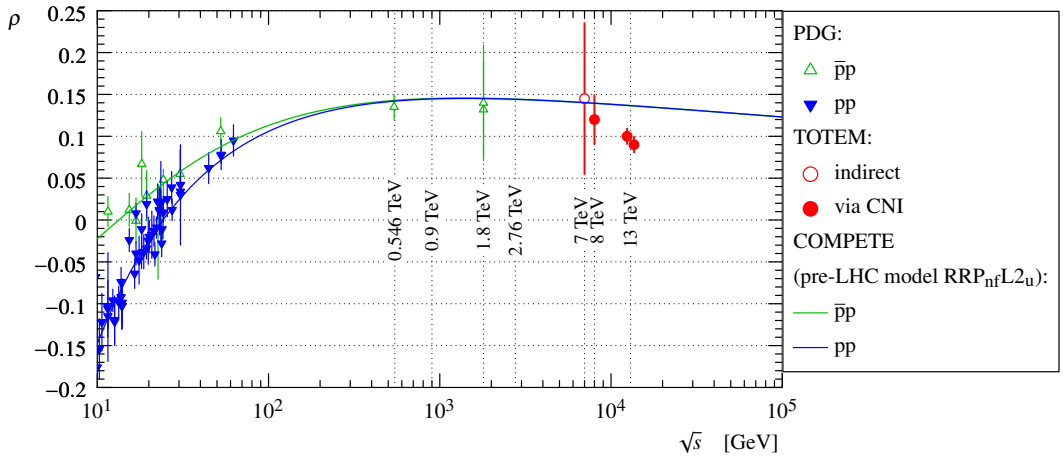

Figure 20.18: The dependence of the ρ parameter on the collision energy. The pp (blue) and $p\bar{p}$ (green) data are taken from [1]. The TOTEM measurements are marked in red. The two points at 13 TeV correspond to two fit cases, discussed in [102], using the same data. The lines represent fits to the data using the COMPETE parameterization [22]. Figure from Ref. [102].

exchange amplitude contribution is sizeable only at very small $|t|$, this way we can study the Odderon at or near to $t = 0$. Indeed, the value of the ratio $\rho \equiv \mathrm{Re}T_{\mathrm{el}}/\mathrm{Im}T_{\mathrm{el}}$, obtained by TOTEM at 13 TeV ($\rho = 0.10 \pm 0.01$ [102]), turns out to be smaller than that expected for the pure even-signature amplitude, see Fig. 20.18.

Based on dispersion relations and assuming the C-even contribution only, from the known total cross sections we would rather expect $\rho \simeq 0.13$–0.14. The difference could indicate that the rise of the total cross section at energies above those of the LHC slows down (see the dispersion relation, Eq. (20.19)) or this could be attributed to an Odderon contribution (see e.g. [210]). However, the Odderon exchange amplitude extracted in this analysis has opposite sign to that for the lowest-α_s-order QCD Odderon, see e.g. [205, 206, 211, 212]. Besides this, the Odderon contribution to ρ, obtained in [210], grows with $\sqrt{s}$ (for $\sqrt{s} > 0.5$ TeV), while in QCD we expect that the Odderon contribution to ρ decreases with energy, since the QCD Odderon intercept is smaller than that of the QCD Pomeron. Note also that recently the ATLAS Collaboration has published new results on elastic pp scattering at 13 TeV using the ALFA proton spectrometer [213]. While the measured value of $\rho = 0.098 \pm 0.011$ appears to be in a good agreement, a smaller total cross-section (with a smaller error bar) $\sigma_{\mathrm{tot}} = 104.7 \pm 1.1$ mb, is obtained when both are compared with TOTEM results at 13 TeV [102].

The values of σ_{tot} measured by ATLAS at 7, 8, and 13 TeV are found systematically lower than the TOTEM numbers. We note that if we used these ALFA values in dispersion relations, we would obtain a smaller ρ ratio for the C-even amplitude as well. Indeed, as shown in Figure 3 of Ref. [214], a good description of both, the σ_{tot} and ρ measurements, is achieved based on a global fit to the data performed using a damped $\ln^2 s$ amplitude and without an assumption of the Odderon. A good description of the ATLAS-ALFA data (χ^2/n.d.f. = 0.85, see table 11 of Ref. [213]) of both σ_{tot} and ρ without an assumption of the Odderon is also obtained in the KMR model [215].

It is worth mentioning also that the Odderon contribution is strongly screened by the multi-Pomeron diagrams, which facilitate the falling-off of ρ with energy increasing, see [216, 217]. On the other hand, analyzing the whole ensemble of high energy elastic pp ($p\bar{p}$) low $|t|$ data, a reasonable description can be obtained using the even-signature amplitude only, that is, without the Odderon. In particular, the RR(PL2)qc model/version of the COMPETE parameterization is consistent with the TOTEM 13 TeV data on

$\sigma_{\rm tot}$ and ρ within 1σ [19]. Another example is the recent analysis in [212] of the low $|t| < 0.1$ GeV^2 elastic data. Fitting all the low-t pp and $p\bar{p}$ data in the range of $\sqrt{s}$ between 13 GeV and 13 TeV without Odderon, Donnachie and Landshoff [212] succeeded to describe the TOTEM cross section with less than 1σ deviation in each $\mathrm{d}\sigma_{\rm el}/\mathrm{d}t$ point (see Fig. 8 of [212]). Note that in this analysis, they get a larger value of ρ close to 0.14 at 13 TeV.

It was proposed also to search for the Odderon in exclusive C-even meson (π^0, η, f_2, η_c, ...) photoproduction (see e.g. [218,219]). However the expected cross sections are small (e.g. for η_c) and in each channel there is a large background caused either by Pomeron-Pomeron fusion (such as CEP of the f_2 meson production in pp or pPb collisions) or due to the vector meson radiative decay (such as $\omega \to \pi^0\gamma$ for the case of pion) [220]. Up to now, no definitive Odderon signal in the C-even meson production has been observed. At the moment there exist only upper limits on the photoproduction cross sections obtained in the measurements at HERA at $\sqrt{s} \simeq 200$ GeV [221–223].

To conclude, let us emphasize that the existence of the C-odd singularity with intercept
$\alpha_{\rm odd}(0) \simeq 1$ is a firm prediction of QCD. At least in the high k_t region there is a well established C-odd three-gluon contribution to the scattering amplitude. However the expected coupling of such an Odderon singularity is numerically very small. Therefore it is quite challenging to observe its manifestation experimentally. Currently it seems to be a bit premature to draw any definite conclusion about an experimental observation of the Odderon signal.

20.7 Asymptotics

The high-energy behaviour of total hadronic cross sections has been one of the oldest problems of strong interactions over many decades, beginning from Heisenberg [224]. The most important bound obtained based on general analytical properties of scattering amplitudes is the FLM bound [47–49]. It states that the growth of the total hadronic cross section with energy does not exceed $\ln^2 s$, see Eq. (20.34).

Recall that we neglected the photon contribution as well as the whole electro-weak sector, and that the parameter in Eq. (20.34) s_0 is an *a priori* unknown scale. However, if we were to assume a reasonable hadronic scale, $s_0 \simeq 1\,\mathrm{GeV}^2$, we would find that Eq. (20.34) implies an unrealistically high upper bound in comparison with the cross sections observed at present collider energies. Nevertheless there is a common trend in the literature (see for instance, reviews [225, 226] and references therein) to fit phenomenologically the total cross section with $\ln^2 s$, keeping in mind the saturation of the FLM bound. Such an asymptotic behaviour is assumed also by the COMPETE collaboration [22], which achieved a comprehensive description of all soft pre-LHC data measured at $\sqrt{s} \geq 4$ GeV as well as total pp cross sections from the LHC available in the first half of 2015 (see Section 51 in [24]).

It is interesting that the Froissart-type $\ln^2 s$ asymptotics of the pp total cross section are also supported by numerical results in lattice QCD [227]. Such a behaviour is also observed in the approach [228] based on Colour Glass Condensate saturation.

Finally, it is worth mentioning that the possibility that *asymptotically* the Pomeron intercept becomes smaller than 1, $\alpha_{\mathbb{P}}(0) < 1$, and at very high energies the total cross section starts to decrease with energy, though highly unlikely, is not yet completely rejected. For instance, such a behaviour is expected in a theory with only the triple-Pomeron coupling, $g_{3\mathbb{P}}$, and which neglects the more complicated multi-Pomeron vertices g_m^n, such as the $2 \to 2$ Pomeron coupling [229, 230].

It was also argued that in the case of an increasing (with energy) cross section the only regime consistent asymptotically with both the s- and the t-channel unitarities is that of a *black* disc whose radius increases as $R = c \cdot \ln s$ [231] (i.e. $R \propto (\ln s)^\gamma$, with $\gamma = 1$ exactly).

20.8 Acknowledgements

It is a pleasure to thank Michael Albrow, Robert Cahn, Robert Ciesielski, Per Grafstrom, Frank Krauss, Paul Newman, Sergey Ostapchenko and Edward Sarkisyan-Grinbaum for discussions, suggestions and comments on this review. Special thanks to Graeme Watt who read the article through and helped to improve the presentation. MT is supported by MEYS of the Czech Republic within project LTT17018. VAK thanks the Institute of Physics of the Czech Academy of Sciences in Prague for hospitality.

[19] We thank Jean-Rene Cudell for clarifying this issue.

Astrophysics and Cosmology

21. Experimental Tests of Gravitational Theory

Revised August 2023 by T. Damour (IHES, Bures-sur-Yvette).

21.1 General Relativity

Einstein's theory of General Relativity (GR), the current "standard" theory of gravitation, describes gravity as a universal deformation of the Minkowski metric:

$$g_{\mu\nu}(x^\lambda) = \eta_{\mu\nu} + h_{\mu\nu}(x^\lambda) \ , \ \text{where } \eta_{\mu\nu} = \text{diag}(-1,+1,+1,+1) \ . \tag{21.1}$$

GR is classically defined by two postulates, embodied in the total action defining the theory:

$$S_{\rm tot}[g_{\mu\nu},\psi,A_\mu,H] = c^{-1}\int d^4x(\mathcal{L}_{\rm Ein}+\mathcal{L}_{\rm SM}) \, . \tag{21.2}$$

The first postulate that states that the Lagrangian density describing the propagation and self-interaction of the gravitational field is

$$\mathcal{L}_{\rm Ein}[g_{\alpha\beta}] = \frac{c^4}{16\pi G}\sqrt{g}g^{\mu\nu}R_{\mu\nu}(g_{\alpha\beta}) \ , \tag{21.3}$$

where G denotes Newton's constant, $g = -\det(g_{\mu\nu})$, $g^{\mu\nu}$ is the matrix inverse of $g_{\mu\nu}$, and where the Ricci tensor $R_{\mu\nu} \equiv R^\alpha{}_{\mu\alpha\nu}$ is the only independent trace of the curvature tensor

$$R^\alpha{}_{\mu\beta\nu} = \partial_\beta\Gamma^\alpha_{\mu\nu} - \partial_\nu\Gamma^\alpha_{\mu\beta} + \Gamma^\alpha_{\sigma\beta}\Gamma^\sigma_{\mu\nu} - \Gamma^\alpha_{\sigma\nu}\Gamma^\sigma_{\mu\beta} \ , \tag{21.4}$$

$$\Gamma^\lambda_{\mu\nu} = \frac{1}{2}g^{\lambda\sigma}(\partial_\mu g_{\nu\sigma} + \partial_\nu g_{\mu\sigma} - \partial_\sigma g_{\mu\nu}) \, . \tag{21.5}$$

The second postulate states that $g_{\mu\nu}$ (and its associated connection) couples universally, and minimally, to all the bosonic (respectively fermionic) fields of the Standard Model by replacing everywhere the Minkowski metric $\eta_{\mu\nu}$ (respectively the flat Minkowski connection). Schematically (suppressing matrix indices and labels for the various gauge fields and fermions and for the Higgs doublet),

$$\begin{aligned}&\mathcal{L}_{\rm SM}[\psi,A_\mu,H,g_{\mu\nu}] = \\ &-\frac{1}{4}\sum\sqrt{g}g^{\mu\alpha}g^{\nu\beta}F^a_{\mu\nu}F^a_{\alpha\beta} - \sum\sqrt{g}\,\overline{\psi}\,\gamma^\mu(D_\mu + \frac{1}{4}\omega_{ij\mu}\gamma^{ij})\psi \\ &-\tfrac{1}{2}\sqrt{g}g^{\mu\nu}\overline{D_\mu H}D_\nu H - \sqrt{g}\,V(H) - \sum\lambda\sqrt{g}\,\overline{\psi}\,H\psi \ .\end{aligned} \tag{21.6}$$

Here $F^a_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g_A f^a{}_{bc}A^b_\mu A^c_\nu$ and the (representation-dependent) gauge-field covariant derivative $D_\mu = \partial_\mu + g_A A^a_\mu T^{\rm rep}_a$ are defined as in Special Relativity, while the derivative of spin-$\frac{1}{2}$ fermions also includes a coupling to the gravitational "spin-connection" $\omega_{ij\mu} = -\omega_{ji\mu}$, via its contraction with $\gamma^{ij} = \frac{1}{2}(\gamma^i\gamma^j - \gamma^j\gamma^i)$, where $i,j = 0,1,2,3$ and $\gamma^i = e^i{}_\mu\gamma^\mu$ are usual (numerical) Dirac matrices satisfying $\gamma^i\gamma^j + \gamma^j\gamma^i = 2\eta^{ij}$. The connection components $\omega_{ij\mu}$ are defined in terms of the local orthonormal frame (vierbein) $e^i{}_\mu$ (such that $g_{\mu\nu} = \eta_{ij}e^i{}_\mu e^j{}_\nu$) used to describe the components of the various fermions ψ, and of its inverse $e_i{}^\mu$ (such that $e_i{}^\mu e^j{}_\mu = \delta^j_i$), by $\omega_{ij\mu} = \frac{1}{2}\left(C_{i[jk]} + C_{j[ki]} - C_{k[ij]}\right)e^k_\mu$ where $C_{i[jk]} = \eta_{is}C^s{}_{[jk]}$, with $C^i{}_{[jk]} \equiv \left(\partial_\mu e^i{}_\nu - \partial_\nu e^i{}_\mu\right)e_j{}^\mu e_k{}^\nu$. From the total action follow Einstein's field equations,

$$R_{\mu\nu} - \tfrac{1}{2}Rg_{\mu\nu} = \frac{8\pi G}{c^4}T_{\mu\nu} \ . \tag{21.7}$$

Here $R = g^{\mu\nu}R_{\mu\nu}$ is the scalar curvature, and $T_{\mu\nu} \equiv g_{\mu\alpha}g_{\nu\beta}T^{\alpha\beta}$ where $T^{\mu\nu} = (2/\sqrt{g})\delta\mathcal{L}_{\rm SM}/\delta g_{\mu\nu}$ is the (symmetric) energy-momentum tensor of the Standard Model matter. The theory is invariant under arbitrary coordinate transformations: $x'^\mu = f^\mu(x^\nu)$ (as well as under arbitrary local SO(3,1) rotations of the vierbein, $e'^i{}_\mu = \Lambda^i{}_j(x)e'^j{}_\mu$). To solve the field equations Eq. (21.7), one needs to fix the coordinate gauge freedom, *e.g.*, the "harmonic gauge" (which is the analogue of the Lorenz gauge, $\partial_\mu A^\mu = 0$, in electromagnetism) corresponds to imposing the condition $\partial_\nu(\sqrt{g}g^{\mu\nu}) = 0$.

In this *Review*, we only consider the classical limit of gravitation (*i.e.* classical matter and classical gravity). Quantum gravitational effects are expected (when considered at low energy) to correct the classical action Eq. (21.2) by additional terms involving quadratic and higher powers of the curvature tensor. This suggests that the validity of classical gravity extends (at most) down to length scales of order the Planck length $L_P = \sqrt{\hbar G/c^3} \simeq 1.62\times10^{-33}$ cm, *i.e.*, up to energy scales of order the Planck energy $E_P = \sqrt{\hbar c^5/G} \simeq 1.22\times10^{19}$ GeV. Considering quantum matter in a classical gravitational background also poses interesting challenges, notably the possibility that the zero-point fluctuations of the matter fields generate a nonvanishing vacuum energy density $\rho_{\rm vac}$, corresponding to a term $-\sqrt{g}\ \rho_{\rm vac}$ in $\mathcal{L}_{\rm SM}$ [1]. This is equivalent to adding a "cosmological constant" term $+\Lambda\, g_{\mu\nu}$ on the left-hand side of Einstein's equations, Eq. (21.7), with $\Lambda = 8\pi G\,\rho_{\rm vac}/c^4$. Recent cosmological observations (see the following *Reviews*) suggest a positive value of Λ corresponding to $\rho_{\rm vac} \approx (2.3\times10^{-3}{\rm eV})^4$. Such a small value has a negligible effect on the non-cosmological tests discussed below.

21.2 Key features and predictions of GR

The definition of GR recalled above makes predictions both about the coupling of gravity to matter, and about the structure of the gravitational field beyond its previously known Newtonian aspects.

21.2.1 *Equivalence Principle*

First, the universal nature of the coupling between $g_{\mu\nu}$ and the Standard Model matter postulated in Eq. (21.6) entails many observable consequences that go under the generic name of "Equivalence Principle".

A first aspect of the Equivalence Principle is that the outcome of a local non-gravitational experiment, referred to local standards, should not depend on where, when, and in which locally inertial frame, the experiment is performed. This means, for instance, that local experiments should neither feel the cosmological evolution of the Universe (constancy of the "constants"), nor exhibit preferred directions in spacetime (isotropy of space, local Lorentz invariance).

A second aspect of the Equivalence Principle is that the kinetic terms, $g^{\mu\nu}\partial_\mu\phi\partial_\nu\phi$ or $\overline{\psi}\gamma^i e_i{}^\mu\partial_\mu\psi$, of all the fields of Nature (including the gravitational field itself) are universally coupled to the same curved spacetime metric $g_{\mu\nu}(x) = \eta_{ij}e^i{}_\mu e^j{}_\nu$. This implies in particular that all massless fields should propagate with the same speed.

A third aspect of the Equivalence Principle is that two (electrically neutral) test bodies dropped at the same location and with the same velocity in an external gravitational field should fall in the same way, independently of their masses and compositions ("universality of free fall" or "Weak Equivalence Principle"). In addition, the study (using the nonlinear structure of GR) of the motion, in an external gravitational field, of bodies having a non-negligible, or even strong, self-gravity (such as planets, neutron stars, or black holes) has shown that the latter property of free-fall universality holds equally well for self-gravitating bodies ("Strong Equivalence Principle").

A last aspect of the Equivalence Principle concerns various universality features of the gravitational redshift of clock rates. GR predicts that, when intercomparing them by means of electromagnetic signals, two (non gravity-based) clocks located along two different spacetime worldlines should exhibit a universal difference in clock rate that depends on their worldlines, but that is independent of their nature and constitution. For instance, two clocks located at two different positions in a static external Newtonian potential $U(\boldsymbol{x}) = \sum Gm/r$ should exhibit, when intercompared by electromagnetic signals, the difference in clock rate, $\tau_1/\tau_2 = \nu_2/\nu_1 = 1 + [U(\boldsymbol{x}_1) - U(\boldsymbol{x}_2)]/c^2 + O(1/c^4)$, ("universal gravitational redshift of clock rates"). Similarly, the comparison of atomic-transition frequencies when observing on Earth a transition that took place on a far-away galaxy should involve (at lowest order in cosmological perturbations) the universal cosmological redshift factor $1+z = a(t_{\rm reception})/a(t_{\rm emission})$ between the Friedmann scale factors $a(t)$ (see below).

21.2.2 *Quasi-stationary, weak-field (post-Newtonian) gravity*

When applied to quasi-stationary, weak-field gravitational fields, Einstein equations, Eq. (21.7), entail a spacetime structure which predicts deviations from Newtonian gravity of the first post-Newtonian (1PN) order, *i.e.*, fractionally smaller than Newtonian effects by a factor $O(v^2/c^2) \sim O(GM/(c^2 r))$. The 1PN-accurate solution of Eq. (21.7) reads (in harmonic gauge)

$$\begin{aligned} g_{00} &= -1 + \frac{2}{c^2}V - \frac{2}{c^4}V^2 + O\left(\frac{1}{c^6}\right) , \\ g_{0i} &= -\frac{4}{c^3}V_i + O\left(\frac{1}{c^5}\right) , \\ g_{ij} &= \delta_{ij}\left[1 + \frac{2}{c^2}V\right] + O\left(\frac{1}{c^4}\right) , \end{aligned} \tag{21.8}$$

where $x^0 = ct$, $i, j = 1, 2, 3$, and where the scalar, V, and vector, V_i, (retarded) potentials are defined in terms of the sources $\sigma = \frac{T^{00}+T^{ii}}{c^2}$, $\sigma_i = \frac{T^{0i}}{c}$ by

$$V = \Box^{-1}_{\rm ret}\left[-4\pi G\sigma\right] \; ; \; V_i = \Box^{-1}_{\rm ret}\left[-4\pi G\sigma_i\right] . \tag{21.9}$$

In GR the gravitational interaction of N moving point masses (labeled by $A = 1, \ldots, N$) is described by a reduced (classical) action that admits a diagrammatic expansion:

$$S_{\rm reduced} = S^{\rm free} + S^{\rm tree-level} + S^{\rm one-loop} + \cdots \tag{21.10}$$

where the free (special-relativistic) action reads

$$\begin{aligned} S^{\rm free} &= -\sum_A \int m_A c \sqrt{-\eta_{\mu\nu} dx^\mu_A dx^\nu_A} \\ &= -\sum_A \int dt m_A c^2 \sqrt{1 - \mathbf{v}^2_A/c^2} , \end{aligned} \tag{21.11}$$

while the tree-level (one-graviton-exchange) interaction term reads

$$S^{\rm tree-level} = -\frac{8\pi G}{c^4}\int d^4x\, T^{\mu\nu}\Box^{-1}(T_{\mu\nu} - \tfrac{1}{2}T\eta_{\mu\nu}) = \int dt L^{(2)} . \tag{21.12}$$

Corresponding to the 1PN-accurate metric of Eq. (21.8), the 1PN-accurate expansion of the latter tree-level, two-body interaction Lagrangian $L^{(2)}$ reads (with $r_{AB} \equiv |\mathbf{x}_A - \mathbf{x}_B|$, $\mathbf{n}_{AB} \equiv (\mathbf{x}_A - \mathbf{x}_B)/r_{AB}$)

$$\begin{aligned} L^{(2)} =& \frac{1}{2}\sum_{A\neq B} \frac{G\, m_A\, m_B}{r_{AB}}\Big[1 + \frac{3}{2c^2}(\boldsymbol{v}^2_A + \boldsymbol{v}^2_B) - \frac{7}{2c^2}(\boldsymbol{v}_A \cdot \boldsymbol{v}_B) \\ & - \frac{1}{2c^2}(\boldsymbol{n}_{AB} \cdot \boldsymbol{v}_A)(\boldsymbol{n}_{AB} \cdot \boldsymbol{v}_B) + O\left(\frac{1}{c^4}\right)\Big] \end{aligned} \tag{21.13}$$

The two-body interactions, Eq. (21.13), exhibit v^2/c^2 corrections to Newton's $1/r$ potential induced by spin-2 exchange ("gravitomagnetism"). Consistency at the 1PN level, $v^2/c^2 \sim G\,m/rc^2$, requires that one also considers the three-body interactions contained in the one-loop contribution $S^{\rm one-loop}$, corresponding to terms induced by some of the three-graviton vertices and other non-linearities (terms $O(h^2)$ and $O(hT)$ in Eq. (21.15) below), *i.e.*, to the $O(V^2)$ term in Eq. (21.8):

$$L^{(3)} = -\frac{1}{2}\sum_{B\neq A\neq C} \frac{G^2\, m_A\, m_B\, m_C}{r_{AB}\, r_{AC}\, c^2} + O\left(\frac{1}{c^4}\right) . \tag{21.14}$$

21.2.3 *Gravitational Waves in GR*

The linearized approximation to Einstein's field equations, Eq. (21.7), in harmonic gauge $\partial^\nu(h_{\mu\nu} - \frac{1}{2}h\eta_{\mu\nu}) = 0$ (with $h \equiv \eta^{\mu\nu}h_{\mu\nu}$), reads

$$\Box h_{\mu\nu} = -\frac{16\pi G}{c^4}(T_{\mu\nu} - \tfrac{1}{2}T\eta_{\mu\nu}) + O(h^2) + O(hT) . \tag{21.15}$$

Outside of any source (*i.e.*, when $T_{\mu\nu} = 0$), this yields $\Box h_{\mu\nu} = 0$, with $\partial^\nu(h_{\mu\nu} - \frac{1}{2}h\eta_{\mu\nu}) = 0$. The generic linearized solution (modulo the diffeomorphism freedom) of the latter vacuum Einstein equations can be written as (with $k^2 = k \cdot k = \eta_{\mu\nu}k^\mu k^\nu$, $k \cdot x = k_\mu x^\mu$)

$$h_{\mu\nu}(x) = \int d^4k \delta(k^2)\epsilon_{\mu\nu}(k)e^{ik\cdot x} , \tag{21.16}$$

where the polarization tensor $\epsilon_{\mu\nu}(k)$ must be transverse ($\epsilon_{\mu\nu}k^\nu = 0$) and traceless ($\eta^{\mu\nu}\epsilon_{\mu\nu} = 0$). In addition, $\epsilon_{\mu\nu}(k)$ can be freely submitted to the gauge freedom $\epsilon'_{\mu\nu} = \epsilon_{\mu\nu} + \xi_\mu k_\nu + \xi_\nu k_\mu$. This implies that gravitational waves (GW) propagate with the speed of light, and (like electromagnetic waves) have only two independent polarizations. In a frame where, say, $k^\mu = (ck, 0, 0, k)$, the two independent linear polarization tensors can be taken to have components only in the transverse 1-2 plane, of the following form: $\epsilon^+_{11} = -\epsilon^+_{22} = \epsilon^+$, with $\epsilon^+_{12} = \epsilon^+_{21} = 0$; or $\epsilon^\times_{12} = +\epsilon^\times_{21} = \epsilon^\times$, with $\epsilon^\times_{11} = \epsilon^\times_{22} = 0$. Under a little-group rotation of angle θ in the 1-2 plane, the two circular polarization amplitudes $\epsilon^{(\pm)} = \epsilon^+ \mp i\,\epsilon^\times$ vary as $\epsilon'^{(\pm)} = e^{\pm 2i\theta}\epsilon^{(\pm)}$, thereby characterizing the helicity-2 nature of GWs.

When solving the inhomogeneous equation Eq. (21.15), taking into account the nonlinear contributions $O(h^2)+O(hT)$, one finds that, to lowest order, the GW amplitude emitted at large distances by a matter distribution is given by the following "quadrupole formula"

$$h^{\rm TT}_{ij}(T, \mathbf{X}) \approx \frac{2G}{c^4}P^{\rm TT}_{ijab}(\mathbf{N})\frac{\ddot{Q}_{ab}(T - R/c)}{R} , \tag{21.17}$$

where $Q_{ij}(t) = \int d^3x\sigma(t, \mathbf{x})(x^i x^j - \frac{1}{3}\delta_{ij}\mathbf{x^2})$ $(a, b, i, j = 1, 2, 3)$ is the quadrupole moment of the source, $R = |\mathbf{X}|$ the distance to the source, $\mathbf{N} = \mathbf{X}/R$ the unit direction from the source to the observer, and $P^{\rm TT}_{ijab}(\mathbf{N}) = (\delta_{ia} - N_iN_a)(\delta_{jb} - N_jN_b) - \frac{1}{2}(\delta_{ij} - N_iN_j)(\delta_{ab} - N_aN_b)$ the transverse-traceless projector onto the 2-plane orthogonal to $\mathbf{N}$.

21.2.4 *Strong gravitational fields: neutron stars and black holes*

The nonlinear structure of Einstein's equations implies many predictions for strong gravitational fields that distinguish GR from Newtonian gravity. For instance, in Newtonian gravity, there is no upper limit to the dimensionless gravitational potential U/c^2, with U satisfying Poisson's equation $\Delta U = -4\pi G\rho$, where ρ denotes the Newtonian mass density. By contrast, in GR, the dimensionless surface gravitational potential $GM/(c^2R)$ of a spherically symmetric (perfect fluid) body cannot exceed $\frac{4}{9}$ [2].

Given an equation of state $p = f(\rho)$ modeling the interior of a (cold) spherically symmetric body (say a non-rotating neutron star), Einstein equations, Eq. (21.7), with $T^{\mu\nu} = (\rho + p)u^\mu u^\nu + pg^{\mu\nu}$, and

$$g_{\mu\nu}dx^\mu dx^\nu = -e^{2\Phi(r)}c^2dt^2 + \frac{dr^2}{1 - \frac{2GM(r)}{c^2 r}} + r^2\left(d\theta^2 + \sin^2\theta d\phi^2\right) , \tag{21.18}$$

yield the following Tolman-Oppenheimer-Volkoff radial equations:

$$p'(r) = -\frac{G(\rho + p/c^2)(M(r) + 4\pi r^3 p/c^2)}{r^2(1 - 2GM(r)/(c^2 r))} ; \tag{21.19}$$

$$M'(r) = 4\pi r^2\rho ; \tag{21.20}$$

$$\Phi'(r) = \frac{G(M(r) + 4\pi r^3 p/c^2)}{r^2(1 - 2GM(r)/(c^2 r))} . \tag{21.21}$$

In the exterior of the star ($r \geq R$) , the metric takes the Schwarzschild form

$$\begin{aligned} g_{\mu\nu}dx^\mu dx^\nu = &-\left(1 - \frac{2GM}{c^2 r}\right)c^2dt^2 + \frac{dr^2}{1 - \frac{2GM}{c^2 r}} \\ &+ r^2\left(d\theta^2 + \sin^2\theta d\phi^2\right) , \end{aligned} \tag{21.22}$$

where $M \equiv M(R)$ is the total gravitational mass of the star. GR predicts, for any given $p = f(\rho)$, several (in principle) observable

features of neutron stars, such as: (i) the maximum mass of a neutron star; (ii) the relation between the radius R and the total mass M; (iii) the dimensionless surface gravitational potential $GM/(c^2R)$ (linked to the surface redshift $\sqrt{-g_{00}} = \sqrt{1-\frac{2GM}{c^2R}}$ measured by an observer at infinity); (iv) the moment of inertia; and (v) the Love number (tidal polarizability). The current uncertainty on the equation of state of a neutron star yields the GR-predicted approximate range for the maximum mass of non-rotating neutron stars $1.5\,M_\odot \lesssim M_{\rm max} \lesssim 2.5\,M_\odot$, and the absolute upper bound $M_{\rm max} < 3\,M_\odot$ [3]. The surface gravitational potential of a typical neutron star is $GM/c^2R_{\rm NS} \simeq 0.17$, which is a factor $\sim 10^8$ higher than the surface potential of the Earth, and a mere factor 3 below the black hole limit $GM/c^2R_{\rm BH} = \frac{1}{2}$ to be discussed next.

The existence of a maximum mass for a neutron star led Oppenheimer and Snyder [4] to predict that the end point of stellar evolution for sufficiently heavy stars, after exhaustion of all thermonuclear sources of energy, will be what are now called "black holes." The latter are solutions of Einstein's equations whose past structure involves a gravitationally collapsing star, but whose presently observable structure is essentially described (for non-rotating black holes) by the vacuum Schwarzschild solution Eq. (21.22). It took many years for theoretical (and mathematical) physicists to understand that the apparent singularity of the Schwarzschild solution at $r = \frac{2GM}{c^2}$ was a coordinate singularity and that the Schwarzschild spacetime was regular at the "black hole horizon", $R_{\rm BH} \equiv \frac{2GM}{c^2}$. The rotating analog of the Schwarzschild spacetime is the Kerr black hole [5].

Black holes are outstanding consequences of GR which enjoy many remarkable properties, notably: (i) presence of a one-way surface (the horizon) for all waves and particles; (ii) absence of "hair" (*i.e.*, barring a possible electric charge, their structure is fully described by only two parameters, total mass, M, and total angular momentum, $J \leq GM^2/c$); (iii) existence of a spectrum of damped quasi-normal vibrational modes; and (iv) a behavior under external perturbations similar to ordinary physical objects satisfying the laws of (dissipative) thermodynamics. Moreover, though no classical waves or particles can get out of the horizon, black holes are predicted to slowly evaporate via quantum particle creation.

21.2.5 *Cosmology*

To complete our short tour of the main predictions of GR, let us mention that GR offers the current standard framework for describing the large-scale structure of the Cosmos, from the nearly homogeneous Big Bang (and its plausible inflationary beginning) to the current inhomogeneous Universe undergoing an accelerated expansion. The spacetime structure on large (temporal and spatial) scales is well described by a solution of Einstein's equations of the form

$$\begin{aligned} ds^2 = &-\left(1+2\Phi(t,\mathbf{x})\right)c^2dt^2 + 2W_i(t,\mathbf{x})dtdx^i \\ &+ a^2(t)\left(\left(1-2\Psi(t,\mathbf{x})\right)\delta_{ij} + h_{ij}(t,\mathbf{x})\right)dx^idx^j , \end{aligned} \tag{21.23}$$

where, after a suitable gauge-fixing [6], $W_i(t,\mathbf{x})$ is transverse, while $h_{ij}(t,\mathbf{x})$ is transverse and traceless. The source $T^{\mu\nu}$ must involve a certain number of postulated ingredients: an inflaton field; the matter of the Standard Model; a dark matter component; and a cosmological constant contribution $T^{\mu\nu}_\Lambda = -\rho_{\rm vac}g^{\mu\nu}$, with $\rho_{\rm vac} \equiv c^4\Lambda/(8\pi G)$. The scale factor $a(t)$ of the Friedmann background metric $ds_0^2 = -c^2dt^2 + a^2(t)\delta_{ij}dx^idx^j$ satisfies the GR-predicted Friedmann equations (with vanishing spatial curvature $k=0$),

$$H^2 \equiv \left(\frac{\dot a}{a}\right)^2 = \frac{8\pi G}{3}\rho_{\rm tot} , \tag{21.24}$$

$$\frac{\ddot a}{a} = -\frac{4\pi G}{3}\left(\rho_{\rm tot} + \frac{3}{c^2}p_{\rm tot}\right) , \tag{21.25}$$

while the scalar $(\Phi(t,\mathbf{x}),\Psi(t,\mathbf{x}))$, vector $(W_i(t,\mathbf{x}))$, and tensor $(h_{ij}(t,\mathbf{x}))$ inhomogeneous perturbations satisfy some GR-predicted propagation equations (coupled to matter perturbations); see [6] and the following *Reviews*. When the cosmic fluid is well approximated by a perfect fluid, Einstein's equations predict the following link between the scalar perturbations

$$\Phi(t,\mathbf{x}) = \Psi(t,\mathbf{x}) . \tag{21.26}$$

21.3 A roadmap of parametrizations of deviations from GR, and of modified gravity

As will be discussed below, all currently performed gravitational experiments are compatible with GR. However, similarly to what is done in discussions of precision electroweak experiments, it is useful to quantify the significance of precision gravitational experiments by parameterizing possible deviations from GR. One can distinguish two main approaches to considering, and parameterizing, deviations from GR: (i) theory-agnostic phenomenological approaches; or, (ii) the study of the predictions of specific classes of alternative theories of gravity. Both types have led to useful ways of discussing tests of gravity. Both types also have their limitations. Considering them together leads to cross-fertilization.

21.3.1 *Theory-agnostic phenomenological approaches to parameterizing deviations from GR*

The theory-agnostic phenomenological approach is the oldest, and, arguably, the most robust one. It essentially consists in starting from specific observable predictions within the considered standard theory, and of deforming them by introducing some free parameters measuring either deviations from effects already present within the standard theory, or new effects absent from the standard theory. A classic example is the periastron advance of Mercury (and the other planets). When working within Newtonian gravity as a standard theory of gravity, the rate of periastron advance of Mercury, $\dot\omega$, is (when neglecting the quadrupole moment of the Sun) a calculable function of the masses and semi-major axes of the other planets of the solar system, say $\dot\omega^{\rm Newton}(m_i,a_i)$. However, $\dot\omega$ is also a directly observable quantity, so that one can parameterize the periastron advance of Mercury by writing

$$\dot\omega^{\rm obs} = \dot\omega^{\rm Newton}(m_i,a_i) + \Delta\dot\omega . \tag{21.27}$$

Using other observable data to determine some "observed" values of the m_i's and a_i's, one can then measure the anomalous periastron precession $\Delta\dot\omega$ and see whether it is compatible with zero, or not. As is well-known, Leverrier used such a methodology and, in 1859, measured an anomalous periastron precession of about $\Delta\dot\omega \simeq 38$ arcsec/century (later re-estimated at 43 arcsec/century), which was explained in 1915 as a GR prediction. Let us discuss further examples of the use of such theory-agnostic approaches for discussing deviations from GR.

21.3.2 *Parameterized post-Newtonian (PPN) formalism.*

When considering the weak-field slow-motion limit appropriate to describing gravitational experiments in the solar system, it has been traditional to parameterize possible (long-range) deviations from the GR-predicted 1PN metric by introducing extra dimensionless coefficients in the various terms of the metric of Eq. (21.8). The minimal version of the parameterized post-Newtonian (PPN) formalism (essentially due to Eddington) involves only two parameters β and γ, namely

$$g_{00} = -1 + \frac{2}{c^2}V - \frac{2\beta}{c^4}V^2 + O\left(\frac{1}{c^6}\right) , \tag{21.28}$$

$$g_{0i} = -\frac{2(\gamma+1)}{c^3}V_i + O\left(\frac{1}{c^5}\right) , \tag{21.29}$$

$$g_{ij} = \delta_{ij}\left[1 + \frac{2\gamma}{c^2}V\right] + O\left(\frac{1}{c^4}\right) , \tag{21.30}$$

with V and V_i defined by Eq. (21.9), with the same vectorial source $\sigma_i = \frac{T^{0i}}{c}$, but a modified scalar source

$$\sigma^{\rm PPN} = \frac{1}{c^2}\left(\left[1 + (3\gamma - 2\beta - 1)\frac{V}{c^2}\right]T^{00} + \gamma\, T^{ii}\right) . \tag{21.31}$$

In GR, $\beta^{\rm GR} = 1$ and $\gamma^{\rm GR} = 1$, so that deviations from GR are parameterized by $\overline{\beta} \equiv \beta - 1$ and $\overline{\gamma} \equiv \gamma - 1$. Richer versions of the

PPN formalism (involving up to ten parameters) were developed in interaction with the study of classes of alternative theories of gravity [7,8]. This led to parameterizing new types of contributions to the 1PN metric that are absent in the GR framework.

When deriving the 1PN-accurate dynamics of N point masses predicted by the PPN-modified metric, Eq. (21.28), one finds that the free Lagrangian is not modified (because we are considering here a Lorentz-invariant subclass of PPN metrics), while there are modifications of both the two-body Lagrangian, $L^{(2)}$, Eq. (21.13), and the three-body one, $L^{(3)}$, Eq. (21.14). More precisely, denoting $\eta \equiv 4\overline{\beta} - \overline{\gamma}$, the Newtonian interaction energy term in Eq. (21.13) is modified into $G_{AB} m_A m_B / r_{AB}$, with a body-dependent gravitational "constant"

$$G_{AB} = G[1+\eta(E_A^{\rm grav}/m_A c^2 + E_B^{\rm grav}/m_B c^2) + O(1/c^4)] \,, \quad (21.32)$$

where $E_A^{\rm grav}$ denotes the gravitational binding energy of body A. In addition, there is the additional contribution $+\overline{\gamma}(\boldsymbol{v}_A - \boldsymbol{v}_B)^2/c^2$ in the brackets on the right-hand side of $L^{(2)}$, Eq. (21.13). As for the three-body interaction term $L^{(3)}$, Eq. (21.14), it is modified by the overall factor $1 + 2\overline{\beta}$.

These results show how the introduction of the two minimal PPN deviation parameters $\overline{\beta} \equiv \beta - 1$ and $\overline{\gamma} \equiv \gamma - 1$ suffices to introduce many different observable effects. Some of them (the ones linked with $\overline{\gamma}$) concern deviations at the linearized (one-graviton-exchange) level (and affect, for instance, light deflection and time-delay effects), while the deviation parameter $\overline{\beta}$ parameterizes effects linked to the cubic vertex of Einstein's gravity (and affects, for instance, periastron precession). Of particular interest is the fact that Eq. (21.32) shows that the combination $\eta \equiv 4\overline{\beta} - \overline{\gamma}$ parameterizes a violation of the Strong Equivalence Principle, because the gravitational interaction between self-gravitating bodies is seen to be influenced by the gravitational binding energy of each body [9]. As stated above, this effect is absent in GR (where $\eta^{\rm GR} = 0$). This is an example where the fact of contrasting GR with some deviations from it gives physical significance to a null effect in GR (namely the universality of free fall of self-gravitating bodies).

Finally, one can extend the PPN formalism by allowing for a slow, phenomenological time variation of Newton's constant:

$$G(t) = G_0 \left[1 + \frac{\dot{G}_0}{G_0} (t - t_0) \right] . \quad (21.33)$$

Here, one assumes that there exist units in which the masses, m_i, of elementary particles stay constant, and that G is measured in such units. A possible time variation of G then corresponds to a possible common variation of the dimensionless couplings $G m_i^2/(\hbar c)$.

21.3.3 *Parameterized post-Keplerian (PPK) formalism.*

The discovery of pulsars (*i.e.*, rotating neutron stars emitting a beam of radio noise) in gravitationally bound orbits [10,11] has given us our first experimental handle on a regime of relativistic gravity going significantly beyond the uniformly weak-field, and quasi-stationary regime of solar-system gravity. Binary pulsars allow us to probe some radiative effects, and also some strong-gravitational-field effects. In these systems, the finite speed of propagation of the gravitational interaction between the pulsar and its companion generates damping-like terms at order $(v/c)^5$ in the equations of motion [12]. These damping forces are the local counterparts of the gravitational radiation emitted at infinity by the system ("gravitational radiation reaction"). They cause the binary orbit to shrink and its orbital period P_b to decrease. The remarkable stability of pulsar clocks has allowed one to measure the corresponding very small orbital period decay $\dot{P}_b \equiv dP_b/dt \sim -(v/c)^5 \sim -10^{-12}$–$10^{-14}$ in several binary systems, thereby giving us a direct experimental handle on the propagation properties of the gravitational field. In addition, the large surface gravitational potential of a neutron star allows one to probe the quasi-static strong-gravitational-field regime, as is discussed below.

It is possible to extract phenomenological (theory-independent) tests of gravity from binary pulsar data by using the parameterized post-Keplerian (PPK) formalism [13]. The basis of this formalism is the fact that, after correcting for the Earth's motion around the Sun and for the dispersion due to propagation in the interstellar plasma, the time of arrival of the Nth pulse t_N can be described by a generic, parameterized "timing formula" [13,14], whose functional form is common to the whole class of tensor-scalar gravitation theories:

$$t_N - t_0 = F[T_N(\nu_p, \dot{\nu}_p, \ddot{\nu}_p) \,; \{p^K\} \,; \{p^{PK}\}] \,. \quad (21.34)$$

Here, T_N is the pulsar proper time corresponding to the Nth turn given by $N/2\pi = \nu_p T_N + \frac{1}{2}\dot{\nu}_p T_N^2 + \frac{1}{6}\ddot{\nu}_p T_N^3$ (with $\nu_p \equiv 1/P_p$ the spin frequency of the pulsar, *etc.*), $\{p^K\} = \{P_b, T_0, e, \omega_0, x\}$ is the set of "Keplerian" parameters (notably, orbital period P_b, eccentricity e, periastron longitude ω_0 and projected semi-major axis $x = a \sin i/c$), and $\{p^{PK}\} = \{k, \gamma_{\rm timing}, \dot{P}_b, r, s, \delta_\theta, \dot{e}, \dot{x}\}$ denotes the set of (separately measurable) "post-Keplerian" parameters. Most important among these are: the fractional periastron advance per orbit $k \equiv \dot{\omega} P_b/2\pi$; a dimensionful time-dilation parameter $\gamma_{\rm timing}$; the orbital period derivative $\dot{P}_b$; and the "range" and "shape" parameters of the gravitational time delay caused by the companion, r and s.

Without assuming any specific theory of gravity, one can phenomenologically analyze the data from any binary pulsar by least-squares fitting the observed sequence of pulse arrival times to the timing formula of Eq. (21.34). This fit yields the "measured" values of the parameters $\{\nu_p, \dot{\nu}_p, \ddot{\nu}_p\}$, $\{p^K\}$, $\{p^{PK}\}$. Now, each specific relativistic theory of gravity predicts that, for instance, k, $\gamma_{\rm timing}$, $\dot{P}_b$, r, and s (to quote parameters that have been successfully measured from some binary pulsar data) are some theory-dependent functions of the Keplerian parameters and of the (unknown) masses m_1, m_2 of the pulsar and its companion. For instance, in GR, one finds (with $M \equiv m_1 + m_2$, $n \equiv 2\pi/P_b$),

$$\begin{aligned}
k^{\rm GR}(m_1, m_2) =& 3(1-e^2)^{-1}(GMn/c^3)^{2/3} \,, \\
\gamma_{\rm timing}^{\rm GR}(m_1, m_2) =& e n^{-1} (GMn/c^3)^{2/3} m_2 (m_1 + 2m_2)/M^2 \,, \\
\dot{P}_b^{\rm GR}(m_1, m_2) =& -(192\pi/5)(1-e^2)^{-7/2} \left(1 + \tfrac{73}{24} e^2 + \tfrac{37}{96} e^4\right) \\
& \times (GMn/c^3)^{5/3} m_1 m_2 / M^2 \,, \\
r^{\rm GR}(m_1, m_2) =& G m_2 / c^3 \,, \\
s^{\rm GR}(m_1, m_2) =& n x (GMn/c^3)^{-1/3} M/m_2 \,.
\end{aligned} \quad (21.35)$$

In alternative gravity theories each of the functions $k^{\rm theory}(m_1, m_2)$, $\gamma_{\rm timing}^{\rm theory}(m_1, m_2)$, $\dot{P}_b^{\rm theory}(m_1, m_2)$, *etc.*, is modified by quasi-static strong field effects (associated with the self-gravities of the pulsar and its companion), while the particular function $\dot{P}_b^{\rm theory}(m_1, m_2)$ is further modified by radiative effects [15–18]. If one measures $N > 2$ PPK parameters from the data of a specific binary pulsar, these N measurements determine, for each given theory, N curves (defined by the N equations $k_i^{\rm theory}(m_1, m_2) = k_i^{\rm obs}$) in the two-dimensional mass plane (m_1, m_2). This yields $N - 2$ tests of the specified theory, according to whether the N curves (or strips) have one point in common, as they should.

21.3.4 *Parameterized-post-Friedmannian (PPF) formalisms.*

We have recalled above that, in GR, the two functions, $\Phi(t, \mathbf{x})$, and $\Psi(t, \mathbf{x})$, parameterizing (in the "longitudinal gauge") the scalar perturbations of the background Friedmann metric are related (in absence of anisotropic stresses) by Eq. (21.26). Several authors [19–28] have defined various types of parameterized-post-Friedmannian (PPF) formalisms involving (generally space and time dependent) phenomenological parameters. The simplest versions of these formalisms involve two phenomenological parameters measuring: (i) the ratio between $\Phi(t, \mathbf{x})$, and $\Psi(t, \mathbf{x})$, say (using a parametrization which parallels the usual PPN parametrization)

$$\Psi(t, \mathbf{x}) = \gamma_{\rm cosmo}(t, \mathbf{x}) \Phi(t, \mathbf{x}) \,; \quad (21.36)$$

and (ii) the effective gravitational constant entering the Poisson equation for $\Phi(t,\mathbf{x})$, say

$$\Delta\Phi(t,\mathbf{x}) = 4\pi G_\Phi(t,\mathbf{x})\delta\rho(t,\mathbf{x})\,. \tag{21.37}$$

However, the peculiarities of cosmological observables limit the domain of applicability of such phenomenological approaches [26] (notably because the strong dependence of cosmological probes on epochs and scales obliges one to rely on specific parameterizations of the functions $\gamma_{\rm cosmo}(t,\mathbf{x})$ and $G_\Phi(t,\mathbf{x})$, *e.g.*, [25, 28]). Approaches based on specific classes of modified-gravity theories allow for a more complete treatment involving, in principle, all existing cosmological observables: Big Bang nucleosynthesis, cosmic microwave background, large-scale structure, Hubble diagram, weak lensing, etc. Discussing the current cosmological tests using either such PPF formalisms, or comparisons with the predictions of modified-gravity theories, is beyond the scope of this review. See [29] for a comprehensive recent discussion. The bottom line is that all present cosmological data have been found to be compatible with GR (within the Friedmann-Lemaître-based ΛCDM model). Beyond the quantitative limits on various parameterized theoretical models [29], one should remember the striking (strong-field-type) qualitative verification of GR embodied in the fact that relativistic cosmological models give an accurate picture of the Universe over a period during which the spatial metric has been blown up by a gigantic factor, say $(1+z)^2 \sim 10^{19}$ between Big Bang nucleosynthesis and now.

21.3.5 *Various phenomenological tests of GR from gravitational wave (GW) data*

The observations by the US-based Laser Interferometer Gravitational-wave Observatory (LIGO), later joined by the Europe-based Virgo detector, of gravitational-wave (GW) signals [30–34], have opened up a novel testing ground for relativistic gravity. The first three observing runs (O1, O2, O3a and O3b) of the LIGO-Virgo collaboration, recently joined by the Japan-based KAGRA detector (LVK collaboration), have led to the confident detection of 93 GW signals, most of which come from binary black-hole coalescences. These observations are summarized in three GW transient catalogs: GWTC-1 [35], GWTC-2 [36] and GWTC-3 [37].

Several approaches have been used to either test consistency with GR, or to look for special types of possible deviations. Making accurate predictions for GW signals from coalescing black holes within GR took years of both analytical [38, 39] and numerical [40] work. Some works have started (both analytically [15, 41–45] and numerically [46–48]) to derive the corresponding predictions within some modified-gravity theories. Phenomenological approaches are very useful for parameterizing general, conceivable deviations from GR when analyzing the GW signals emitted by coalescing black holes or neutron stars.

A first phenomenological, global consistency test simply consists of measuring the noise-weighted correlation $\mathcal{C}$ between each detected strain signal and the corresponding best-fit GR-predicted waveform. $\mathcal{C}^{\rm obs}$ should be equal to 1, modulo statistical (and/or systematic) errors.

Various other phenomenological tests of the structure of the GR-predicted waveforms emitted by coalescing compact binaries have been suggested. One general idea [49–51] (dubbed "parameterized post-Einsteinian formalism" in [52]) is to modify the GR-predicted Fourier-domain value $\psi(f)$ of the phase of black-hole coalescence GW signals $h(f) = A(f)e^{i\psi(f)}$ by introducing GR-deviation parameters, say

$$\psi(f) = \sum_i \left[p_i^{\rm GR,NS}(m_1,m_2)(1+\delta\hat{p}_i) + p_i^{\rm GR,S}(m_1,m_2,S_1,S_2)\right] \times u_i(f). \tag{21.38}$$

Here, the $u_i(f)$'s define a basis of functions of the GW frequency f, and the superscript NS refers to the nonspinning contribution, while the superscript S refers to the spinning one. Such a GR-modification directly applies to the phenomenological representation [53] of $\psi(f)$, and can be generalized to any waveform model by adding the non-GR phase term $\sum_i p_i^{\rm GR,NS}(m_1,m_2)\delta\hat{p}_i u_i(f)$ to the corresponding GR-predicted Fourier-domain phase $\psi(f)$ [54]. For instance, the leading-order (LO), quadrupolar term in the GR phase evolution during the early inspiral corresponds to $u_0(f) = f^{-5/3}$ and $p_0^{\rm GR} = \frac{3(m_1+m_2)^2}{128 m_1 m_2}(\pi G(m_1+m_2)/c^3)^{-5/3}$, while the next-to-leading-order (NLO) term is a $O(v^2/c^2)$ correction $p_2^{\rm GR}u_2(f)$ with $u_2(f) = f^{-1}$. In the phenomenological model [53] these terms (as well as the other inspiral contributions) are cut-off beyond the frequency $G(m_1+m_2)f/c^3 = 0.018$.

Each dimensionless parameter $\delta\hat{p}_i$ introduces a fractional deviation from the corresponding individual phasing GR effect having the frequency dependence $u_i(f)$, and can, in principle, be extracted by fitting the inspiral part of the observed waveform to the deformed template of Eq. (21.38). However, one must also use this deformed template for simultaneously extracting the values of m_1, m_2, S_1, and S_2. Together with signal-to-noise ratio (SNR) considerations, and parameter-correlation issues, this limits the applicability of such a test to introducing only one deformation parameter $\delta\hat{p}_i$ at a time. A particularly meaningful test [49] is to leave undeformed the LO and NLO terms $p_0^{\rm GR}u_0(f) + p_2^{\rm GR}u_2(f)$ and to vary the third coefficient p_3 parameterizing the next, "GW tail"-related $O(v^3/c^3)$ correction, with $u_3(f) = f^{-2/3}$. Another well-motivated test [52] is to introduce a new coefficient $\delta\hat{p}_{-2}$, which is absent in GR, and which parameterizes an $O((\frac{v}{c})^{-2})$ fractional correction to the LO, quadrupolar term, thereby allowing for a possible dipolar GW flux (indeed, dipolar GW radiation generally exists in theories containing scalar excitations). As $p_{-2}^{\rm GR}$ vanishes, $\delta\hat{p}_{-2}$ is added as an absolute deviation, scaled by the LO term $p_0^{\rm GR}$.

The coalescence of two black holes, or of a black hole and a neutron star (or of two heavy-enough neutron stars) leads to the formation of a black hole that is initially formed in a perturbed state. The relaxation of the latter perturbed black hole into its stationary, equilibrium state leads to the emission of characteristic (rapidly decaying) ringing GW modes (a.k.a. quasi-normal modes) [55, 56], whose frequencies and decay times are functions of the mass (M_f) and spin ($S_f \equiv GM_f^2 a_f/c$) of the final black hole, say

$$\omega_a = (c^3/GM_f)[2\pi\hat{f}_a^{\rm QNM}(a_f) - i/\hat{\tau}_a^{\rm QNM}(a_f)]\,, \tag{21.39}$$

where $a = 1, 2, \ldots$ labels the various ringing modes, starting from the least-damped one. In principle, if the SNR is large enough, one can directly test for the presence of one or several of these modes in the post-merger signal, and measure both $\mathrm{Re}(\omega_a)$ and $\mathrm{Im}(\omega_a)$ in a theory-independent way. These phenomenological measurements then lead to null tests of GR, from which one can extract theoretical information about eventual deviations from GR [57, 58].

As recalled above, GR predicts that GWs propagate (in vacuum) at exactly the same speed as light (*i.e.*, they have the same dispersion law $g^{\mu\nu}k_\mu k_\nu = 0$ in curved spacetime). Deviations from such a universal, scale-free dispersion law can be phenomenologically parameterized in several ways. If one phenomenologically assumes that the graviton dispersion law includes a mass term, say $g^{\mu\nu}k_\mu k_\nu + m_g^2/\hbar^2 = 0$, or some more general type of frequency-dependent modification, such changes affect the phasing of the inspiral GW signal and can be directly tested [59]. When one observes *both* GWs and electromagnetic waves emitted by the same system, one can also directly test whether both types of waves propagate in the same way.

Let us now present some examples of theory-dependent discussions of experimental tests based on considering specific classes of alternative theories. The most conservative deviations from Einstein's pure spin-2 theory are defined by adding new, bosonic, light or massless, macroscopically coupled fields.

21.3.6 *Gravity tests within classes of tensor-scalar theories of gravity*

The possible existence of new gravitational-strength couplings leading to deviations from Einsteinian (and Newtonian) gravity has been suggested by many natural extensions of GR, starting with the classic Kaluza-Klein idea, and continuing up to now with the study of extended supergravity theories, and of (super-

)string theory. In particular, a recurrent suggestion of such theories (which dates back to pioneering work by Jordan, and by Fierz [60]) is the existence of a scalar field φ coupled both to the scalar curvature R and to the various ${F^a_{\mu\nu}}^2$ gauge-field actions. Such fields ("dilaton" or "moduli") generically appear in string theory and are massless at the tree-level, but could acquire a self-interaction potential $V(\varphi)$ beyond the tree-level.

The exchange of such a dilaton-like field leads to several types of observational deviations from GR. For experimental limits on the gravitational inverse-square-law (down to the micrometer range) see Refs. [61–65]. If the potential $V(\varphi)$ is zero or negligible for the considered range, the coupling of φ to ${F^a_{\mu\nu}}^2$ leads to apparent violations of the weak equivalence principle, with rather specific composition-dependence [66]. Next, when neglecting the fractionally small composition-dependent effects, such a field approximately couples to the trace of the energy-momentum tensor $T = g_{\mu\nu}T^{\mu\nu}$. The most general such theory contains (after suitable field redefinitions) two arbitrary functions of the scalar field, namely the self-interaction potential $V(\varphi)$, and a matter-coupling function $a(\varphi)$:

$$\mathcal{L}_{\rm tot}[g_{\mu\nu},\varphi,\psi,A_\mu,H] = \frac{c^4}{16\pi G_*}\sqrt{g}(R(g_{\mu\nu}) - 2g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi) - \sqrt{g}V(\varphi) + \mathcal{L}_{\rm SM}[\psi,A_\mu,H,\widetilde{g}_{\mu\nu}]\,. \tag{21.40}$$

Here G_* is a "bare" Newton constant, and the Standard Model matter is coupled not to the "Einstein" (pure spin-2) metric $g_{\mu\nu}$, but to the conformally related ("Jordan-Fierz") metric

$$\widetilde{g}_{\mu\nu} = \exp(2a(\varphi))g_{\mu\nu}. \tag{21.41}$$

The scalar field equation

$$\Box_g\varphi = \frac{4\pi G}{c^4}\left(-\alpha(\varphi)T + \frac{\partial V(\varphi)}{\partial\varphi}\right), \tag{21.42}$$

features

$$\alpha(\varphi) \equiv \partial a(\varphi)/\partial\varphi\,, \tag{21.43}$$

as the basic (field-dependent) coupling between φ and matter [15, 67]. The best-known, special case of these theories is the one-parameter (ω) Jordan-Fierz-Brans-Dicke theory [68], with $V(\varphi) = 0$ and $a(\varphi) = \alpha_0\varphi$, leading to a field-independent coupling $\alpha(\varphi) = \alpha_0$ (with ${\alpha_0}^2 = 1/(2\omega+3)$). More generally, if we consider the massless theories ($V(\varphi) = 0$) with arbitrary (non-linear) coupling function $a(\varphi)$, they modify Einstein's predictions in the weak-field slow-motion limit appropriate to describing gravitational experiments in the solar system (1PN approximation) only through the appearance of exactly the same two "post-Einstein" dimensionless parameters $\overline{\gamma} = \gamma - 1$ and $\overline{\beta} = \beta - 1$ that entered the minimal (Eddington) PPN formalism presented above. However, we now have the following theoretical expressions relating the latter phenomenological parameters to the coupling functions entering the tensor-scalar action Eq. (21.40):

$$\overline{\gamma} = -2\frac{\alpha_0^2}{1+\alpha_0^2}\,; \tag{21.44}$$

$$\overline{\beta} = +\tfrac{1}{2}\frac{\beta_0\alpha_0^2}{(1+\alpha_0^2)^2}\,. \tag{21.45}$$

Here $\alpha_0 \equiv \alpha(\varphi_0)$, and $\beta_0 \equiv \partial\alpha(\varphi_0)/\partial\varphi_0$, with φ_0 denoting the vacuum expectation value (VEV) of φ around the solar system. In addition, the observable value $G^{\rm obs}$ of the gravitational constant is found to be field-dependent and given (at a place where $\varphi = \varphi_0$) by

$$G^{\rm obs} = G(\varphi_0) \equiv G_*\exp[2a(\varphi_0)](1+\alpha_0^2)\,. \tag{21.46}$$

This makes it clear that the parameter $\overline{\gamma}$ is the basic post-Einstein parameter, which measures the admixture of an additional field (here a spin-0 field) to the pure spin-2 GR. One also sees how the parameter $\overline{\beta}$ is linked to non-linear effects (here coupling terms $\beta_0(\varphi-\varphi_0)^2T$ in the action), and how the Nordtvedt parameter $\eta \equiv 4\overline{\beta} - \overline{\gamma}$ is related to the field-dependence of $G^{\rm obs}$ ($\eta = (\alpha_0/(1+\alpha_0^2))\partial\ln G(\varphi_0)/\partial\varphi_0$).

The advantage of a theory-dependent approach, such as Eq. (21.40), over the phenomenological minimal PPN approach of Eq. (21.28), is that it allows one to consistently predict the observational deviations from GR in all possible gravity regimes: the quasi-stationary weak-field regime; the wavelike weak-field regime; the strong-field regime; the cosmological regime, etc. All such observational deviations can be consistently worked out once one chooses specific forms of the coupling function $a(\varphi)$, and of $V(\varphi)$. The simple choice of a two-parameter quadratic coupling function, say $a(\varphi) = \alpha_0(\varphi-\varphi_0) + \frac{1}{2}\beta_0(\varphi-\varphi_0)^2$, has been found useful for describing many possible observable deviations from GR.

The observable consequences for binary pulsar observations of the strong-field and radiative effects linked to the coupling to φ have been explicitly worked out in Refs. [15, 44] in the case where φ is massless (see Ref. [69] for the case where φ is massive). In particular, the strong-field nature of the pulsar tests is demonstrated by the fact that some tensor-scalar theories can be as close as desired to GR in the weak-field regime of the solar-system (*i.e.*, $\overline{\gamma}$ and $\overline{\beta}$ can be as small as desired, or even exactly zero), while developing (via a "spontaneous scalarization" mechanism) differences of order unity with GR in binary pulsar experiments [17, 18].

21.3.7 *Attractor and screening mechanisms in modified gravity*

As will follow from the discussion of experimental data below, the comparison between the predictions of general massless tensor-scalar theories and current data shows that the basic coupling parameter α_0 must be tuned to a small value (especially when allowing for composition-dependent effects). This raises the issue of the naturalness of such small coupling parameters. It has been shown in this respect that, in many tensor-scalar theories, there is an *attractor mechanism* by which the cosmological evolution naturally drives the VEV $\varphi_0(t)$ towards a value for which the coupling parameter $\alpha_0 = \alpha(\varphi_0)$ vanishes, thereby making it natural to expect only small deviations from GR (at least for the weak-field regime) at our current cosmological epoch [70, 71].

There are other theoretical mechanisms (generically called "screening mechanisms") that could explain why a theory of gravity whose theoretical content significantly differs from that of GR could naturally pass all the stringent, GR-compatible experimental limits that will be discussed below. In particular, when considering a self-interacting scalar field ($V(\varphi) \neq 0$), the interplay between the two terms on the right-hand side of Eq. (21.42) tends to drive the local VEV φ_0 of φ to a density-dependent value. In turn, this leads to a corresponding density-dependent effective mass $m_0(\varphi_0) = \sqrt{4\pi G\partial^2V(\varphi_0)/\partial\varphi_0^2}$ of the φ field, and to density-dependent matter couplings [72]. Various choices of the functions $V(\varphi)$ and $a(\varphi)$ can then reduce the φ-induced deviations from GR in dense environments while still allowing for significant deviations in different (*e.g.*, cosmological) regimes [73–77].

Other screening mechanisms have been invoked, based on an environment dependence mediated by (first or second) derivatives of a scalar degree of freedom. Roughly speaking, such mechanisms involve a (possibly effective) scalar degree of freedom φ that satisfies a field equation that is more general than Eq. (21.42) in that the left-hand side, $\Box_g\varphi$, is replaced by a non-linear function of φ, $\partial\varphi$ and $\partial^2\varphi$. The presence of non-linear derivative self-interactions of φ can weaken the effective coupling of φ to matter. A simple toy-model showing this weakening would be to replace Eq. (21.42) by an equation of the form

$$Z(\varphi,\partial\varphi,\partial^2\varphi)\Box_g\varphi = \frac{4\pi G}{c^4}\left(-\alpha(\varphi)T + \frac{\partial V(\varphi)}{\partial\varphi}\right). \tag{21.47}$$

Such an equation is equivalent, at a first level of approximation, to replacing the gravitational constant G entering Eq. (21.42) by $G_{\rm eff}(\varphi_0,\partial\varphi_0,\partial^2\varphi_0) \equiv G/Z_0$, where $Z_0 \equiv Z(\varphi_0,\partial\varphi_0,\partial^2\varphi_0)$. This has a screening effect if $Z_0 \gg 1$. Indeed, the replacement $G \to G_{\rm eff}$ diminishes the strength of the interaction potential due to φ exchange by a factor of $1/Z_0$. In addition, the range of this

interaction is also affected: $m_0(\varphi_0) = \sqrt{4\pi G \partial^2 V(\varphi_0)/\partial\varphi_0^2} \to m_{0\rm eff}(\varphi_0, \partial\varphi_0, \partial^2\varphi_0) = \sqrt{4\pi G_{\rm eff}\partial^2 V(\varphi_0)/\partial\varphi_0^2} = Z_0^{-1/2} m_0$.

Screening mechanisms based on such non-linear derivative self-interactions are often referred to as being "Vainshtein-like" because a similar mechanism was first invoked in Ref. [78] as a conjectural way to ensure that the extra degrees of freedom associated with a massive (rather than massless) graviton become effectively weakly coupled to matter within a large domain around gravitational sources. Here, one is considering massive deformations of the massless spin-2 metric field of GR by a very small mass, possibly of cosmological scale: $m_g \sim \hbar H_0 \sim 10^{-33}$ eV. The construction of ghost-free potential terms for a spin-2 field has turned out to be a delicate matter [79]. The phenomenology of a very-low-mass graviton is still partly uncontrolled, both because of the unknown extent to which the Vainshtein screening is really active, and because of subtle constraints linked to an eventual UV completion of the theory beyond the unusually low energy scale where it becomes strongly coupled:

$$\Lambda_{\rm strong\ coupling} \sim (M_{\rm Planck} m_0^2)^{1/3} \sim 10^{-13} \left(\frac{m_0}{\hbar H_0}\right)^{2/3} {\rm eV}\,. \tag{21.48}$$

The search for modified gravity theories incorporating an extra scalar degree of freedom potentially able to yield a Vainshtein-like screening led to writing down the following general class of tensor-scalar Lagrangian [80, 81]:

$$\begin{aligned} L_{\rm tot}[g_{\mu\nu},\varphi,\psi] =& G_2(\varphi,X) - G_3(\varphi,X)\Box_g\varphi + G_4(\varphi,X)R \\ &+ G_{4X}(\varphi,X)[(\Box_g\varphi)^2 - \varphi^{\mu\nu}\varphi_{\mu\nu}] \\ &+ G_5(\varphi,X)G^{\mu\nu}\varphi_{\mu\nu} - \frac{1}{6}G_{5X}(\varphi,X)[(\Box_g\varphi)^3 \\ &- 3\Box_g\varphi\varphi^{\mu\nu} + 2\varphi_{\mu\nu}\varphi^{\mu\lambda}\varphi^{\nu}_{\lambda}] + L_{\rm matter}[g_{\mu\nu},\psi]\,. \end{aligned} \tag{21.49}$$

Here $g_{\mu\nu}$ denotes the matter-coupled metric, $X \equiv -\frac{1}{2}g^{\mu\nu}\partial_\mu\varphi\partial_\nu\varphi$, $\varphi_{\mu\nu} \equiv \nabla_\mu\nabla_\nu\varphi$, $G^{\mu\nu} \equiv R^{\mu\nu} - \frac{1}{2}Rg^{\mu\nu}$, and the various coefficients $G_n(\varphi, X)$ are arbitrary functions of two variables (with $G_{nX} \equiv \partial G_n/\partial X$). The field equations derived from the Lagrangian of Eq. (21.49) are only of second order in derivatives in spite of the non-linear structure of $L_{\rm tot}$. This implies that the tensor-scalar theories defined by Eq. (21.49) feature three degrees of freedom, corresponding to a massless spin-2 excitation (GW) and a spin-0 excitation. Contrary to the simpler tensor-scalar theories of Eq. (21.40), it is found that the speed of propagation of GWs implied by Eq. (21.49) is generically different from the speed of light:

$$\frac{c_{\rm GW}^2}{c^2} = \frac{G_4 - X(\ddot{\varphi}G_{5X} + G_{5\varphi})}{G_4 - 2XG_{4X} - X(H\dot{\varphi}G_{5X} - G_{5\varphi})}\,. \tag{21.50}$$

More general modified gravity models have been proposed (see, *e.g.* Refs. [82, 83]). Apart from the simplest of them, most of these models have a rather artificial flavor, and do not lead to convincing alternative explanations either of dark matter or of dark energy. In addition, many of them do not lead (contrary to GR) to mathematically "well-posed" evolution problems [84–86]. This entails a serious challenge to deriving strong-field predictions for such models. It has been argued that many of these (dark-energy motivated) models should be viewed as effective field theory (EFT) approximations that need some sort of UV completion at an unusually low frequency scale [87]. In spite of these shortcomings, such models are conceptually interesting because they give examples of deviations for various predictions of GR, existing independently from each other, in various regimes. For instance, some special tensor-scalar models lead to black hole solutions modified by scalar-hair [88–90]. For other types of black holes with scalar-hair, see Ref. [91]. This shows the interest of phenomenologically testing, in a democratic and agnostic way, all conceivable deviations from GR.

Let us now turn to briefly presenting current experimental results of various phenomenological tests of the main GR predictions recalled in Section 21.2 above.

21.4 Experimental tests of the Equivalence Principle (*i.e.*, of the matter-gravity coupling)

21.4.1 *Tests of the constancy of constants*

Stringent limits on a possible time variation of the basic coupling constants have been obtained by analyzing a natural fission reactor phenomenon that took place at Oklo, Gabon, two billion years ago [92,93]. These limits are at the 1×10^{-8} level for the fractional variation of the fine-structure constant $\alpha_{\rm em}$ [93], and at the 4×10^{-9} level for the fractional variation of the ratio $m_q/\Lambda_{\rm QCD}$ between the light quark masses and $\Lambda_{\rm QCD}$ [94]. The determination of the lifetime of Rhenium 187 from isotopic measurements of some meteorites dating back to the formation of the solar system (about 4.6 Gyr ago) yields comparably strong limits [95]. Measurements of absorption lines in astronomical spectra also give stringent limits on the variability of both $\alpha_{\rm em}$ and $\mu = m_p/m_e$ at cosmological redshifts, *e.g.*,

$$\Delta\alpha_{\rm em}/\alpha_{\rm em} = (1.2 \pm 1.7_{\rm stat} \pm 0.9_{\rm sys}) \times 10^{-6}\,, \tag{21.51}$$

at redshifts $z = 1.0$–2.4 [96], and

$$|\Delta\mu/\mu| < 4\times10^{-7} (95\%\ {\rm C.L.})\,, \tag{21.52}$$

at a redshift $z = 0.88582$ [97]. There are also significant limits on the variation of $\alpha_{\rm em}$ and $\mu = m_p/m_e$ at redshift $z \sim 10^3$ from cosmic microwave background data, *e.g.*, $\Delta\alpha_{\rm em}/\alpha_{\rm em} = (3.6 \pm 3.7)\times10^{-3}$ [98]. Direct laboratory limits (based on monitoring the frequency ratio of several different atomic clocks) on the present time variation of $\alpha_{\rm em}$, and $\mu = m_p/m_e$ have reached the levels [99, 100]

$$\begin{aligned} d\ln(\alpha_{\rm em})/dt &= (1.8 \pm 2.5) \times 10^{-19} {\rm yr}^{-1}, \\ d\ln(\mu)/dt &= (-8 \pm 36) \times 10^{-18} {\rm yr}^{-1}. \end{aligned} \tag{21.53}$$

There are also experimental limits on a possible dependence of coupling constants on the gravitational potential [99, 100].

Experimental limits on the present time variation of the gravitational constant, Eq. (21.33), have been derived from planetary ephemerides [101], lunar laser ranging [102], and binary-pulsar data [103, 104]. The most stringent limits come from lunar-laser-ranging data [102]:

$$\frac{\dot{G}_0}{G_0} = (7.1 \pm 7.6) \times 10^{-14}\ {\rm yr}^{-1}\,. \tag{21.54}$$

21.4.2 *Tests of the isotropy of space and of Local Lorentz invariance*

The highest precision tests of the isotropy of space have been performed by looking for possible quadrupolar shifts of nuclear energy levels [105]. The (null) results can be interpreted as testing the fact that the various pieces in the matter Lagrangian, Eq. (21.6), are indeed coupled to the same external metric $g_{\mu\nu}$ to the 10^{-29} level.

Stringent tests of possible violations of local Lorentz invariance in gravitational interactions have been obtained both from solar-system data [8] and pulsar data [106, 107]. For astrophysical constraints on possible Planck-scale violations of Lorentz invariance, see Ref. [108].

21.4.3 *Tests of the universality of free fall (weak, and strong equivalence principles)*

The universality of the acceleration of free fall has been verified, for laboratory bodies, both on the ground [109, 110] (at the 10^{-13} level), and in space [111, 112] (at the 10^{-15} level):

$$\begin{aligned} (\Delta a/a)_{\rm BeTi} &= (0.3 \pm 1.8) \times 10^{-13}\,; \\ (\Delta a/a)_{\rm BeAl} &= (-0.7 \pm 1.3) \times 10^{-13}\,; \\ (\Delta a/a)_{\rm TiPt} &= (-1.5 \pm 2.3({\rm stat}) \pm 1.5({\rm syst})) \times 10^{-15}\,. \end{aligned} \tag{21.55}$$

The universality of free fall has also been verified when comparing the fall of classical and quantum objects (at the 6×10^{-9} level

[113]), or of two quantum objects (at the $(0.3 \pm 5.4) \times 10^{-7}$ [114], and $(1 \pm 1.4) \times 10^{-9}$, levels [115]).

The universality of free fall of self-gravitating bodies (strong equivalence principle) has been verified in both the weak-gravity, and the strong-gravity regimes. The gravitational accelerations of the Earth and the Moon toward the Sun have been checked to agree at the 10^{-13} level [102]

$$(\Delta a/a)_{\rm EarthMoon} = (-3 \pm 5) \times 10^{-14}. \qquad (21.56)$$

The latter result constrains the Nordtvedt PPN parameter [9] $\eta \equiv 4\overline{\beta} - \overline{\gamma}$ to the 10^{-4} level:

$$\eta = (-0.2 \pm 1.1) \times 10^{-4}\,. \qquad (21.57)$$

See below for strong-field tests of the strong equivalence principle.

Finally, the universality of the gravitational redshift of clock rates has been verified at the 10^{-4} level by comparing a hydrogen-maser clock flying on a rocket up to an altitude of about 10,000 km to a similar clock on the ground [116]. The redshift due to a height change of only 33 cm has been detected by comparing two optical clocks based on $^{27}Al^{+}$ ions [117]. The gravitational redshift has also been detected in the orbit of a star near the supermassive black hole at the center of our Galaxy [118, 119], and its universality has been verified at the 5% level [120].

21.5 Tests of quasi-stationary, weak-field gravity

All currently performed gravitational experiments in the solar system, including perihelion advances of planetary orbits, the bending and delay of electromagnetic signals passing near the Sun, and very accurate ranging data to the Moon obtained by laser echoes, are compatible with the post-Newtonian results of Eq. (21.15), Eq. (21.13), and Eq. (21.14). The "gravito-magnetic" interactions $\propto v_A v_B$ contained in Eq. (21.13) are involved in many of these experimental tests. They have been particularly tested in lunar-laser-ranging data [121], in the combined LAGEOS-LARES satellite data [122, 123], and in the dedicated Gravity Probe B mission [124].

To assess in a quantitative manner the results of the various solar-system tests of gravity it is convenient to express them in terms of the PPN parameters defined above. The best current limit on the post-Einstein parameter $\overline{\gamma} \equiv \gamma - 1$ is

$$\overline{\gamma} = (2.1 \pm 2.3) \times 10^{-5}\,, \qquad (21.58)$$

as deduced from the additional Doppler shift experienced by radio-wave beams connecting the Earth to the Cassini spacecraft when they passed near the Sun [125].

The (cubic-vertex-related) post-Einstein parameter $\overline{\beta} \equiv \beta - 1$ is constrained at the 10^{-4} level both from a study of the global sensitivity of planetary ephemerides to post-Einstein parameters [101],

$$|\overline{\beta}| < 7 \times 10^{-5}\,, \qquad (21.59)$$

and from lunar-laser-ranging data [102]

$$\overline{\beta} = (-4.5 \pm 5.6) \times 10^{-5}\,. \qquad (21.60)$$

The periastron advance of the star S2 around the Galactic center massive black hole has been observed to agree with GR within 20% [126]. More stringent limits on $\overline{\gamma}$ (*i.e.* the coupling of φ to matter) are obtained in dilaton-like models where scalar couplings violate the Equivalence Principle [127].

21.6 Tests of strong-field gravity (neutron stars and black holes)

Experimental tests of strong-field gravity have been obtained in various physical systems, notably binary pulsars and coalescing binary black holes.

It is convenient to quantitatively express binary-pulsar tests of strong-field gravity by using the PPK formalism defined above. We recall that the measurement of N phenomenological PPK parameters leads to $N - 2$ tests of strong-field gravity. In all, *thirteen* tests of strong-field and/or radiative gravity have been obtained in the four different (double neutron-star) binary pulsar systems PSR1913+16 [10, 11, 128], PSR1534+12 [129–131], PSR J1141−6545 [132–135], and PSR J0737−3039 A,B [136–140]. These consist of $N - 2 = 5 - 2 = 3$ tests from PSR1913+16 ; $5 - 2 = 3$ tests from PSR1534+12; $4 - 2 = 2$ tests from PSR J1141−6545; and $7 - 2 = 5$ tests from PSR J0737−3039 (see, also, Ref. [141] for additional, less accurate tests of relativistic gravity). Among these tests, four of them (those involving the measurement of the PPK parameter $\dot{P}_b$) probe radiative effects, and will be discussed in the following section. The four binary pulsar systems PSR1913+16, PSR1534+12, PSR J1141−6545, and PSR J0737−3039 A,B have given nine tests of quasi-static, strong-field gravity. GR passes all these tests within the measurement accuracy. Let us only highlight here some of the most accurate strong-field tests.

In the binary pulsar PSR 1534+12 [129] one has measured *five* post-Keplerian parameters: k, $\gamma_{\rm timing}$, r, s, and (with less accuracy) $\dot{P}_b$ [130, 131]. This yields *three* tests of relativistic gravity. Among these tests, the two involving the measurements of k, $\gamma_{\rm timing}$, r, and s accurately probe strong field gravity, without mixing of radiative effects [130]. The most precise (10^{-3} level) of these pure strong-field tests is the one obtained by combining the measurements of k, $\gamma_{\rm timing}$, and s; namely, [131],

$$\left[\frac{s^{\rm obs}}{s^{\rm GR}[k^{\rm obs}, \gamma_{\rm timing}^{\rm obs}]}\right]_{1534+12} = 1.002 \pm 0.002\,. \qquad (21.61)$$

The discovery of the remarkable *double* binary pulsar PSR J0737−3039 A and B [136, 137] has led to the measurement of *seven* independent parameters [138–140]: five of them are the post-Keplerian parameters k, $\gamma_{\rm timing}$, r, s, and $\dot{P}_b$ entering the relativistic timing formula of the fast-spinning pulsar PSR J0737−3039 A; a sixth is the ratio $R = x_B/x_A$ between the projected semi-major axis of the more slowly spinning companion pulsar PSR J0737−3039 B, and that of PSR J0737−3039 A (the theoretical prediction for the ratio $R = x_B/x_A$, considered as a function of the (inertial) masses $m_1 = m_A$ and $m_2 = m_B$, is $R^{\rm theory} = m_1/m_2 + O((v/c)^4)$ [13, 14], independently of the gravitational theory considered). Finally, the seventh parameter $\Omega_{\rm SO,B}$ is the angular rate of (spin-orbit) precession of PSR J0737−3039 B around the total angular momentum vector [139, 140]. These seven measurements give us *five* tests of relativistic gravity [138, 142, 143], four of which are quasi-static, strong-field tests. GR passes all those tests with flying colors [144]. The most accurate is at the 2×10^{-4} level:

$$\left[\frac{s^{\rm obs}}{s^{\rm GR}[k^{\rm obs}, \gamma_{\rm timing}{}^{\rm obs}]}\right]_{0737-3039} = 1.00009 \pm 0.00018\,. \qquad (21.62)$$

Binary pulsar data on other types of pulsar systems can be used to test strong-field aspects of the "strong equivalence principle," namely the GR prediction that strong-self-gravity objects (such as neutron stars) should fall with the same acceleration as weak-self-gravity objects (such as white-dwarfs) in the (external) gravitational field created by other objects (such as the Galaxy, or another white dwarf). The first binary-pulsar tests of this property have been obtained in nearly circular binary systems (made of a neutron star and a white dwarf) falling in the field of the Galaxy, and have led to strong-field confirmations (at the 2×10^{-3} level) of the strong equivalence principle [104, 145–147]. The remarkable discovery of the pulsar PSR J0337+1715 in a hierarchical triple system [148] has allowed one to derive a much more accurate test of the strong equivalence principle because the inner binary (comprising a pulsar and a close white-dwarf companion) falls toward the outer white-dwarf companion with an acceleration that is 10^8 times larger than the Galactic acceleration. This leads to a 95% confidence level limit on a possible fractional difference in free-fall acceleration of the pulsar and its close companion of [149, 150]

$$|\Delta a/a| < 2.05 \times 10^{-6}\ (95\%\ \text{C.L.})\,. \qquad (21.63)$$

This limit yields strong constraints on tensor-scalar gravity models.

Measurements over several years of the pulse profiles of various pulsars have detected secular changes compatible with the prediction [151] that the general relativistic spin-orbit coupling should

cause a secular change in the orientation of the pulsar beam with respect to the line of sight ("geodetic precession"). Such confirmations of general-relativistic spin-orbit effects were obtained in PSR 1913+16 [152], PSR B1534+12 [131], PSR J1141−6545 [153], PSR J0737−3039 [139, 140], and PSR J1906+0746 [154, 155]. In some cases (notably PSR 1913+16 and PSR J1906+0746) the secular change in the orientation of the pulsar beam is expected to lead to the disappearance of the beam (as seen on the Earth) on a human time scale (the second pulsar in the double system PSR J0737−3039 already disappeared in March 2008 and is expected to reappear around 2035 [140]).

Recently, the ultimate strong-field regime of black holes has started to be quantitatively probed via GW observations. The LIGO-Virgo(-Kagra) collaboration has detected (starting in September 2015) GW signals [35], which, besides testing the radiative structure of gravity (see next section), are in excellent qualitative and quantitative agreement with the structure and dynamics of black-hole horizons in GR. Because of the mixing of strong-field effects with radiative effects during the coalescence of two black holes, and because of the lack of detailed alternative-theory predictions for this process (see, however, Refs. [46–48]), it is not easy to set quantitative limits on possible strong-field deviations from GR, independently of radiative effects. Direct tests of the existence of black-hole horizons are scarce (see, however, Sec. VIIIB of [156] which reports the lack of any statistical evidence for GW echoes).

Let us also mention that the Event Horizon Telescope collaboration has obtained event-horizon-scale images of the supermassive black hole candidates in the center of the giant elliptical galaxy M87, and in the center of our Galaxy. These images are consistent with GR models of accreting Kerr black holes [157, 158]. For discussions of the corresponding constraints on the black hole geometry in the vicinity of the light ring see Refs. [159–161].

21.7 Tests of radiative gravity (both in binary-pulsar data and in GW data)

Experimental confirmations of the GR predictions for the radiative structure of gravity have been obtained both in binary-pulsar data and in the observation of GW signals from coalescing compact binaries (binary black holes and binary neutron stars).

Binary-pulsar observations involving the measurement of the orbital period derivative $\dot{P}_b$ give *direct* experimental tests of the reality of gravitational radiation, and, in particular, an experimental confirmation that the speed of propagation of gravity c_g is equal to the speed of light c (indeed, as recalled above, $\dot{P}_b$ is a consequence of the propagation of the gravitational interaction between the two neutron stars [12]). Even in the presence of screening mechanisms within the binary system, the value of $\dot{P}_b$ yields a measurement of the speed of propagation of GWs at the 10^{-2} level [162]. The currently most accurate binary-pulsar tests of the radiative properties of gravity come from the binary neutron-star systems PSR1913+16 and PSR J0737−3039 A,B, as well as from several neutron-star-white-dwarf systems, notably PSR J1738+0333.

After subtracting a small ($\sim 10^{-14}$ level in $\dot{P}_b^{\rm obs} = (-2.423 \pm 0.001) \times 10^{-12}$), but significant, "Galactic" perturbing effect (linked to Galactic accelerations and to the pulsar proper motion) [163], one finds that the phenomenological test obtained by combining the measurements of the three PPK parameters $(k - \gamma_{\rm timing} - \dot{P}_b)_{1913+16}$ is passed by GR with complete success [128]:

$$\left[\frac{\dot{P}_b^{\rm obs} - \dot{P}_b^{\rm gal}}{\dot{P}_b^{\rm GR}[k^{\rm obs}, \gamma_{\rm timing}^{\rm obs}]}\right]_{1913+16} = 0.9983 \pm 0.0016 \ . \qquad (21.64)$$

Here $\dot{P}_b^{\rm GR}[k^{\rm obs}, \gamma_{\rm timing}^{\rm obs}]$ is the result of inserting in $\dot{P}_b^{\rm GR}(m_1, m_2)$ the values of the masses predicted by the two equations $k^{\rm obs} = k^{\rm GR}(m_1, m_2)$, and $\gamma_{\rm timing}^{\rm obs} = \gamma_{\rm timing}^{\rm GR}(m_1, m_2)$. This yields experimental evidence for the reality of gravitational radiation damping forces at the $(-1.7 \pm 1.6) \times 10^{-3}$ level.

An even better experimental test of the radiative structure of gravity (6×10^{-5} level) has been recently obtained from the combined measurement in PSR J0737−3039 A,B of the three parameters k, s, and $\dot{P}_b$ [144]:

$$\left[\frac{\dot{P}_b^{\rm obs} - \dot{P}_b^{\rm gal}}{\dot{P}_b^{\rm GR}[k^{\rm obs}, s^{\rm obs}]}\right]_{0737-3039} = 0.999963 \pm 0.000063 \ . \qquad (21.65)$$

In addition to the above tests, further very stringent tests of radiative gravity follow from the measurement of the orbital period decay $\dot{P}_b$ of low-eccentricity pulsar-white dwarf systems. Notably, the system PSR J1738+0333 yields an intrinsic orbital decay of [164]

$$\left[\dot{P}_b^{\rm obs} - \dot{P}_b^{\rm gal}\right]_{1738+0333} = (-25.9 \pm 3.2) \times 10^{-15} \, , \qquad (21.66)$$

to be compared to

$$\left[\dot{P}_b^{\rm GR}\right]_{1738+0333} = (-27.7^{+1.5}_{-1.9}) \times 10^{-15} \, . \qquad (21.67)$$

The fractional agreement between the (corrected) observed period decay and the GR-predicted one seems to be quantitatively less impressive than the double-neutron-star results cited above, but the crucial point is that asymmetric binary systems (such as neutron-star-white-dwarf ones) are strong emitters of dipolar gravitational radiation in tensor-scalar theories, with $\dot{P}_b$ scaling (modulo matter-scalar couplings) like $m_1 m_2/(m_1 + m_2)^2 (v/c)^3$, instead of the parametrically smaller GR-predicted quadrupolar radiation $\dot{P}_b \sim (v/c)^5$ [7, 15]. In view of the very small absolute value of $\dot{P}_b$, this makes such systems (and notably PSR J1738+0333) very sensitive probes of tensor-scalar gravity [103, 164–168]. It is then useful to turn to a theory-dependent analysis of pulsar data. Such an analysis (see, *e.g.*, [17, 130, 164, 167, 168]) leads to excluding a large portion of the parameter space of tensor-scalar gravity allowed by solar-system tests. As a result, the basic matter-scalar coupling α_0^2 is more strongly constrained, over most of the parameter space, than the best current solar-system limits of Eq. (21.58) (namely below the 10^{-5} level) [164, 167].

We now turn to the tests of radiative gravity that can be deduced from the GW data gathered from the first three observing runs of the LIGO-Virgo-Kagra collaboration. All currently detected GW signals are consistent with GR predictions. Several phenomenological approaches were used and led to setting limits on possible deviations from GR [51, 156, 169, 170].

A theory-agnostic quantitative assessment on possible deviations from GR is given by measuring the agreement between the full observed GW signal of coalescing binary black holes, and the GR-predicted one. One of the strongest results was obtained with the first event: GW150914, which had an SNR of 24. The noise-weighted correlation between the GW150914 signal and the best-fit GR-predicted waveform was found to be $\geq 97\%$ [51, 169]. In other words, GR-violation effects that cannot be reabsorbed in a redefinition of physical parameters are limited (in a noise-weighted sense) to less than 3%.

Besides checking the agreement between the *full* observed GW signals and the corresponding best-fit full signals predicted by GR, one also tested the consistency between separate parts of the signals. A first approach [156, 169, 170] separates: (i) the lower-frequency signal emitted during the *inspiral* phase (considered up to the innermost stable circular orbit); and (ii) the higher-frequency remaining signal emitted during the *postinspiral* phase, comprising the late-inspiral, the merger, and the ringdown. Separately fitting each of these partial signals to GR-based templates then yields separate estimates of the binary's parameters, leading to separate estimates of the mass M_f and dimensionless spin parameter $a_f = J_f/(GM_f^2)$ of the final black hole that would be formed (in GR) by the coalescence of the two initial black holes. The consistency with GR then consists in testing whether the two estimates $(M_f, a_f)_{\rm insp}$ and $(M_f, a_f)_{\rm postinsp}$ are compatible with each other. They were found to be compatible for all events whose corresponding separate SNRs made such an analysis meaningful (see Figs. 3 and 4 in [170] and Fig.3 in [156]). Quantitatively, the

(population-marginalized) fractional differences

$$\frac{\Delta M_f}{\bar{M}_f} = 2\frac{M_f^{\rm insp} - M_f^{\rm postinsp}}{M_f^{\rm insp} + M_f^{\rm postinsp}},$$
$$\frac{\Delta a_f}{\bar{a}_f} = 2\frac{a_f^{\rm insp} - a_f^{\rm postinsp}}{a_f^{\rm insp} + a_f^{\rm postinsp}}, \qquad (21.68)$$

between the two estimates were found to be consistent with zero (*i.e.* with GR) [156]

$$\frac{\Delta M_f}{\bar{M}_f} = -0.02^{+0.07}_{-0.06},$$
$$\frac{\Delta a_f}{\bar{a}_f} = -0.06^{+0.10}_{-0.07}. \qquad (21.69)$$

A second approach studies the consistency of the ringdown GW signal (emitted by the final, vibrating black hole) with GR predictions. See, in particular, section VIIIA, and Figs. 13 and 14, of [156]. The results are rather sensitive to various data analysis assumptions (notably the use of complete waveform models versus an analysis using only the ringdown signal). Though there is no clear sign of any deviations from GR, the current SNRs do not yield strong theory-agnostic evidence for the presence of ringing overtones.

The parametrization of Eq. (21.38) for possible deviations in the frequency dependence of the Fourier-domain phase $\psi(f)$ of the black hole coalescence GW signal was used to measure best-fit values for each fractional deviation parameter $\delta\hat{p}_i$, considered separately (the other ones being set to zero). In all cases, the posterior distribution for each $\delta\hat{p}_i$ is consistent with the GR value, *i.e.*, $\delta\hat{p}_i^{\rm GR} = 0$ (see Fig. 6 in [156]). The current limits on $\delta\hat{p}_i$ are (roughly) of order unity, except for the two parameters highlighted above: $\delta\hat{p}_3$ (parameterizing the $O((\frac{v}{c})^3)$ fractional correction to the LO, quadrupolar term); and $\delta\hat{p}_{-2}$ (parameterizing a possible dipolar-radiation-related $O((\frac{v}{c})^{-2})$ fractional correction to the LO, quadrupolar term). Ref. [170] gives 90%-credible intervals for $\delta\hat{p}_3$ of $-0.02^{+0.11}_{-0.10}$ (when using a phenomenological model [53]), and $-0.01^{+0.10}_{-0.11}$ (when using an effective one-body model [38]). Ref. [156] gives a 90%-credible upper bound for a possible dipolar term of $|\delta\hat{p}_{-2}| \leq 7.3 \times 10^{-4}$.

As recalled above, GR predicts that the polarization content of GWs is pure helicity-2, *i.e.* described by the two independent components of a traceless tensor transverse to the propagation direction. A (massless) scalar excitation would add a pure-trace "breathing mode" in the plane transverse to the propagation direction. A phenomenological approach to generic metric theories of gravity would allow for up to six polarizations for a GW [171], namely two tensor, two vector and two scalar modes. The LVK collaboration tested possible polarization deviations from GR in various ways [33,156,169]. Recent results are given in section VII of [156]. Though pure-scalar, pure-vector and vector-scalar hypotheses are significantly disfavored, any mixed hypothesis involving tensor modes (i.e., tensor-scalar, tensor-vector, and tensor-vector-scalar) cannot be ruled out conclusively.

GR also predicts that GWs are non dispersive, and propagate at the same speed as light. One can phenomenologically modify the GR-predicted GW phase evolution by adding the putative effect of an anomalous dispersion relation of the form $E^2 = p^2c^2 + Ap^\alpha c^\alpha$. GW data have been used to set bounds on the anomalous coefficient A for various values of the exponent α. The case $\alpha = 0$ is equivalent to assuming that gravitons disperse as a massive particle [59]. The current (90%-credibility) phenomenological GW limit on the graviton mass is $m_g \leq 1.27 \times 10^{-23}{\rm eV}/c^2$ [156]. This is 2.5 times more stringent than the Solar System bound of $3.16 \times 10^{-23}{\rm eV}/c^2$ [65].

Finally, a very constraining bound on the speed of propagation of gravity $c_{\rm GW}$ was derived from the observed time delay of 1.7 s between GW170817 and the associated γ-ray burst. Namely, the fractional difference between $c_{\rm GW}$ and $c_{\rm light} \equiv c$ is constrained to be [172]

$$-3 \times 10^{-15} < \frac{c_{\rm GW} - c}{c} < +7 \times 10^{-16}\,. \qquad (21.70)$$

When comparing the latter bound to the prediction Eq. (21.50) from general second-order tensor-scalar theories, Eq. (21.49), one is led to conclude that the coupling function $G_5(\varphi, X)$ has to be ignored and that the coupling function $G_4(\varphi, X)$ has to be restricted to depend only on φ. This drastically reduces the viable tensor-scalar modified-gravity models [173–176].

Let us finally mention that four pulsar timing arrays have recently given tantalizing evidence for the existence of a stochastic background of gravitational waves with frequency $\sim 10^{-9}$ Hz [177–180].

21.8 Conclusions

All present experimental tests are compatible with the predictions of the current "standard" theory of gravitation, Einstein's General Relativity. Let us recap the main tests. The universality of the coupling between matter and gravity (Equivalence Principle) has been verified at around the 10^{-15} level. Solar system experiments have tested the weak-field predictions of Einstein's theory at the few times 10^{-5} level. The propagation properties (in the near zone) of relativistic gravity, as well as several of its static strong-field aspects, have been verified at the 10^{-4} level (or better) in several binary pulsar experiments. Interferometric detectors of gravitational radiation have given direct observational proofs of the existence, and properties, of gravitational waves (in the wave zone), and of the existence of coalescing black holes, and they have already set strong limits on possible deviations; in particular: an upper bound $|\delta\hat{p}_{-2}| < 7.3 \times 10^{-4}$ on a possible dipolar contribution to the GW flux; the $O(10^{-15})$ bound of Eq. (21.70) on the speed of gravity; and confirmation of the tensor polarization structure of gravitational waves. In addition, laboratory experiments have set strong constraints on sub-millimeter modifications of Newtonian gravity, while many different cosmological data sets have been used to set limits on possible GR deviations on cosmological scales [29]. In spite of the uneasiness of having to assume the existence of dark matter, and the presence of an unnaturally small cosmological constant (as dark energy), General Relativity stands out as a uniquely successful description of gravity on all the scales that have been explored so far. There are no modified-gravity models which naturally pass all existing experimental tests, while either explaining away the need for dark matter or for dark energy.

22. Big-Bang Cosmology

Revised August 2023 by K.A. Olive (Minnesota U.) and J.A. Peacock (Edinburgh U.).

22.1 Introduction to the standard big-bang model

The observed expansion of the Universe [1–3] is a natural (almost inevitable) result of any homogeneous and isotropic cosmological model based on general relativity. However, by itself, the Hubble expansion does not provide sufficient evidence for what we generally refer to as the Big-Bang model of cosmology. While general relativity is in principle capable of describing the cosmology of any given distribution of matter, it is extremely fortunate that our Universe appears to be homogeneous and isotropic on large scales. Together, homogeneity and isotropy allow us to extend the Copernican Principle to the Cosmological Principle, stating that all spatial positions in the Universe are essentially equivalent.

The formulation of the Big-Bang model began in the 1940s with the work of George Gamow and his collaborators, Ralph Alpher and Robert Herman. In order to account for the possibility that the abundances of the elements had a cosmological origin, they proposed that the early Universe was once very hot and dense (enough so as to allow for the nucleosynthetic processing of hydrogen), and has subsequently expanded and cooled to its present state [4, 5]. In 1948, Alpher and Herman predicted that a direct consequence of this model is the presence of a relic background radiation with a temperature of order a few kelvin [6,7]. Of course this radiation was observed 16 years later as the cosmic microwave background (CMB) [8]. Indeed, it was the observation of this radiation that singled out the Big-Bang model as the prime candidate to describe our Universe. Subsequent work on Big-Bang nucleosynthesis further confirmed the necessity of our hot and dense past. See Sec. 22.3.7 for a brief discussion of BBN, and Sec. 24 of this *Review* for a detailed discussion of BBN. These relativistic cosmological models face severe problems with their initial conditions, to which the best modern solution is inflationary cosmology, discussed in Sec. 22.3.5 and in – Sec. 23 of this *Review*. If correct, these ideas would strictly render the term 'Big Bang' redundant, since it was first coined by Hoyle to represent a criticism of the lack of understanding of the initial conditions.

22.1.1 *The Robertson-Walker Universe*

The observed homogeneity and isotropy enable us to describe the overall geometry and evolution of the Universe in terms of two cosmological parameters accounting for the spatial curvature and the overall expansion (or contraction) of the Universe. These two quantities appear in the most general expression for a space-time metric that has a (3D) maximally symmetric subspace of a 4D space-time, known as the Robertson-Walker metric:

$$ds^2 = dt^2 - R^2(t)\left[\frac{dr^2}{1-kr^2} + r^2\left(d\theta^2 + \sin^2\theta\, d\phi^2\right)\right]. \quad (22.1)$$

Note that we adopt $c = 1$ throughout. By rescaling the radial coordinate, we can choose the curvature constant k to take only the discrete values $+1$, -1, or 0 corresponding to closed, open, or spatially flat geometries. In this case, it is often more convenient to re-express the metric as

$$ds^2 = dt^2 - R^2(t)\left[d\chi^2 + S_k^2(\chi)\left(d\theta^2 + \sin^2\theta\, d\phi^2\right)\right], \quad (22.2)$$

where the function $S_k(\chi)$ is $(\sin\chi, \chi, \sinh\chi)$ for $k = (+1, 0, -1)$. The coordinate r [in Eq. (22.1)] and the 'angle' χ [in Eq. (22.2)] are both dimensionless; the dimensions are carried by the cosmological scale factor, $R(t)$, which determines proper distances in terms of the comoving coordinates. A common alternative is to define a dimensionless scale factor, $a(t) = R(t)/R_0$, where $R_0 \equiv R(t_0)$ is R at the present epoch. It is also sometimes convenient to define a dimensionless or conformal time coordinate, η, by $d\eta = dt/R(t)$. Along constant spatial sections, the proper time is defined by the time coordinate, t. Similarly, for $dt = d\theta = d\phi = 0$, the proper distance is given by $R(t)\chi$. For standard texts on cosmological models see *e.g.*, Refs. [9–16].

22.1.2 *The redshift*

The cosmological redshift is a direct consequence of the Hubble expansion, determined by $R(t)$. A local observer detecting light from a distant emitter sees a redshift in frequency. We can define the redshift as

$$z \equiv \frac{\nu_1 - \nu_2}{\nu_2} \simeq v_{12}, \quad (22.3)$$

where ν_1 is the frequency of the emitted light, ν_2 is the observed frequency, and v_{12} is the relative velocity between the emitter and the observer. While the definition, $z = (\nu_1 - \nu_2)/\nu_2$ is valid in general, relating the redshift to a simple relative velocity is only correct on small scales (*i.e.*, less than cosmological scales) such that the expansion velocity is non-relativistic. For light signals, we can use the metric given by Eq. (22.1) and $ds^2 = 0$ to write

$$v_{12} = \dot{R}\,\delta r = \frac{\dot{R}}{R}\,\delta t = \frac{\delta R}{R} = \frac{R_2 - R_1}{R_1}, \quad (22.4)$$

where $\delta r(\delta t)$ is the radial coordinate (temporal) separation between the emitter and observer. Noting that physical distance, D, is $R\delta r$ or δt, Eq. (22.4) gives us Hubble's law, $v = HD$. In addition, we obtain a simple relation between the redshift and the scale factor:

$$1 + z = \frac{\nu_1}{\nu_2} = \frac{R_2}{R_1}. \quad (22.5)$$

This result does not depend on the non-relativistic approximation.

22.1.3 *The Friedmann equations of motion*

The cosmological equations of motion are derived from Einstein's equations:

$$\mathcal{R}_{\mu\nu} - \tfrac{1}{2} g_{\mu\nu}\mathcal{R} = 8\pi G_{\rm N} T_{\mu\nu} + \Lambda g_{\mu\nu}\,. \quad (22.6)$$

Gliner [17] and Zeldovich [18] pioneered the modern view, in which the Λ term is set on the rhs and interpreted as an effective energy-momentum tensor $T_{\mu\nu}$ for the vacuum of $\Lambda g_{\mu\nu}/8\pi G_{\rm N}$. It is common to assume that the matter content of the Universe is a perfect fluid, for which

$$T_{\mu\nu} = -p g_{\mu\nu} + (p + \rho)\, u_\mu u_\nu, \quad (22.7)$$

where $g_{\mu\nu}$ is the space-time metric described by Eq. (22.1), p is the isotropic pressure, ρ is the energy density and $u = (1, 0, 0, 0)$ is the velocity vector for the isotropic fluid in co-moving coordinates. With the perfect fluid source, Einstein's equations lead to the Friedmann equations:

$$H^2 \equiv \left(\frac{\dot{R}}{R}\right)^2 = \frac{8\pi\, G_{\rm N}\, \rho}{3} - \frac{k}{R^2} + \frac{\Lambda}{3}, \quad (22.8)$$

and

$$\frac{\ddot{R}}{R} = \frac{\Lambda}{3} - \frac{4\pi G_{\rm N}}{3}\ (\rho + 3p), \quad (22.9)$$

where $H(t)$ is the Hubble parameter and Λ is the cosmological constant. The first of these is sometimes called *the* Friedmann equation. Energy conservation via $T^{\mu\nu}_{\ \ ;\mu} = 0$, leads to a third useful equation [which can also be derived from Eq. (22.8) and Eq. (22.9)]:

$$\dot{\rho} = -3H\,(\rho + p)\,. \quad (22.10)$$

Equation (22.10) can also be simply derived as a consequence of the first law of thermodynamics.

Equation (22.8) has a simple classical mechanical analog if we neglect (for the moment) the cosmological term Λ. By interpreting $-k/R^2$ Newtonianly as a 'total energy', then we see that the evolution of the Universe is governed by a competition between the potential energy, $8\pi G_{\rm N}\rho/3$, and the kinetic term $(\dot{R}/R)^2$. For $\Lambda = 0$, it is clear that the Universe must be expanding or contracting (except at the turning point prior to collapse in a closed Universe). The ultimate fate of the Universe is determined by the curvature constant k. For $k = +1$, the Universe will recollapse in a finite time, whereas for $k = 0, -1$, the Universe will expand indefinitely. These simple conclusions can be altered when $\Lambda \neq 0$ or more generally with some component with $(\rho + 3p) < 0$.

22.1.4 *Definition of cosmological parameters*

In addition to the Hubble parameter, it is useful to define several other measurable cosmological parameters. The Friedmann equation can be used to define a critical density such that $k = 0$ when $\Lambda = 0$:

$$\rho_c \equiv \frac{3H^2}{8\pi G_N} = 1.88 \times 10^{-26}\, h^2 \text{ kg m}^{-3} = 1.05 \times 10^{-5}\, h^2 \text{ GeV cm}^{-3}, \quad (22.11)$$

where the scaled Hubble parameter, h, is defined by

$$H \equiv 100\, h \text{ km s}^{-1} \text{ Mpc}^{-1} \Rightarrow H^{-1} = 9.778\, h^{-1} \text{ Gyr} = 2998\, h^{-1} \text{ Mpc}. \quad (22.12)$$

The cosmological density parameter Ω_{tot} is defined as the energy density relative to the critical density:

$$\Omega_{tot} = \rho/\rho_c. \quad (22.13)$$

Note that one can now rewrite the Friedmann equation as

$$k/R^2 = H^2(\Omega_{tot} - 1)\ . \quad (22.14)$$

From Eq. (22.14), one can see that when $\Omega_{tot} > 1$, $k = +1$ and the Universe is closed, when $\Omega_{tot} < 1$, $k = -1$ and the Universe is open, and when $\Omega_{tot} = 1$, $k = 0$, and the Universe is spatially flat.

It is often necessary to distinguish different contributions to the density. It is therefore convenient to define present-day density parameters for pressureless matter (Ω_m) and relativistic particles (Ω_r), plus the quantity $\Omega_\Lambda = \Lambda/3H^2$. In more general models, we may wish to drop the assumption that the vacuum energy density is constant, and we therefore denote the present-day density parameter of the vacuum by Ω_v. The Friedmann equation then becomes

$$k/R_0^2 = H_0^2(\Omega_m + \Omega_r + \Omega_v - 1), \quad (22.15)$$

where the subscript 0 indicates present-day values. Thus, it is the sum of the densities in matter, relativistic particles, and vacuum that determines the overall sign of the curvature. Note that the quantity $-k/R_0^2H_0^2$ is sometimes referred to as Ω_K. This usage is unfortunate: it encourages one to think of curvature as a contribution to the energy density of the Universe, which is not correct.

22.1.5 *Standard Model solutions*

Much of the history of the Universe in the standard Big-Bang model can be easily described by assuming that either matter or radiation dominates the total energy density. During inflation and again today the expansion rate for the Universe is accelerating, and we should allow for domination by a cosmological constant or some other form of dark energy. In the following, we shall delineate the solutions to the Friedmann equation when a single component dominates the energy density. Each component is distinguished by an equation of state parameter $w = p/\rho$. We concentrate on solutions that expand at early times, although the Friedmann equation also permits a time-reversed contracting solution.

22.1.5.1 *Solutions for a general equation of state*

Let us first assume a general equation of state parameter for a single component, w, which is constant. In this case, Eq. (22.10) can be written as $\dot\rho = -3(1+w)\rho\dot R/R$ and is easily integrated to yield

$$\rho \propto R^{-3(1+w)}. \quad (22.16)$$

Note that at early times when R is small, the less singular curvature term k/R^2 in the Friedmann equation can be neglected so long as $w > -1/3$. Curvature domination occurs at rather late times (if a cosmological constant term does not dominate sooner). For $w \neq -1$, one can insert this result into the Friedmann equation Eq. (22.8), and if one neglects the curvature and cosmological constant terms, it is easy to integrate the equation to obtain

$$R(t) \propto t^{2/[3(1+w)]}. \quad (22.17)$$

22.1.5.2 *A Radiation-dominated Universe*

In the early hot and dense Universe, it is appropriate to assume an equation of state corresponding to a gas of radiation (or relativistic particles) for which $w = 1/3$. In this case, Eq. (22.16) becomes $\rho \propto R^{-4}$. The 'extra' factor of $1/R$ is due to the cosmological redshift; not only is the number density of particles in the radiation background decreasing as R^{-3} since volume scales as R^3, but in addition each particle's energy is decreasing as $E \propto \nu \propto R^{-1}$. Similarly, one can substitute $w = 1/3$ into Eq. (22.17) to obtain

$$R(t) \propto t^{1/2}; \qquad H = 1/2t. \quad (22.18)$$

22.1.5.3 *A Matter-dominated Universe*

At relatively late times, non-relativistic matter eventually dominates the energy density over radiation [see Eq. (22.3.8)]. A pressureless gas ($w = 0$) leads to the expected dependence $\rho \propto R^{-3}$ from Eq. (22.16) and, if $k = 0$, we obtain

$$R(t) \propto t^{2/3}; \qquad H = 2/3t. \quad (22.19)$$

22.1.5.4 *A Universe dominated by vacuum energy*

If there is a dominant source of vacuum energy, V_0, it would act as a cosmological constant with $\Lambda = 8\pi G_N V_0$ and equation of state $w = -1$. In this case, the solution to the Friedmann equation when curvature is neglected is particularly simple and leads to an exponential expansion of the Universe:

$$R(t) \propto e^{\sqrt{\Lambda/3}\,t}. \quad (22.20)$$

More generally we could write

$$a(t) = \sinh^{2/3}(\sqrt{3\Lambda}t/2), \quad (22.21)$$

which describes a flat Universe containing both matter and vacuum energy, with $a(t)$ being the scale factor normalized to unity when both components are equal.

A key parameter is the equation of state of the vacuum, $w \equiv p/\rho$; this need not be the $w = -1$ of Λ, and may not even be constant [19–21]. There is much interest in the more general possibility of a dynamically evolving vacuum energy, for which the name 'dark energy' has become commonly used. A variety of techniques exist whereby the vacuum density as a function of time may be measured, usually expressed as the value of w as a function of epoch [22, 23]. The best current measurement for the equation of state (assumed constant, but without assuming zero curvature) is $w = -1.028 \pm 0.031$ [24]. Unless stated otherwise, we will assume that the vacuum energy is a cosmological constant with $w = -1$ exactly.

The presence of vacuum energy can dramatically alter the fate of the Universe. For example, if $\Lambda < 0$, the Universe will eventually recollapse independent of the sign of k. For large values of $\Lambda > 0$ (larger than the Einstein static value needed to halt any cosmological expansion or contraction), even a closed Universe will expand forever. One way to quantify this is the deceleration parameter, q_0, defined as

$$q_0 = -\left.\frac{R\ddot R}{\dot R^2}\right|_0 = \frac{1}{2}\Omega_m + \Omega_r + \frac{(1+3w)}{2}\Omega_v. \quad (22.22)$$

This equation shows us that $w < -1/3$ for the vacuum may lead to an accelerating expansion. To the continuing astonishment of cosmologists, such an effect has been observed: one piece of direct evidence is the supernova Hubble diagram [25–30] (see Fig. 22.1 below). Current data indicate that vacuum energy is indeed the largest contributor to the cosmological density budget, with $\Omega_v = 0.685 \pm 0.007$ and $\Omega_m = 0.315 \pm 0.007$ if $k = 0$ is assumed [24].

The existence of this constituent is without doubt the greatest puzzle raised by the current cosmological model; the final section of this review discusses some of the ways in which the vacuum-energy problem is being addressed. For more details, see Dark Energy – Sec. 28 of this *Review*.

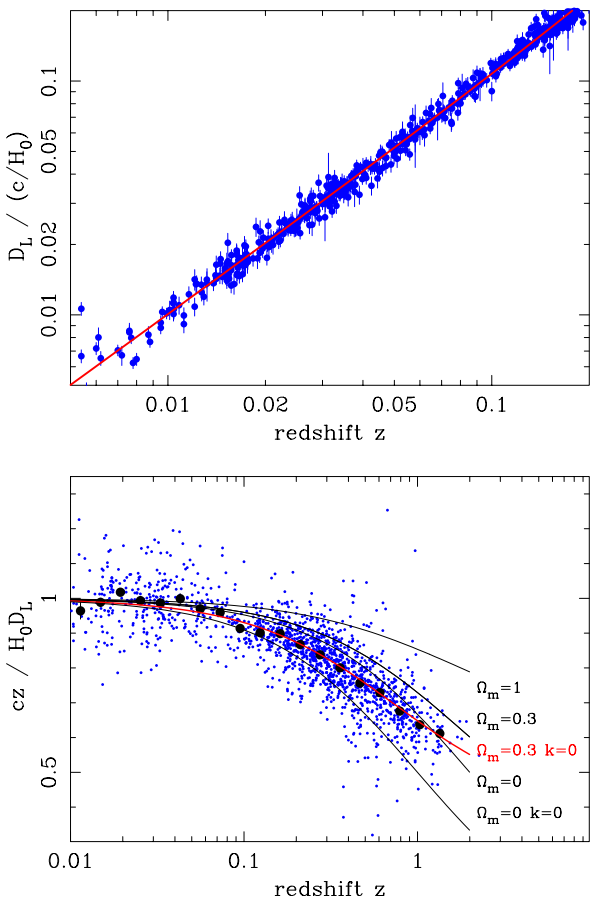

Figure 22.1: The type Ia supernova Hubble diagram, based on 1650 publicly available supernova distance estimates [28–30]. The first panel shows that for $z \ll 1$ the large-scale Hubble flow is indeed linear and uniform; the second panel shows an expanded scale, with the linear trend divided out, and with the redshift range extended to show how the Hubble law becomes nonlinear ($\Omega_r = 0$ is assumed). Larger points with errors show median values in redshift bins. Comparison with the prediction of Friedmann models favors a vacuum-dominated Universe.

22.2 Introduction to observational cosmology

22.2.1 *Fluxes, luminosities, and distances*

The key quantities for observational cosmology can be deduced quite directly from the metric.

(1) The *proper* transverse size of an object seen by us to subtend an angle $d\psi$ is its comoving size $d\psi\, S_k(\chi)$ times the scale factor at the time of emission:

$$d\ell = d\psi\; R_0 S_k(\chi)/(1+z). \tag{22.23}$$

(2) The apparent flux density of an object is deduced by allowing its photons to flow through a sphere of current radius $R_0 S_k(\chi)$; but photon energies and arrival rates are redshifted, and the bandwidth $d\nu$ is reduced. The observed photons at frequency ν_0 were emitted at frequency $\nu_0(1+z)$, so the flux density is the luminosity at this frequency, divided by the total area, divided by $1+z$:

$$S_\nu(\nu_0) = \frac{L_\nu([1+z]\nu_0)}{4\pi R_0^2 S_k^2(\chi)(1+z)}. \tag{22.24}$$

These relations lead to the following common definitions:

$$\begin{aligned} \text{angular-diameter distance} \quad & D_A = (1+z)^{-1} R_0 S_k(\chi); \\ \text{luminosity distance} \quad & D_L = (1+z)\; R_0 S_k(\chi)\;. \end{aligned} \tag{22.25}$$

These distance-redshift relations are expressed in terms of observables by using the equation of a null radial geodesic ($R(t)d\chi = dt$) plus the Friedmann equation:

$$\begin{aligned} R_0\, d\chi = \frac{1}{H(z)}\, dz = \frac{1}{H_0}\, \big[& (1-\Omega_m-\Omega_v-\Omega_r)(1+z)^2 \\ & + \Omega_v(1+z)^{3+3w} + \Omega_m(1+z)^3 \\ & + \Omega_r(1+z)^4\big]^{-1/2}\, dz. \end{aligned} \tag{22.26}$$

The main scale for the distance here is the Hubble length, $1/H_0$. The flux density is the product of the specific intensity I_ν and the solid angle $d\Omega$ subtended by the source: $S_\nu = I_\nu\, d\Omega$. Combining the angular size and flux-density relations thus gives the relativistic version of surface-brightness conservation:

$$I_\nu(\nu_0) = \frac{B_\nu([1+z]\nu_0)}{(1+z)^3}, \tag{22.27}$$

where B_ν is surface brightness (luminosity emitted into unit solid angle per unit area of source). We can integrate over ν_0 to obtain the corresponding total or bolometric formula:

$$I_{\rm tot} = \frac{B_{\rm tot}}{(1+z)^4}. \tag{22.28}$$

This cosmology-independent form expresses Liouville's Theorem: photon phase-space density is conserved along rays.

22.2.2 *Distance data and geometrical tests of cosmology*

In order to confront these theoretical predictions with data, we have to bridge the divide between two extremes. Nearby objects may have their distances measured quite easily, but their radial velocities are dominated by deviations from the ideal Hubble flow, which typically have a magnitude of several hundred $\mathrm{km\,s^{-1}}$. On the other hand, objects at redshifts $z \gtrsim 0.01$ will have observed recessional velocities that differ from their ideal values by $\lesssim 10\%$, but absolute distances are much harder to supply in this case. The traditional solution to this problem is the construction of the distance ladder: an interlocking set of methods for obtaining relative distances between various classes of object, which begins with absolute distances at the 10 to 100 pc level, and terminates with galaxies at significant redshifts. This is discussed in the article on Cosmological Parameters – Sec. 25 of this *Review*.

One of the key developments in this area has been the use of type Ia supernovae (SNe), which now allow measurement of relative distances with 5% precision. In combination with improved Cepheid data from the *HST* plus improved measurements of the distance to the LMC (or alternatively a direct geometrical distance to the maser galaxy NGC4258), SNe results extend the distance ladder to the point where deviations from uniform expansion are negligible, leading to the best existing Cepheid-based value for H_0: $(73.0 \pm 1.0)\,\mathrm{km\,s^{-1}Mpc^{-1}}$ [31]. Better still, the analysis of high-z SNe has allowed a simple and direct test of cosmological geometry to be carried out: as shown in Fig. 22.1 and Fig. 22.2, supernova data and measurements of CMB anisotropies strongly favor a $k = 0$ model dominated by vacuum energy. It is worth noting that there is some tension (4.2σ) between the Cepheid and CMB determinations of H_0 (the latter is $(67.4 \pm 0.5)\,\mathrm{km\,s^{-1}Mpc^{-1}}$ [24]). While it is remarkable that the two very different methods give such similar results, the formal disagreement shows that either there are unidentified systematic errors or that some new post-CDM physics is required; there is no current consensus in the community on these alternatives. We do note that a recent analysis of SNe Ia with a calibration of the tip of the red-giant branch gives a result close to that of the CMB: $(69.8 \pm 0.6\,(\mathrm{stat.}) \pm 1.6\,(\mathrm{sys.}))\,\mathrm{km\,s^{-1}Mpc^{-1}}$ [32, 33]. See Cosmological Parameters – Sec. 25 of this *Review* for a more comprehensive review of Hubble parameter determinations.

22.2.3 *Age of the Universe*

The most striking conclusion of relativistic cosmology is that the Universe has not existed forever. The dynamical result for

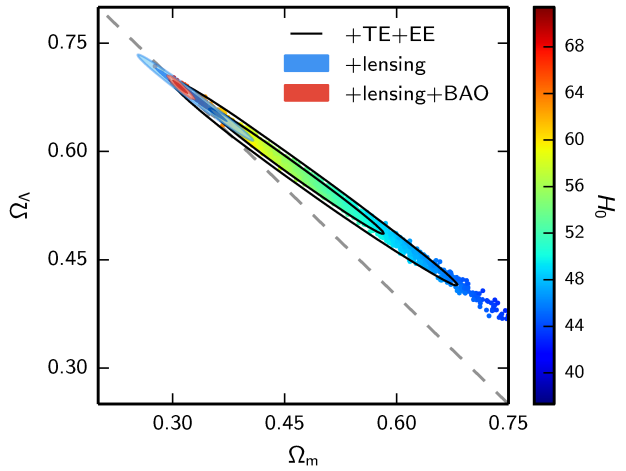

Figure 22.2: Likelihood-based probability densities over the plane Ω_Λ (*i.e.*, Ω_v assuming $w = -1$) versus Ω_m. The colored locus derives from *Planck* [34] and shows that the CMB alone requires a flat Universe $\Omega_v + \Omega_m \simeq 1$ if the Hubble constant is not too high. The SNe Ia results [35] very nearly constrain the orthogonal combination $\Omega_v - \Omega_m$, and the intersection of these constraints directly favors a flat model with $\Omega_m \simeq 0.3$, as does the measurement of the baryon acoustic oscillation lengthscale (for which a joint constraint is shown on this plot). The CMB alone is capable of breaking the degeneracy with H_0 by using the measurements of gravitational lensing that can be made with modern high-resolution CMB data.

the age of the Universe may be written as

$$H_0 t_0 = \int_0^\infty \frac{dz}{(1+z)H(z)} = \int_0^\infty \frac{dz}{(1+z)\,[(1+z)^2(1+\Omega_m z) - z(2+z)\Omega_v]^{1/2}}, \quad (22.29)$$

where we have neglected Ω_r and chosen $w = -1$. Over the range of interest ($0.1 \lesssim \Omega_m \lesssim 1$, $|\Omega_v| \lesssim 1$), this exact answer may be approximated to a few per cent accuracy by

$$H_0 t_0 \simeq \tfrac{2}{3}\,(0.7\Omega_m + 0.3 - 0.3\Omega_v)^{-0.3}. \quad (22.30)$$

For the special case that $\Omega_m + \Omega_v = 1$, the integral in Eq. (22.29) can be expressed analytically as

$$H_0 t_0 = \frac{2}{3\sqrt{\Omega_v}}\,\ln\frac{1+\sqrt{\Omega_v}}{\sqrt{1-\Omega_v}} \quad (\Omega_m < 1). \quad (22.31)$$

The most accurate means of obtaining ages for astronomical objects is based on the natural clocks provided by radioactive decay. The use of these clocks is complicated by a lack of knowledge of the initial conditions of the decay. In the Solar System, chemical fractionation of different elements helps pin down a precise age for the pre-Solar nebula of 4.6 Gyr, but for stars it is necessary to attempt an a priori calculation of the relative abundances of nuclei that result from supernova explosions. In this way, a lower limit for the age of stars in the local part of the Milky Way of about 11 Gyr is obtained [36, 37].

The other major means of obtaining cosmological age estimates is based on the theory of stellar evolution. In principle, the main-sequence turnoff point in the color-magnitude diagram of a globular cluster should yield a reliable age. But these have been controversial, owing to theoretical uncertainties in the evolution model – as well as observational uncertainties in the distance, dust extinction, and metallicity of clusters. The present consensus favors ages for the oldest clusters of about 13 Gyr [38].

These methods are all consistent with the age deduced from studies of structure formation, using the microwave background and large-scale structure: $t_0 = (13.80 \pm 0.02)$ Gyr [24], where the extra accuracy comes at the price of assuming the simple 6-parameter ΛCDM model to be true.

22.2.4 *Horizon, isotropy, flatness problems*

For photons, the radial equation of motion is just $c\,dt = R\,d\chi$. How far can a photon get in a given time? The answer is clearly

$$\Delta\chi = \int_{t_1}^{t_2} \frac{dt}{R(t)} \equiv \Delta\eta, \quad (22.32)$$

i.e., just the interval of conformal time. We can replace dt by $dR/\dot{R}$, which the Friedmann equation says is $\propto dR/\sqrt{\rho R^2}$ at early times. Thus, this integral converges if $\rho R^2 \to \infty$ as $t_1 \to 0$, otherwise it diverges. Provided the equation of state is such that ρ changes faster than R^{-2}, light signals can only propagate a finite distance between the Big Bang and the present; there is then said to be a particle horizon. Such a horizon therefore exists in conventional Big-Bang models, which are dominated by radiation ($\rho \propto R^{-4}$) at early times.

At late times, the integral for the horizon is largely determined by the matter-dominated phase, for which

$$D_H = R_0\,\chi_H \equiv R_0 \int_0^{t(z)} \frac{dt}{R(t)} \simeq \frac{6000}{\sqrt{\Omega_m z}}\,h^{-1}\,\mathrm{Mpc} \quad (z \gg 1). \quad (22.33)$$

The horizon at the time of formation of the microwave background ('last scattering': $z \simeq 1100$) was thus of order 100 *Mpc* in size, subtending an angle of about 1°. Why then are the large number of causally disconnected regions we see on the microwave sky all at the same temperature? The Universe is very nearly isotropic and homogeneous, even though the initial conditions appear not to permit such a state to be constructed.

A related problem is that the $\Omega = 1$ Universe is unstable:

$$\Omega(a) - 1 = \frac{\Omega - 1}{1 - \Omega + \Omega_v a^2 + \Omega_m a^{-1} + \Omega_r a^{-2}}\,, \quad (22.34)$$

where Ω with no subscript is the total density parameter, and $a(t) = R(t)/R_0$. This requires $\Omega(t)$ to be unity to arbitrary precision as the initial time tends to zero; a Universe of non-zero curvature today requires very finely tuned initial conditions.

22.3 The Hot Thermal Universe

22.3.1 *Thermodynamics of the early Universe*

As alluded to above, we expect that much of the early Universe can be described by a radiation-dominated equation of state. In addition, through much of the radiation-dominated period, thermal equilibrium is established by the rapid rate of particle interactions relative to the expansion rate of the Universe (see Sec. 22.3.3 below). In equilibrium, it is straightforward to compute the thermodynamic quantities, ρ, p, and the entropy density, s. In general, the energy density for a given particle type i can be written as

$$\rho_i = \int E_i\, dn_{q_i}, \quad (22.35)$$

with the density of states given by

$$dn_{q_i} = \frac{g_i}{2\pi^2}\,(\exp[(E_{q_i} - \mu_i)/T_i] \pm 1)^{-1}\; q_i^2\, dq_i, \quad (22.36)$$

where g_i counts the number of degrees of freedom for particle type i, $E_{q_i}^2 = m_i^2 + q_i^2$, μ_i is the chemical potential, and the $\pm$ corresponds to either Fermi or Bose statistics. Similarly, we can define the pressure of a perfect gas as

$$p_i = \frac{1}{3}\int \frac{q_i^2}{E_i}\, dn_{q_i}. \quad (22.37)$$

The number density of species i is simply

$$n_i = \int dn_{q_i}, \quad (22.38)$$

and the entropy density is

$$s_i = \frac{\rho_i + p_i - \mu_i n_i}{T_i} \ . \tag{22.39}$$

In the Standard Model, a chemical potential is often associated with baryon number, and since the net baryon density relative to the photon density is known to be very small (of order 10^{-9}), we can neglect any such chemical potential when computing total thermodynamic quantities.

For photons, we can compute all of the thermodynamic quantities rather easily. Taking $g_i = 2$ for the 2 photon polarization states, we have (in units where $\hbar = k_B = 1$)

$$\rho_\gamma = \frac{\pi^2}{15} T^4, \quad p_\gamma = \frac{1}{3}\rho_\gamma, \quad s_\gamma = \frac{4\rho_\gamma}{3T}, \quad n_\gamma = \frac{2\zeta(3)}{\pi^2} T^3, \tag{22.40}$$

with $2\zeta(3)/\pi^2 \simeq 0.2436$. Note that Eq. (22.10) can be converted into an equation for entropy conservation. Recognizing that $\dot{p} = s\dot{T}$, Eq. (22.10) becomes

$$d(sR^3)/dt = 0. \tag{22.41}$$

For radiation, this corresponds to the relationship between expansion and cooling, $T \propto R^{-1}$ in an adiabatically expanding Universe. Note also that both s and n_γ scale as T^3.

22.3.2 *Radiation content of the Early Universe*

At the very high temperatures associated with the early Universe, massive particles are pair produced, and are part of the thermal bath. If for a given particle species i we have $T \gg m_i$, then we can neglect the mass in Eq. (22.35) to Eq. (22.39), and the thermodynamic quantities are easily computed as in Eq. (22.40). In general, we can approximate the energy density (at high temperatures) by including only those particles with $m_i \ll T$. In this case, we have

$$\rho = \left(\sum_{\rm B} g_{\rm B} + \frac{7}{8} \sum_{\rm F} g_{\rm F} \right) \frac{\pi^2}{30} T^4 \equiv \frac{\pi^2}{30} N(T)\, T^4, \tag{22.42}$$

where $g_{\rm B(F)}$ is the number of degrees of freedom of each boson (fermion) and the sum runs over all boson and fermion states with $m \ll T$. The factor of 7/8 is due to the difference between the Fermi and Bose integrals. Eq. (22.42) defines the effective number of degrees of freedom, $N(T)$, by taking into account new particle degrees of freedom as the temperature is raised. This quantity, calculated from high temperature lattice QCD, is plotted in Fig. 22.3 [39]. Near the QCD transition, there is a slight difference between the coefficient of T^4 for ρ and the coefficient of T^3 for the entropy density $s = (2\pi^2/45) N_s(T) T^3$ [40], as seen in the figure.

The value of $N(T)$ at any given temperature depends on the particle physics model. In the standard SU(3) × SU(2) × U(1) model, we can specify $N(T)$ up to temperatures of $O(100)$ GeV. The change in N (ignoring mass effects) can be seen in the table below.

Temperature	New Particles	$4N(T)$
$T < m_e$	γ's + ν's	29
$m_e < T < m_\mu$	$e^\pm$	43
$m_\mu < T < m_\pi$	$\mu^\pm$	57
$m_\pi < T < T_c$ †	π's	69
$T_c < T < m_{\rm strange}$	π's + $u, \bar{u}, d, \bar{d}$ + gluons	205
$m_s < T < m_{\rm charm}$	$s, \bar{s}$	247
$m_c < T < m_\tau$	$c, \bar{c}$	289
$m_\tau < T < m_{\rm bottom}$	$\tau^\pm$	303
$m_b < T < m_{\rm W,Z}$	$b, \bar{b}$	345
$m_{W,Z} < T < m_{\rm Higgs}$	$W^\pm, Z$	381
$m_H < T < m_{\rm top}$	H^0	385
$m_t < T$	$t, \bar{t}$	427

†T_c corresponds to the confinement-deconfinement transition between quarks and hadrons.

At higher temperatures, $N(T)$ will be model-dependent. For example, in the minimal SU(5) model, one needs to add 24 states to $N(T)$ for the charged and colored X and Y gauge bosons, another 24 from the adjoint Higgs, and another six scalar degrees of freedom (in addition to the four associated with the complex Higgs doublet already counted in the longitudinal components of $W^\pm$ and Z, and in H) from the $\bar{5}$ of Higgs. Hence for $T > m_X$ in minimal SU(5), $N(T) = 160.75$. In a supersymmetric model this would at least double.

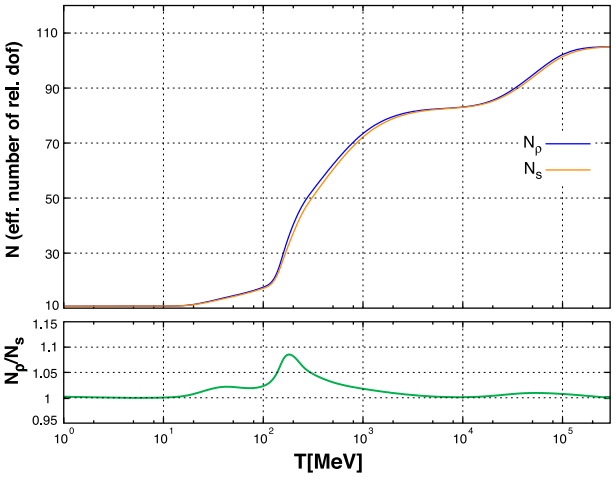

Figure 22.3: The effective numbers of relativistic degrees of freedom as a function of temperature. The sharp drop corresponds to the quark-hadron transition. The bottom panel shows the relative ratio between the number of degrees of freedom characterizing the energy density and the entropy.

In the radiation-dominated epoch, Eq. (22.10) can be integrated (neglecting the T-dependence of N), giving us a relationship between the age of the Universe and its temperature:

$$t = \left(\frac{90}{32\pi^3 G_N N(T)} \right)^{1/2} T^{-2} \ . \tag{22.43}$$

This can be expressed more conveniently in the form

$$t\, T_{\rm MeV}^2 = 2.4 [N(T)]^{-1/2}, \tag{22.44}$$

where t is measured in seconds and $T_{\rm MeV}$ in units of MeV.

22.3.3 *Neutrinos and equilibrium*

Due to the expansion of the Universe, certain rates may be too slow to either establish or maintain equilibrium. Quantitatively, for each particle i, a minimal condition for equilibrium requires that the interaction rate Γ_i involving that type of particle should be larger than the expansion rate of the Universe:

$$\Gamma_i > H. \tag{22.45}$$

Recalling that the age of the Universe is determined by H^{-1}, this condition is equivalent to requiring that on average, at least one interaction has occurred over the lifetime of the Universe.

A good example for a process that goes in and out of equilibrium is the weak interaction of neutrinos. On dimensional grounds, one can estimate the thermally averaged scattering cross-section:

$$\langle \sigma v \rangle \sim O(10^{-2}) T^2 / m_W^4 \tag{22.46}$$

for $T \lesssim m_W$. Recalling that the number density of leptons is $n \propto T^3$, we can compare the weak interaction rate, $\Gamma_{\rm wk} \sim n \langle \sigma v \rangle$, with the expansion rate and so obtain

$$H = \left(\frac{8\pi G_N \rho}{3} \right)^{1/2} = \left(\frac{8\pi^3}{90} N(T) \right)^{1/2} T^2 / M_P \simeq 1.66 N(T)^{1/2} T^2 / M_P, \tag{22.47}$$

where the Planck mass $M_P = G_N^{-1/2} = 1.22 \times 10^{19}$ GeV.

Neutrinos will be in equilibrium when $\Gamma_{\rm wk} > H$ or

$$T > (500\, m_W^4 / M_P)^{1/3} \sim 1\,{\rm MeV}. \tag{22.48}$$

However, this condition assumes $T \ll m_{\rm W}$; for higher temperatures, we should write $\langle\sigma v\rangle \sim O(10^{-2})/T^2$, so that $\Gamma \sim 10^{-2}T$. Thus, in the very early stages of expansion, at temperatures $T \gtrsim 10^{-2}M_{\rm P}/\sqrt{N}$, equilibrium will not have been established.

Having attained a quasi-equilibrium stage, the Universe then cools further to the point where the interaction and expansion timescales match once again. The temperature at which these rates are equal is commonly referred to as the neutrino decoupling or freeze-out temperature and is defined by $\Gamma_{\rm wk}(T_{\rm d}) = H(T_{\rm d})$. For $T < T_d$, neutrinos drop out of equilibrium. The Universe becomes transparent to neutrinos and their momenta simply redshift with the cosmic expansion. The effective neutrino temperature will simply fall with $T \propto 1/R$.

Soon after decoupling, $e^{\pm}$ pairs in the thermal background begin to annihilate (when $T \lesssim m_e$). Because the neutrinos are decoupled, the energy released due to annihilation heats up the photon background relative to the neutrinos. The change in the photon temperature can be easily computed from entropy conservation. The neutrino entropy must be conserved separately from the entropy of interacting particles. A straightforward computation yields

$$T_\nu = (4/11)^{1/3}\, T_\gamma \simeq 1.9\,{\rm K}. \tag{22.49}$$

The total entropy density is therefore given by the contribution from photons and three flavors of neutrinos:

$$s = \frac{4}{3}\frac{\pi^2}{30}\left(2 + \frac{21}{4}(T_\nu/T_\gamma)^3\right) T_\gamma^3 = \frac{4}{3}\frac{\pi^2}{30}\left(2 + \frac{21}{11}\right) T_\gamma^3 = 7.04\, n_\gamma. \tag{22.50}$$

Similarly, the total relativistic energy density is given by

$$\rho_r = \frac{\pi^2}{30}\left[2 + \frac{21}{4}(T_\nu/T_\gamma)^4\right] T_\gamma^4 \simeq 1.68\rho_\gamma. \tag{22.51}$$

In practice, a small correction is needed to this, since neutrinos are not totally decoupled at $e^{\pm}$ annihilation: the effective number of massless neutrino species is 3.044, rather than 3 [41].

This expression ignores neutrino rest masses, but current oscillation data require at least one neutrino eigenstate to have a mass exceeding 0.06 eV. In this minimal case, $\Omega_\nu h^2 = 6 \times 10^{-4}$, so the neutrino contribution to the matter budget would be negligibly small (which is our normal assumption). However, a nearly degenerate pattern of mass eigenstates could allow larger densities, since oscillation experiments only measure differences in m^2 values. Note that a 0.06-eV neutrino has $T_\nu = m_\nu$ at $z \simeq 357$, so the above expression for the total present relativistic density is really only an extrapolation. However, neutrinos are almost certainly relativistic at all epochs where the radiation content of the Universe is dynamically significant. Combining *Planck* data with data from large-scale structure surveys such as DES [42] provides an upper limit to the sum of neutrino masses, $\Sigma m_\nu < 0.13$ eV, and may provide the first measurement of a neutrino mass (as opposed to a difference of neutrino mass^2 from oscillation data) from future surveys. See Neutrinos in Cosmology – Sec. 26 of this *Review* for a detailed discussion of neutrinos in cosmology.

22.3.4 *Field theory and phase transitions*

It is very likely that the Universe has undergone one or more phase transitions during the course of its evolution [43–46]. Our current vacuum state is described by SU(3)$_c\times$ U(1)$_{\rm em}$, which in the Standard Model is a remnant of an unbroken SU(3)$_c\times$ SU(2)$_L\times$ U(1)$_Y$ gauge symmetry. Symmetry breaking occurs when a non-singlet gauge field (the Higgs field in the Standard Model) picks up a non-vanishing vacuum expectation value, determined by a scalar potential. For example, a simple (non-gauged) potential describing symmetry breaking is $V(\phi) = \frac{1}{4}\lambda\phi^4 - \frac{1}{2}\mu^2\phi^2 + V(0)$. The resulting expectation value is simply $\langle\phi\rangle = \mu/\sqrt{\lambda}$.

In the early Universe, finite temperature radiative corrections typically add terms to the potential of the form ϕ^2T^2. Thus, at very high temperatures, the symmetry is restored and $\langle\phi\rangle = 0$. As the Universe cools, depending on the details of the potential, symmetry breaking will occur via a first-order phase transition in which the field tunnels through a potential barrier, or via a second-order transition in which the field evolves smoothly from one state to another (as would be the case for the above example potential).

The evolution of scalar fields can have a profound impact on the early Universe. The equation of motion for a scalar field ϕ can be derived from the energy-momentum tensor:

$$T_{\mu\nu} = \partial_\mu\phi\partial_\nu\phi - \frac{1}{2}g_{\mu\nu}\partial_\rho\phi\partial^\rho\phi - g_{\mu\nu}V(\phi). \tag{22.52}$$

By associating $\rho = T_{00}$ and $p = R^{-2}(t)T_{ii}$ we have

$$\begin{aligned} \rho &= \frac{1}{2}\dot\phi^2 + \frac{1}{2}R^{-2}(t)(\nabla\phi)^2 + V(\phi)\,; \\ p &= \frac{1}{2}\dot\phi^2 - \frac{1}{6}R^{-2}(t)(\nabla\phi)^2 - V(\phi)\ , \end{aligned} \tag{22.53}$$

and from Eq. (22.10) we can write the equation of motion as follows (by considering a homogeneous region, we can ignore the gradient terms):

$$\ddot\phi + 3H\dot\phi = -\partial V/\partial\phi. \tag{22.54}$$

22.3.5 *Inflation*

In Sec. 22.2.4, we discussed some of the problems associated with the standard Big-Bang model. However, during a phase transition, our assumptions of an adiabatically expanding Universe are generally not valid. If, for example, a phase transition occurred in the early Universe such that the field evolved slowly from the symmetric state to the global minimum, the Universe may have been dominated by the vacuum energy density associated with the potential near $\phi \simeq 0$. During this period of slow evolution, the energy density due to radiation will fall below the vacuum energy density, $\rho \ll V(0)$. When this happens, the expansion rate will be dominated by the constant V(0), and we obtain the exponentially expanding solution given in Eq. (22.20). When the field evolves towards the global minimum it will begin to oscillate about that minimum, energy will be released during its decay, and a hot thermal Universe will be restored. If released fast enough, it will produce radiation at a temperature $NT_{\rm R}{}^4 \lesssim V(0)$. In this reheating process, entropy has been created and the final value of RT is greater than the initial value of RT. Thus, we see that, during a phase transition, the relation $RT \sim$ constant need not hold true. This is the basis of the inflationary Universe scenario [47–49].

If, during the phase transition, the value of RT changed by a factor of $O(10^{29})$, the cosmological problems discussed above would be solved. The observed isotropy would be generated by the immense expansion; one small causal region could get blown up, and thus our entire visible Universe would have been in thermal contact some time in the past. In addition, the density parameter Ω would have been driven to 1 (with exponential precision). Density perturbations will be stretched by the expansion, $\lambda \propto R(t)$. Thus it will appear that $\lambda \gg H^{-1}$ or that the perturbations have left the horizon, where in fact the size of the causally connected region is now no longer simply H^{-1}. However, not only does inflation offer an explanation for large scale perturbations, it also offers a source for the perturbations themselves through quantum fluctuations.

Problems with early models of inflation based on either a first-order [50] or second-order [51,52] phase transition of a Grand Unified Theory led to models invoking a completely new scalar field: the inflaton, ϕ. The potential of this field, $V(\phi)$, needs to have a very low gradient and curvature in order to match observed metric fluctuations. For a more thorough discussion of the problems of early models and a host of current models being studied see the review on inflation – Sec. 23 of this *Review*. In most current inflation models, reheated bubbles typically do not percolate, so inflation is 'eternal' and continues with exponential expansion in the region outside the bubbles. These causally disconnected bubble Universes constitute a 'multiverse', where low-energy physics can vary between different bubbles. This has led to a controversial 'anthropic' approach to cosmology [53–55], where observer selection within the multiverse can be introduced as a means of understanding *e.g.* why the observed level of vacuum energy is so low (because larger values suppress growth of structure).

22.3.6 *Baryogenesis*

The Universe appears to be populated exclusively with matter rather than antimatter [56, 57]. Indeed antimatter is only detected in accelerators or in cosmic rays. However, the presence of antimatter in the latter is understood to be the result of collisions of primary particles in the interstellar medium. There is in fact strong evidence against primary forms of antimatter in the Universe. Furthermore, the density of baryons compared to the density of photons is extremely small, $\eta \sim 10^{-9}$.

The production of a net baryon asymmetry requires baryon number violating interactions, C and CP violation, and a departure from thermal equilibrium [58]. The first two of these ingredients are expected to be contained in Grand Unified Theories (GUTs) as well as in the non-perturbative sector of the Standard Model; the third can be realized in an expanding Universe where, as we have seen, interactions come in and out of equilibrium.

There are several interesting and viable mechanisms for the production of the baryon asymmetry. While we cannot review any of them here in any detail, we mention some of the important scenarios. In all cases, all three ingredients listed above are incorporated. One of the first mechanisms was based on the out of equilibrium decay of a massive particle such as a superheavy GUT gauge or Higgs boson [59, 60]. A novel mechanism involving the decay of flat directions in supersymmetric models is known as the Affleck-Dine scenario [61]. There is also the possibility of generating the baryon asymmetry at the electroweak scale using the non-perturbative interactions of sphalerons [62]. Because these interactions conserve the sum of baryon and lepton number, $B + L$, it is possible to first generate a lepton asymmetry (*e.g.*, by the out-of-equilibrium decay of a superheavy right-handed neutrino), which is converted to a baryon asymmetry at the electroweak scale [63]. This mechanism is known as lepto-baryogenesis, or simply leptogenesis.

22.3.7 *Nucleosynthesis*

An essential element of the standard cosmological model is Big-Bang nucleosynthesis (BBN), the theory that predicts the abundances of the light element isotopes D, ^{3}He, ^{4}He, and ^{7}Li. Nucleosynthesis takes place at a temperature scale of order 1 MeV. The nuclear processes lead primarily to ^{4}He, with a primordial mass fraction of about 25%. Lesser amounts of the other light elements are produced: about 10^{-5} of D and ^{3}He and about 10^{-10} of ^{7}Li by number relative to H. The abundances of the light elements depend almost solely on one key parameter, the baryon-to-photon ratio, η. The nucleosynthesis predictions can be compared with observational determinations of the abundances of the light elements. Consistency between theory and observations, driven primarily by recent D/H measurements [64, 65], leads to a range of [66]

$$5.8 \times 10^{-10} < \eta < 6.3 \times 10^{-10}. \tag{22.55}$$

The value of η is related to the baryon density as follows:

$$\Omega_{\rm b} = 3.66 \times 10^7 \eta\, h^{-2}, \tag{22.56}$$

or $10^{10}\eta = 274\Omega_{\rm b}h^2$. The *Planck* result [24] for $\Omega_{\rm b}h^2$ of 0.0224 $\pm$ 0.0002 translates into a value of $\eta = 6.12 \pm 0.04$. This result can be used to 'predict' the light element abundances, which can in turn be compared with observation [67]. The resulting D/H abundance is in excellent agreement with that found in quasar absorption systems. It is in reasonable agreement with the helium abundance observed in extragalactic HII regions (once systematic uncertainties are accounted for). The BBN predicted Li abundance is systematically higher than the Li abundance observed in the atmospheres of halo dwarf stars [68], but there is mounting evidence that effects of stellar depletion cannot be ignored so that the stellar abundances of Li may not correspond to the primordial abundance [69]. See BBN – Sec. 24 of this *Review* for a detailed discussion of BBN, in addition to references [66, 70–74].

22.3.8 *The transition to a matter-dominated Universe*

In the Standard Model, the temperature (or redshift) at which the Universe undergoes a transition from a radiation-dominated to a matter-dominated Universe is determined by the amount of dark matter. Assuming three nearly massless neutrinos, the energy density in radiation at temperatures $T \ll 1$ MeV, is given by

$$\rho_{\rm r} = \frac{\pi^2}{30}\left[2 + \frac{21}{4}\left(\frac{4}{11}\right)^{4/3}\right] T^4. \tag{22.57}$$

In the absence of non-baryonic dark matter, the matter density can be written as

$$\rho_{\rm m} = m_{\rm N}\eta\, n_\gamma, \tag{22.58}$$

where $m_{\rm N}$ is the nucleon mass. Recalling that $n_\gamma \propto T^3$ [*cf.* Eq. (22.40)], we can solve for the temperature or redshift at the matter-radiation equality when $\rho_{\rm r} = \rho_{\rm m}$:

$$T_{\rm eq} = 0.22\, m_{\rm N}\,\eta \qquad \text{or} \qquad (1 + z_{\rm eq}) = 0.22\,\eta\frac{m_{\rm N}}{T_0}, \tag{22.59}$$

where T_0 is the present temperature of the microwave background. For $\eta = 6.1 \times 10^{-10}$, this corresponds to a temperature $T_{\rm eq} \simeq 0.13$ eV or $(1+z_{\rm eq}) \simeq 550$. A transition this late would be problematic for structure formation (see Sec. 22.4.5).

The redshift of matter domination can be pushed back significantly if non-baryonic dark matter is present. If instead of Eq. (22.58), we write

$$\rho_{\rm m} = \Omega_{\rm m}\rho_{\rm c}\left(\frac{T}{T_0}\right)^3, \tag{22.60}$$

we find that

$$T_{\rm eq} = 0.9\frac{\Omega_{\rm m}\rho_{\rm c}}{T_0^3} \qquad \text{or} \qquad (1 + z_{\rm eq}) = 2.4 \times 10^4 \Omega_{\rm m} h^2. \tag{22.61}$$

22.4 The Universe at late times

22.4.1 *The CMB*

One form of the infamous Olbers' paradox says that, in Euclidean space, surface brightness is independent of distance. Every line of sight will terminate on matter that is hot enough to be ionized and so scatter photons: $T \gtrsim 10^3$ K, and the sky should therefore shine as brightly as the surface of the Sun. The reason the night sky is dark is entirely due to the expansion, which cools the radiation temperature to 2.73 K. This gives a Planck function peaking at around 1 mm to produce the CMB.

The CMB spectrum is a very accurate match to a Planck function [75]; see also CMB – Sec. 29 of this *Review*. The COBE estimate of the temperature is [76]

$$T = (2.7255 \pm 0.0006)\,{\rm K}. \tag{22.62}$$

The lack of any distortion of the Planck spectrum is a strong physical constraint. It is very difficult to account for in any expanding Universe other than one that passes through a hot stage. Alternative schemes for generating the radiation, such as thermalization of starlight by dust grains, inevitably generate a superposition of temperatures. What is required in addition to thermal equilibrium is that $T \propto 1/R$, so that radiation from different parts of space arrive at an observer with the same apparent temperature.

Although it is common to speak of the CMB as originating at 'recombination', a more accurate terminology is the era of 'last scattering'. In practice, this takes place at $z \simeq 1100$, almost independently of the main cosmological parameters, at which time the fractional ionization is very small. This occurred when the age of the Universe was about 370,000 years. But the CMB photons themselves were not generated at this point, and were the result of thermalization at $z \sim 10^7$. See CMB – Sec. 29 of this *Review* for a full discussion of the CMB.

22.4.2 *Matter in the Universe*

One of the main tasks of cosmology is to measure the density of the Universe, and how this is divided between dark matter and baryons. The baryons consist partly of stars, with $0.002 \lesssim \Omega_* \lesssim 0.003$ [77] but mainly inhabit the intergalactic medium (IGM). One powerful way in which this can be studied is via the absorption of light from distant luminous objects such as quasars. Even very small amounts of neutral hydrogen can

absorb rest-frame UV photons (the Gunn-Peterson effect), and should suppress the continuum by a factor $\exp(-\tau)$, where

$$\tau \simeq 10^{4.62} h^{-1} \left[\frac{n_{\rm HI}(z)/{\rm m}^{-3}}{(1+z)\sqrt{1+\Omega_{\rm m} z}} \right] , \qquad (22.63)$$

and this expression applies while the Universe is matter dominated ($z \gtrsim 1$ in the $\Omega_{\rm m} = 0.3$ $\Omega_{\rm v} = 0.7$ model). At $z < 6$, the dominant effect on quasar spectra is a 'forest' of narrow absorption lines, which produce a mean $\tau = 1$ in the Lyα forest at about $z = 3$, and so we have $\Omega_{\rm HI} \simeq 10^{-6.7} h^{-1}$. This is such a small number that the IGM must be very highly ionized at these redshifts, apart from a few high-density clumps. But at $z > 6$ there is good evidence for a 'reionization' era at which the general IGM is not so strongly ionized [78]. As discussed below, this ionized IGM at low z is also detectable via the secondary Compton scattering of CMB photons.

The Lyα forest is of great importance in pinning down the abundance of deuterium. Because electrons in deuterium differ in reduced mass by about 1 part in 4000 compared to hydrogen, each absorption system in the Lyα forest is accompanied by an offset deuterium line. By careful selection of systems with an optimal HI column density, a measurement of the D/H ratio can be made. This has now been done with high accuracy in 10 quasars, with consistent results [64]. Combining these determinations with the theory of primordial nucleosynthesis yields a baryon density of $\Omega_{\rm b} h^2 = 0.021$–$0.023$ (95% confidence) in excellent agreement with the *Planck* result. For more details, see BBN – Sec. 24 of this *Review*.

Ionized IGM can also be detected in emission when it is densely clumped, via bremsstrahlung radiation. This generates the spectacular X-ray emission from rich clusters of galaxies. Studies of this phenomenon allow us to achieve an accounting of the total baryonic material in clusters. Within the central $\simeq 1$ Mpc, the masses in stars, X-ray emitting gas, and total dark matter can be determined with reasonable accuracy (perhaps 20% rms), and this allows a minimum baryon fraction to be determined [79, 80]:

$$\frac{M_{\rm baryons}}{M_{\rm total}} \gtrsim 0.009 + (0.066 \pm 0.003)\, h^{-3/2}. \qquad (22.64)$$

Because clusters are the largest collapsed structures, it is reasonable to take this as applying to the Universe as a whole. This equation implies a minimum baryon fraction of perhaps 12% (for reasonable h), which is too high for $\Omega_{\rm m} = 1$ if we take $\Omega_{\rm b} h^2 \simeq 0.02$ from nucleosynthesis. This is therefore one of the more robust arguments in favor of $\Omega_{\rm m} \simeq 0.3$; for more details, see Cosmological Parameters – Sec. 25 of this *Review*. This argument is also consistent with the inference on $\Omega_{\rm m}$ that can be made from Fig. 22.2.

This method is much more robust than the older classical technique for weighing the Universe: '$L \times M/L$'. The overall light density of the Universe is reasonably well determined from redshift surveys of galaxies, so that a good determination of mass M and luminosity L for a single object suffices to determine $\Omega_{\rm m}$ – but only *if* the mass-to-light ratio were universal.

22.4.3 *Gravitational lensing*

A robust method for determining masses in cosmology is to use gravitational light deflection. Most systems can be treated as a geometrically thin gravitational lens, where the light bending is assumed to take place only at a single distance. Simple geometry then determines a mapping between the coordinates in the intrinsic source plane (S) and the observed image plane (I):

$$\alpha(D_{\rm L}\theta_{\rm I}) = \frac{D_{\rm S}}{D_{\rm LS}}(\theta_{\rm I} - \theta_{\rm S}), \qquad (22.65)$$

where the angles $\theta_{\rm I}, \theta_{\rm S}$, and α are in general two-dimensional vectors on the sky. The distances $D_{\rm LS}$ etc. are given by an extension of the usual distance-redshift formula:

$$D_{\rm LS} = \frac{R_0 S_k(\chi_{\rm S} - \chi_{\rm L})}{1 + z_{\rm S}}. \qquad (22.66)$$

This is the angular-diameter distance for objects on the source plane as perceived by an observer on the lens.

Solutions of this equation divide into weak lensing, where the mapping between source plane and image plane is one-to-one, and strong lensing, in which multiple imaging is possible. For circularly-symmetric lenses, an on-axis source is multiply imaged into a 'caustic' ring, whose radius is the Einstein radius:

$$\begin{aligned} \theta_{\rm E} &= \left(4GM\, \frac{D_{\rm LS}}{D_{\rm L} D_{\rm S}} \right)^{1/2} \\ &= \left(\frac{M}{10^{11.09} {\rm M}_\odot} \right)^{1/2} \left(\frac{D_{\rm L} D_{\rm S}/D_{\rm LS}}{\rm Gpc} \right)^{-1/2} \quad \text{arcsec} . \end{aligned} \qquad (22.67)$$

The observation of 'arcs' (segments of near-perfect Einstein rings) in rich clusters of galaxies has thus given very accurate masses for the central parts of clusters – generally in good agreement with other indicators, such as analysis of X-ray emission from the cluster IGM [81, 82].

Gravitational lensing has also developed into a particularly promising probe of cosmological structure on 10-Mpc to 100-Mpc scales. Weak image distortions manifest themselves as an additional ellipticity of galaxy images ('shear'), which can be observed by averaging many images together (the corresponding flux amplification is less readily detected). The result is a 'cosmic shear' field of order 1% ellipticity, coherent over scales of around 30 arcmin, which is directly related to the cosmic mass field. For this reason, weak lensing is seen as potentially the cleanest probe of matter fluctuations, next to the CMB. Already, impressive results have been obtained in measuring cosmological parameters, based on survey data from only $\sim 10^3$ deg^2 [83, 84]. A particular strength of lensing is its ability to measure the amplitude of mass fluctuations; this can be deduced from the amplitude of CMB fluctuations, but only with low precision on account of the poorly-known optical depth due to Compton scattering after reionization. However, the effect of weak lensing on the CMB map itself can be detected via the induced non-Gaussian signal, and this gives the CMB greater internal power [85]. The main difficulty of principle with lensing is that part of the signal is generated by small-scale density fluctuations; thus a model is required for nonlinear evolution, including astrophysical effects that separate baryons and dark matter. In this respect, the CMB is a cleaner probe of the primordial fluctuations.

22.4.4 *Density fluctuations*

The overall properties of the Universe are very close to being homogeneous; and yet telescopes reveal a wealth of detail on scales varying from single galaxies to large-scale structures of size exceeding 100 Mpc. The existence of these structures must be telling us something important about the initial conditions of the Big Bang, and about the physical processes that have operated subsequently. This motivates the study of the density perturbation field, defined as

$$\delta(\mathbf{x}) \equiv \frac{\rho(\mathbf{x}) - \langle\rho\rangle}{\langle\rho\rangle}. \qquad (22.68)$$

A critical feature of the δ field is that it inhabits a Universe that is isotropic and homogeneous in its large-scale properties. This suggests that the statistical properties of δ should also be statistically homogeneous – *i.e.*, it is a stationary random process.

It is often convenient to describe δ as a Fourier superposition:

$$\delta(\mathbf{x}) = \sum \delta_{\mathbf{k}} e^{-i\mathbf{k}\cdot\mathbf{x}}. \qquad (22.69)$$

We avoid difficulties with an infinite Universe by applying periodic boundary conditions in a cube of some large volume V. The cross-terms vanish when we compute the variance in the field, which is just a sum over modes of the power spectrum:

$$\langle\delta^2\rangle = \sum |\delta_{\mathbf{k}}|^2 \equiv \sum P(k). \qquad (22.70)$$

Note that the statistical nature of the fluctuations must be isotropic, so we write $P(k)$ rather than $P(\mathbf{k})$. The $\langle \dots \rangle$ average here is a volume average. Cosmological density fields are an example of an ergodic process, in which the average over a large

volume tends to the same answer as the average over a statistical ensemble.

The statistical properties of discrete objects sampled from the density field are often described in terms of N-point correlation functions, which represent the excess probability over random for finding one particle in each of N boxes in a given configuration. For the 2-point case, the correlation function is readily shown to be identical to the autocorrelation function of the δ field: $\xi(r) = \langle\delta(x)\delta(x+r)\rangle$.

The power spectrum and correlation function are Fourier conjugates, and thus are equivalent descriptions of the density field (similarly, k-space equivalents exist for the higher-order correlations). It is convenient to take the limit $V \to \infty$ and use k-space integrals, defining a dimensionless power spectrum, which measures the contribution to the fractional variance in density per unit logarithmic range of scale, as $\Delta^2(k) = d\langle\delta^2\rangle/d\ln k = Vk^3P(k)/2\pi^2$:

$$\xi(r) = \int \Delta^2(k)\,\frac{\sin kr}{kr}\,d\ln k; \quad \Delta^2(k) = \frac{2}{\pi}k^3\int_0^\infty \xi(r)\,\frac{\sin kr}{kr}\,r^2\,dr. \tag{22.71}$$

For many years, an adequate approximation to observational data on galaxies was $\xi = (r/r_0)^{-\gamma}$, with $\gamma \simeq 1.8$ and $r_0 \simeq 5\,h^{-1}$ Mpc. Modern surveys are now able to probe into the large-scale linear regime where unaltered traces of the curved post-recombination spectrum can be detected [86–88].

22.4.5 *Formation of cosmological structure*

The simplest model for the generation of cosmological structure is gravitational instability acting on some low-amplitude initial fluctuations (for the origin of which a theory such as inflation is required). If the perturbations are adiabatic (*i.e.*, fractionally perturb number densities of photons and matter equally), the linear growth law for matter fluctuations is simple:

$$\delta \propto \begin{cases} a^2(t) & \text{(radiation domination; } \Omega_{\rm r} = 1\text{);} \\ a(t) & \text{(matter domination; } \Omega_{\rm m} = 1\text{) .} \end{cases} \tag{22.72}$$

For low-density Universes, the growth is slower:

$$d\ln\delta/d\ln a \simeq \Omega_{\rm m}^{\gamma}(a), \tag{22.73}$$

where the parameter γ is close to 0.55 independent of the vacuum density [89,90].

The alternative perturbation mode is isocurvature: only the equation of state changes, and the total density is initially unperturbed. These modes perturb the total entropy density, and thus induce additional large-scale CMB anisotropies [91]. Although the character of perturbations in the simplest inflationary theories are purely adiabatic, correlated adiabatic and isocurvature modes are predicted in many models; the simplest example is the curvaton, which is a scalar field that decays to yield a perturbed radiation density. If the matter content already exists at this time, the overall perturbation field will have a significant isocurvature component. Such a prediction is inconsistent with current CMB data [92], and most analyses of CMB and large-scale structure (LSS) data assume the adiabatic case to hold exactly.

Linear evolution preserves the shape of the power spectrum. However, a variety of processes mean that growth actually depends on the matter content.

1. Pressure opposes gravity effectively for wavelengths below the horizon length while the Universe is radiation dominated. The *comoving* horizon size at $z_{\rm eq}$ is therefore an important scale:

$$D_{\rm H}(z_{\rm eq}) = \frac{2(\sqrt{2}-1)}{(\Omega_{\rm m}z_{\rm eq})^{1/2}H_0} = \frac{16.0}{\Omega_{\rm m}h^2}\,{\rm Mpc}\ . \tag{22.74}$$

2. At early times, dark matter particles will undergo free streaming at the speed of light, and so erase all scales up to the horizon – a process that only ceases when the particles go nonrelativistic. For light massive neutrinos, this happens at $z_{\rm eq}$; all structure up to the horizon-scale power-spectrum break is in fact erased. Hot(cold) dark matter models are thus sometimes dubbed large(small)-scale damping models.
3. A further important scale arises where photon diffusion can erase perturbations in the matter – radiation fluid; this process is named Silk damping.

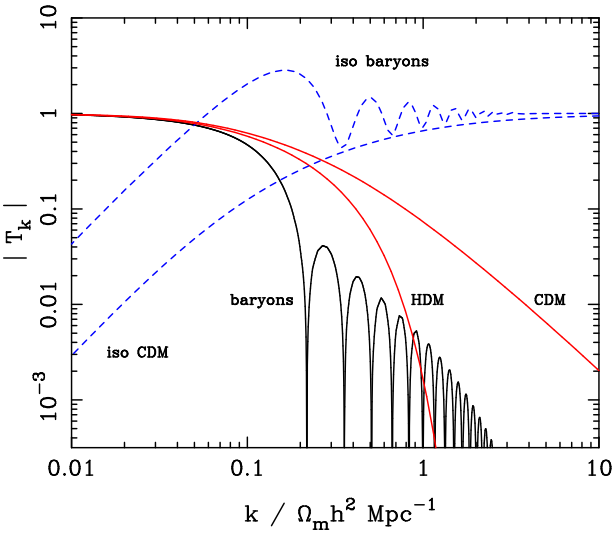

Figure 22.4: A plot of transfer functions for various models. For adiabatic models, $T_k \to 1$ at small k, whereas the opposite is true for isocurvature models. For dark-matter models, the characteristic wavenumber scales proportional to $\Omega_{\rm m}h^2$. The scaling for baryonic models does not obey this exactly; the plotted cases correspond to $\Omega_{\rm m} = 1$, $h = 0.5$.

The overall effect is encapsulated in the transfer function, which gives the ratio of the late-time amplitude of a mode to its initial value (see Fig. 22.4). The overall power spectrum is thus the primordial scalar-mode power law, times the square of the transfer function:

$$P(k) \propto k^{n_{\rm s}}\,T_k^2. \tag{22.75}$$

The most generic power-law index is $n_{\rm s} = 1$: the 'Zeldovich' or 'scale-invariant' spectrum. Inflationary models tend to predict a small 'tilt:' $|n_{\rm s} - 1| \lesssim 0.05$ [12,13]. On the assumption that the dark matter is cold, the power spectrum then depends on five parameters: $n_{\rm s}$, h, $\Omega_{\rm b}$, $\Omega_{\rm c}$ ($\equiv \Omega_{\rm m} - \Omega_{\rm b}$), and an overall amplitude. The latter is often specified as σ_8, the linear-theory fractional rms in density when a spherical filter of radius $8\,h^{-1}$ Mpc is applied in linear theory. This scale can be probed directly via weak gravitational lensing, and also via its effect on the abundance of rich galaxy clusters. The normalization derived from samples of X-ray clusters has been given variously as [93,94]

$$\sigma_8 = [0.746 \pm 0.012({\rm stat.}) \pm 0.022({\rm sys.})](\Omega_{\rm m}/0.3)^{-0.47}; \tag{22.76}$$

$$\sigma_8 = [0.81 \pm 0.03](\Omega_{\rm m}/0.3)^{-0.17}. \tag{22.77}$$

The higher figure is well consistent with *Planck*, whereas the lower is rather similar to the normalization inferred from weak lensing [95]:

$$\sigma_8 \simeq [0.790^{+0.018}_{-0.014}](\Omega_{\rm m}/0.3)^{-0.5}. \tag{22.78}$$

This figure is in 1.9σ tension with the *Planck* values of $(\sigma_8, \Omega_{\rm m}) = (0.811 \pm 0.006, 0.315 \pm 0.007)$. If real, such a discrepancy could indicate interesting new physics; but the current evidence is not strong enough to make such a claim. However, it is worth noting that the CMB requires an almost perfect degeneracy, $\Omega_{\rm m}h^3 =$ constant for flat models, so that raising h as far as allowed by the CMB would require a lower density, which would reduce the tension with the amplitude of the lensing measurements.

A direct measure of mass inhomogeneity is valuable, since the galaxies inevitably are biased with respect to the mass. This means that the fractional fluctuations in galaxy number, $\delta n/n$,

may differ from the mass fluctuations, $\delta\rho/\rho$. It is commonly assumed that the two fields obey some proportionality on large scales where the fluctuations are small, $\delta n/n = b\delta\rho/\rho$, but even this is not guaranteed [96].

The main shape of the transfer function is a break around the horizon scale at $z_{\rm eq}$, which depends just on $\Omega_{\rm m}h$ when wavenumbers are measured in observable units ($h\,{\rm Mpc}^{-1}$). For reasonable baryon content, weak oscillations in the transfer function are also expected, and these BAOs (baryon acoustic oscillations) have been clearly detected [97,98]. As well as directly measuring the baryon fraction, the scale of the oscillations directly measures the acoustic horizon at decoupling; this can be used as an additional standard ruler for cosmological tests, and the BAO signature has become one of the most important applications of large galaxy surveys. Overall, current power-spectrum data [86–88] favor $\Omega_{\rm m}h \simeq 0.20$ and a baryon fraction of about 0.15 for $n_{\rm s} \simeq 1$ (see Fig. 22.5).

In principle, accurate data over a wide range of k could determine both $\Omega_{\rm m}h$ and n, but in practice there is a strong degeneracy between these. In order to constrain $n_{\rm s}$ itself, it is necessary to examine data on anisotropies in the CMB.

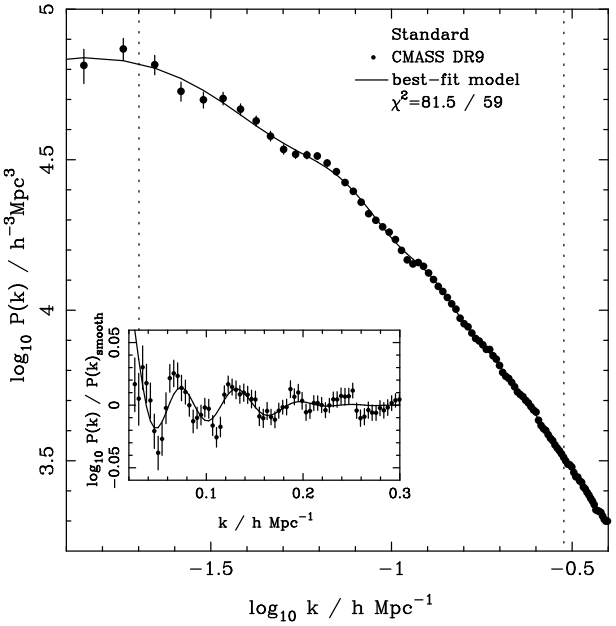

Figure 22.5: The galaxy power spectrum from the SDSS BOSS survey [88]. The solid points with error bars show the power estimate. The solid line shows a standard ΛCDM model with $\Omega_{\rm b}h^2 \simeq 0.02$ and $\Omega_{\rm m}h \simeq 0.2$. The inset amplifies the region where BAO features are visible. The fact that these perturb the power by $\sim 20\%$ rather than order unity is direct evidence that the matter content of the Universe is dominated by collisionless dark matter.

22.4.6 *CMB anisotropies*

The CMB has a clear dipole anisotropy, of magnitude 1.23×10^{-3}. This is interpreted as being due to the Earth's motion, which is equivalent to a peculiar velocity for the Milky Way of

$$v_{\rm MW} \simeq 600\,{\rm km\,s^{-1}} \quad \text{towards} \quad (\ell, b) \simeq (270^\circ, 30^\circ). \tag{22.79}$$

A continuing challenge in cosmology is to demonstrate that this dipole is indeed kinematic, as opposed to representing a violation of large-scale isotropy. Galaxy surveys have attempted to identify the accelerating superclusters responsible for the motion [99], but there are also claims that the observed matter distribution contains an intrinsic dipole, which would be incompatible with the standard interpretation [100], but see also Ref. [101].

All higher-order multipole moments of the CMB are however much smaller than the dipole (of order 10^{-5}), and interpreted as signatures of density fluctuations at last scattering ($\simeq 1100$). To analyze these, the sky is expanded in spherical harmonics as explained in the review on the CMB – Sec. 29 of this *Review*. The dimensionless power per ln k or 'bandpower' for the CMB is defined as

$$\mathcal{T}^2(\ell) = \frac{\ell(\ell+1)}{2\pi}\, C_\ell. \tag{22.80}$$

This function encodes information from the three distinct mechanisms that cause CMB anisotropies:

- (1) Gravitational (Sachs – Wolfe) perturbations. Photons from high-density regions at last scattering have to climb out of potential wells, and are thus redshifted.
- (2) Intrinsic (adiabatic) perturbations. In high-density regions, the coupling of matter and radiation can compress the radiation also, giving a higher temperature.
- (3) Velocity (Doppler) perturbations. The plasma has a nonzero velocity at recombination, which leads to Doppler shifts in frequency and hence shifts in brightness temperature.

Because the potential fluctuations obey Poisson's equation, $\nabla^2\Phi/a^2 = 4\pi G\bar{\rho}\delta$, and the comoving velocity field satisfies the continuity equation $\nabla\cdot\mathbf{u} = -\dot{\delta}$, the resulting different powers of k ensure that the Sachs-Wolfe effect dominates on large scales and adiabatic effects on small scales.

The relation between angle and comoving distance on the last-scattering sphere requires the comoving angular-diameter distance to the last-scattering sphere; because of its high redshift, this is effectively identical to the horizon size at the present epoch, $D_{\rm H}$:

$$\begin{aligned} D_{\rm H} &= \frac{2}{\Omega_{\rm m}H_0} \quad (\Omega_{\rm v} = 0); \\ D_{\rm H} &\simeq \frac{2}{\Omega_{\rm m}^{0.4}H_0} \quad (\text{flat} : \Omega_{\rm m} + \Omega_{\rm v} = 1)\ . \end{aligned} \tag{22.81}$$

These relations show how the CMB is strongly sensitive to curvature: the horizon length at last scattering is $\propto 1/\sqrt{\Omega_{\rm m}}$, so that this subtends an angle that is virtually independent of $\Omega_{\rm m}$ for a flat model. Observations of a peak in the CMB power spectrum at relatively large scales ($\ell \simeq 221$) are thus strongly inconsistent with zero-Λ models with low density: current CMB + BAO + lensing data require $\Omega_{\rm m} + \Omega_{\rm v} = 0.999 \pm 0.004$ (95%) [24]. (See *e.g.*, Fig. 22.2).

In addition to curvature, the CMB encodes information about several other key cosmological parameters. Within the compass of simple adiabatic CDM models, there are nine of these:

$$\omega_{\rm c},\ \omega_{\rm b},\ \Omega_{\rm tot},\ h,\ \tau,\ n_{\rm s},\ n_{\rm t},\ r,\ Q. \tag{22.82}$$

The symbol ω denotes the physical density, Ωh^2: the transfer function depends only on the densities of CDM ($\omega_{\rm c}$) and baryons ($\omega_{\rm b}$). Transcribing the power spectrum at last scattering into an angular power spectrum brings in the total density parameter ($\Omega_{\rm tot} \equiv \Omega_{\rm m} + \Omega_{\rm v} = \Omega_{\rm c} + \Omega_{\rm b} + \Omega_{\rm v}$) and h: there is a near-exact geometrical degeneracy [102] between these that keeps the angular-diameter distance to last scattering invariant, so that models with substantial spatial curvature and large vacuum energy cannot be ruled out without prior knowledge of the Hubble parameter. Alternatively, the CMB alone cannot measure the Hubble parameter without taking into account the line-of-sight information from CMB lensing.

A further possible degeneracy involves the tensor contribution to the CMB anisotropies. These are important at large scales (up to the horizon scales); for smaller scales, only scalar fluctuations (density perturbations) are important. Each of these components is characterized by a spectral index, n, and a ratio between the power spectra of tensors and scalars (r). See Cosmological Parameters – Sec. 25 of this *Review* for a technical definition of the r parameter. Finally, the overall amplitude of the spectrum must be specified (Q), together with the optical depth to Compton scattering owing to recent reionization (τ). Adding a large tensor contribution reduces the contrast between low ℓ and the peak at $\ell \simeq 221$ (because the tensor spectrum has no acoustic component). The previous relative height of the peak can be recovered by increasing $n_{\rm s}$ to increase the small-scale power in the scalar

component; this in turn over-predicts the power at $\ell \sim 1000$, but this effect can be counteracted by raising the baryon density [103]. This approximate 3-way degeneracy is broken as we increase the range of multipoles sampled.

The reason the tensor component is introduced, and why it is so important, is that it is the only non-generic prediction of inflation. Slow-roll models of inflation involve two dimensionless parameters:

$$\epsilon \equiv \frac{M_{\rm P}^2}{16\pi}\left(\frac{V'}{V}\right)^2; \qquad \eta \equiv \frac{M_{\rm P}^2}{8\pi}\left(\frac{V''}{V}\right), \tag{22.83}$$

where V is the inflaton potential, and dashes denote derivatives with respect to the inflation field. In terms of these, the tensor-to-scalar ratio is $r \simeq 16\epsilon$, and the spectral indices are $n_{\rm s} = 1-6\epsilon+2\eta$ and $n_{\rm t} = -2\epsilon$. The natural expectation of inflation is that the quasi-exponential phase ends once the magnitudes of the slow-roll parameters become of order unity, so that both $n_{\rm s} \neq 1$ and a significant tensor component are expected. These predictions can be avoided in some models, but it is undeniable that observation of such features would be a great triumph for inflation. Cosmology therefore stands at a fascinating point, given that the most recent CMB data reject the zero-tensor $n_{\rm s} = 1$ model at more than 8σ: $n_{\rm s} = 0.965 \pm 0.004$ [24]. This rejection is strong enough that it is also able to break the tensor degeneracy, so that no model with $n_{\rm s} = 1$ is acceptable, whatever the value of r.

The current limit on r is < 0.036 at 95% confidence [104, 105]. In conjunction with the measured value of $n_{\rm s}$, this upper limit sits close to the prediction of a linear potential (i.e. $|\eta| \ll |\epsilon|$). Any further reduction in the limit on r will force η to be negative – i.e. a convex potential at the point where LSS scales were generated (sometimes called a 'hilltop'), in contrast to simple early models such as $V(\phi) = m^2\phi^2$ or $\lambda\phi^4$, which are now excluded. Examples of models that are currently in excellent agreement with the *Planck* results are the Starobinsky model of $\mathcal{R} + \mathcal{R}^2$ gravity [106], or the Higgs-inflation model where the Higgs field is non-minimally coupled [107]. Assuming 55 e-foldings of inflation, these models predict $n_{\rm s} = 0.965$ and $r = 0.0035$. Assuming that no systematic error in the CMB data can be identified, cosmology has thus passed a critical hurdle in rejecting scale-invariant fluctuations. The years ahead will be devoted to the task of searching for the tensor fluctuations – for which the main tool will be the polarization of the CMB [14].

22.4.6.1 *CMB foregrounds*

As the quality of CMB data improves, there is a growing interest in effects that arise along the line of sight. The CMB temperature is perturbed by dark-matter structures and by Compton scattering from ionized gas. In the former case, we have the integrated Sachs-Wolfe effect, which is sensitive to the time derivative of the gravitational potential. In the linear regime, this is damped when the Universe becomes Λ-dominated, and this is an independent way of detecting Λ [108]. The potential also causes gravitational lensing of the CMB: structures at $z \simeq 1$–2 displace features on the CMB sky by about 2 arcmin over coherent degree-scale patches. Detection of these distortions allows a map to be made of overdensity projected from $z = 0$ to 1100 [85]. This is a very powerful calibration for direct studies of gravitational lensing using galaxies. Finally, Comptonization affects the CMB in two ways: the thermal Sunyaev-Zeldovich effect measures the blurring of photon energies by hot gas; and the kinetic Sunyaev-Zeldovich effect is sensitive to the bulk velocity of the gas. Both these effects start to dominate over the intrinsic CMB fluctuations at multipoles $\ell \gtrsim 2000$ [109].

22.4.7 *Probing dark energy and the nature of gravity*

The most radical element of our current cosmological model is the dark energy that accelerates the expansion. The energy density of this component is approximately $(2.2\,{\rm meV})^4$ (for $w = -1$, $\Omega_v = 0.68$, $h = 0.67$), or roughly $10^{-123} M_{\rm P}^4$, and such an unnaturally small number is hard to understand. Various quantum effects (most simply, zero-point energy) should make contributions to the vacuum energy density. These may be truncated by new physics at high energy, but this presumably occurs at $> 1\,{\rm TeV}$ scales, not meV; thus the apparent energy scale of the vacuum is at least 10^{15} times smaller than its natural value. A classic review of this situation is given by Weinberg [53], which lists extreme escape routes – especially the multiverse viewpoint, according to which low values of Λ are rare, but high values suppress the formation of structure and observers. It is certainly impressive that Weinberg used such reasoning to predict the value of Λ before any data strongly indicated a non-zero value.

But it may be that the phenomenon of dark energy is entirely illusory. The necessity for this constituent arises from using the Friedmann equation to describe the evolution of the cosmic expansion; if this equation is incorrect, it would require the replacement of Einstein's relativistic theory of gravity with some new alternative. A frontier of current cosmological research is to distinguish these possibilities [110, 111]. We also note that it has been suggested that dark energy might be an illusion even within general relativity, owing to an incorrect treatment of averaging in an inhomogeneous Universe [112,113]. Most would argue that a standard Newtonian treatment of such issues should be adequate inside the cosmological horizon, but debate on this issue continues.

Dark energy can differ from a classical cosmological constant in being a dynamical phenomenon [114, 115], *e.g.*, a rolling scalar field (sometimes dubbed 'quintessence'). Empirically, this means that it is endowed with two thermodynamic properties that astronomers can try to measure: the bulk equation of state, and the sound speed. If the sound speed is close to the speed of light, the effect of this property is confined to very large scales, and mainly manifests itself in the large-angle multipoles of the CMB anisotropies [116]. The equation of state parameter governs the rate of change of the vacuum density: $d\ln\rho_v/d\ln a = -3(1+w)$, so it can be accessed via the evolving expansion rate, $H(a)$. This can be measured most cleanly by using the inbuilt natural ruler of large-scale structure: the BAO horizon scale [117]:

$$D_{\rm BAO} \simeq 147.0\,(\Omega_{\rm m}h^2/0.1424)^{-0.253}(\Omega_{\rm b}h^2/0.0224)^{-0.128}\ {\rm Mpc}. \tag{22.84}$$

Observing the equivalent acoustic scale at last scattering in the CMB yields the precise geometrical degeneracy $\Omega_m h^3 = 0.09633 \pm 0.00029$ [24].

$H(a)$ is measured by radial clustering, since $dr/dz = c/H$; clustering in the plane of the sky measures the integral of this. The expansion rate is also measured by the growth of density fluctuations, where the pressure-free growth equation for the density perturbation is $\ddot{\delta} + 2H(a)\dot{\delta} = 4\pi G\rho_0\,\delta$. Thus, both the scale and amplitude of density fluctuations are sensitive to $w(a)$ – but only weakly. These observables typically change by only $\sim 0.2\%$ for a 1% change in w. Current constraints [24] place a constant w to within 5–10% of -1, depending on the data combination chosen. A substantial improvement in this precision will require us to limit systematics in data to a few parts in 1000.

Testing whether theories of gravity require revision can also be done using data on cosmological inhomogeneities. Two separate issues arise, concerning the metric perturbation potentials Ψ and Φ, which affect respectively the time and space parts of the metric. In Einstein gravity, these potentials are both equal to the Newtonian gravitational potential, which satisfies Poisson's equation: $\nabla^2\Phi/a^2 = 4\pi G\bar{\rho}\delta$. Empirically, modifications of gravity require us to explore a change with scale and with time of the 'slip' (Ψ/Φ) and the effective G on the rhs of the Poisson equation. The former aspect can only be probed via gravitational lensing, whereas the latter can be addressed on 10–100 Mpc scales via the growth of clustering. Various schemes for parameterizing modified gravity exist, but a practical approach is to assume that the growth rate can be tied to the density parameter: $d\ln\delta/d\ln a = \Omega_{\rm m}^{\gamma}(a)$ [89,90]. The parameter γ is close to 0.55 for standard relativistic gravity, but can differ by around 0.1 from this value in many non-standard models. Clearly this parameterization is incomplete, since it explicitly rejects the possibility of early dark energy ($\Omega_{\rm m}(a) \to 1$ as $a \to 0$), but it is a convenient way of capturing the power of various experiments. Current data are consistent with standard ΛCDM [118], and exclude variations in slip or effective G of larger than a few times 10%.

Current planning envisages a set of satellite probes that, a decade hence, will have pursued these fundamental tests via gravitational lensing measurements over thousands of square degrees,

$> 10^8$ redshifts, and photometry of > 1000 supernovae (Euclid in Europe, Roman Space Telescope in the USA) [22, 23]. These experiments will measure both w and the perturbation growth rate to an accuracy of around 1%. The outcome will be either a validation of the standard relativistic vacuum-dominated Big Bang cosmology at a level of precision far beyond anything attempted to date, or the opening of entirely new directions in cosmological models. For a more complete discussion of dark energy and future probes see Dark Energy – Sec. 28 of this *Review*.

23. Inflation

Revised August 2023 by J. Ellis (King's Coll. London; CERN) and D. Wands (Portsmouth U.).

23.1 Motivation and Introduction

The standard Big-Bang model of cosmology provides a successful framework in which to understand the thermal history of our Universe and the growth of cosmic structure, but it is essentially incomplete. As described in Sec. 22.2.4, Big-Bang cosmology requires very specific initial conditions. It postulates a uniform cosmological background, described by a spatially-flat, homogeneous and isotropic Robertson-Walker (RW) metric (Eq. (22.1) in "Big Bang Cosmology" review), with scale factor $R(t)$. Within this setting, it also requires an initial almost scale-invariant distribution of primordial density perturbations as seen, for example, in the cosmic microwave background (CMB) radiation (described in Chap. 29, "Cosmic Microwave Background" review), on scales far larger than the causal horizon at the time the CMB photons last scattered.

The Hubble expansion rate, $H \equiv \dot{R}/R$, in a RW cosmology is given by the Friedmann constraint equation (Eq. (22.8) in "Big Bang Cosmology" review)

$$H^2 = \frac{8\pi\rho}{3M_P^2} + \frac{\Lambda}{3} - \frac{k}{R^2}\,, \tag{23.1}$$

where k/R^2 is the intrinsic spatial curvature. We use natural units such that the speed of light $c = 1$ and hence we have the Planck mass $M_P = G_N^{-1/2} \simeq 10^{19}$ GeV (see "Astrophysical Constants and Parameters"). A cosmological constant, Λ, of the magnitude required to accelerate the Universe today (see Chap. 28, "Dark Energy" review) would have been completely negligible in the early Universe where the energy density $\rho \gg M_P^2\Lambda \sim 10^{-12}(\mathrm{eV})^4$. The standard early Universe cosmology, described in Sec. 22.1.5 in "Big Bang Cosmology" review, is thus dominated by non-relativistic matter ($p_m \ll \rho_m$) or radiation ($p_r = \rho_r/3$ for an isotropic distribution). This leads to a decelerating expansion with $\ddot{R} < 0$.

The hypothesis of inflation [1,2] postulates a period of accelerated expansion, $\ddot{R} > 0$, in the very early Universe, preceding the standard radiation-dominated era, which offers a physical model for the origin of these initial conditions, as reviewed in [3–7]. Such a period of accelerated expansion (i) drives a curved Robertson-Walker spacetime (with spherical or hyperbolic spatial geometry) towards spatial flatness, and (ii) it also expands the causal horizon beyond the present Hubble length, so as to encompass all the scales relevant to describe the large-scale structure observed in our Universe today, via the following two mechanisms.

1. A spatially-flat Universe with vanishing spatial curvature, $k = 0$, has the dimensionless density parameter $\Omega_{tot} = 1$, where we define (Eq. (22.13) in "Big Bang Cosmology" review; see Chap. 25, "Cosmological Parameters" review for more complete definitions)

$$\Omega_{tot} \equiv \frac{8\pi\rho_{tot}}{3M_P^2H^2}\,, \tag{23.2}$$

with $\rho_{tot} \equiv \rho + \Lambda M_P^2/8\pi$. If we re-write the Friedmann constraint (Eq. (23.1)) in terms of Ω_{tot} we have

$$1 - \Omega_{tot} = -\frac{k}{\dot{R}^2}\,. \tag{23.3}$$

Observations require $|1-\Omega_{tot,0}| < 0.005$ today [8], where the subscript 0 denotes the present-day value. Taking the time derivative of Eq. (23.3) we obtain

$$\frac{d}{dt}\left(1 - \Omega_{tot}\right) = -2\frac{\ddot{R}}{\dot{R}}\left(1 - \Omega_{tot}\right)\,. \tag{23.4}$$

Thus in a decelerating expansion, $\dot{R} > 0$ and $\ddot{R} < 0$, any small initial deviation from spatial flatness grows, $(d/dt)|1-\Omega_{tot}| > 0$. A small value such as $|1-\Omega_{tot,0}| < 0.005$ today requires an even smaller value at earlier times, e.g., $|1 - \Omega_{tot}| < 10^{-5}$ at the last scattering of the CMB, which appears unlikely, unless for some reason space is exactly flat. However, an extended period of accelerated expansion in the very early Universe, with $\dot{R} > 0$ and $\ddot{R} > 0$ and hence $(d/dt)|1 - \Omega_{tot}| < 0$, can drive Ω_{tot} sufficiently close to unity, so that $|1 - \Omega_{tot,0}|$ remains unobservable small today, even after the radiation- and matter-dominated eras, for a wide range of initial values of Ω_{tot}.

2. The comoving distance (the present-day proper distance) traversed by light between cosmic time t_1 and t_2 in an expanding Universe can be written, (see Eq. (22.32) in "Big Bang Cosmology" review), as

$$D_0(t_1, t_2) = R_0\int_{t_1}^{t_2}\frac{dt}{R(t)} = R_0\int_{\ln R_1}^{\ln R_2}\frac{d(\ln R)}{\dot{R}}\,. \tag{23.5}$$

In standard decelerated (radiation- or matter-dominated) cosmology the integrand, $1/\dot{R}$, decreases towards the past, and there is a finite comoving distance traversed by light (a particle horizon) since the Big Bang ($R_1 \to 0$). For example, the comoving size of the particle horizon at the CMB last-scattering surface ($R_2 = R_{lss}$) corresponds to $D_0 \sim 100\,\mathrm{Mpc}$, or approximately 1° on the CMB sky today (see Sec. 22.2.4 in "Big Bang Cosmology" review). However, during a period of inflation, $1/\dot{R}$ increases towards the past, and hence the integral (Eq. (23.5)) diverges as $R_1 \to 0$, allowing an arbitrarily large causal horizon, dependent only upon the duration of the accelerated expansion. Assuming that the Universe inflates with a finite Hubble rate H_* at $t_1 = t_*$, ending with $H_{end} < H_*$ at $t_2 = t_{end}$, we have

$$D_0(t_*, t_{end}) > \left(\frac{R_0}{R_{end}}\right)H_*^{-1}\left(e^{N_*} - 1\right)\,, \tag{23.6}$$

where $N_* \equiv \ln(R_{end}/R_*)$ describes the duration of inflation, measured in terms of the logarithmic expansion (or "e-folds") from $t_1 = t_*$ up to the end of inflation at $t_2 = t_{end}$, and R_0/R_{end} is the subsequent expansion from the end of inflation to the present day. If inflation occurs above the TeV scale, the comoving Hubble scale at the end of inflation, $(R_0/R_{end})H_{end}^{-1}$, is less than one astronomical unit ($\sim 10^{11}$ m), and a causally-connected patch can encompass our entire observable Universe today, which has a size $D_0 > 30$ Gpc, if there were more than 40 e-folds of inflation ($N_* > 40$). If inflation occurs at the GUT scale (10^{15} GeV) then we require more than 60 e-folds.

Producing an accelerated expansion in general relativity requires an energy-momentum tensor with negative pressure, $p < -\rho/3$ (see Eq. (22.9) in "Big Bang Cosmology" review and Chap. 28, "Dark Energy" review), quite different from the hot dense plasma of relativistic particles in the hot Big Bang. However a positive vacuum energy $V > 0$ does exert a negative pressure, $p_V = -\rho_V$. The work done by the cosmological expansion must be negative in this case so that the local vacuum energy density remains constant in an expanding Universe, $\dot{\rho}_V = -3H(\rho_V + p_V) = 0$. Therefore, a false vacuum state can drive an exponential expansion, corresponding to a de Sitter spacetime with a constant Hubble rate $H^2 = 8\pi\rho_V/3M_P^2$ on spatially-flat hypersurfaces.

A constant vacuum energy V, equivalent to a cosmological constant Λ in the Friedmann equation Eq. (23.1), cannot provide a complete description of inflation in the early Universe, since inflation must necessarily have come to an end in order for the standard Big-Bang cosmology to follow. A phase transition to the present true vacuum is required to release the false vacuum energy into the energetic plasma of the hot Big Bang and produce the large total entropy of our observed Universe today. Thus, we must necessarily study dynamical models of inflation, where the time-invariance of the false vacuum state is broken by a time-dependent field. A first-order phase transition would produce a very inhomogeneous Universe [9] unless a time-dependent scalar field leads to a rapidly changing percolation rate [10–12]. However,

a second-order phase transition [13, 14], controlled by a slowly-rolling scalar field, can lead to a smooth classical exit from the vacuum-dominated phase.

As a spectacular bonus, quantum fluctuations in that scalar field could provide a source of almost scale-invariant density fluctuations [15, 16], as detected in the CMB (see Chap. 29), which are thought to be the origin of the structures seen in the Universe today.

Accelerated expansion and primordial perturbations can also be produced in some modified gravity theories (e.g., [1, 17]), which introduce additional non-minimally coupled degrees of freedom. Such inflation models can often be conveniently studied by transforming variables to an 'Einstein frame' in which Einstein's equations apply with minimally coupled scalar fields [18–20].

In the following we will review scalar field cosmology in general relativity and the spectra of primordial fluctuations produced during inflation, before studying selected inflation models.

23.2 Scalar Field Cosmology

The energy-momentum tensor for a canonical scalar field ϕ with self-interaction potential $V(\phi)$ is given in Eq. (22.52) in "Big Bang Cosmology" review. In a homogeneous background this corresponds to a perfect fluid with density

$$\rho = \frac{1}{2}\dot{\phi}^2 + V(\phi)\,, \tag{23.7}$$

and isotropic pressure

$$p = \frac{1}{2}\dot{\phi}^2 - V(\phi)\,, \tag{23.8}$$

while the 4-velocity is proportional to the gradient of the field, $u^\mu \propto \nabla^\mu\phi$.

A field with vanishing potential energy acts like a stiff fluid with $p = \rho = \dot{\phi}^2/2$, whereas if the time-dependence vanishes we have $p = -\rho = -V$ and the scalar field is uniform in time and space. Thus a classical, potential-dominated scalar-field cosmology, with $p \simeq -\rho$, can naturally drive a quasi-de Sitter expansion; the slow time-evolution of the energy density weakly breaks the exact $O(1,3)$ symmetry of four-dimensional de Sitter spacetime down to a Robertson-Walker (RW) spacetime, where the scalar field plays the role of the cosmic time coordinate.

In a scalar-field RW cosmology the Friedmann constraint equation (Eq. (23.1)) reduces to

$$H^2 = \frac{8\pi}{3M_P^2}\left(\frac{1}{2}\dot{\phi}^2 + V\right) - \frac{k}{R^2}\,, \tag{23.9}$$

while energy conservation (Eq. (22.10) in "Big Bang Cosmology" review) for a homogeneous scalar field reduces to the Klein-Gordon equation of motion (Eq. (22.54) in "Big Bang Cosmology" review)

$$\ddot{\phi} = -3H\dot{\phi} - V'(\phi)\,. \tag{23.10}$$

The evolution of the scalar field is thus driven by the potential gradient $V' = dV/d\phi$, subject to damping by the Hubble expansion $3H\dot{\phi}$.

If we define the Hubble slow-roll parameter

$$\epsilon_H \equiv -\frac{\dot{H}}{H^2}\,, \tag{23.11}$$

then we see that inflation ($\ddot{R} > 0$ and hence $\dot{H} > -H^2$) requires $\epsilon_H < 1$. In this case the spatial curvature decreases relative to the scalar field energy density as the Universe expands. Hence, in the following we drop the spatial curvature and consider a spatially-flat RW cosmology, assuming that inflation has lasted sufficiently long that our observable Universe is very close to spatially flatness. However, we note that bubble nucleation, leading to a first-order phase transition during inflation, can lead to homogeneous hypersurfaces with a hyperbolic ('open') geometry, effectively resetting the spatial curvature inside the bubble [21]. This is the basis of so-called open inflation models [22–24], where inflation inside the bubble has a finite duration, leaving a finite negative spatial curvature.

In a scalar field-dominated cosmology (Eq. (23.11)) gives

$$\epsilon_H = \frac{3\dot{\phi}^2}{2V + \dot{\phi}^2}\,, \tag{23.12}$$

in which case we see that inflation requires a potential-dominated expansion, $\dot{\phi}^2 < V$.

23.2.1 *Slow-Roll Inflation*

It is commonly assumed that the field acceleration term, $\ddot{\phi}$, in (Eq. (23.10)) can be neglected, in which case one can give an approximate solution for the inflationary attractor [25]. This slow-roll approximation reduces the second-order Klein-Gordon equation (Eq. (23.10)) to a first-order system, which is over-damped, with the potential gradient being approximately balanced against to the Hubble damping:

$$3H\dot{\phi} \simeq -V'\,, \tag{23.13}$$

and at the same time that the Hubble expansion (Eq. (23.9)) is dominated by the potential energy

$$H^2 \simeq \frac{8\pi}{3M_P^2}V(\phi)\,, \tag{23.14}$$

corresponding to $\epsilon_H \ll 1$.

A necessary condition for the validity of the slow-roll approximation is that the potential slow-roll parameters

$$\epsilon \equiv \frac{M_P^2}{16\pi}\left(\frac{V'}{V}\right)^2\,, \quad \eta \equiv \frac{M_P^2}{8\pi}\left(\frac{V''}{V}\right)\,, \tag{23.15}$$

are small, i.e., $\epsilon \ll 1$ and $|\eta| \ll 1$, requiring the potential to be correspondingly flat. If we identify V'' with the effective mass of the field, we see that the slow-roll approximation requires that the mass of the scalar field must be small compared with the Hubble scale. We note that the Hubble slow-roll parameter (Eq. (23.11)) coincides with the potential slow-roll parameter, $\epsilon_H \simeq \epsilon$, to leading order in the slow-roll approximation.

The slow-roll approximation allows one to determine the Hubble expansion rate as a function of the scalar field value, and vice versa. In particular, we can express, in terms of the scalar field value during inflation, the total logarithmic expansion, or number of "e-folds":

$$\begin{aligned} N_* &\equiv \ln\left(\frac{R_{end}}{R_*}\right) \\ &= \int_{t_*}^{t_{end}} H dt \simeq -\int_{\phi_*}^{\phi_{end}} \sqrt{\frac{4\pi}{\epsilon}}\frac{d\phi}{M_P} \text{ for } V' > 0\,. \end{aligned} \tag{23.16}$$

Given that the slow-roll parameters are approximately constant during slow-roll inflation, $d\epsilon/dN \simeq 2\epsilon(\eta - 2\epsilon) = \mathcal{O}(\epsilon^2)$, we have

$$N_* \simeq \frac{4}{\sqrt{\epsilon}}\frac{\Delta\phi}{M_P}\,. \tag{23.17}$$

Since we require $N > 40$ to solve the flatness, horizon and entropy problems of the standard Big Bang cosmology, we require either very slow roll, $\epsilon < 0.01$, or a large change in the value of the scalar field relative to the Planck scale, $\Delta\phi > M_P$.

23.2.2 *Reheating*

Slow-roll inflation can lead to an exponentially large Universe, close to spatial flatness and homogeneity, but the energy density is locked in the potential energy of the scalar field, and needs to be converted to particles and thermalised to recover a hot Big Bang cosmology at the end of inflation [26, 27]. This process is usually referred to as reheating, although there was not necessarily any preceding thermal era. Reheating can occur when the scalar field evolves towards the minimum of its potential, converting the potential energy first to kinetic energy. This can occur either through the breakdown of the slow-roll condition in single-field models, or due to an instability triggered by the inflaton reaching

a critical value, in multi-field models known as hybrid inflation models [28].

Close to a simple minimum, the scalar field potential can be described by a quadratic function, $V = m^2\phi^2/2$, where m is the mass of the field. We can obtain slow-roll inflation in such a potential at large field values, $\phi \gg M_P$. However, for $\phi \ll M_P$ the field approaches an oscillatory solution:

$$\phi(t) \simeq \frac{M_P}{\sqrt{3\pi}} \frac{\sin(mt)}{mt} \,. \tag{23.18}$$

For $|\phi| < M_P$ the Hubble rate drops below the inflaton mass, $H < m$, and the field oscillates many times over a Hubble time. Averaging over several oscillations, $\Delta t \gg m^{-1}$, we find $\langle\dot\phi^2/2\rangle_{\Delta t} \simeq \langle m^2\phi^2/2\rangle_{\Delta t}$ and hence

$$\langle\rho\rangle_{\Delta t} \simeq \frac{M_P^2}{6\pi t^2} \,, \quad \langle p\rangle_{\Delta t} \simeq 0 \,. \tag{23.19}$$

This coherent oscillating field corresponds to a condensate of non-relativistic massive inflaton particles, driving a matter-dominated era at the end of inflation, with scale factor $R \propto t^{2/3}$.

The inflaton condensate can lose energy through perturbative decays due to terms in the interaction Lagrangian, such as

$$\mathcal{L}_{int} \subset -\lambda_i\sigma\phi\chi_i^2 - \lambda_j\phi\bar\psi_j\psi_j \tag{23.20}$$

that couple the inflation to scalar fields χ_i or fermions ψ_j, where σ has dimensions of mass and the λ_i are dimensionless couplings. When the mass of the inflaton is much larger than the decay products, the decay rate is given by [29]

$$\Gamma_i = \frac{\lambda_i^2\sigma^2}{8\pi m} \,, \quad \Gamma_j = \frac{\lambda_j^2 m}{8\pi} \,. \tag{23.21}$$

These decay products must in turn thermalise with Standard Model particles before we recover conventional hot Big Bang cosmology. An upper limit on the reheating temperature after inflation is given by [27]

$$T_{rh} = 0.2 \left(\frac{100}{g_*}\right)^{1/4} \sqrt{M_P\Gamma_{tot}} \,, \tag{23.22}$$

where g_* is the effective number of degrees of freedom and Γ_{tot} is the total decay rate for the inflaton, which is required to be less than m for perturbative decay.

The baryon asymmetry of the Universe must be generated after the main release of entropy during inflation, which is an important constraint on possible models. Also, the fact that the inflaton mass is much larger than the mass scale of the Standard Model opens up the possibility that it may decay into massive stable or metastable particles that could be connected with dark matter, constraining possible models. For example, in the context of supergravity models the reheat temperature is constrained by the requirement that gravitinos are not overproduced, potentially destroying the successes of Big Bang nucleosynthesis. For a range of gravitino masses one must require $T_{rh} < 10^9$ GeV [30, 31].

The process of inflaton decay and reheating can be significantly altered by interactions leading to space-time dependences in the effective masses of the fields. In particular, parametric resonance can lead to explosive, non-perturbative decay of the inflaton in some cases, a process often referred to as preheating [26, 32]. For example, an interaction term of the form

$$\mathcal{L}_{int} \subset -\lambda^2\phi^2\chi^2 \,, \tag{23.23}$$

leads to a time-dependent effective mass for the χ field as the inflaton ϕ oscillates. This can lead to non-adiabatic particle production if the bare mass of the χ field is small for large couplings or for rapid changes of the inflaton field. The process of preheating is highly model-dependent, but it highlights the possible role of non-thermal particle production after and even during inflation.

23.3 Primordial Perturbations from Inflation

Although inflation was originally discussed as a solution to the problem of initial conditions required for homogeneous and isotropic hot Big Bang cosmology, it was soon realised that inflation also offered a mechanism to generate the inhomogeneous initial conditions required for the formation of large-scale structure [15–17, 33].

23.3.1 *Metric Perturbations*

In a homogeneous classical inflationary cosmology driven by a scalar field, the inflaton field is uniform on constant-time hypersurfaces, $\phi = \phi_0(t)$. However, quantum fluctuations inevitably break the spatial symmetry leading to an inhomogeneous field:

$$\phi(t, x^i) = \phi_0(t) + \delta\phi(t, x^i) \,. \tag{23.24}$$

At the same time, one should consider inhomogeneous perturbations of the RW spacetime metric (see, e.g., [34–36]):

$$\begin{aligned} ds^2 = (1+2A)dt^2 - 2RB_i dt dx^i \\ - R^2\left[(1+2C)\delta_{ij} + \partial_i\partial_j E + h_{ij}\right] dx^i dx^j \,, \end{aligned} \tag{23.25}$$

where A, B, E and C are scalar perturbations while h_{ij} represents transverse and tracefree, tensor metric perturbations. Vector metric perturbations can be eliminated using Einstein constraint equations in a scalar field cosmology.

The tensor perturbations remain invariant under a temporal gauge transformation $t \to t + \delta t(t, x^i)$, but both the scalar field and the scalar metric perturbations transform. For example, we have

$$\delta\phi \to \delta\phi - \dot\phi_0\delta t \,, \quad C \to C - H\delta t \,. \tag{23.26}$$

However, there are gauge invariant combinations, such as [37]

$$Q = \delta\phi - \frac{\dot\phi_0}{H} C \,, \tag{23.27}$$

which describes the scalar field perturbations on spatially-flat ($C = 0$) hypersurfaces. This is simply related to the curvature perturbation on uniform-field ($\delta\phi = 0$) hypersurfaces:

$$\mathcal{R} = C - \frac{H}{\dot\phi_0}\delta\phi = -\frac{H}{\dot\phi_0} Q \,, \tag{23.28}$$

which coincides in slow-roll inflation, $\rho \simeq \rho(\phi)$, with the curvature perturbation on uniform-density hypersurfaces [16]

$$\zeta = C - \frac{H}{\dot\rho_0}\delta\rho \,. \tag{23.29}$$

Thus scalar field and scalar metric perturbations are coupled by the evolution of the inflaton field.

23.3.2 *Gravitational waves from inflation*

The tensor metric perturbation, h_{ij} in Eq. (23.25), is gauge-invariant and decoupled from the scalar perturbations at first order. This represents the free excitations of the spacetime, i.e., gravitational waves, which are the simplest metric perturbations to study at linear order.

Each tensor mode, with wavevector $\vec{k}$, has two linearly-independent transverse and trace-free polarization states:

$$h_{ij}(\vec{k}) = h_{\vec{k}} q_{ij} + \bar h_{\vec{k}} \bar q_{ij} \,. \tag{23.30}$$

The linearised Einstein equations then yield the same evolution equation for the amplitude as that for a massless field in RW spacetime:

$$\ddot h_{\vec{k}} + 3H\dot h_{\vec{k}} + \frac{k^2}{R^2} h_{\vec{k}} = 0 \,, \tag{23.31}$$

(and similarly for $\bar h_{\vec{k}}$). This can be re-written in terms of the conformal time, $\eta = \int dt/R$, and the conformally rescaled field:

$$u_{\vec{k}} = \frac{M_P R h_{\vec{k}}}{\sqrt{32\pi}} \,. \tag{23.32}$$

This conformal field then obeys the wave equation for a canonical scalar field in Minkowski spacetime with a time-dependent mass:

$$u''_{\vec{k}} + \left(k^2 - \frac{R''}{R}\right) u_{\vec{k}} = 0\,. \tag{23.33}$$

During slow roll

$$\frac{R''}{R} \simeq (2-\epsilon)R^2H^2\,. \tag{23.34}$$

This makes it possible to quantise the linearised metric fluctuations, $u_{\vec{k}} \to \hat{u}_{\vec{k}}$, on sub-Hubble scales, $k^2/R^2 \gg H^2$, where the background expansion can be neglected.

Crucially, in an inflationary expansion, where $\ddot{R} > 0$, the comoving Hubble length $H^{-1}/R = 1/\dot{R}$ decreases with time. Thus, all modes start inside the Hubble horizon and it is possible to take the initial field fluctuations to be in a vacuum state at early times or on small scales:

$$\langle u_{\vec{k}_1} u_{\vec{k}_2}\rangle = \frac{i}{2}(2\pi)^3\delta^{(3)}\left(\vec{k}_1+\vec{k}_2\right)\,. \tag{23.35}$$

In terms of the amplitude of the tensor metric perturbations, this corresponds to

$$\langle h_{\vec{k}_1} h_{\vec{k}_2}\rangle = \frac{1}{2}\frac{\mathcal{P}_t(k_1)}{4\pi k_1^3}(2\pi)^3\delta^{(3)}\left(\vec{k}_1+\vec{k}_2\right)\,, \tag{23.36}$$

where the factor $1/2$ appears due to the two polarization states that contribute to the total tensor power spectrum:

$$\mathcal{P}_t(k) = \frac{64\pi}{M_P^2}\left(\frac{k}{2\pi R}\right)^2\,. \tag{23.37}$$

On super-Hubble scales, $k^2/R^2 \ll H^2$, we have the growing mode solution to Eq. (23.33), $u_{\vec{k}} \propto R$, corresponding to $h_{\vec{k}} \to$ constant, i.e., tensor modes are frozen-in on super-Hubble scales, both during and after inflation. Thus, connecting the initial vacuum fluctuations on sub-Hubble scales to the late-time power spectrum for tensor modes at Hubble exit during inflation, $k = R_*H_*$, we obtain

$$\mathcal{P}_t(k) \simeq \frac{64\pi}{M_P^2}\left(\frac{H_*}{2\pi}\right)^2\,. \tag{23.38}$$

In the de Sitter limit, $\epsilon \to 0$, the Hubble rate becomes time-independent and the tensor spectrum on super-Hubble scales becomes scale-invariant [39]. However slow-roll evolution leads to weak time dependence of H_* and thus a scale-dependent spectrum on large scales, with a spectral tilt

$$n_t \equiv \frac{d\ln\mathcal{P}_t}{d\ln k} \simeq -2\epsilon_*\,. \tag{23.39}$$

23.3.3 *Density Perturbations from single-field inflation*

The inflaton field fluctuations on spatially-flat hypersurfaces are coupled to scalar metric perturbations at first order, but these can be eliminated using the Einstein constraint equations to yield an evolution equation

$$\ddot{Q}_{\vec{k}} + 3H\dot{Q}_{\vec{k}} + \left[\frac{k^2}{R^2} + V'' - \frac{8\pi}{M_P^2R^3}\frac{d}{dt}\left(\frac{R^3\dot{\phi}^2}{H}\right)\right]Q_{\vec{k}} = 0\,. \tag{23.40}$$

Terms proportional to M_P^{-2} represent the effect on the field fluctuations of gravity at first order. As can be seen, this vanishes in the limit of a constant background field, and hence is suppressed in the slow-roll limit, but it is of the same order as the effective mass, $V'' = 3\eta H^2$, so must be included if we wish to model deviations from exact de Sitter symmetry.

This wave equation can also be written in the canonical form for a free field in Minkowski spacetime if we define [37]

$$v_{\vec{k}} \equiv RQ_{\vec{k}}\,, \tag{23.41}$$

to yield

$$v''_{\vec{k}} + \left(k^2 - \frac{z''}{z}\right)v_{\vec{k}} = 0\,, \tag{23.42}$$

where we define

$$z \equiv \frac{R\dot{\phi}}{H}\,, \qquad \frac{z''}{z} \simeq (2+5\epsilon-3\eta)R^2H^2\,, \tag{23.43}$$

where the last approximate equality holds to leading order in the slow-roll approximation.

As previously done for gravitational waves, we quantise the linearised field fluctuations $v_{\vec{k}} \to \hat{v}_{\vec{k}}$ on sub-Hubble scales, $k^2/R^2 \gg H^2$, where the background expansion can be neglected. Thus, we impose

$$\langle v_{\vec{k}_1} v'_{\vec{k}_2}\rangle = \frac{i}{2}\delta^{(3)}\left(\vec{k}_1+\vec{k}_2\right)\,. \tag{23.44}$$

In terms of the field perturbations, this corresponds to

$$\langle Q_{\vec{k}_1} Q_{\vec{k}_2}\rangle = \frac{\mathcal{P}_Q(k_1)}{4\pi k_1^3}(2\pi)^3\delta^{(3)}\left(\vec{k}_1+\vec{k}_2\right)\,, \tag{23.45}$$

where the power spectrum for vacuum field fluctuations on sub-Hubble scales, $k^2/R^2 \gg H^2$, is simply

$$\mathcal{P}_Q(k) = \left(\frac{k}{2\pi R}\right)^2\,, \tag{23.46}$$

yielding the classic result for the vacuum fluctuations for a massless field in de Sitter at Hubble exit, $k = R_*H_*$:

$$\mathcal{P}_Q(k) \simeq \left(\frac{H}{2\pi}\right)^2_*\,. \tag{23.47}$$

In practice there are slow-roll corrections due to the small but finite mass (η) and field evolution (ϵ) [40].

Slow-roll corrections to the field fluctuations are small on sub-Hubble scales, but can become significant as the field and its perturbations evolve over time on super-Hubble scales. Thus, it is helpful to work instead with the curvature perturbation, ζ defined in equation (Eq. (23.29)), which remains constant on super-Hubble scales for adiabatic density perturbations both during and after inflation [16,41]. Thus we have an expression for the primordial curvature perturbation on super-Hubble scales produced by single-field slow-roll inflation:

$$\mathcal{P}_\zeta(k) = \left[\left(\frac{H}{\dot{\phi}}\right)^2\mathcal{P}_Q(k)\right]_* \simeq \frac{4\pi}{M_P^2}\left[\frac{1}{\epsilon}\left(\frac{H}{2\pi}\right)^2\right]_*\,. \tag{23.48}$$

Comparing this with the primordial gravitational wave power spectrum (Eq. (23.38)) we obtain the tensor-to-scalar ratio

$$r \equiv \frac{\mathcal{P}_t}{\mathcal{P}_\zeta} \simeq 16\epsilon_*\,. \tag{23.49}$$

Note that the scalar amplitude is boosted by a factor $1/\epsilon_*$ during slow-roll inflation, because small scalar field fluctuations can lead to relatively large curvature perturbations on hypersurfaces defined with respect to the density if the potential energy is only weakly dependent on the scalar field, as in slow roll. Indeed, the de Sitter limit is singular, since the potential energy becomes independent of the scalar field at first order, $\epsilon \to 0$, and the curvature perturbation on uniform-density hypersurfaces becomes ill-defined.

We note that in single-field inflation the tensor-to-scalar ratio and the tensor tilt (Eq. (23.39)) at the same scale are both determined by the first slow-roll parameter at Hubble exit, ϵ_*, giving rise to an important consistency test for single-field slow-roll inflation:

$$n_t \simeq -\frac{r}{8}\,. \tag{23.50}$$

This may be hard to verify if r is small, making any tensor tilt n_t difficult to measure. On the other hand, it does offer a way to rule out single-field slow-roll inflation if either r or n_t is large.

Given the relatively large scalar power spectrum, it has proved easier to measure the scalar tilt, conventionally defined as $n_s - 1$.

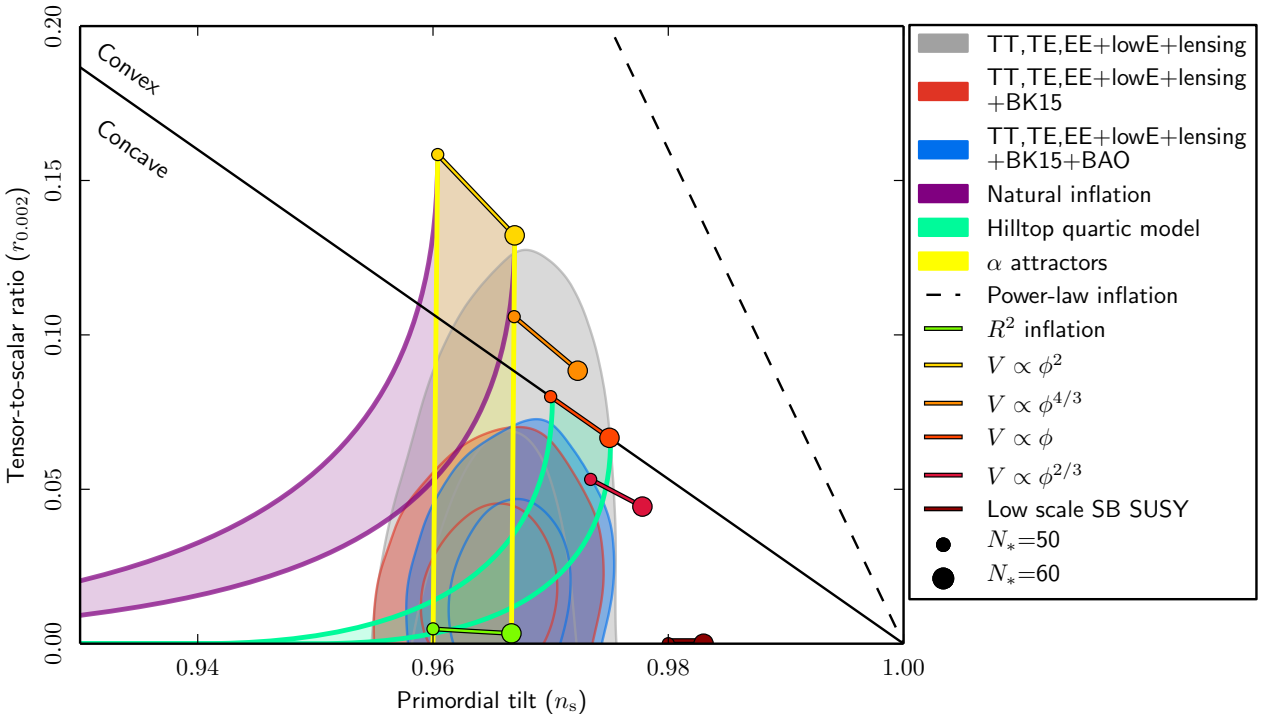

Figure 23.1: The marginalized joint 68 and 95% CL regions for the tilt in the scalar perturbation spectrum, n_s, and the relative magnitude of the tensor perturbations, r, obtained from the *Planck* 2018 and lensing data alone, and their combinations with BICEP2/Keck Array (BK15) and (optionally) BAO data, confronted with the predictions of some of the inflationary models discussed in this review. This figure is taken from [38].

Slow-roll corrections lead to slow time-dependence of both H_* and ϵ_*, giving a weak scale-dependence of the scalar power spectrum:

$$n_s - 1 \equiv \frac{d\ln\mathcal{P}_\zeta}{d\ln k} \simeq -6\epsilon_* + 2\eta_* \,, \tag{23.51}$$

and a running of this tilt at second-order in slow roll:

$$\frac{dn_s}{d\ln k} \simeq -8\epsilon_*(3\epsilon_* - 2\eta_*) - 2\xi_*^2 \,, \tag{23.52}$$

where the running introduces a new slow-roll parameter at second-order:

$$\xi^2 = \frac{M_P^4}{64\pi^2}\frac{V'V'''}{V^2} \,. \tag{23.53}$$

23.3.4 *Observational Bounds*

The observed scale-dependence of the power spectrum makes it necessary to specify the comoving scale, k, at which quantities are constrained and hence the Hubble-exit time, $k = a_* H_*$, when the corresponding theoretical quantities are calculated during inflation. This is usually expressed in terms of the number of e-folds from the end of inflation [42]:

$$N_*(k) \simeq 67 - \ln\left(\frac{k}{a_0 H_0}\right) + \frac{1}{4}\ln\left(\frac{V_*^2}{M_P^4\rho_{end}}\right) + \frac{1}{12}\ln\left(\frac{\rho_{rh}}{\rho_{end}}\right) - \frac{1}{12}\ln(g_*), \tag{23.54}$$

where H_0^{-1}/a_0 is the present comoving Hubble length. Different models of reheating and and thus different reheat temperatures and densities, ρ_{rh} in Eq. (23.54), lead to a range of possible values for N_* corresponding to a fixed physical scale, and hence we have a range of observational predictions for a given inflation model, as seen in Fig. 23.1.

The *Planck* 2018 temperature and polarization data (see Chap. 29, "Cosmic Microwave Background" review) are consistent with a smooth featureless power spectrum over a range of comoving wavenumbers, $0.008\ h^{-1}\ \mathrm{Mpc}^{-1} \le k \le 0.1\ h\ \mathrm{Mpc}^{-1}$. In the absence of running, the data measure the spectral index to be [38]

$$n_s = 0.9649 \pm 0.0042 \,, \tag{23.55}$$

corresponding to a deviation from scale-invariance exceeding the 7σ level. If running of the spectral tilt is included in the model, this is constrained to be [38]

$$\frac{dn_s}{d\ln k} = -0.0045 \pm 0.0067 \tag{23.56}$$

at the 95% CL, assuming no running of the running. The most recent analysis [43] of the BICEP, Keck Array and Planck data places an upper bound on the tensor-to-scalar ratio

$$r < 0.036 \,, \tag{23.57}$$

at the 95% CL.

These observational bounds can be converted into bounds on the slow-roll parameters and hence the potential during slow-roll inflation. Setting higher-order slow-roll parameters (beyond second-order in horizon-flow parameters [44]) to zero, the *Planck* collaboration obtain the following 95% CL bounds when lensing and BK15 data are included [38]

$$\epsilon < 0.0044 \,, \tag{23.58}$$

$$\eta = -0.015 \pm 0.006 \,, \tag{23.59}$$

$$\xi^2 = 0.0029^{+0.0073}_{-0.0069} \,, \tag{23.60}$$

which can be used to constrain models, as discussed in the next Section.

Fig. 23.1, which is taken from [38], compares observational CMB constraints on the tilt, n_s, in the spectrum of scalar perturbations and the ratio, r, between the magnitudes of tensor and scalar perturbations. Important rôles are played by data from the *Planck* satellite and on lensing, the BICEP2/Keck Array (BK15) and measurements of baryon acoustic oscillations (BAO). The reader is referred to [38] for technical details. These experimental constraints are compared with the predictions of some

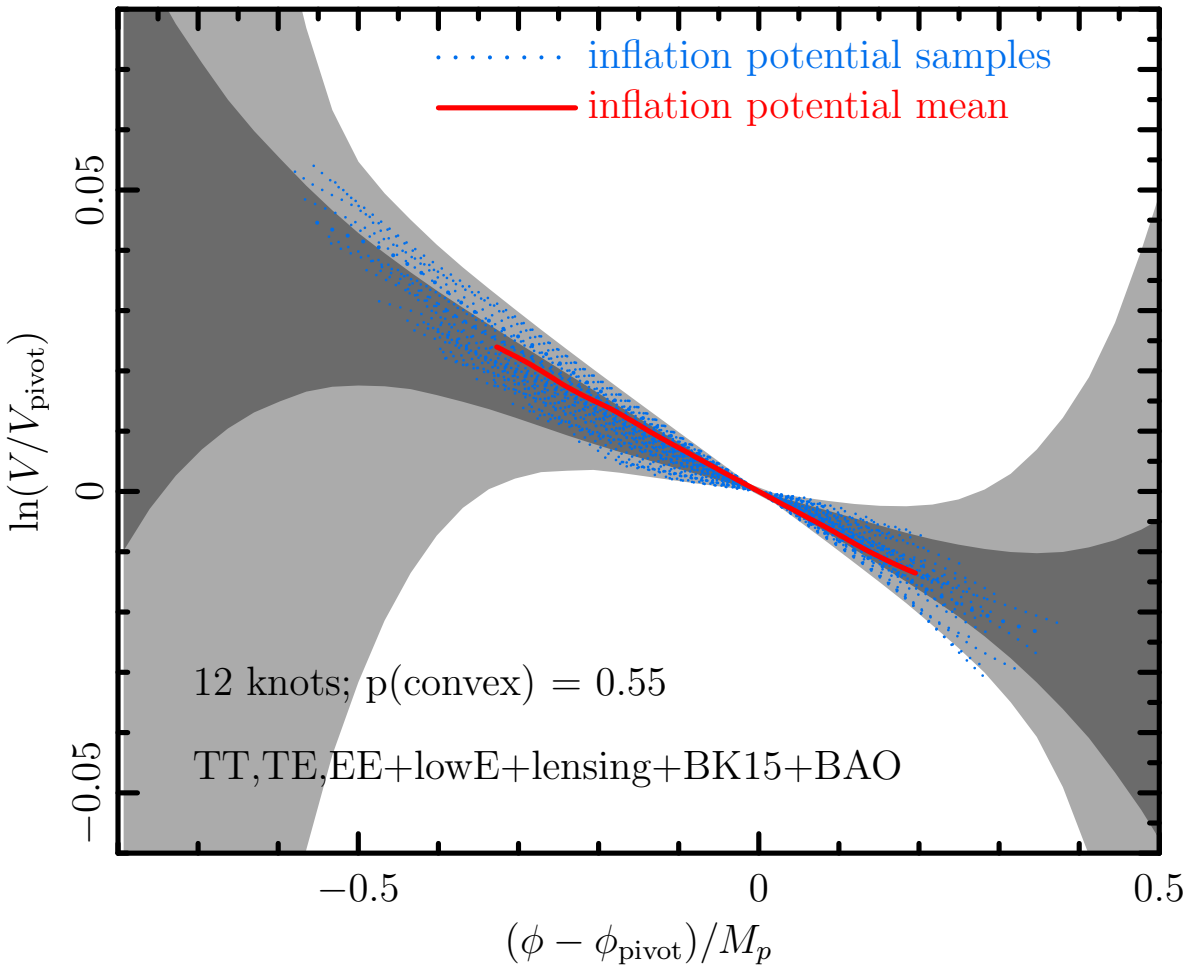

Figure 23.2: The result of reconstructing a single-field inflaton potential using a cubic-spline power-spectrum mode expansion and the the full *Planck*, lensing, BK15 and BAO data set. This figure is taken from [38].

of the inflationary models discussed in this review. Generally speaking, models with a concave potential are favored over those with a convex potential, and models with power-law inflation are now excluded, as opposed to models with de Sitter-like (quasi-)exponential expansion.

There is no significant evidence for local features within the range of inflaton field values probed by the data [38]. However, the data may be used to reconstruct partially the effective inflationary potential over a range of inflaton field values, assuming that it is suitably smooth. The result of one such exercise by the *Planck* collaboration [38] in the framework of a generic single-field inflaton potential is shown in Fig. 23.2. This reconstruction assumes a cubic-spline power-spectrum mode expansion and employs the full *Planck*, lensing, BK15 and BAO data set. The reader is again referred to [38] for technical details. We see that the effective inflaton potential is relatively well reconstructed over field values ϕ within ± 0.5 of the chosen pivot value, but the potential is only very weakly constrained for larger values of $|\phi - \phi_{pivot}|$, providing wide scope for inflationary model-builders.

23.4 Models

23.4.1 *Pioneering Models*

The paradigm of the inflationary Universe was proposed in [2], where it was pointed out that an early period of (near-)exponential expansion, in addition to resolving the horizon and flatness problems of conventional Big-Bang cosmology as discussed above (the possibility of a de Sitter phase in the early history of the Universe was also proposed in the non-minimal gravity model of [1], with the motivation of avoiding an initial singularity), would also dilute the prior abundance of any unseen heavy, (meta-)stable particles, as exemplified by monopoles in grand unified theories (GUTs; see Chap. 93, "Grand Unified Theories" review). The original proposal was that this inflationary expansion took place while the Universe was in a metastable state (a similar suggestion was made in [45, 46], where in [45] it was also pointed out that such a mechanism could address the horizon problem) and was terminated by a first-order transition due to tunnelling though a potential barrier. However, it was recognized already in [2] that this 'old inflation' scenario would need modification if the transition to the post-inflationary Universe were to be completed smoothly without generating unacceptable inhomogeneities.

This 'graceful exit' problem was addressed in the 'new inflation' model of [13] (see also [14] and footnote [39] of [2]), which studied models based on an SU(5) GUT with an effective potential of the Coleman-Weinberg type (i.e., dominated by radiative corrections), in which inflation could occur during the roll-down from the local maximum of the potential towards a global minimum. However, it was realized that the Universe would evolve to a different minimum from the Standard Model [47], and it was also recognized that density fluctuations would necessarily be too large [15], since they were related to the GUT coupling strength.

These early models of inflation assumed initial conditions enforced by thermal equilibrium in the early Universe. However, this assumption was questionable: indeed, it was not made in the model of [1], in which a higher-order gravitational curvature term was assumed to arise from quantum corrections, and the assumption of initial thermal equilibrium was jettisoned in the 'chaotic' inflationary model of [48]. These are the inspirations for much recent inflationary model building, so we now discuss them in more detail, before reviewing contemporary models.

In this section we will work in natural units where we set the reduced Planck mass to unity, i.e., $8\pi/M_P^2 = 1$. All masses are thus relative to the reduced Planck scale.

23.4.2 R^2 *Inflation*

The first-order Einstein-Hilbert action, $(1/2)\int d^4x\sqrt{-g}R$, where R is the Ricci scalar curvature, is the minimal possible theory consistent with general coordinate invariance. However, it is possible that there might be non-minimal corrections to this action, and the unique second-order possibility is

$$S = \frac{1}{2}\int d^4x\sqrt{-g}\left(R + \frac{R^2}{6M^2}\right) . \tag{23.61}$$

It was pointed out in [1] that an R^2 term could be generated by quantum effects, and that (Eq. (23.61)) could lead to de Sitter-like expansion of the Universe. Scalar density perturbations in this model were calculated in [17]. Because the initial phase was (almost) de Sitter, these perturbations were (approximately) scale-invariant, with magnitude $\propto M$. It was pointed out in [17] that requiring the scalar density perturbations to lie in the range 10^{-3} to 10^{-5}, consistent with upper limits at that time, would require $M \sim 10^{-3}$ to 10^{-5} in Planck units, and it was further suggested in that these perturbations could lead to the observed large-scale structure of the Universe, including the formation of galaxies.

Although the action (Eq. (23.61)) does not contain an explicit scalar field, [17] reduced the calculation of density perturbations to that of fluctuations in the scalar curvature R, which could be identified (up to a factor) with a scalar field of mass M. The formal equivalence of R^2 gravity (Eq. (23.61)) to a theory of gravity with a massive scalar ϕ had been shown in [18], see also [19]. The effective scalar potential for what we would nowadays call the 'inflaton' [49] takes the form

$$S = \frac{1}{2}\int d^4x\sqrt{-g}\left[R + (\partial_\mu\phi)^2 - \frac{3}{2}M^2(1 - e^{-\sqrt{2/3}\phi})^2\right] \tag{23.62}$$

when the action is written in the Einstein frame, and the potential is shown as the solid black line in Fig. 23.3. Using (Eq. (23.48)), one finds that the amplitude of the scalar density perturbations in this model is given by

$$\Delta_{\mathcal{R}} = \frac{3M^2}{8\pi^2}\sinh^4\left(\frac{\phi}{\sqrt{6}}\right) , \tag{23.63}$$

The measured magnitude of the density fluctuations in the CMB requires $M \simeq 1.3\times10^{-5}$ in Planck units (assuming $N_* \simeq 55$), so one of the open questions in this model is why M is so small. Obtaining $N_* \simeq 55$ also requires an initial value of $\phi \simeq 5.5$, i.e., a super-Planckian initial condition, and another issue for this and many other models is how the form of the effective potential is protected and remains valid at such large field values. Using Eq. (23.51) one finds that $n_s \simeq 0.965$ for $N_* \simeq 55$ and using (Eq. (23.49)) one finds that $r \simeq 0.0035$. These predictions are consistent with the present data from *Planck* and other experiments, as seen in Fig. 23.1.

23.4.3 *Chaotic Models with Power-Law Potentials*

As has already been mentioned, a key innovation in inflationary model-building was the suggestion to abandon the questionable assumption of a thermal initial state, and consider 'chaotic' initial conditions with very general forms of potential [48]. (Indeed, the R^2 model discussed above can be regarded as a prototype of this approach.) The chaotic approach was first proposed in the context of a simple power-law potential of the form $\mu^{4-\alpha}\phi^\alpha$, and the specific example of $\lambda\phi^4$ was studied in [48]. Such models make the following predictions for the slow-roll parameters ϵ and η:

$$\epsilon \;=\; \frac{1}{2}\left(\frac{\alpha}{\phi}\right)^2 , \;\; \eta \;=\; \frac{\alpha(\alpha-1)}{\phi^2} , \tag{23.64}$$

leading to the predictions

$$r \;\approx\; \frac{4\alpha}{N_*} , \qquad n_s - 1 \;\approx\; -\frac{\alpha+2}{2N_*} , \tag{23.65}$$

which are shown in Fig. 23.1 for some illustrative values of α. We note that the prediction of the original ϕ^4 model lies out of the frame, with values of r that are too large and values of n_s that are too small. The ϕ^3 model has similar problems, and would in any case require modification in order to have a well-defined minimum. The simplest possibility is ϕ^2, but this is now also disfavored by the data, at the 95% CL if only the *Planck* data are considered, and more strongly if other data are included, as seen in Fig. 23.1. (For non-minimal models of quadratic inflation that avoid this problem, see, e.g., [51].)

Indeed, as can be seen in Fig. 23.1, all single-field models with a convex potential (i.e., one curving upwards) are disfavored compared to models with a concave potential.

23.4.4 *Hilltop Models*

This preference for a concave potential motivates interest in 'hilltop' models [52], whose starting-point is a potential of the form

$$V(\phi) \;=\; \Lambda^4\left[1 - \left(\frac{\phi}{\mu}\right)^p + \ldots\right] , \tag{23.66}$$

where the ... represent extra terms that yield a positive semi-definite potential. To first order in the slow-roll parameters, when $x \equiv \phi/\mu$ is small, one has

$$n_s \;\simeq\; 1 - p(p-1)\mu^{-2}\frac{x^{p-2}}{(1-x^p)} - \frac{3}{8}r , \qquad r \;\simeq\; 8p^2\mu^{-2}\frac{x^{2p-2}}{(1-x^p)^2} . \tag{23.67}$$

As seen in Fig. 23.1, a hilltop model with $p = 4$ can be compatible with the *Planck* and other measurements, if $\mu \gg M_P$.

23.4.5 *D-Brane Inflation*

Many scenarios for inflation involving extra dimensions have been proposed, e.g., the possibility that observable physics resides on a three-dimensional brane, and that there is an inflationary potential that depends on the distance between our brane and an antibrane, with a potential of the form [53]

$$V(\phi) \;=\; \Lambda^4\left[1 - \left(\frac{\mu}{\phi}\right)^p + \ldots\right] . \tag{23.68}$$

In this scenario the effective potential vanishes in the limit $\phi \to \infty$, corresponding to complete separation between our brane and the antibrane. The predictions for n_s and r in this model can be obtained from (Eq. 23.67) by exchanging $p \leftrightarrow -p$, and are also consistent with the *Planck* and other data.

23.4.6 *Natural Inflation*

Also seen in Fig. 23.1 are the predictions of 'natural inflation' [54], in which one postulates a non-perturbative shift symmetry that suppresses quantum corrections, so that a hierarchically small scale of inflation, $H \ll M_P$, is technically natural. In the simplest models, there is a periodic potential of the form

$$V(\phi) \;=\; \Lambda^4\left[1 + \cos\left(\frac{\phi}{f}\right)\right] , \tag{23.69}$$

where f is a dimensional parameter reminiscent of an axion decay constant (see the next subsection) [55], which must have a value $> M_P$. Natural inflation can yield predictions similar to quadratic inflation (which are no longer favored, as already discussed), but can also yield an effective convex potential. Thus, it may lead to values of r that are acceptably small, but for values of n_s that are in tension with the data, as seen in Fig. 23.1.

23.4.7 *Axion Monodromy Models*

The effective potentials in stringy models [56, 57] motivated by axion monodromy may be of the form

$$V(\phi) \;=\; \mu^{4-\alpha}\phi^\alpha + \Lambda^4 e^{-C\left(\frac{\phi}{\phi_0}\right)^{p_\Lambda}}\cos\left[\gamma + \frac{\phi}{f}\left(\frac{\phi}{\phi_0}\right)^{p_f+1}\right] , \tag{23.70}$$

where μ, Λ, f and ϕ_0 are parameters with the dimension of mass, and C, p, p_Λ, p_f and γ are dimensionless constants, generalizing the potential ([54]) in the simplest models of natural inflation. The oscillations in (Eq. 23.70) are associated with the axion field, and powers $p_\Lambda, p_f \neq 0$ may arise from ϕ-dependent evolutions of

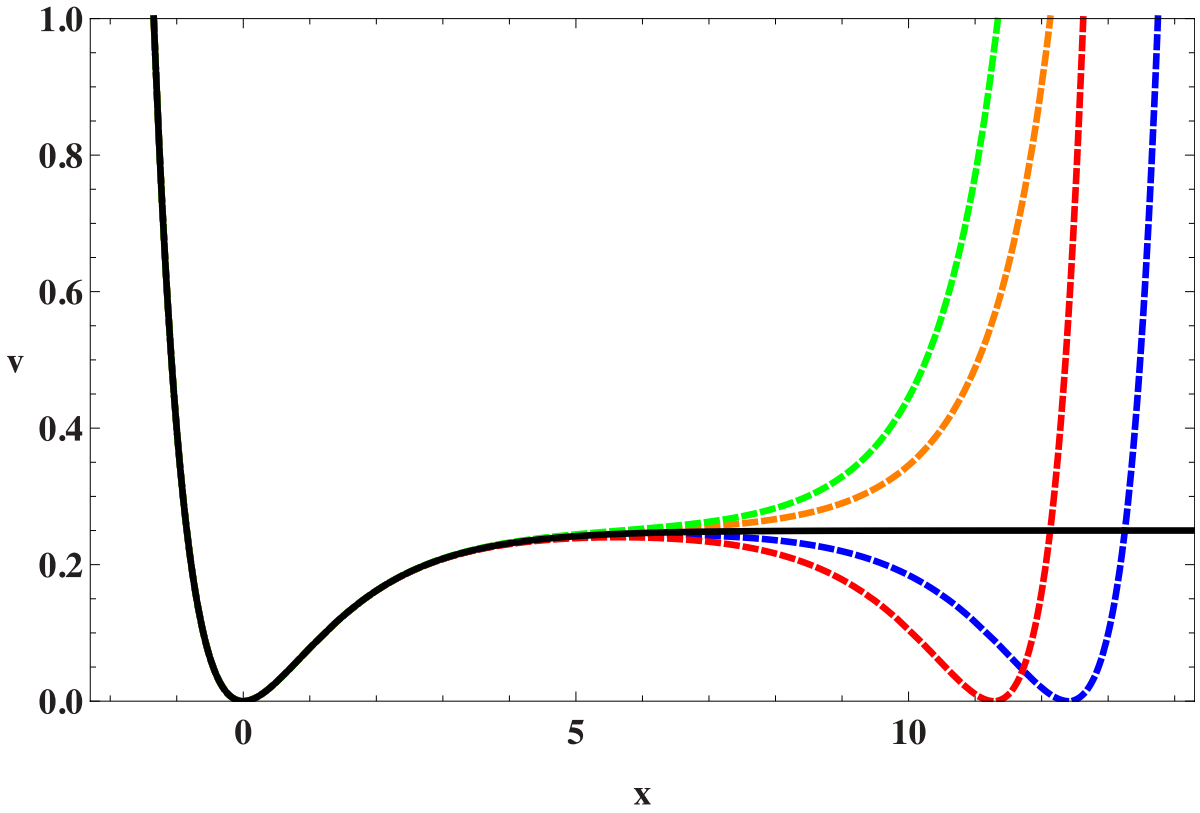

Figure 23.3: The inflationary potential V in the R^2 model (solid black line) compared with its form in various no-scale models discussed in detail in [50] (dashed coloured lines).

string moduli. Since the exponential prefactor in (Eq. 23.70) is due to non-perturbative effects that may be strongly suppressed, the oscillations may be unobservable small. Specific string models having ϕ^α with $\alpha = 4/3, 1$ or $2/3$ have been constructed in [56,57], providing some motivation for the low-power models mentioned above.

As seen in Fig. 23.1, the simple axion monodromy models with the power $\alpha = 4/3$ or 1 are no longer compatible with the current CMB data at the 95% CL, while $\alpha = 2/3$ is only marginally compatible at 95% CL. The *Planck* Collaboration has also searched for characteristic effects associated with the second term in (Eq. (23.70)), such as a possible drift in the modulation amplitude (setting $p_\Lambda = C = 0$), and a possible drifting frequency generated by $p_f \neq 0$, without finding any compelling evidence [38].

23.4.8 *Higgs Inflation*

Since the energy scale during inflation is commonly expected to lie between the Planck and TeV scales, it may serve as a useful bridge with contacts both to string theory or some other quantum theory of gravity, on the one side, and particle physics on the other side. However, as the above discussion shows, much of the activity in building models of inflation has been largely independent of specific connections with these subjects, though some examples of string-motivated models of inflation were mentioned above.

The most economical scenario for inflation might be to use as inflaton the only established scalar field, namely the Higgs field (see Chap.11, "Status of Higgs boson physics" review). A specific model assuming a non-minimal coupling of the Higgs field h to gravity was constructed in [58]. Its starting-point is the action

$$S = \int d^4x\sqrt{-g}\left[\frac{M^2+\xi h^2}{2}R + \frac{1}{2}\partial_\mu h\partial^\mu h - \frac{\lambda}{4}(h^2-v^2)^2\right], \tag{23.71}$$

where v is the Higgs vacuum expectation value. The model requires $\xi \gg 1$, in which case it can be rewritten in the Einstein frame as

$$S = \int d^4x\sqrt{-g}\left[\frac{1}{2}R + \frac{1}{2}\partial_\mu\chi\partial^\mu\chi - U(\chi)\right], \tag{23.72}$$

where the effective potential for the canonically-normalized inflaton field χ has the form

$$U(\chi) = \frac{\lambda}{4\xi^2}\left[1+\exp\left(-\frac{2\chi}{\sqrt{6}M_P}\right)\right]^{-2}, \tag{23.73}$$

which is similar to the effective potential of the R^2 model at large field values. As such, the model inflates successfully if $\xi \simeq 5\times10^4\ m_h/(\sqrt{2}v)$, with predictions for n_s and r that are indistinguishable from the predictions of the R^2 model shown in Fig. 23.1.

This model is very appealing, but must confront several issues. One is to understand the value of ξ, and another is the possibility of unitarity violation. However, a more fundamental issue is whether the effective quartic Higgs coupling is positive at the scale of the Higgs field during inflation. Extrapolations of the effective potential in the Standard Model using the measured values of the masses of the Higgs boson and the top quark indicate that probably $\lambda < 0$ at this scale [59], though there are still significant uncertainties associated with the appropriate input value of the top mass and the extrapolation to high renormalization scales.

23.4.9 *Supersymmetric Models of Inflation*

Supersymmetry [60] is widely considered to be a well-motivated possible extension of the Standard Model that might become apparent at the TeV scale. It is therefore natural to consider supersymmetric models of inflation. These were originally proposed because of the problems of the new inflationary theory [13, 14] based on the one-loop (Coleman-Weinberg) potential for breaking SU(5). Several of these problems are related to the magnitude of the effective potential parameters: in any model of inflation based on an elementary scalar field, some parameter in the effective potential must be small in natural units, e.g., the quartic

coupling λ in a chaotic model with a quartic potential, or the mass parameter μ in a model of chaotic quadratic inflation. These parameters are renormalized multiplicatively in a supersymmetric theory, so that the quantum corrections to small values would be under control. Hence, it was suggested that inflation cries out for supersymmetry [61], though non-supersymmetric resolutions of the problems of Coleman-Weinberg inflation are also possible: see, e.g., Ref. [62].

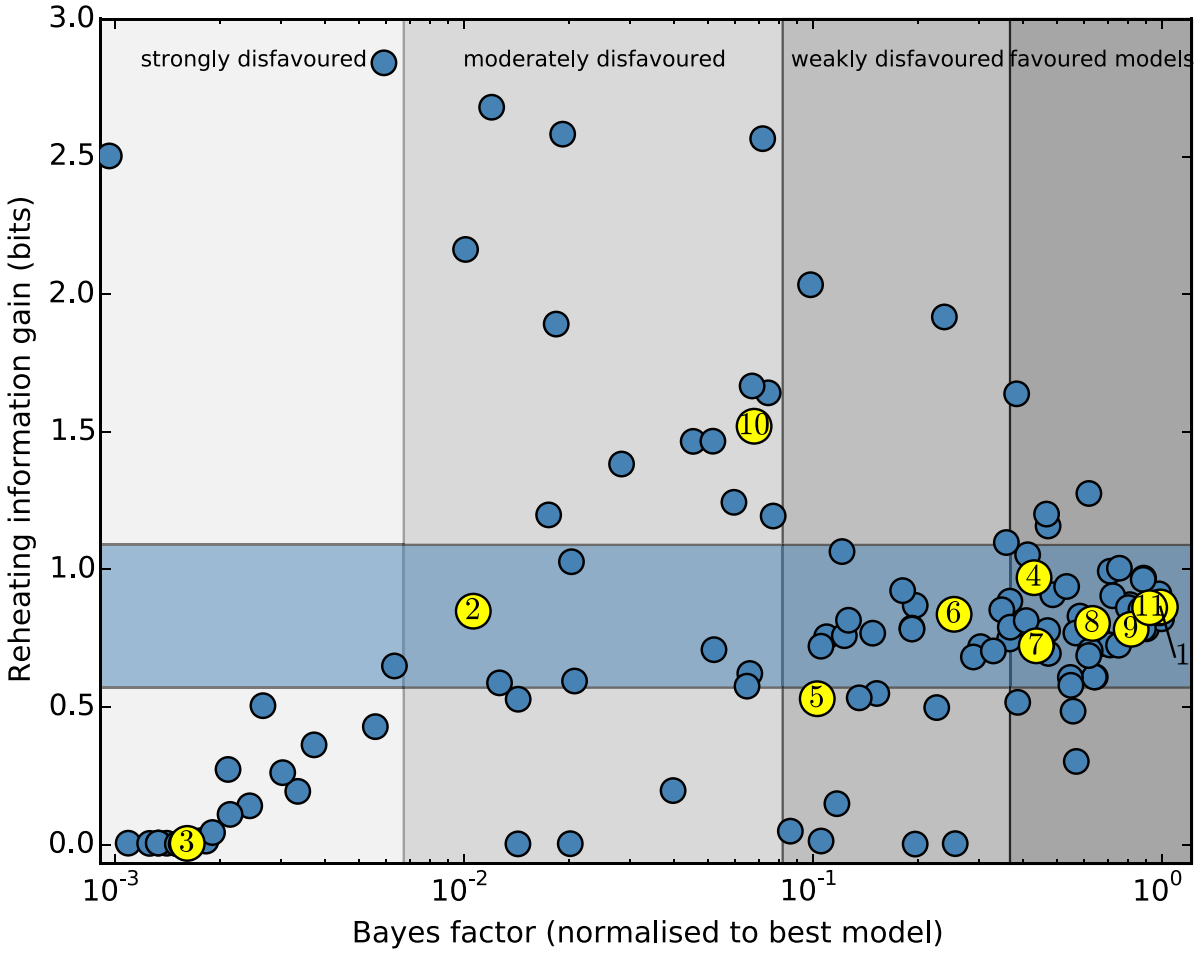

Figure 23.4: The Bayes factors calculated in [63] for a large sample of inflationary models using *Planck* 2015 data [64]. Those highlighted in yellow are featured in this review, according to the numbers listed in the text.

In the Standard Model there is only one scalar field that could be a candidate for the inflaton, namely the Higgs field discussed above, but even the minimal supersymmetric extension of the Standard Model (MSSM) contains many scalar fields. However, none of these is a promising candidate for the inflaton. The minimal extension of the MSSM that may contain a suitable candidate is the supersymmetric version of the minimal seesaw model of neutrino masses, which contains the three supersymmetric partners of the heavy singlet (right-handed) neutrinos. One of these singlet sneutrinos $\tilde{\nu}$ could be the inflaton [65]: it would have a quadratic potential, the mass coefficient required would be $\sim 10^{13}$ GeV, very much in the expected ball-park for singlet (right-handed) neutrino masses, and sneutrino inflaton decays also could give rise to the cosmological baryon asymmetry via leptogenesis. However, as seen in Fig. 23.1 and already discussed, a purely quadratic inflationary potential is no longer favored by the data. This difficulty could in principle be resolved in models with multiple sneutrinos [66], or by postulating a trilinear sneutrino coupling and hence a superpotential of Wess-Zumino type [67], which can yield successful inflation with predictions intermediate between those of natural inflation and hilltop inflation in Fig. 23.1.

Finally, we note that it is also possible to obtain inflation via supersymmetry breaking, as in the model [68] whose predictions are illustrated in Fig. 23.1.

23.4.10 *Supergravity Models*

Any model of early-Universe cosmology, and specifically inflation, must necessarily incorporate gravity. In the context of supersymmetry this requires an embedding in some supergravity theory [69, 70]. An $\mathcal{N} = 1$ supergravity theory is specified by three functions: a Hermitian function of the matter scalar fields ϕ^i, called the Kähler potential K, that describes its geometry, a holomorphic function of the superfields, called the superpotential W, which describes their interactions, and another holomorphic function $f_{\alpha\beta}$, which describes their couplings to gauge fields V_α [71].

The simplest possibility is that the Kähler metric is flat:

$$K = \phi^i \phi_i^* \,, \tag{23.74}$$

where the sum is over all scalar fields in the theory, and the simplest inflationary model in minimal supergravity had the superpotential [72]

$$W = m^2(1 - \phi)^2 \,, \tag{23.75}$$

Where ϕ is the inflaton. However, this model predicts a tilted scalar perturbation spectrum, $n_s = 0.933$, which is now in serious disagreement with the data from *Planck* and other experiments shown in Fig. 23.1.

Moreover, there is a general problem that arises in any supergravity theory coupled to matter, namely that, since its ef-

fective scalar potential contains a factor of e^K, scalars typically receive squared masses $\propto H^2 \sim V$, where H is the Hubble parameter [73], an issue called the 'η problem'. The theory given by (Eq. (23.75)) avoids this η problem, but a generic supergravity inflationary model encounters this problem of a large inflaton mass. Moreover, there are additional challenges for supergravity inflation associated with the spontaneous breaking of local supersymmetry [74–76].

Various approaches to the η problem in supergravity have been proposed, including the possibility of a shift symmetry [77], and one possibility that has attracted renewed attention recently is no-scale supergravity [78,79]. This is a form of supergravity with a Kähler potential that can be written in the form [80]

$$K \;=\; -3\ln\left(T+T^*-\frac{\sum_i|\phi^i|^2}{3}\right)\,, \qquad (23.76)$$

which has the special property that it naturally has a flat potential, at the classical level and before specifying a non-trivial superpotential. As such, no-scale supergravity is well-suited for constructing models of inflation. Adding to its attraction is the feature that compactifications of string theory to supersymmetric four-dimensional models yield effective supergravity theories of the no-scale type [81]. There are many examples of superpotentials that yield effective inflationary potentials for either the T field (which is akin to a modulus field in some string compactification) or a ϕ field (generically representing matter) that are of the same form as the effective potential of the R^2 model (Eq. (23.62)) when the magnitude of the inflaton field $\gg 1$ in Planck units, as required to obtain sufficiently many e-folds of inflation, N_* [82, 83]. This framework also offers the possibility of using a suitable superpotential to construct models with effective potentials that are similar, but not identical, to the R^2 model, as shown by the dashed coloured lines in Fig. 23.3.

23.4.11 *Other Exponential Potential Models*

This framework also offers the possibility [82] of constructing models in which the asymptotic constant value of the potential at large inflaton field values is approached via a different exponentially-suppressed term:

$$V(\phi) \;=\; A\left[1-\delta e^{-B\phi}+\mathcal{O}(e^{-2B\phi})\right]\,, \qquad (23.77)$$

where the magnitude of the scalar density perturbations fixes A, but δ and B are regarded as free parameters. In the case of R^2 inflation $\delta = 2$ and $B = \sqrt{2/3}$. In a model such as (Eq. (23.77)), one finds at leading order in the small quantity $e^{-B\phi}$ that

$$\begin{aligned} n_s &= 1-2B^2\delta e^{-B\phi}\,,\\ r &= 8B^2\delta^2 e^{-2B\phi}\,,\\ N_* &= \frac{1}{B^2\delta}e^{+B\phi}\,. \end{aligned} \qquad (23.78)$$

yielding the relations

$$n_s \;=\; 1-\frac{2}{N_*}\,,\quad r \;=\; \frac{8}{B^2N_*^2}\,. \qquad (23.79)$$

These relations correspond to the class of models labeled as 'α attractors' [84] in Fig. 23.1. CMB bounds on the tensor-to-scalar ratio translate into an upper bound on the parameter $\alpha = 2/3B^2$ in α-attractor models, which determines the curvature of the Kähler manifold in supergravity models [85]. There are generalizations of the simplest no-scale model (Eq. (23.76)) with prefactors before the $\ln(\dots)$ that are 1 or 2, leading to larger values of $B = \sqrt{2}$ or 1, respectively, and hence smaller values of r than in the R^2 model. CMB constraints on the scalar spectral index can also place a lower bound on the magnitude of α [86], due to the implicit dependence of N_* upon α [87].

23.5 Model Comparison

Given a particular inflationary model, one can obtain constraints on the model parameters, informed by the likelihood, corresponding to the probability of the data given a particular choice of parameters (see Sec. 40, "Statistics" review). In the light of the detailed constraints on the statistical distribution of primordial perturbations now inferred from high-precision observations of the cosmic microwave background, it is also possible to make quantitative comparison of the statistical evidence for or against different inflationary models. This can be done either by comparing the logarithm of the maximum likelihood that can be obtained for the data using each model, i.e., the minimum χ^2 (with some correction for the number of free parameters in each model), or by a Bayesian model comparison [88] (see also Sec. 40.3.4 in "Statistics" review).

In such a Bayesian model comparison one computes [7] the evidence, $\mathcal{E}(\mathcal{D}|\mathcal{M}_A)$ for a model, $\mathcal{M}_A$, given the data $\mathcal{D}$. This corresponds to the likelihood, $\mathcal{L}(\theta_{Aj}) = p(\mathcal{D}|\theta_{Aj},\mathcal{M}_A)$, integrated over the assumed prior distribution, $\pi(\theta_{Aj}|\mathcal{M}_A)$, for all the model parameters θ_{Aj}:

$$\mathcal{E}(\mathcal{D}|\mathcal{M}_A) = \int \mathcal{L}(\theta_{Aj})\pi(\theta_{Aj}|\mathcal{M}_A)d\theta_{Aj}\,. \qquad (23.80)$$

The posterior probability of the model given the data follows from Bayes' theorem

$$p(\mathcal{M}_A|\mathcal{D}) = \frac{\mathcal{E}(\mathcal{D}|\mathcal{M}_A)\pi(\mathcal{M}_A)}{p(\mathcal{D})}\,, \qquad (23.81)$$

where the prior probability of the model is given by $\pi(\mathcal{M}_A)$. Assuming that all models are equally likely a priori, $\pi(\mathcal{M}_A) = \pi(\mathcal{M}_B)$, the relative probability of model A relative to a reference model, in the light of the data, is thus given by the Bayes factor

$$B_{A,ref} = \frac{\mathcal{E}(\mathcal{D}|\mathcal{M}_A)}{\mathcal{E}(\mathcal{D}|\mathcal{M}_{ref})}\,. \qquad (23.82)$$

Computation of the multi-dimensional integral (Eq. (23.80)) is a challenging numerical task. Even using an efficient sampling algorithm requires hundreds of thousands of likelihood computations for each model, though slow-roll approximations can be used to calculate rapidly the primordial power spectrum using the APSIC numerical library [7] for a large number of single-field, slow-roll inflation models.

The change in χ^2 for selected slow-roll models relative to the Starobinsky R^2 inflationary model, used as a reference, is given in Table 23.1 (taken from [38]). All the other inflation models require a substantial amplitude of tensor modes, and so have an increased χ^2 with respect to the Starobinsky and other models with a scalar tilt but small tensor modes. Table 23.1 also shows the Bayesian evidence for ($\ln B_{A,ref} > 0$) or against ($\ln B_{A,ref} < 0$) a selection of inflation models using the *Planck* analysis priors [38]. The Starobinsky R^2 inflationary model may be chosen as a reference [38] that provides a good fit to current data. Higgs inflation [58] is indistinguishable using current data, making the model comparison "inconclusive" on the Jeffrey's scale ($|\ln B_{A,ref}| < 1$). (Recall, though, that this model is disfavored by the measured values of the Higgs and top quark masses [59].) We note that although α-attractor models can provide a good fit to the data, they are disfavored relative to the Starobinsky model due to their larger prior volume. There is now strong evidence ($|\ln B_{A,ref}| > 5$) against large-field models such as chaotic inflation with a quadratic or a quartic potential. Indeed, over 30% of the slow-roll inflation models considered in Ref. [7] are strongly disfavored by the *Planck* data.

The Bayes factors for a wide selection of slow-roll inflationary models are displayed in Fig. 23.4, which is adapted from Fig. 3 in [63], where more complete descriptions of the models and the calculations of the Bayes factors using *Planck* 2015 data [64] are given. Models discussed in this review are highlighted in yellow, and numbered as follows: (1) R^2 inflation (Sec. 23.4.2) and models with similar predictions, such as Higgs inflation (Sec. 23.4.8) and no-scale supergravity inflation (Sec. 23.4.10); chaotic inflation models (2) with a ϕ^2 potential; (3) with a ϕ^4 potential; (4) with a $\phi^{2/3}$ potential, and (5) with a ϕ^p potential marginalising over $p \in [0.2, 6]$ (Sec. 23.4.3); hilltop inflation models (6) with $p = 2$; (7) with $p = 4$ and (8) marginalising over p (Sec. 23.4.4); (9) brane

Table 23.1: Observational evidence for and against selected inflation models: $\Delta\chi^2$ and the Bayes factors are calculated relative to the Starobinsky R^2 inflationary model, which is treated as a reference. Results from *Planck* 2018 analysis [38].

Model	$\Delta\chi^2$	$\ln B_{A,ref}$
R^2 inflation	0	0
Power-law potential $\phi^{2/3}$	+4.0	−4.6
Power-law potential ϕ^2	+21.6	< -10
Power-law potential ϕ^4	+75.3	< -10
Natural inflation	+9.9	−6.6
Hilltop quartic model	-0.3	−1.4

inflation Sec. 23.4.5); (10) natural inflation (Sec. 23.4.6); (11) exponential potential models such as α-attractors (Sec. 23.4.11). As seen in Fig. 23.4 and discussed in the next Section, constraints on reheating are starting to provide additional information about models of inflation.

23.6 Constraints on Reheating

One connection between inflation and particle physics is provided by inflaton decay, whose products are expected to have thermalized subsequently. As seen in Eq. (23.54), the number of e-folds required during inflation depends on details of this reheating process, including the matter density upon reheating, denoted by ρ_{th}, which depends in turn on the inflaton decay rate Γ_ϕ. We see in Fig. 23.1 that, within any specific inflationary model, both n_s and particularly r are sensitive to the value of N_*. In particular, the uncertainty in the experimental measurement of n_s is comparable to the variation in many model predictions for $N_* \in [50, 60]$. This implies that the data start to constrain scenarios for inflaton decay in many models. For example, it is clear from Fig. 23.1 that $N_* = 60$ would be preferred over $N_* = 50$ in a chaotic inflationary model with a quadratic potential.

As a specific example, let us consider α-attractor models that predict small values of r. As seen in Fig. 23.1, within these models the combination of *Planck*, BICEP2/Keck Array and BAO data would require a limited range of n_s, corresponding to a limited range of N_*, as seen by comparing the left and right vertical axes in Fig. 23.5:

$$N_* \gtrsim 52 \quad (68\%\ \text{CL}), \quad N_* \gtrsim 44 \quad (95\%\ \text{CL})\,. \tag{23.83}$$

Within any specific model for inflaton decay, these bounds can be translated into constraints on the effective decay coupling. For example, if one postulates a two-body inflaton decay (Eq. (23.21)), the bounds (Eq. (23.83)) can be translated into bounds on $y^2 \equiv 8\pi\Gamma/m$. This is illustrated in Fig. 23.5 [85], where any value of $N_{0.05}$ (the number of e-folds for a scale 0.05 Mpc^{-1}, on the left vertical axis), corresponding to the scalar tilt n_s shown on the right vertical axis, when projected onto the diagonal line representing one of the three illustrated choices of α-attractor models, corresponds to a specific value of y (lower horizontal axis) and T_{reh} (upper horizontal axis). For example, for $\alpha = 1$ one has

$$y \gtrsim 10^{-10} \quad (68\%\ \text{CL}), \quad y \gtrsim 10^{-17} \quad (95\%\ \text{CL})\,. \tag{23.84}$$

These bounds are not very constraining, but they can be expected to improve significantly in the coming years and thereby provide significant information on the connections between inflation and particle physics.

23.7 Beyond Single-Field Slow-Roll Inflation

There are numerous possible scenarios beyond the simplest single-field models of slow-roll inflation. These include models with features in the potential leading to deviations from slow roll, as well as theories in which non-canonical fields are considered, such as k-inflation [89] or DBI inflation [90], and multiple-field models, such as the curvaton scenario [91]. As well as altering the single-field slow-roll predictions for the primordial curvature power spectrum (Eq. (23.48)) and the tensor-scalar ratio (Eq. (23.49)), they may introduce new quantities that vanish in single-field slow-roll models, such as isocurvature matter perturbations, corresponding to entropy fluctuations in the photon-to-matter ratio, at first order:

$$S_m = \frac{\delta n_m}{n_m} - \frac{\delta n_\gamma}{n_\gamma} = \frac{\delta\rho_m}{\rho_m} - \frac{3}{4}\frac{\delta\rho_\gamma}{\rho_\gamma}\,. \tag{23.85}$$

Another possibility is non-Gaussianity in the distribution of the primordial curvature perturbation (see Chap. 29, "Cosmic Microwave Background" review), encoded in higher-order correlators such as the primordial bispectrum [92]

$$\langle\zeta(\mathbf{k})\zeta(\mathbf{k}')\zeta(\mathbf{k}'')\rangle \equiv (2\pi)^3\delta(\mathbf{k}+\mathbf{k}'+\mathbf{k}'')B_\zeta(k,k',k'')\,, \tag{23.86}$$

which is often expressed in terms of a dimensionless non-linearity parameter

$$f_{NL} \propto B_\zeta(k,k',k'')/P_\zeta(k)P_\zeta(k').$$

The three-point function (Eq. (23.86)) can be thought of as defined on a triangle whose sides are $\mathbf{k}, \mathbf{k}', \mathbf{k}''$, of which only two are independent, since they sum to zero. Further assuming statistical isotropy ensures that the bispectrum depends only on the magnitudes of the three vectors, k, k' and k''. The search for f_{NL} and other non-Gaussian effects was a prime objective of the *Planck* data analysis [93, 94].

23.7.1 *Enhanced perturbations on small scales*

Although the observed primordial power spectrum on CMB scales is constrained to be almost scale invariant, consistent with the simplest slow-roll inflation models, the form of the power spectrum is largely unconstrained on much smaller scales, corresponding to scales that would have left the horizon closer to the end of inflation. Although free-streaming and other damping of perturbations in the primordial plasma are expected to have washed out small-scale fluctuations in the matter sector [95], gravitational relics such as primordial black holes [96, 97] or induced gravitational waves [98–101] produced by sufficiently large primordial density perturbations could have survived and might be detectable in the present day. Rapid growth of the power spectrum on small scales requires violation of slow roll in single-field models [102]. This could arise from features in the scalar field potential, such as an inflection point [103], leading to a transient phase of ultra-slow-roll evolution [104, 105] which can give a k^4-rise in the scalar power spectrum on small scales [106, 107].

The LIGO-Virgo-KAGRA collaboration has placed an upper limit on such a stochastic gravitational wave background (SGWB), conventionally expressed in terms of the effective density of gravitational waves per logarithmic frequency interval, of $\Omega_{GW} \leq 5.8 \times 10^{-9}$ for a scale-invariant spectrum in the frequency range $20 - 77$ Hz [108]. On the other hand, pulsar timing arrays have found growing evidence for a low-frequency SGWB at nano-Hertz frequencies [109–112]. While this could be associated with an astrophysical background due to supermassive black hole binary systems, the NANOGrav collaboration report that a cosmological background provides a better fit to their 15-year dataset [113]. This could be generated by large primordial density fluctuations on the corresponding comoving scales, $k \sim 10^6$ Mpc^{-1}, but these are constrained by the production of primordial black holes of approximately solar mass [114] and possible one-loop or higher-order corrections to the primordial power spectrum on CMB scales.

23.7.2 *Effective Field Theory of Inflation*

Since slow-roll inflation is a phase of accelerated expansion with an almost constant Hubble parameter, one may think of inflation in terms of an effective theory where the de Sitter spacetime symmetry is spontaneously broken down to RW symmetry by the time-evolution of the Hubble rate, $\dot{H} \neq 0$. There is then a Goldstone boson, π, associated with the spontaneous breaking of time-translation invariance, which can be used to study model-independent properties of inflation. The Goldstone boson describes a spacetime-dependent shift of the time coordinate, corresponding to an adiabatic perturbation of the matter fields:

$$\delta\phi_i(t,\vec{x}) = \phi_i(t + \pi(t,\vec{x})) - \phi_i(t)\,. \tag{23.87}$$

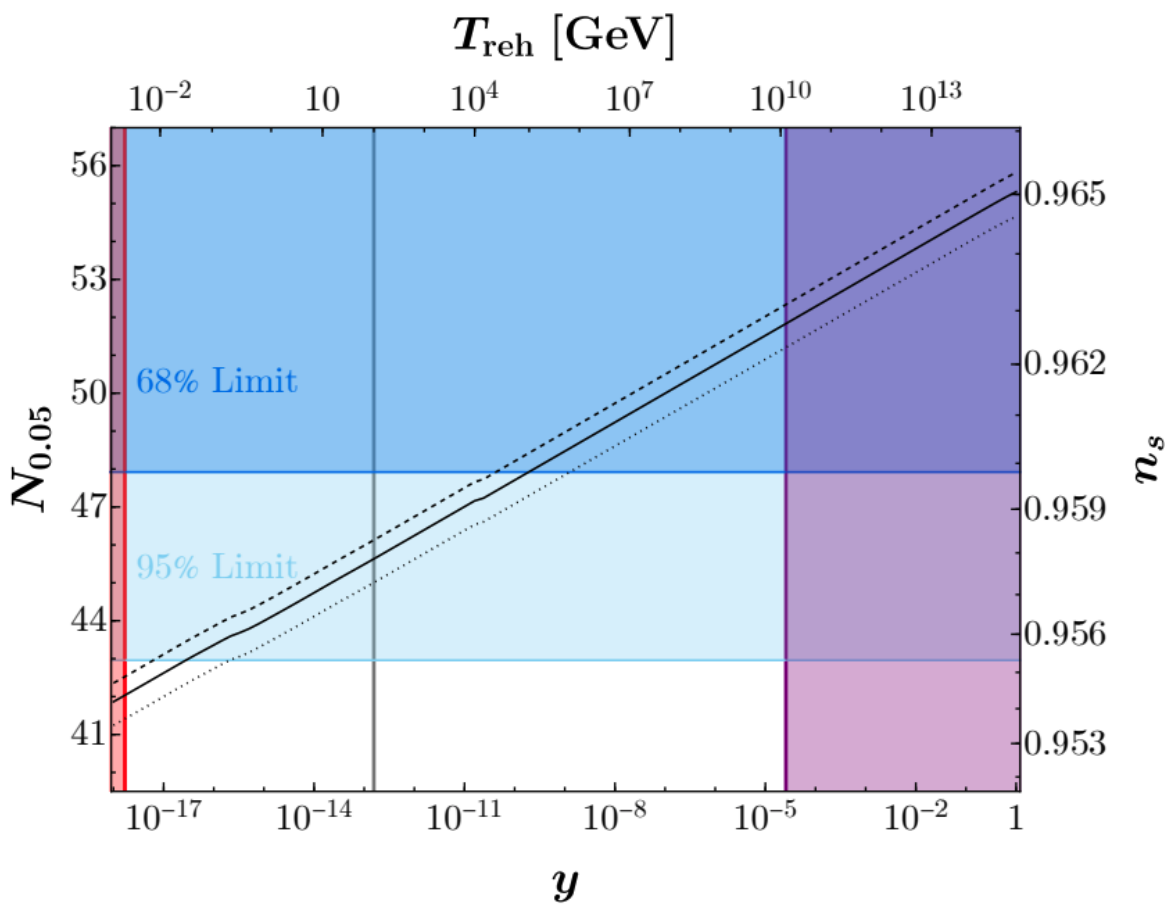

Figure 23.5: lllustration of the impact of the BICEP/Keck [43] and other constraints on the inflaton decay coupling, y, and the number of e-folds at a scale 0.05 Mpc^{-1}, $N_{0.05}$, in α-attractor models of inflation. The horizontal blue lines are 68% and 95% C.L. lower limits on n_s. The left and right axes show the relation between $N_{0.05}$ and n_s and the top and bottom scales show the relation between the inflaton coupling, y, and the reheating temperature, T_{reh}. The diagonal dashed, solid and dotted black lines illustrate the correlations between these quantities for α-attractor models with $\alpha = 0.1$, 1, and 5. We also include the lower limit on y from Big Bang Nucleosynthesis (red line), the constraint that T_{reh} be no smaller than the electroweak scale (gray line), and a constraint from gravitino production (purple line) for $\alpha = 1$, which strengthens for smaller α. Plot taken from Ref. [85].

Thus adiabatic field fluctuations can be absorbed into the spatial metric perturbation, $\mathcal{R}$ in Eq. (23.28) at first order, in the comoving gauge:

$$\mathcal{R} = -H\pi\,, \tag{23.88}$$

where we define π on spatially-flat hypersurfaces. In terms of inflaton field fluctuations, we can identify $\pi \equiv \delta\phi/\dot{\phi}$, but in principle this analysis is not restricted to inflation driven by scalar fields.

The low-energy effective action for π can be obtained by writing down the most general Lorentz-invariant action and expanding in terms of π. The second-order effective action for the free-field wave modes, π_k, to leading order in slow roll is then

$$S_\pi^{(2)} = -\int d^4x\sqrt{-g}\frac{M_P^2\dot{H}}{c_s^2}\left[\dot{\pi}_k^2 - \frac{c_s^2}{R^2}(\nabla\pi)^2\right]\,, \tag{23.89}$$

where ϵ_H is the Hubble slow-roll parameter (Eq. (23.11)). We identify c_s^2 with an effective sound speed, generalising canonical slow-roll inflation, which is recovered in the limit $c_s^2 \to 1$.

The scalar power spectrum on super-Hubble scales (Eq. (23.48)) is enhanced for a reduced sound speed, leading to a reduced tensor-scalar ratio (Eq. (23.49))

$$\mathcal{P}_\zeta(k) \simeq \frac{4\pi}{M_P^2}\frac{1}{c_s^2\epsilon}\left(\frac{H}{2\pi}\right)^2_*\,, \qquad r \simeq 16(c_s^2\epsilon)_*\,. \tag{23.90}$$

At third perturbative order and to lowest order in derivatives, one obtains [115]

$$S_\pi^{(3)} = \int d^4x\sqrt{-g}\frac{M_P^2(1-c_s^2)\dot{H}}{c_s^2}\left[\frac{\dot{\pi}(\nabla\pi)^2}{R^2} - \left(1+\frac{2}{3}\frac{\tilde{c}_3}{c_s^2}\right)\dot{\pi}^3\right]\,. \tag{23.91}$$

Note that this expression vanishes for canonical fields with $c_s^2 = 1$. For $c_s^2 \neq 1$ the cubic action is determined by the sound speed and an additional parameter $\tilde{c}_3$. Both terms in the cubic action give rise to primordial bispectra that are well approximated by equilateral bispectra. However, the shapes are not identical, so one can find a linear combination for which the equilateral bispectra of each term cancel, giving rise to a distinctive orthogonal-type bispectrum [115].

Analysis based on *Planck* 2018 temperature and polarization data has placed bounds on several bispectrum shapes including equilateral and orthogonal shapes [94]:

$$f_{NL}^{equil} = -26 \pm 47\,, \qquad f_{NL}^{orthog} = -38 \pm 24 \quad (68\%\ \text{CL})\,. \tag{23.92}$$

For the simplest case of a constant sound speed, and marginalising over $\tilde{c}_3$, this provides a bound on the inflaton sound speed [94]

$$c_s \geq 0.021 \quad (95\%\ \text{CL})\,. \tag{23.93}$$

For a specific model such as DBI inflation [90], corresponding to $\tilde{c}_3 = 3(1-c_s^2)/2$, one obtains a tighter bound [94]:

$$c_s^{DBI} \geq 0.086 \quad (95\%\ \text{CL})\,. \tag{23.94}$$

The *Planck* team have analysed a wide range of non-Gaussian templates from different inflation models, including tests for deviations from an initial Bunch-Davies vacuum state, direction-dependent non-Gaussianity, and feature models with oscillatory bispectra [94]. No individual feature or resonance is above the three-σ significance level after accounting for the look-elsewhere effect. These results are consistent with the simplest canonical, slow-roll inflation models, but do not rule out most alternative models; rather, bounds on primordial non-Gaussianity place important constraints on the parameter space for non-canonical models.

23.7.3 *Multi-Field Fluctuations*

There is a very large literature on two- and multi-field models of inflation, most of which lies beyond the scope of this review [116, 117]. However, two important general topics merit being mentioned here, namely residual isocurvature perturbations and the possibility of non-Gaussian effects in the primordial perturbations.

One might expect that other scalar fields besides the inflaton might have non-negligible values that evolve and fluctuate in parallel with the inflaton, without necessarily making the dominant contribution to the energy density during the inflationary epoch. However, the energy density in such a field might persist beyond the end of inflation before decaying, at which point it might come to dominate (or at least make a non-negligible contribution to) the total energy density. In such a case, its perturbations could end up generating the density perturbations detected in the CMB. This could occur due to a late-decaying scalar field [91] or a field fluctuation that modulates the end of inflation [118] or the inflaton decay [119].

23.7.3.1 *Isocurvature Perturbations*

Primordial perturbations arising in single-field slow-roll inflation are necessarily adiabatic, i.e., they affect the overall density without changing the ratios of different contributions, such as the photon-matter ratio, $\delta(n_\gamma/n_m)/(n_\gamma/n_m)$. This is because inflaton perturbations represent a local shift of the time, as described in section Sec. 23.7.2:

$$\pi = \frac{\delta n_\gamma}{\dot{n}_\gamma} = \frac{\delta n_m}{\dot{n}_m} \,. \tag{23.95}$$

However, any light scalar field (i.e., one with effective mass less than the Hubble scale) acquires a spectrum of nearly scale-invariant perturbations during inflation. Fluctuations orthogonal to the inflaton in field space are decoupled from the inflaton at Hubble-exit, but can affect the subsequent evolution of the density perturbation. In particular, they can give rise to local variations in the equation of state (non-adabatic pressure perturbations) that can alter the primordial curvature perturbation ζ on super-Hubble scales. Since these fluctuations are statistically independent of the inflaton perturbations at leading order in slow roll [117], non-adiabatic field fluctuations can only increase the scalar power spectrum with respect to adiabatic perturbations at Hubble exit, while leaving the tensor modes unaffected at first perturbative order. Thus, the single-field result for the tensor-scalar ratio (Eq. (23.49)) becomes an inequality [120]

$$r \leq 16\epsilon_* \,. \tag{23.96}$$

Hence, an observational upper bound on the tensor-scalar ratio does not bound the slow-roll parameter ϵ in multi-field models.

If all the scalar fields present during inflation eventually decay completely into fully thermalized radiation, these field fluctuations are converted fully into adiabatic perturbations in the primordial plasma [121]. On the other hand, non-adiabatic field fluctuations can also leave behind primordial isocurvature perturbations (Eq. (23.85)) after inflation. In multi-field inflation models it is thus possible for non-adiabatic field fluctuations to generate both curvature and isocurvature perturbations leading to correlated primordial perturbations [122].

The amplitudes of any primordial isocurvature perturbations (Eq. (23.85)) are strongly constrained by the current CMB data, especially on large angular scales. Using temperature and low-ℓ polarization data yields the following bound on the amplitude of cold dark matter isocurvature perturbations at scale $k = 0.002h^{-1}\mathrm{Mpc}^{-1}$ (marginalising over the correlation angle and in the absence of primordial tensor perturbations) [38]:

$$\frac{\mathcal{P}_{S_m}}{\mathcal{P}_\zeta + \mathcal{P}_{S_m}} < 0.025 \text{ (95\% CL)} \,. \tag{23.97}$$

For fully (anti-)correlated isocurvature perturbations, corresponding to a single isocurvature field providing a source for both the curvature and residual isocurvature perturbations, the bounds become significantly tighter [38]:

$$\frac{\mathcal{P}_{S_m}}{\mathcal{P}_\zeta + \mathcal{P}_{S_m}} < 0.0002 \text{ (95\% CL), correlated} \,, \tag{23.98}$$

$$\frac{\mathcal{P}_{S_m}}{\mathcal{P}_\zeta + \mathcal{P}_{S_m}} < 0.003 \text{ (95\% CL), anti-correlated} \tag{23.99}$$

23.7.3.2 *Local-Type Non-Gaussianity*

Since non-adiabatic field fluctuations in multi-field inflation may lead the to evolution of the primordial curvature perturbation at all orders, it becomes possible to generate significant non-Gaussianity in the primordial curvature perturbation. Non-linear evolution on super-Hubble scales leads to local-type non-Gaussianity, where the local integrated expansion is a non-linear function of the local field values during inflation, $N(\phi_i)$. While the field fluctuations at Hubble exit, $\delta\phi_{i*}$, are Gaussian in the slow-roll limit, the curvature perturbation, $\zeta = \delta N$, becomes a non-Gaussian distribution [123]:

$$\zeta = \sum_i \frac{\partial N}{\partial \phi_i}\delta\phi_i + \frac{1}{2}\sum_{i,j}\frac{\partial^2 N}{\partial\phi_i\partial\phi_j}\delta\phi_i\delta\phi_j + \ldots \tag{23.100}$$

with non-vanishing bispectrum in the squeezed limit ($k_1 \approx k_2 \gg k_3$):

$$B_\zeta(k_1,k_2,k_3) \approx \frac{12}{5} f_{NL}^{local} \frac{\mathcal{P}_\zeta(k_1)}{4\pi k_1^3}\frac{\mathcal{P}_\zeta(k_3)}{4\pi k_3^3} \,, \tag{23.101}$$

where

$$\frac{6}{5} f_{NL}^{local} = \frac{\sum_{i,j}\frac{\partial^2 N}{\partial\phi_i\partial\phi_j}}{\left(\sum_i \frac{\partial N}{\partial\phi_i}\right)^2} \,. \tag{23.102}$$

Both equilateral and orthogonal bispectra, discussed above in the context of generalised single field inflation, vanish in the squeezed limit, enabling the three types of non-Gaussianity to be distinguished by observations, in principle.

Non-Gaussianity during multi-field inflation is highly model dependent, though f_{NL}^{local} can often be smaller than unity in multi-field slow-roll inflation [124]. Scenarios where a second light field plays a role during or after inflation can make distinctive predictions for f_{NL}^{local}, such as $f_{NL}^{local} = -5/4$ in some curvaton scenarios [123, 125] or $f_{NL}^{local} = 5$ in simple modulated reheating scenarios [119, 126]. By contrast the constancy of ζ on super-Hubble scales in single-field slow-roll inflation leads to a very small non-Gaussianity [127, 128], and in the squeezed limit we have the simple result $f_{NL}^{local} = 5(1 - n_S)/12$ [129, 130].

A combined analysis of the *Planck* 2018 temperature and polarization data [94] yields the following range for f_{NL}^{local} defined in (Eq. (23.102)):

$$f_{NL}^{local} = -1 \pm 5 \quad (68\% \text{ CL}) \,. \tag{23.103}$$

This sensitivity is sufficient to rule out parameter regimes giving rise to relatively large non-Gaussianity, but insufficient to probe $f_{NL}^{local} = \mathcal{O}(\epsilon)$, as expected in single-field models, or the range $f_{NL}^{local} = \mathcal{O}(1)$ found in the simplest two-field models.

Local-type primordial non-Gaussianity can also give rise to a striking scale-dependent bias in the distribution of collapsed dark matter halos and thus the galaxy distribution [131, 132]. Bounds from high-redshift galaxy surveys are not currently competitive

with the best CMB constraints. An analysis based on the clustering of quasars in the final data release (DR16) of the extended Baryon acoustic Oscillation Spectroscopic Survey (eBOSS) [133] yields

$$f_{NL}^{local} = -12 \pm 21 \quad (68\%\ \mathrm{CL})\,. \tag{23.104}$$

A recent analysis based on the clustering of luminous red galaxies in imaging surveys from the Dark Energy Spectroscopic Instrument (DESI) [134] finds $f_{NL}^{local} = 47^{+14}_{-11}$, suggesting that $f_{NL}^{local} > 0$ at more than 99.9% confidence, although the possibility that this could be due to unforeseen systematics cannot yet be excluded.

23.8 Initial Conditions and Fine-tuning

This review is based on the assumption that the inflationary paradigm is valid. However, it remains the object of many criticisms (see, e.g., [135]), many of them related to the perceived unnaturalness of the required initial conditions.

Most work on inflation is done in the context of RW cosmology, which assumes a high degree of symmetry, or small inhomogeneous perturbations (usually first order) about an RW cosmology. The isotropic RW space-time is an attractor for many homogeneous but anisotropic cosmologies in the presence of a false vacuum energy density [136], or a scalar field with suitable self-interaction potential energy [137,138]. However it is much harder to establish the range of highly inhomogeneous initial conditions that yield a successful RW Universe, with only limited studies initially (see, e.g., [139,140]). A related open question is the general nature of the pre-inflationary state of the inflaton and other fields that could have provided initial conditions suitable for inflation [135]. They would need to have satisfied non-trivial homogeneity and isotropy conditions, and one may ask how these could have arisen, whether these are plausible, and whether there may be some observable signature of the pre-inflationary state. These and other criticisms of inflation were addressed in [141], which presented studies of the sensitivity of inflation to the initial conditions. Complementing the studies reported in [141], there have been numerical relativity investigations of highly inhomogeneous initial conditions [142–144]. The general conclusion is that inflation is rather robust with respect to inhomogeneities in the initial conditions in both the scalar field profile and the extrinsic curvature, including large tensor perturbations.

To quantify the fine-tuning of initial conditions requires a measure in the space of possible cosmologies [145], however it has been argued that some of the measures historically used to frame this problem are formally invalid [146]. It is sometimes also objected that inflationary models predict the existence of a multiverse, and potentially a loss of predictive power [147], if it undergoes the process termed eternal inflation [148–150]. However, whether this is actually a bug or a feature remains a topic of debate [151, 152]. The existence of the multiverse is a purely philosophical problem, unless it has observable consequences, e.g., in the CMB.

One might expect signatures of any pre-inflationary state to appear at large angular scales, i.e., low multipoles ℓ. Indeed, various anomalies have been noted in the large-scale CMB anisotropies, as also discussed in Chap. 29, the "Cosmic Microwave Background" review, including a possible suppression of the quadrupole and other very large-scale anisotropies, an apparent feature in the range $\ell \approx 20$ to 30, and a possible hemispheric asymmetry. However, none of these are highly significant statistically, in view of the limitations due to cosmic variance [64]. They cannot yet be regarded as signatures of initial conditions, the multiverse or some pre-inflationary dynamics, such as might emerge from string theory.

A different kind of initial condition problem, called the trans-Planckian problem [153], is that the perturbations now seen in the CMB would have had wavelengths shorter than the Planck length at the onset of inflation. However, under quite general and conservative assumptions the usual inflationary predictions would be quite robust [154], with the possibility of $\mathcal{O}((H/m_P)^n)$ corrections that might have interesting signatures in the CMB [155].

When inflation was first proposed [1] [2] there was no evidence for the existence of scalar fields or the accelerated expansion of the Universe. The situation has changed dramatically in recent years with the observational evidence that the cosmic expansion is currently accelerating and with the discovery of a scalar particle, namely the Higgs boson (see Chap. 11, "Status of Higgs boson physics" review). Combined with the lack of any widely accepted alternative model for the origin of cosmic structure, these discoveries have lent support to the idea of a primordial accelerated expansion driven by a scalar field, i.e., cosmological inflation. In parallel, successive CMB experiments have been consistent with generic predictions of inflationary models, although without yet providing irrefutable evidence. It was concluded in [141] that the inflationary paradigm is not currently in trouble. However, we note that inflation via a formally elementary scalar inflaton should probably only be regarded as an effective field theory valid at energy densities hierarchically smaller than the Planck scale. It should eventually be embedded in a suitable ultraviolet completion, on which inflationary dynamics may be our clearest window.

23.9 Future Probes of Inflation

Prospective future CMB experiments, both ground- and space-based are reviewed in the separate PDG "Cosmic Microwave Background" review, Chap. 29. The main emphasis in CMB experiments in the coming years will be on ground-based experiments providing improved measurements of B-mode polarization and greater sensitivity to the tensor-to-scalar ratio r, and more precise measurements at higher ℓ that will constrain n_s better. As is apparent from Fig. 23.1 and the discussion of models such as R^2 inflation, there is a strong incentive to reach a 5-σ sensitivity to $r \sim 3$ to 4×10^{-3}. This could be achieved with a moderately-sized space mission with large sky coverage [156], improvements in delensing and foreground measurements. The discussion in Sec. 23.3 (see also Fig. 23.5), also brought out the importance of reducing the uncertainty in n_s, as a way to constrain post-inflationary reheating and the connection to particle physics. CMB temperature anisotropies probe primordial density perturbations down to comoving scales of order 50 Mpc, beyond which scale secondary sources of anisotropy dominate. CMB spectral distortions could potentially constrain the amplitude and shape of primordial density perturbations on comoving scales from Mpc to kpc due to distortions caused by the Silk damping of pressure waves in the radiation dominated era, before the last scattering of the CMB photons but after the plasma can be fully thermalised [95].

Improved sensitivity to non-Gaussianities is also a priority. In addition to CMB measurements, future large-scale structure surveys will also have roles to play as probes into models of inflation, for which there are excellent prospects. Current surveys such as DESI may reach $\Delta f_{NL} \sim 4$ [157] comparable with the *Planck* sensitivity. In the future, radio surveys such as SKA will measure large-scale structure out to redshift $z \sim 3$ [158], initially through mapping the intensity of the neutral hydrogen 21-cm line, and eventually through radio galaxy surveys which will probe local-type non-Gaussianity to $f_{NL} \sim 1$.

Galaxy clustering using DESI and *Euclid* satellite data could also constrain the running of the scalar tilt to a precision of $\Delta\alpha_s \approx 0.0028$, a factor of 2 improvement on *Planck* constraints, or a precision of 0.0016 using LSST data [157].

As an example of a proposed future satellite mission, *SPHEREx* [159] will use measurements of the galaxy power spectrum to target a measurement of the running of the scalar spectral index with a sensitivity $\Delta\alpha_s \sim 10^{-3}$ and local-type primordial non-Gaussianity, $\Delta f_{NL} \sim 1$. Including information from the galaxy bispectrum one might reduce the measurement error on non-Gaussianity to $\Delta f_{NL} \sim 0.2$, making it possible to distinguish between single-field slow-roll models and alternatives such as the curvaton scenario for the origin of structure, which generate $f_{NL} \sim 1$.

Finally we note that future gravitational wave experiments such as the Laser Interferometer Space Antenna (LISA) will be sensitive to a stochastic gravitational wave background, including tensor perturbations produced during inflation or induced by large primordial density perturbations on small scales after inflation [160], which could provide constraints on inflationary perturbations on smaller scales.

24. Big Bang Nucleosynthesis

Revised August 2023 by B.D. Fields (Astronomy, Illinois U.; Physics, Illinois U.), P. Molaro (INAF-OATS Trieste; IFPU) and S. Sarkar (Rudolf Peierls, Oxford U.).

24.1 Abstract

Big-Bang nucleosynthesis (BBN) offers the deepest reliable probe of the early Universe, being based on well-understood Standard Model physics [1]. Predictions of the abundances of the light elements, D, ^{3}He, ^{4}He, and ^{7}Li, synthesized at the end of the *first three minutes*, are in good overall agreement with the primordial abundances inferred from observational data, thus validating the standard hot Big-Bang cosmology (see [2–5] for reviews). This is particularly impressive given that these abundances span nine orders of magnitude – from ^{4}He/H~ 0.08 down to ^{7}Li/H$\sim 10^{-10}$ (ratios by number). Thus BBN provides powerful constraints on possible deviations from the standard cosmology, and on new physics beyond the Standard Model [6–9].

24.2 Theory

The synthesis of the light elements is sensitive to physical conditions in the early radiation-dominated era at a temperature $T \sim 1$ MeV, corresponding to an age $t \sim 1$ s. At higher temperatures, weak interactions were in thermal equilibrium, thus fixing the ratio of the neutron and proton number densities to be $n/p = \mathrm{e}^{-Q/T}$, where $Q = 1.293$ MeV is the neutron-proton mass difference. As the temperature dropped, the neutron-proton inter-conversion rate per nucleon, $\Gamma_{n\leftrightarrow p} \sim G_{\rm F}^2 T^5$, fell faster than the Hubble expansion rate, $H \sim \sqrt{g_* G_{\rm N}}\, T^2$, where g_* counts the number of relativistic particle species determining the energy density in radiation (see 'Big Bang Cosmology' — Sec. 22 of this *Review*). This resulted in departure from chemical equilibrium (*freeze-out*) at $T_{\rm fr} \sim (g_* G_{\rm N}/G_{\rm F}^4)^{1/6} \simeq 1$ MeV. The neutron fraction at this time, $n/p = \mathrm{e}^{-Q/T_{\rm fr}} \simeq 1/6$, is thus sensitive to every known physical interaction, since Q is determined by both strong and electromagnetic interactions while $T_{\rm fr}$ depends on the weak as well as gravitational interactions. Moreover, the sensitivity to the Hubble expansion rate affords a probe of, *e.g.,* the number of relativistic neutrino species [10]. After freeze-out, the neutrons were free to β-decay, so the neutron fraction dropped to $n/p \simeq 1/7$ by the time nuclear reactions began. A simplified analytic model of freeze-out yields the n/p ratio to an accuracy of $\sim 1\%$ [11,12].

The rates of these reactions depend on the density of baryons (strictly speaking, nucleons), which is usually expressed normalized to the relic blackbody photon density as $\eta \equiv n_b/n_\gamma$. As we shall see, all the light-element abundances can be explained with $\eta_{10} \equiv \eta \times 10^{10}$ in the range 6.143 ± 0.190. With n_γ fixed by the present CMB temperature 2.7255 K (see 'Cosmic Microwave Background' — Sec. 29 of this *Review*), this can be stated as the allowed range for the baryon mass density today, $\rho_{\rm b} = (4.2\pm0.1)\times10^{-31}$ g cm^{-3}, or as the baryonic fraction of the critical density, $\Omega_{\rm b} = \rho_b/\rho_{\rm crit} \simeq \eta_{10} h^{-2}/274 = (0.02244 \pm 0.00069) h^{-2}$, where $h \equiv H_0/100$ km s^{-1} Mpc^{-1} is the present Hubble parameter (see 'The Cosmological Parameters' — Sec. 25 of this *Review*).

The nucleosynthesis chain begins with the formation of deuterium in the process $p(n,\gamma)$D. However, photo-dissociation by the high number density of photons delays production of deuterium (and other complex nuclei) until well after T drops below the binding energy of deuterium, $\Delta_{\rm D} = 2.23$ MeV. The quantity $\eta^{-1}\mathrm{e}^{-\Delta_{\rm D}/T}$, *i.e.,* the number of photons per baryon above the deuterium photo-dissociation threshold, falls below unity at $T \simeq 0.1$ MeV; nuclei can then begin to form without being immediately photo-dissociated again. Only 2-body reactions, such as $\mathrm{D}(p,\gamma)^3$He and $^3\mathrm{He}(\mathrm{D},p)^4$He are important because the density by this time has become rather low – comparable to that of air!

Nearly all neutrons end up bound in the most stable light element ^{4}He. Heavier nuclei do not form in any significant quantity both because of the absence of stable nuclei with mass number 5 or 8 (which impedes nucleosynthesis via n^4He, p^4He or ^{4}He^{4}He reactions), and the large Coulomb barriers for reactions such as $^3\mathrm{He}(^4\mathrm{He},\gamma)^7$Li and $^3\mathrm{He}(^4\mathrm{He},\gamma)^7$Be. Hence the primordial mass fraction of ^{4}He, $Y_{\rm p} \equiv \rho(^4\mathrm{He})/\rho_{\rm b}$, can be estimated by the simple counting argument

$$Y_{\rm p} = \frac{2(n/p)}{1+n/p} \simeq 0.25 \qquad (24.1)$$

where strictly speaking this gives the baryon fraction in ^{4}He, which is what we will quote throughout. This differs slightly from the mass fraction due to small binding energy corrections.

There is little sensitivity here to the actual nuclear reaction rates for the production of ^{4}He. Nuclear rates are, however, critically important in determining the other 'left-over' abundances: D and ^{3}He at the level of a few times 10^{-5} by number relative to H, and ^{7}Li/H at the level of about 10^{-10} (when η_{10} is in the range 1–10). These values can be understood in terms of approximate analytic arguments [12,13].

The elemental abundances shown in Fig. 24.1 as a function of η_{10} were calculated using an updated version [14] of the Wagoner code [1]; other versions [15–17] too are publicly available. The ^{4}He curve includes small corrections due to radiative processes at zero and finite temperatures [18], non-equilibrium neutrino heating during $e^\pm$ annihilation [19], and finite nucleon mass effects [20]; the range primarily reflects the 2σ uncertainty in the neutron lifetime. The spread in the curves for D, ^{3}He, and ^{7}Li corresponds to the 2σ uncertainties in nuclear cross sections, as estimated by Monte Carlo methods [21–24]. The input nuclear data have been carefully reassessed [2, 14, 21–31], leading to improved precision for the abundance predictions. In particular, the uncertainty in ^{7}Li/H at interesting values of η has been reduced recently by a factor ~ 2, a consequence of a similar reduction in the error budget [32] for the dominant mass-7 production channel $^3\mathrm{He}(^4\mathrm{He},\gamma)^7$Be. Polynomial fits to the predicted abundances and the error correlation matrix have been given in refs. [23, 33]. The boxes in Fig 24.1 show the observationally inferred primordial abundances with their associated uncertainties, as discussed below.

The nuclear reaction cross sections important for BBN have all been measured at the relevant energies. Recently however there have been substantial advances in the precision of light element observations (e.g., D/H) and in the determination of cosmological parameters (e.g., from *Planck*). This motivates corresponding improvement in BBN predictions and thus in the key reaction cross sections. Recent measurements of $\mathrm{D}(p,\gamma)^3$He by the LUNA collaboration have significantly improved the precision of D/H predictions [34]. Even so, the nuclear uncertainties still leave D/H prediction errors larger than those of the observations [14, 30, 31]. The $\mathrm{D}(\mathrm{D},n)^3$He and $\mathrm{D}(\mathrm{D},p)^3H$ reactions now not only dominate the uncertainty budget, but they can give significantly different D/H predictions depending on whether one uses just the empirical determination of the cross sections, or also uses theory to guide the functional form. Clearly, more experimental data is needed.

An additional experimental parameter important in determining the light element abundances is the neutron lifetime, τ_n, which normalizes (the inverse of) $\Gamma_{n\leftrightarrow p}$. Its value has been revised downwards to $\tau_n = 879.4 \pm 0.6$ s (see *N* Baryons Listing).

24.3 Observations: the Light Element Abundances

BBN theory predicts the universal abundances of D, ^{3}He, ^{4}He, and ^{7}Li which are essentially fixed by $t \sim 180$ s. However, abundances are *derived* at much later epochs, after stellar nucleosynthesis commenced. Stars produce heavy elements such as C, N, O, and Fe ("metals"), while the ejected remains of stellar processing alters the light element abundances from their primordial values. Thus, one seeks astrophysical sites with low metal abundances to measure light element abundances that are closer to primordial.

BBN is the only significant source of deuterium which is entirely destroyed when it is cycled into stars [35]. Thus, any detection provides a lower limit to primordial $\mathrm{D/H}|_{\rm p}$, and an upper limit on η_{10}. The best proxy to the primordial value of D is its measure in distant and chemically unprocessed matter, where stellar processing (astration) is minimal [35, 36]. This has become possible with the advent of large telescopes, but after nearly three decades

of observational efforts we have only 11 determinations listed in Table 24.1 [37–43].

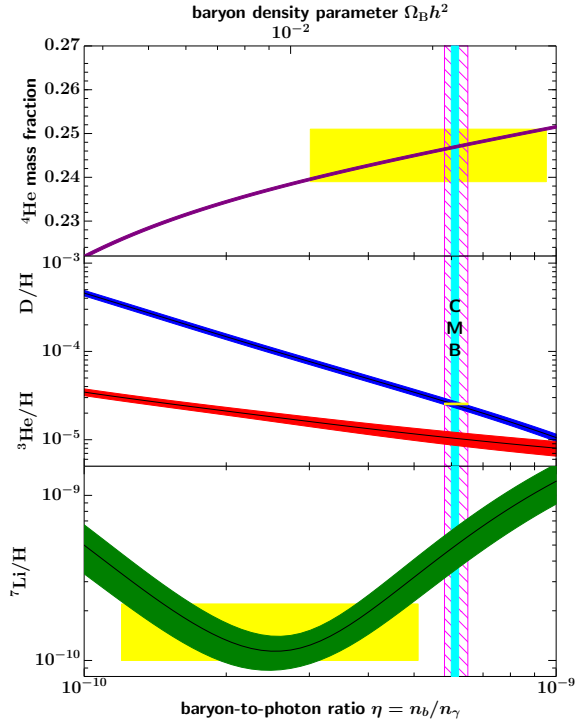

Figure 24.1: The primordial abundances of ^{4}He, D, ^{3}He, and ^{7}Li as predicted by the standard model of Big-Bang nucleosynthesis — the bands show the 95% CL range [44]. Boxes indicate the observed light element abundances. The narrow vertical band indicates the CMB measure of the cosmic baryon density, while the wider band indicates the BBN D+^{4}He concordance range (both at 95% CL).

High-resolution spectra reveal the presence of D in high-redshift, low-metallicity quasar absorption systems via its isotope-shifted Lyman-α absorption features, though, unfortunately, these are often obscured or contaminated by the hydrogen features of the Lyman-α forest. A few DLA systems show D lines resolved up to the higher members of the Lyman series. Recent determinations [38, 40] and re-analyses [41–43] provide strikingly improved precision over earlier work. D/H shows no correlation with metallicity, redshift, or the neutral hydrogen column density N(HI) ($= \int_{\rm los} n_{\rm HI}\, ds$) integrated over the line-of-sight through the absorber. Metallicities of the absorbers are $(0.001 - 0.03)\times$ Solar, and the level astration is estimated at the 0.1-1 % level [36]. In the Galaxy DI/HI measurements are anti-correlated with metal abundances, which suggests that interstellar D partly resides in dust particles [45]. However, in the absorbers where deuterium is measured, the dust content is small, as implied by Solar proportions of the abundances of refractory and non refractory elements. Thus, the neutral atomic ratio DI/HI $\equiv$ D/H should match the underlying isotope ratio, and be truly representative of the primordial value D/H|$_{\rm p}$. The weighted mean of the 11 most precise measurements in Table 24.1 is D/H|$_{\rm p} \times 10^6 = (25.47 \pm 0.25)$. However, these measurements provide $\chi^2/(N-1) = 1.295$, showing that some error is underestimated. We thus increase the uncertainty by a factor $S = \sqrt{\chi^2/(N-1)} = 1.137$ and the recommended value is:

$$\mathrm{D/H}|_{\rm p} \times 10^6 = (25.47 \pm 0.29). \qquad (24.2)$$

Considering also the previous determinations of [46–50], the weighted mean of 16 measurements is D/H|$_{\rm p} \times 10^6 = (25.36 \pm 0.26)$, while different selections provide D/H|$_{\rm p} \times 10^6 = (25.27 \pm 0.30)$ [43] or D/H|$_{\rm p} \times 10^6 = (25.45 \pm 0.25)$ [42]. These are all consistent with each other, even without the S correction.

The primordial ^{4}He abundance is best determined through recombination emission lines of He and H in the most metal-poor extragalactic HII (ionized) regions, *viz.* blue compact galaxies, generally found at low redshift. There is now a large body of data on ^{4}He and CNO in these galaxies, with over 1000 such systems in the Sloan Digital Sky Survey alone [51]. These data confirm that the stellar contribution to the helium abundance is positively correlated with metal production, so extrapolation to zero metallicity gives the primordial ^{4}He abundance $Y_{\rm p}$. However, HII regions are complex systems and several physical parameters enter in the He/H determination, notably the electron density and temperature, as well as reddening. Thus, systematic effects dominate the uncertainties in the abundance determination [52, 53]. A major step forward has been the inclusion of the He λ10830 infrared emission line which shows a strong dependence on the electron density and is thus useful to break the degeneracy with the temperature, allowing for a more robust helium abundance determination. In recent works the underlying ^{4}He stellar absorption, and/or the newly derived values of the HeI-recombination and H-excitation-collisional coefficients are adressed and the ^{4}He abundances have increased significantly. Some recent results are reported in Table 24.2.

There is a reassuring convergence towards the value of $Y_{\rm p} = 0.245$ between detailed analyses of specific extragalactic HII regions with other (statistically more significant) analyses of many systems. Thus our recommended ^{4}He abundance is:

$$Y_{\rm p} = 0.245 \pm 0.003. \qquad (24.3)$$

The central value is close to the mean/weighted average of the values in Table 24.2, however we caution that combining these partially overlapping data sets is not straightforward. The uncertainty reflects the combined statistical and systematic errors, with the latter, estimated to be ± 0.002 [59], being dominant.

The best suited objects for the determination of primordial ^{7}Li are metal-poor stars in the Galactic halo, which have metallicities going down to 10^{-6} of the Solar value [61]. Observations have long shown [62–65] that ^{7}Li does not vary significantly in halo dwarfs with metallicities $\lesssim 1/30$ of Solar — the *Spite plateau* [62, 66]. Recent observations show a puzzling drop in the Li/H abundance in metal-poor stars with [Fe/H] < -3.0 [67–69]. This becomes particularly acute at the very low metallicity end where only one star out of the seven dwarfs with metallicities [Fe/H] $\lesssim -4.5$ shows a ^{7}Li abundance close to the Spite Plateau, while in the others where it ought to be present it is either lower or totally absent [61,70]. The reason for the increase in scatter at low metallicity is unknown and prevents derivation of the primordial ^{7}Li value by extrapolation to zero metallicity [68, 69].

To estimate the primordial ^{7}Li value we consider only stars with metallicity in the range $-2.8 <$ [Fe/H] < -1.5 [69], where no scatter in excess of the observational errors is observed. This yields:

$$\mathrm{Li/H}|_{\rm p} = (1.6 \pm 0.3) \times 10^{-10}. \qquad (24.4)$$

Strictly speaking the suggested primordial ^{7}Li abundance should be considered a *lower bound* rather than a measure. In fact, ^{7}Li in Pop II stars may have been partially destroyed due to mixing of the outer layers with the hotter interior [71]. Such processes can be constrained by the absence of significant scatter in ^{7}Li versus T_{eff} [64], but ^{7}Li depletion by a factor as large as ~ 1.8 may have occurred [64, 72]. Stellar determination of Li abundances typically sum over both ^{6}Li and ^{7}Li isotopes. however, high-precision measurements indicate ^{6}Li/^{7}Li ≤ 0.05, thus confirming that ^{7}Li is dominant [73].

The primordial abundance of ^{3}He has the poorest observational determination of all of the light nuclides. The only data available come from the Solar system and from solar-metallicity HII regions in the Galaxy [74]. Therefore, inferring the primordial ^{3}He abundance is problematic, compounded by the fact that stellar nucleosynthesis models for ^{3}He are in conflict with observations. Consequently, we consider it inappropriate to use ^{3}He (and also D+^{3}He) as a cosmological probe.

Table 24.1: D/H measurements. For systems with multiple measurements we used the most recent one which is generally more precise.

24.4 Concordance, Dark Matter, and the CMB

We now use the observed light element abundances to test the theory. We first consider standard BBN, which is based on Standard Model physics alone, so $N_\nu = 3$ and the only free parameter is the baryon-to-photon ratio η. (The implications of BBN for physics beyond the Standard Model will be considered below). Thus, any abundance measurement determines η, and additional measurements overconstrain the theory and thereby provide a consistency check.

While the η ranges spanned by the boxes in Fig 24.1 do not all overlap, they are all within a factor ~ 2 of each other. In particular, the lithium abundance corresponds to η values that are inconsistent with that of the (now very precise) D/H abundance as well as the less-constraining ^{4}He abundance. This discrepancy marks the *lithium problem*. The problem could simply reflect difficulty in determining the primordial lithium abundance, or could hint at a more fundamental omission in the theory. The possibility that lithium reveals new physics is addressed in detail in the next section. If however we exclude the lithium constraint because its inferred abundance suffers from systematic uncertainties, then D/H and ^{4}He are in agreement. The concordant η range is essentially determined by D/H, and yields [75]

$$\eta_{10} = 6.040 \pm 0.118 \qquad (24.5)$$

where the errors are 1σ. Despite the lithium problem, the overall concordance remains remarkable: using only well-established microphysics we can extrapolate back to $t \sim 1$ s to predict light element abundances spanning nine orders of magnitude, in approximate agreement with observation. This is a major success for the standard cosmology, and inspires confidence in extrapolation back to such early times.

This concordance provides a measure of the baryon content:

$$\Omega_{\rm b}{\rm h}^2 = 0.02205 \pm 0.00043 \qquad (24.6)$$

where again errors are 1σ, a result that plays a key role in our understanding of the matter budget of the Universe. First of all $\Omega_{\rm b} \ll 1$, *i.e.*, baryons cannot close the Universe [76]. Furthermore, the cosmic density of (optically) luminous matter is $\Omega_{\rm lum} \simeq 0.0024{\rm h}^{-1}$ [77], so that $\Omega_{\rm b} \gg \Omega_{\rm lum}$: most baryons are optically dark, probably in the form of a diffuse intergalactic medium [78]. Finally, given that $\Omega_{\rm m} \sim 0.3$ (see the 'Dark Matter' and 'Cosmological Parameters' reviews), we infer that most matter in the Universe is not only dark, but also takes some non-baryonic (more precisely, non-nucleonic) form.

The BBN prediction for the cosmic baryon density can be tested through precision measurements of CMB temperature fluctuations (see the 'Cosmic Microwave Background' review). One can determine η from the amplitudes of the acoustic peaks in the CMB angular power spectrum [79], making it possible to compare two measures of η using very different physics, at two widely separated epochs. In the standard cosmology, there is no change in η between BBN and CMB decoupling, thus, a comparison of $\eta_{\rm BBN}$ and $\eta_{\rm CMB}$ is a key test. Agreement would endorse the standard picture, while disagreement could point to new physics during/-between the BBN and CMB epochs.

The analysis described in the Cosmic Microwave Background review (Sec.29), based on *Planck* TT, TE, EE + lowE data and lensing, yields $\Omega_{\rm b}{\rm h}^2 = 0.02237 \pm 0.00015$ [80], which corresponds to $\eta_{10} = 6.12 \pm 0.04$ [81]. This result depends weakly on the primordial helium abundance, and the fiducial *Planck* analysis uses BBN theory to fix $Y_{\rm p}(\eta)$. Without BBN theory, the *Planck* TT, TE, EE + lowE data plus lensing give $\Omega_{\rm b}{\rm h}^2 = 0.02230 \pm 0.00021$, corresponding to $\eta_{10} = 6.104 \pm 0.058$. As shown in Fig. 24.1, this CMB estimate of the baryon density (narrow vertical band) is consistent with the BBN range, *i.e.*, in good agreement with the value inferred from high-redshift D/H measurements and local ^{4}He determinations; together these observations span diverse environments from redshifts $z \sim 1000$ to the present. Combining the CMB and BBN sharpens the baryon measures to $\eta_{10} = 6.115 \pm 0.038$ and $\Omega_{\rm b}h^2 = 0.02233 \pm 0.00014$ [75].

The ^{4}He abundance is proportional to the n/p ratio when the weak-interaction rate falls behind the Hubble expansion rate at $T_{\rm fr} \sim 1$ MeV. The presence of additional neutrino flavors (or of any other relativistic species) at this time increases g_*, hence the expansion rate, leading to a larger value of $T_{\rm fr}$, n/p, and therefore $Y_{\rm p}$ [10, 82]. In the Standard Model at $T = 1$ MeV, $g_* = 5.5 + \frac{7}{4}N_\nu$, where N_ν is the *effective* number of (nearly) massless neutrino flavors. The helium curves in 24.1 were computed taking $N_\nu = 3$; small corrections for non-equilibrium neu-

trino heating [19] are included in the thermal evolution and lead to an effective $N_\nu = 3.044$ compared to assuming instantaneous neutrino freezeout (see 'Big Bang Cosmology' — Sec. 22 of this *Review*). The computed ^{4}He abundance scales as $\Delta Y_{\rm p} \simeq 0.013 \Delta N_\nu$ [11]. Clearly the central value for N_ν from BBN will depend on η, which is independently determined (with weaker sensitivity to N_ν) by the adopted D or ^{7}Li abundance. For example, if the best value for the observed primordial ^{4}He abundance is 0.249, then, for $\eta_{10} \sim 6$, the central value for N_ν is very close to 3. A maximum likelihood analysis on η and N_ν based on ^{4}He and D abundances nearly identical to those above finds the (correlated) 68% CL ranges to be $\eta_{10} = 6.088 \pm 0.054$ and $N_\nu = 2.898 \pm 0.141$ [44,75,83]. Identical results are obtained using a simpler method to extract such bounds based on χ^2 statistics, given a set of input abundances [84].

The CMB damping tail is sensitive to the primordial ^{4}He abundance independently of both BBN and local ^{4}He measurements [85]. The *Planck* analysis using TT, TE, EE+lowE and lensing but not the BBN $Y_{\rm p}(\eta)$ relation gives a ^{4}He mass fraction $0.239^{+0.024}_{-0.025}$, and nucleon fraction $Y_{\rm p} = 0.240^{+0.24}_{-0.25}$, both at 95% CL [80]. This is consistent with the HII region helium abundance determination. Moreover, this value is consistent with the Standard ($N_\nu = 3$) BBN prediction for $Y_{\rm p}$ with the *Planck*-determined baryon density. This concordance represents a successful CMB-only test of BBN.

The precision determination of the baryon density using the CMB motivates using this as an input to BBN calculations. Within the context of the Standard Model, BBN then becomes a zero-parameter theory, and the light element abundances are completely determined to within the uncertainties in $\eta_{\rm CMB}$ and the BBN theoretical errors. Comparison with the observed abundances then can be used to test the astrophysics of post-BBN light element evolution [86]. Alternatively, one can consider possible physics beyond the Standard Model (*e.g.*, which might change the expansion rate during BBN) and then use all of the abundances to test such models; this is discussed in 24.6 below.

24.5 The Lithium Problem and its Possible Resolution

As Fig. 24.1 shows, stellar Li/H measurements are inconsistent with the D/H (and CMB) measurements, given the error budgets we have quoted. For instance, the value of $\mathrm{Li/H}|_{\rm p} = (4.72 \pm 0.7) \times 10^{-10}$ [44] is a factor 3.1 higher than in eq.24.4 which is a 4.4 σ discrepancy.

Stars that have been accreted by the Milky Way Gyrs ago from external galaxies show the same abundances as those in the Milky Way, showing that the Li problem is universal [87–89]. The question then becomes pressing as to whether this mismatch comes from systematic errors in the observed abundances, and/or uncertainties in stellar astrophysics or nuclear inputs, or whether there might be new physics at work [9]. Nuclear inputs (cross sections) for BBN reactions are constrained by extensive laboratory measurements; to increase ^{7}Be destruction requires enhancement of otherwise subdominant processes that can be attained by missed resonances in a few reactions such as $^7\mathrm{Be}(d,p)2\alpha$ if the compound nuclear state properties are particularly favorable [29, 90–92]. However, experimental searches have now closed off these possibilities [93–95], making a *nuclear fix* increasingly unlikely.

Another means to solve the lithium problem is by *in situ* destruction over the long lifetimes of the host halo stars. Stellar depletion mechanisms include diffusion, rotationally induced mixing, or pre-main-sequence depletion. These effects certainly occur, but to reduce lithium to the required levels generally requires some *ad hoc* mechanism and fine tuning of the initial stellar parameters [72, 96–98]. General features of diffusive models are a dispersion in the Li abundances and a pronounced downturn in the Li abundances at the hot end of the Li plateau. Some extra turbulence needs to be invoked to limit diffusion in the hotter stars and to restore uniform Li abundance along the Spite plateau [98]. Li abundances for over 100 000 field stars have been obtained in the GALAH (Galactic Archeology with HERMES) survey. Warm stars with [Fe/H] in between -1.0 and -0.5 form an elevated plateau consistent with the BBN prediction and it has been suggested that this could have been also true for the more metal poor stars which have evolved further [99]. Li destruction in the pre-Main sequence phase has been also proposed [97].

Recent ^{6}Li measurements have cast new light on the lithium problem. BBN production of ^{6}Li is negligible [100]; instead it is created much later by energetic cosmic-ray p and ^{4}He interactions with interstellar gas, in fusion reactions such as $^4\mathrm{He}+^4\mathrm{He} \rightarrow {}^{6,7}\mathrm{Li} + \cdots$. and spallation reactions on interstellar carbon, nitrogen, and oxygen such as $p_{\rm cr} + {}^{16}\mathrm{O} \rightarrow {}^{6,7}\mathrm{Li}{}^{9}\mathrm{Be}{}^{10,11}\mathrm{B} + \cdots$. Thus ^{6}Li, beryllium, and boron are co-produced, and the detection of Be and B in metal-poor stars thus requires cosmic-ray ^{6}Li was present when these stars were formed. ^{6}Li detections were reported for some of these stars [101–103], and because the weakly-bound ^{6}Li nucleus is more easily destroyed than ^{7}Li, the survival of ^{6}Li implied that ^{7}Li destruction should be small. But new observations place strong upper limits on ^{6}Li/H in the plateau stars where this isotope had long been reported to exist [104]. This removes the ^{6}Li argument against stellar depletion. Indeed, detailed models of cosmic-ray lithium production can quantify the ^{6}Li depletion, and may suggest the ^{7}Li destruction could be sufficient to explain the mismatch between the observed Li abundance and the expected BBN ^{7}Li [105]. This line of argument supports the predictions of stellar depletion as the possible resolution of the lithium problem [72, 96–98]. Additional ^{6}Li limits or detections, in concert with model calculations, can firm up this conclusion.

Observations of interstellar lithium in low-metallicity systems probe lithium abundances not subject to stellar depletion. Measurements of interstellar Li/H in the Small Magellanic Cloud lie near the primordial level, but also are consistent with Milky Way stellar abundances at that metallicity ($\sim 1/4$ solar) [106]. Additional such measurements in more metal-poor systems would be of great interest.

It remains possible that the lithium problem points to new physics. Nucleosynthesis models in which the baryon-to-photon ratio is inhomogeneous can alter abundances for a given $\eta_{\rm BBN}$, but will overproduce ^{7}Li [107]. Entropy generation by some non-standard process could have decreased η between the BBN era and CMB decoupling, however the lack of spectral distortions in the CMB rules out any significant energy injection up to a redshift $z \sim 10^7$ [108]. The most intriguing resolution of the lithium problem thus involves new physics during BBN [7–9]

We summarize the general features of such solutions here, and later consider examples in the context of specific particle physics models. Many proposed solutions introduce perturbations to light-element formation during BBN; while all element abundances may suffer perturbations, the interplay of ^{7}Li and D is often the most important *i.e.* observations of D often provide the strongest constraints on the allowed perturbations to ^{7}Li. In this connection it is important to note that the new, very precise determination of D/H will significantly constrain the ability of such models to ameliorate or solve the lithium problem.

A well studied class of models invokes the injection of suprathermal hadronic or electromagnetic particles due to decays of dark matter particles. The effects are complex and depend on the nature of the decaying particles and their branchings and spectra. However, the models that most successfully solve the lithium problem generally feature non-thermal nucleons, which dissociate all light elements. Dissociation of even a small fraction of ^{4}He introduces a large abundance of free neutrons, which quickly thermalize. The thermal neutrons drive the $^7\mathrm{Be}(n,p)^7\mathrm{Li}$ conversion of ^{7}Be. The resulting ^{7}Li has a lower Coulomb barrier relative to ^{7}Be and is readily destroyed via $^7\mathrm{Li}(p,\alpha)^4\mathrm{He}$ [109, 110]]. But ^{4}He dissociation also produces D directly as well as via nonthermal neutron $n(p,\gamma)d$ reactions. This introduces a tension between Li/H reduction and D/H enhancement that becomes increasingly restrictive with the increasing precision of deuterium observations. Indeed, this now forces particle injection scenarios to make very small ^{7}Li perturbations — far short of the level needed. An exception is a recent model wherein MeV-scale decays by construction avoid ^{4}He dissociation and associated D/H overproduction, instead *borrowing* neutrons by dissociating only deuterons [111].

Another important class of models retains the standard cosmic

particle content, but changes their interactions via time variations in the fundamental constants [112–118]. Here too, the details are model-dependent, but scenarios that solve or alleviate the lithium problem often feature perturbations to the deuteron binding energy. A weaker D binding leads to the D bottleneck being overcome later, so that element formation commences at a lower temperature and lower density. This leads in turn to slower nuclear rates that freeze out earlier. The net result is a *higher* final D/H, due to less efficient processing into ^{4}He, but also *lower* Li, due to suppressed production via $^3\mathrm{He}(\alpha,\gamma)^7\mathrm{Be}$.

The *cosmological lithium problem* remains an unresolved issue in BBN. Nevertheless, the remarkable concordance between the CMB and the D (as well as ^{4}He) abundance, is a non-trivial success, and provides important constraints on the early Universe.

24.6 Beyond the Standard Model

Given the simple physics underlying BBN, it is remarkable that it still provides the most effective test for the cosmological viability of ideas concerning physics beyond the Standard Model. Although baryogenesis and inflation must have occurred at higher temperatures in the early Universe, we do not as yet have 'standard models' for these, so BBN still marks the boundary between the established and the speculative in Big Bang cosmology. It might appear possible to push the boundary back to the quark-hadron transition at $T \sim \Lambda_{\rm QCD}$, or electroweak symmetry breaking at $T \sim 1/\sqrt{G_{\rm F}}$; however, so far no observable relics of these epochs have been identified, either theoretically or observationally. Thus, although the Standard Model provides a precise description of physics up to the Fermi scale, cosmology cannot be traced in detail before the BBN era.

The CMB power spectrum in the damping tail is independently sensitive to N_ν (*e.g.* [119]). The CMB value $N_\nu^{\rm CMB}$ probes the cosmic radiation content at (re)combination, so a discrepancy would imply new physics or astrophysics. Indeed, observations by the South Pole Telescope implied $N_\nu^{\rm CMB} = 3.85 \pm 0.62$ [120], prompting discussion of *dark radiation* such as sterile neutrinos [121]. However, *Planck* 2018 results give $N_\nu^{\rm CMB} = 2.92^{+0.36}_{+0.37}$, 95% CL, when using Planck TT, TE, EE+lowE, a result quite consistent with 3 Standard Model neutrinos [80] (and adjusting for the CMB's measurement of $N_{\rm eff} = 3.044$ due to neutrino heading effects [122–124]). Indeed, the BBN and CMB constraints on N_ν are independent and of similar precision, so that it is now possible to limit any *change* in this parameter (and/or the baryon-to-photon ratio) between nucleosynthesis and recombination [75]. This can, for example, constrain models with late particle decays, or with early dark energy.

Just as one can use the measured helium abundance to place limits on g_* [82, 113, 125–127], any changes in the strong, weak, electromagnetic, or gravitational coupling constants, arising *e.g.*, from the dynamics of new dimensions, can be similarly constrained [128], as can any speed-up of the expansion rate in, *e.g.*, scalar-tensor theories of gravity [129].

The limits on N_ν can be translated into limits on other types of particles or particle masses that would affect the expansion rate of the Universe during nucleosynthesis. For example, consider *sterile* neutrinos with only right-handed interactions of strength $G_{\rm R} < G_{\rm F}$. Such particles would decouple at higher temperature than (left-handed) neutrinos, so their number density ($\propto T^3$) relative to neutrinos would be reduced by any subsequent entropy release, *e.g.*, due to annihilations of massive particles that become non-relativistic between the two decoupling temperatures. Thus, (relativistic) particles with less than full strength weak interactions contribute less to the energy density than particles that remain in equilibrium up to the time of nucleosynthesis [130]. If we impose $N_\nu < 4$ as an illustrative constraint, then the three right-handed neutrinos must have a temperature $3(T_{\nu_{\rm R}}/T_{\nu_{\rm L}})^4 < 1$. Since the temperature of the decoupled $\nu_{\rm R}$ is determined by entropy conservation (see 'Big Bang Cosmology' — Sec. 22 of this *Review*), $T_{\nu_{\rm R}}/T_{\nu_{\rm L}} = [(43/4)/g_*(T_{\rm d})]^{1/3} < 0.76$, where $T_{\rm d}$ is the decoupling temperature of the $\nu_{\rm R}$. This requires $g_*(T_{\rm d}) > 24$, so decoupling must have occurred at $T_{\rm d} > 140$ MeV. The decoupling temperature is related to $G_{\rm R}$ through $(G_{\rm R}/G_{\rm F})^2 \sim (T_{\rm d}/3\,{\rm MeV})^{-3}$, where 3 MeV is the decoupling temperature for $\nu_{\rm L}$s. This yields a limit $G_{\rm R} \lesssim 10^{-2} G_{\rm F}$. The above argument sets lower limits on the masses of new Z' gauge bosons to which right-handed neutrinos would be coupled in models of superstrings [131], or extended technicolour [132]. Similarly a Dirac magnetic moment for neutrinos, which would allow the right-handed states to be produced through scattering and thus increase g_*, can be significantly constrained [133], as can any new interactions for neutrinos that have a similar effect [134–136]. Right-handed states can be populated directly by helicity-flip scattering if the neutrino mass is large enough, and this property has been used to infer a bound of $m_{\nu_\tau} \lesssim 1$ MeV (taking $N_\nu < 4$) [137]. If there is mixing between active and sterile neutrinos then the effect on BBN is more complicated [138, 139].

BBN limits on the cosmic expansion rate constrain supersymmetric scenarios in which the neutralino or gravitino are very light, so that they contribute to g_* [140]. A gravitino in the mass range $\sim 10^{-4} - 10$ eV will affect the expansion rate of the Universe similarly to a light neutralino (which is however now probably ruled out by collider data, especially the decays of the Higgs-like boson). The net contribution to N_ν then ranges between 0.74 and 1.69, depending on the gravitino and slepton masses [141].

The limit on the expansion rate during BBN can also be translated into bounds on the mass/lifetime of non-relativistic particles that decay during BBN. This results in an even faster speed-up rate, and typically also changes the entropy [142–144]. If the decays include Standard Model particles, the resulting electromagnetic [145] [86, 131, 146] and/or hadronic [147, 148] cascades can strongly perturb the light elements, which leads to even stronger constraints. Such arguments have been applied to rule out an MeV mass for ν_τ, which decays during nucleosynthesis [149].

Decaying-particle arguments have proved very effective in probing supersymmetry. Light-element abundances generally are complementary to accelerator data in constraining SUSY parameter space, with BBN reaching to values kinematically inaccessible to the LHC. Much recent interest has focused on the case in which the next-to-lightest supersymmetric particle is metastable and decays during or after BBN. The constraints on unstable particles discussed above imply stringent bounds on the allowed abundance of such particles [109]; if the metastable particle is charged (*e.g.*, the stau), then it is possible for it to form atom-like electromagnetic bound states with nuclei, and the resulting impact on light elements can be quite complex [8, 90, 150]. Moreover, SUSY decays can destroy ^{7}Li and/or produce ^{6}Li, leading to a possible supersymmetric solution to the lithium problems noted above [151] (see [7] for a review).

These arguments impose powerful constraints on supersymmetric inflationary cosmology [86, 131, 146–148], particularly thermal leptogenesis [152]. These limits can be evaded only if the gravitino is massive enough to decay before BBN, i.e., $m_{3/2} \gtrsim 50$ TeV [153] (which would be unnatural), or if it is in fact the lightest supersymmetric particle and thus stable [131, 146, 154, 155]. Similar constraints apply to moduli – very weakly coupled fields in string theory that obtain an electroweak-scale mass from supersymmetry breaking [156].

Finally, we mention that BBN places powerful constraints on the possibility that there are new large dimensions in nature, perhaps enabling the scale of quantum gravity to be as low as the electroweak scale [157]. Thus, Standard Model fields may be localized on a *brane*, while gravity alone propagates in the *bulk*. It has been further noted that the new dimensions may be non-compact, even infinite [158], and the cosmology of such models has attracted considerable attention. The expansion rate in the early Universe can be significantly modified, so BBN is able to set interesting constraints on such possibilities [159, 160].

25. Cosmological Parameters

Revised August 2023 by O. Lahav (UCL) and A.R. Liddle (ULisboa).

25.1 Parametrizing the Universe

Rapid advances in observational cosmology have led to the establishment of a precision cosmological model, with many of the key cosmological parameters determined to one or two significant figure accuracy. Particularly prominent are measurements of cosmic microwave background (CMB) anisotropies, with the highest precision observations being those of the *Planck* Satellite [1, 2], which supersede the landmark *WMAP* results [3,4]. However the most accurate model of the Universe requires consideration of a range of observations, with complementary probes providing consistency checks, lifting parameter degeneracies, and enabling the strongest constraints to be placed.

The term 'cosmological parameters' now has a wide scope, and may include the parameterization of some functions as well as simple numbers describing properties of the Universe. The original usage referred to the parameters describing the global dynamics of the Universe, such as its expansion rate and curvature. Now we wish to know how the matter budget of the Universe is built up from its constituents: baryons, photons, neutrinos, dark matter, and dark energy. We also need to describe the nature of perturbations in the Universe, through global statistical descriptors such as the matter and radiation power spectra. There may be additional parameters describing the physical state of the Universe, such as the ionization fraction as a function of time during the era since recombination. Typical comparisons of cosmological models with observational data now feature between five and ten parameters.

25.1.1 *The global description of the Universe*

Ordinarily, the Universe is taken to be a perturbed Robertson–Walker space-time, with dynamics governed by Einstein's equations. This is described in detail in the Big-Bang Cosmology chapter in this volume. Using the density parameters Ω_i for the various matter species and Ω_Λ for the cosmological constant, the Friedmann equation can be written

$$\sum_i \Omega_i + \Omega_\Lambda - 1 = \frac{k}{R^2 H^2}\,, \tag{25.1}$$

where the sum is over all the different species of material in the Universe. This equation applies at any epoch, but later in this article we will use the symbols Ω_i and Ω_Λ to refer specifically to the present-epoch values.

The complete present-epoch state of the homogeneous Universe can be described by giving the current-epoch values of all the density parameters and the Hubble constant h (the present-day Hubble parameter being written $H_0 = 100h\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$). A typical collection would be baryons Ω_b, photons Ω_γ, neutrinos Ω_ν, and cold dark matter Ω_c (given charge neutrality, the electron density is guaranteed to be too small to be worth considering separately and is effectively included with the baryons). The spatial curvature can then be determined from the other parameters using Eq. (25.1). The total present matter density $\Omega_\mathrm{m} = \Omega_\mathrm{c} + \Omega_\mathrm{b}$ may be used in place of the cold dark matter density Ω_c.

These parameters also allow us to track the history of the Universe, at least back until an epoch where interactions allow interchanges between the densities of the different species; this is believed to have last happened at neutrino decoupling, shortly before Big-Bang Nucleosynthesis (BBN). To probe further back into the Universe's history requires assumptions about particle interactions, and perhaps about the nature of physical laws themselves.

The standard neutrino sector has three flavors. For neutrinos of mass in the range $5\times10^{-4}\,\mathrm{eV}$ to 1 MeV, the density parameter in neutrinos is predicted to be

$$\Omega_\nu h^2 = \frac{\sum m_\nu}{93.12\,\mathrm{eV}}\,, \tag{25.2}$$

where the sum is over all families with mass in that range (higher masses need a more sophisticated calculation). We use units with $c = 1$ throughout. Results on atmospheric and Solar neutrino oscillations [5] imply non-zero mass-squared differences between the three neutrino flavors. These oscillation experiments cannot tell us the absolute neutrino masses, but within the normal assumption of a mass hierarchy suggest a lower limit of approximately 0.06 eV for the sum of the neutrino masses (see the Neutrino chapter).

Even a mass this small has a potentially observable effect on the formation of structure, as neutrino free-streaming damps the growth of perturbations. Analyses commonly now either assume a neutrino mass sum fixed at this lower limit, or allow the neutrino mass sum to be a variable parameter. To date there is no decisive evidence of any effects from either neutrino masses or an otherwise non-standard neutrino sector, and observations impose quite stringent limits; see the Neutrinos in Cosmology chapter. However, we note that the inclusion of the neutrino mass sum as a free parameter can affect the derived values of other cosmological parameters.

25.1.2 *Inflation and perturbations*

A complete model of the Universe must include a description of deviations from homogeneity, at least statistically. Indeed, the most powerful probes of the parameters described above come from the evolution of perturbations, so their study is naturally intertwined with the determination of cosmological parameters.

There are many different notations used to describe the perturbations, both in terms of the quantity used and the definition of the statistical measure. We use the dimensionless power spectrum Δ^2 as defined in the Big Bang Cosmology section (also denoted $\mathcal{P}$ in some of the literature). If the perturbations obey Gaussian statistics, the power spectrum provides a complete description of their properties.

From a theoretical perspective, a useful quantity to describe the perturbations is the curvature perturbation $\mathcal{R}$, which measures the spatial curvature of a comoving slicing of the space-time. A simple case is the Harrison–Zeldovich spectrum, which corresponds to a constant $\Delta^2_\mathcal{R}$. More generally, one can approximate the spectrum by a power law, writing

$$\Delta^2_\mathcal{R}(k) = \Delta^2_\mathcal{R}(k_*)\left[\frac{k}{k_*}\right]^{n_\mathrm{s}-1}\,, \tag{25.3}$$

where n_s is known as the spectral index, always defined so that $n_\mathrm{s} = 1$ for the Harrison–Zeldovich spectrum, and k_* is an arbitrarily chosen scale. The initial spectrum, defined at some early epoch of the Universe's history, is usually taken to have a simple form such as this power law, and we will see that observations require n_s close to one. Subsequent evolution will modify the spectrum from its initial form.

The simplest mechanism for generating the observed perturbations is the inflationary cosmology, which posits a period of accelerated expansion in the Universe's early stages [6, 7]. It is a useful working hypothesis that this is the sole mechanism for generating perturbations, and it may further be assumed to be the simplest class of inflationary model, where the dynamics are equivalent to that of a single scalar field ϕ with canonical kinetic energy slowly rolling on a potential $V(\phi)$. One may seek to verify that this simple picture can match observations and to determine the properties of $V(\phi)$ from the observational data. Alternatively, more complicated models, perhaps motivated by contemporary fundamental physics ideas, may be tested on a model-by-model basis (see more in the Inflation chapter in this volume).

Inflation generates perturbations through the amplification of quantum fluctuations, which are stretched to astrophysical scales by the rapid expansion. The simplest models generate two types, density perturbations that come from fluctuations in the scalar field and its corresponding scalar metric perturbation, and gravitational waves that are tensor metric fluctuations. The former experience gravitational instability and lead to structure formation, while both generate CMB anisotropies. Defining slow-roll parameters (with primes indicating derivatives with respect to the scalar field, and $m_\mathrm{Pl} \equiv \sqrt{\hbar c/G}$ the Planck mass) as

$$\epsilon = \frac{m_\mathrm{Pl}^2}{16\pi}\left(\frac{V'}{V}\right)^2 \quad , \quad \eta = \frac{m_\mathrm{Pl}^2}{8\pi}\frac{V''}{V}\,, \tag{25.4}$$

which should satisfy $\epsilon, |\eta| \ll 1$, the spectra can be computed using the slow-roll approximation as

$$\Delta^2_{\mathcal{R}}(k) \simeq \left.\frac{8}{3m_{\rm Pl}^4}\,\frac{V}{\epsilon}\right|_{k=aH} \quad , \quad \Delta^2_{\rm t}(k) \simeq \left.\frac{128}{3m_{\rm Pl}^4}\,V\right|_{k=aH} . \quad (25.5)$$

In each case, the expressions on the right-hand side are to be evaluated when the scale k is equal to the Hubble radius during inflation. The symbol '$\simeq$' here indicates use of the slow-roll approximation, which is expected to be accurate to a few percent or better.

From these expressions, we can compute the spectral indices [8]:

$$n_{\rm s} \simeq 1 - 6\epsilon + 2\eta \quad ; \quad n_{\rm t} \simeq -2\epsilon\,. \quad (25.6)$$

Another useful quantity is the ratio of the two spectra, defined by

$$r \equiv \frac{\Delta^2_{\rm t}(k_*)}{\Delta^2_{\mathcal{R}}(k_*)}\,. \quad (25.7)$$

We have

$$r \simeq 16\epsilon \simeq -8n_{\rm t}\,, \quad (25.8)$$

which is known as the consistency equation.

One could consider corrections to the power-law approximation, which we discuss later. However, for now we make the working assumption that the spectra can be approximated by such power laws. The consistency equation shows that r and $n_{\rm t}$ are not independent parameters, and so the simplest inflation models give initial conditions described by three parameters, usually taken as $\Delta^2_{\mathcal{R}}$, $n_{\rm s}$, and r, all to be evaluated at some scale k_*, usually the 'statistical center' of the range explored by the data. Alternatively, one could use the parametrization V, ϵ, and η, all evaluated at a point on the putative inflationary potential.

After the perturbations are created in the early Universe, they undergo a complex evolution up until the time they are observed in the present Universe. When the perturbations are small, this can be accurately followed using a linear theory numerical code such as `CAMB` or `CLASS` [9]. This works right up to the present for the CMB, but for density perturbations on small scales nonlinear evolution is important and can be addressed by a variety of semi-analytical and numerical techniques. However the analysis is made, the outcome of the evolution is in principle determined by the cosmological model and by the parameters describing the initial perturbations, and hence can be used to determine them.

Of particular interest are CMB anisotropies. Both the total intensity and two independent polarization modes are predicted to have anisotropies. These can be described by the radiation angular power spectra C_ℓ as defined in the CMB article in this volume, and again provide a complete description if the density perturbations are Gaussian.

25.1.3 *The standard cosmological model*

We now have most of the ingredients in place to describe the cosmological model. Beyond those of the previous subsections, we need a measure of the ionization state of the Universe. The Universe is known to be highly ionized at redshifts below 5 or so (otherwise radiation from distant quasars would be heavily absorbed in the ultra-violet), and the ionized electrons can scatter microwave photons, altering the pattern of observed anisotropies. The most convenient parameter to describe this is the optical depth to scattering τ (*i.e.*, the probability that a given photon scatters once); in the approximation of instantaneous and complete reionization, this could equivalently be described by the redshift of reionization $z_{\rm i}$.

As described in Sec. 25.4, models based on these parameters are able to give a good fit to the complete set of high-quality data available at present, and indeed some simplification is possible. Observations are consistent with spatial flatness, and the inflation models so far described automatically generate negligible spatial curvature, so we can set $k = 0$; the density parameters then must sum to unity, and so one of them can be eliminated. The neutrino energy density is often not taken as an independent parameter; provided that the neutrino sector has the standard interactions, the neutrino energy density, while relativistic, can be related to the photon density using thermal physics arguments, and a minimal assumption takes the neutrino mass sum to be that of the lowest mass solution to the neutrino oscillation constraints, namely 0.06 eV. In addition, there is no observational evidence for the existence of tensor perturbations (with the upper limits now starting to become constraining on models), and so r could be set to zero. This leaves seven parameters, which is the smallest set that can usefully be compared to the present cosmological data. This model is referred to by various names, including ΛCDM, the concordance cosmology, and the standard cosmological model.

Of these parameters, only Ω_γ is accurately measured directly. The radiation density is dominated by the energy in the CMB, and the *COBE* satellite FIRAS experiment determined its temperature to be $T = (2.7255 \pm 0.0006)\,{\rm K}$ [10],[1] corresponding to $\Omega_\gamma = 2.47 \times 10^{-5} h^{-2}$. It typically can be taken as fixed when fitting other data. Hence the minimum number of cosmological parameters varied in fits to data is six, though as described below there may additionally be many 'nuisance' parameters necessary to describe astrophysical processes influencing the data.

In addition to this minimal set, there is a range of other parameters that might prove important in future as the datasets further improve, but for which there is so far no direct evidence, allowing them to be set to specific values for now. We discuss various speculative options in the next section. For completeness at this point, we mention one other interesting quantity, the helium fraction, which is a non-zero parameter that can affect the CMB anisotropies at a subtle level. It is usually fixed in microwave anisotropy studies, but the data are approaching a level where allowing its variation may become mandatory.

In conventional parameter estimation, a set of parameters is chosen by hand and the aim is to constrain their values. The higher-level inference problem of model selection instead compares different choices of parameter sets, as is necessary to assess whether observations are pointing towards inclusion of new physical effects. Bayesian inference offers an attractive framework for cosmological model selection, setting a tension between model predictiveness and ability to fit the data [11], and its use is becoming widespread.

25.1.4 *Derived parameters*

The parameter list of the previous subsection is sufficient to give a complete description of cosmological models that agree with observational data. However, it is not a unique parameterization, and one could instead use parameters derived from that basic set. Parameters that can be obtained from the set given above include the age of the Universe, the present horizon distance, the present neutrino background temperature, the epoch of matter–radiation equality, the epochs of recombination and decoupling, the epoch of transition to an accelerating Universe, the baryon-to-photon ratio, and the baryon-to-dark-matter density ratio. In addition, the physical densities of the matter components, $\Omega_i h^2$, are often more useful than the density parameters. The density perturbation amplitude can be specified in many different ways other than the large-scale primordial amplitude, for instance, in terms of its effect on the CMB, or by specifying a short-scale quantity, a common choice being the present linear-theory mass dispersion in a radius of $8\,h^{-1}$Mpc, known as σ_8.

Different types of observation are sensitive to different subsets of the full cosmological parameter set, and some are more naturally interpreted in terms of some of the derived parameters of this subsection than on the original base parameter set. In particular, most types of observation feature degeneracies whereby they are unable to separate the effects of simultaneously varying specific combinations of several of the base parameters.

25.2 Extensions to the standard model

At present, there is no positive evidence in favor of extensions of the standard model. These are becoming increasingly constrained by the data, though there always remains the possibility of trace effects at a level below present observational capability.

[1] All quoted uncertainties in this article are 1σ/68% confidence and all upper limits are 95% confidence. Cosmological parameters sometimes have significantly non-Gaussian uncertainties. Values from original sources have been rounded according to the conventions of this volume.

25.2.1 *More general perturbations*

The standard cosmology assumes adiabatic, Gaussian perturbations. Adiabaticity means that all types of material in the Universe share a common perturbation, so that if the space-time is foliated by constant-density hypersurfaces, then all fluids and fields are homogeneous on those slices, with the perturbations completely described by the variation of the spatial curvature of the slices. Gaussianity means that the initial perturbations obey Gaussian statistics, with the amplitudes of waves of different wavenumbers being randomly drawn from a Gaussian distribution of width given by the power spectrum. Note that gravitational instability generates non-Gaussianity; in this context, Gaussianity refers to a property of the initial perturbations, before they evolve.

The simplest inflation models, based on one dynamical field, predict adiabatic perturbations and a level of non-Gaussianity that is too small to be detected by any experiment so far conceived. For present data, the primordial spectra are usually assumed to be power laws.

25.2.1.1 *Non-power-law spectra*

For typical inflation models, it is an approximation to take the spectra as power laws, albeit usually a good one. As data quality improves, one might expect this approximation to come under pressure, requiring a more accurate description of the initial spectra, particularly for the density perturbations. In general, one can expand $\ln \Delta^2_{\mathcal{R}}$ as

$$\ln \Delta^2_{\mathcal{R}}(k) = \ln \Delta^2_{\mathcal{R}}(k_*) + (n_{\mathrm{s},*} - 1) \ln \frac{k}{k_*} + \frac{1}{2} \left. \frac{dn_{\mathrm{s}}}{d \ln k} \right|_* \ln^2 \frac{k}{k_*} + \cdots , \tag{25.9}$$

where the coefficients are all evaluated at some scale k_*. The term $dn_{\mathrm{s}}/d \ln k|_*$ is often called the running of the spectral index [12]. Once non-power-law spectra are allowed, it is necessary to specify the scale k_* at which the spectral index is defined.

25.2.1.2 *Isocurvature perturbations*

An isocurvature perturbation is one that leaves the total density unperturbed, while perturbing the relative amounts of different materials. If the Universe contains N fluids, there is one growing adiabatic mode and $N-1$ growing isocurvature modes (for reviews see Ref. [7] and Ref. [13]). These can be excited, for example, in inflationary models where there are two or more fields that acquire dynamically-important perturbations. If one field decays to form normal matter, while the second survives to become the dark matter, this will generate a cold dark matter isocurvature perturbation.

In general, there are also correlations between the different modes, and so the full set of perturbations is described by a matrix giving the spectra and their correlations. Constraining such a general construct is challenging, though constraints on individual modes are beginning to become meaningful, with no evidence that any other than the adiabatic mode must be non-zero.

25.2.1.3 *Seeded perturbations*

An alternative to laying down perturbations at very early epochs is that they are seeded throughout cosmic history, for instance by topological defects such as cosmic strings. It has long been excluded that these are the sole original of structure, but they could contribute part of the perturbation signal, current limits being just a few percent [14]. In particular, cosmic defects formed in a phase transition ending inflation is a plausible scenario for such a contribution.

25.2.1.4 *Non-Gaussianity*

Multi-field inflation models can also generate primordial non-Gaussianity (reviewed, *e.g.*, in Ref. [7]). The extra fields can either be in the same sector of the underlying theory as the inflaton, or completely separate, an interesting example of the latter being the curvaton model [15]. Current upper limits on non-Gaussianity are becoming stringent, but there remains strong motivation to push down those limits and perhaps reveal trace non-Gaussianity in the data. If non-Gaussianity is observed, its nature may favor an inflationary origin, or a different one such as topological defects.

25.2.2 *Dark matter properties*

Dark matter properties are discussed in the Dark Matter chapter in this volume. The simplest assumption concerning the dark matter is that it has no significant interactions with other matter, and that its particles have a negligible velocity as far as structure formation is concerned. Such dark matter is described as 'cold,' and candidates include the lightest supersymmetric particle, the axion, and primordial black holes. As far as astrophysicists are concerned, a complete specification of the relevant cold dark matter properties is given by the density parameter Ω_{c}, though those seeking to detect it directly need also to know its interaction properties.

Cold dark matter is the standard assumption and gives an excellent fit to observations, except possibly on the shortest scales where there remains some controversy concerning the structure of dwarf galaxies and possible substructure in galaxy halos. It has long been excluded for all the dark matter to have a large velocity dispersion, so-called 'hot' dark matter, as it does not permit galaxies to form; for thermal relics the mass must be above about 1 keV to satisfy this constraint, though relics produced non-thermally, such as the axion, need not obey this limit. However, in future further parameters might need to be introduced to describe dark matter properties relevant to astrophysical observations. Suggestions that have been made include a modest velocity dispersion (warm dark matter) and dark matter self-interactions. There remains the possibility that the dark matter is comprised of two separate components, *e.g.*, a cold one and a hot one, an example being if massive neutrinos have a non-negligible effect.

25.2.3 *Relativistic species*

The number of relativistic species in the young Universe (omitting photons) is denoted N_{eff}. In the standard cosmological model only the three neutrino species contribute, and its baseline value is assumed fixed at 3.044 (the small shift from 3 is because of a slight predicted deviation from a thermal distribution [16]). However other species could contribute, for example an extra neutrino, possibly of sterile type, or massless Goldstone bosons or other scalars. It is hence interesting to study the effect of allowing this parameter to vary, and indeed although 3.044 is consistent with the data, most analyses currently suggest a somewhat higher value (*e.g.*, Ref. [17]).

25.2.4 *Dark energy and modified gravity*

While the standard cosmological model given above features a cosmological constant, in order to explain observations indicating that the Universe is presently accelerating, further possibilities exist under the general headings of 'dark energy' and 'modified gravity'. These topics are described in detail in the Dark Energy chapter in this volume. This article focuses on the case of the cosmological constant, since this simple model is a good match to existing data. We note that more general treatments of dark energy/modified gravity will lead to weaker constraints on other parameters.

25.2.5 *Complex ionization history*

The full ionization history of the Universe is given by the ionization fraction as a function of redshift z. The simplest scenario takes the ionization to have the small residual value left after recombination up to some redshift z_{i}, at which point the Universe instantaneously reionizes completely. Then there is a one-to-one correspondence between τ and z_{i} (that relation, however, also depending on other cosmological parameters). An accurate treatment of this process will track separate histories for hydrogen and helium. While currently rapid ionization appears to be a good approximation, as data improve a more complex ionization history may need to be considered.

25.2.6 *Varying 'constants'*

Variation of the fundamental constants of Nature over cosmological times is another possible enhancement of the standard cosmology. There is a long history of study of variation of the gravitational constant G_{N}, and more recently attention has been drawn to the possibility of small fractional variations in the fine-structure constant. There is presently no observational evidence for the former, which is tightly constrained by a variety of mea-

surements. Evidence for the latter has been claimed from studies of spectral line shifts in quasar spectra at redshift $z \simeq 2$ [18], but this is presently controversial and in need of further observational study.

25.2.7 *Cosmic topology*

The usual hypothesis is that the Universe has the simplest topology consistent with its geometry, for example that a flat Universe extends forever. Observations cannot tell us whether that is true, but they can test the possibility of a non-trivial topology on scales up to roughly the present Hubble scale. Extra parameters would be needed to specify both the type and scale of the topology; for example, a cuboidal topology would need specification of the three principal axis lengths and orientation. At present, there is no evidence for non-trivial cosmic topology [19].

25.3 Cosmological Probes

The goal of the observational cosmologist is to utilize astronomical information to derive cosmological parameters. The transformation from the observables to the parameters usually involves many assumptions about the nature of the data, as well as of the dark sector. Below we outline the physical processes involved in each of the major probes, and the main recent results. The first two subsections concern probes of the homogeneous Universe, while the remainder consider constraints from perturbations.

In addition to statistical uncertainties we note three sources of systematic uncertainties that will apply to the cosmological parameters of interest: (i) due to the assumptions on the cosmological model and its priors (*i.e.*, the number of assumed cosmological parameters and their allowed range); (ii) due to the uncertainty in the astrophysics of the objects (*e.g.*, light-curve fitting for supernovae or the mass–temperature relation of galaxy clusters); and (iii) due to instrumental and observational limitations (*e.g.*, the effect of 'seeing' on weak gravitational lensing measurements, or beam shape on CMB anisotropy measurements).

These systematics, the last two of which appear as 'nuisance parameters', pose a challenging problem to the statistical analysis. We attempt a statistical fit to the whole Universe with 6 to 12 parameters, but we might need to include hundreds of nuisance parameters, some of them highly correlated with the cosmological parameters of interest (for example time-dependent galaxy biasing could mimic the growth of mass fluctuations). Fortunately, there is some astrophysical prior knowledge on these effects, and a small number of physically-motivated free parameters would ideally be preferred in the cosmological parameter analysis.

25.3.1 *Measures of the Hubble constant*

In 1929, Edwin Hubble discovered the law of expansion of the Universe by measuring distances to nearby galaxies. The slope of the relation between the distance and recession velocity is defined to be the present-epoch Hubble constant, H_0. Astronomers argued for decades about the systematic uncertainties in various methods and derived values over the wide range $40\,\mathrm{km\,s^{-1}\,Mpc^{-1}} \lesssim H_0 \lesssim 100\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$.

One of the most reliable results on the Hubble constant came from the Hubble Space Telescope *(HST)* Key Project [20]. This study used the empirical period–luminosity relation for Cepheid variable stars, and calibrated a number of secondary distance indicators: Type Ia Supernovae (SNe Ia); the Tully–Fisher relation; surface-brightness fluctuations; and Type II Supernovae. Various systematics are under investigation, for example *JWST* is helping understanding of the effect of field crowding. This approach has been further extended, *e.g.* using *HST* observations of Cepheids in the hosts of 42 SNe Ia and exploiting Gaia EDR3 parallaxes, the SH0ES team derived $H_0 = (73.0 \pm 1.0)\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ [21].

Three other methods have been used recently. One is a calibration of the tip of the red-giant branch applied to Type Ia supernovae, the Carnegie–Chicago Hubble Programme (CCHP), finding $H_0 = (69.8 \pm 0.6\,(\mathrm{stat.}) \pm 1.6\,(\mathrm{sys.}))\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ [22]. The second uses the method of time delay in gravitationally-lensed quasars; Birrer et al. [23] find $H_0 = 67.4^{+4.1}_{-3.2}\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ from a sample of 40 lenses. A third method that came to fruition recently is based on gravitational waves; the 'bright standard siren' method applied to the binary neutron star GW170817 yields $H_0 = 70^{+12}_{-8}\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ [24]. Adding two 'dark standard siren' systems shifts this to $H_0 = 73^{+11}_{-8}\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ [25], still dominated by the single bright siren system. The 47 sources in the third Gravitational-Wave Transient Catalog (GWTC-3), again combined with the bright siren, yield the similar result $H_0 = 68^{+12}_{-8}\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ [26]. When many more gravitational-wave events have been acquired, the future uncertainties on H_0 from standard sirens will get smaller.

The determination of H_0 by the *Planck* Collaboration [2] gives a lower value than most of the above methods, $H_0 = (67.4 \pm 0.5)\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$. As they discuss, there is a strong degeneracy of H_0 with other parameters, particularly Ω_m and the neutrino mass. It is worth noting that using the 'inverse distance ladder' method gives a result $H_0 = (67.8 \pm 1.3)\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ [27], close to the *Planck* result. The inverse distance ladder relies on absolute-distance measurements from baryon acoustic oscillations (BAOs) to calibrate the intrinsic magnitude of the SNe Ia (rather than nearby Cepheids and parallax). This measurement was derived from 207 spectroscopically-confirmed Type Ia supernovae from the Dark Energy Survey (DES), an additional 122 low-redshift SNe Ia, and measurements of BAOs. A combination of DES Year 3 (Y3) clustering and weak lensing with BAO and BBN (assuming ΛCDM) gives $H_0 = (67.6 \pm 0.9)\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$ [28]. The completed Extended Baryon Oscillation Spectroscopic Survey (eBOSS) [29] inverse distance ladder result, within an assumed extended cosmological model, is $H_0 = (68.2 \pm 0.8)\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$, also close to the *Planck* value.

The tension between the H_0 values from *Planck* and the traditional cosmic distance-ladder methods, with the SH0ES result deviating from *Planck* by about 5σ, is under intense investigation for potential systematic effects. There is possibly a trend for higher H_0 derived from the nearby Universe and a lower H_0 from the early Universe, which has led some researchers to propose a time-variation of the dark energy component or other exotic scenarios. Ongoing studies are addressing the question of whether the Hubble tension is due to systematics in at least one of the probes, or a signature of new physics. Figure 25.1 shows a selection of recent H_0 values, summarizing the current status of the Hubble constant tension. See Ref. [30] for a review.

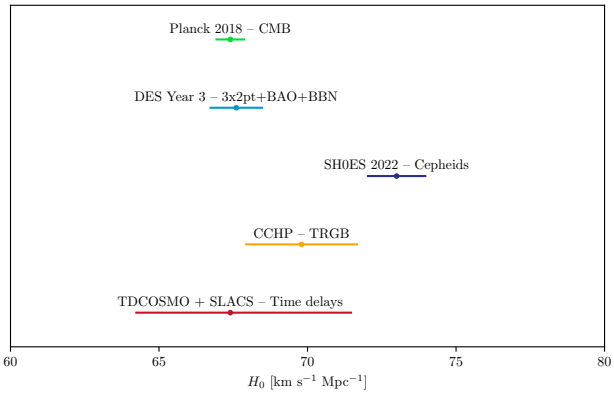

Figure 25.1: A selection of recent H_0 measurements from the various projects as described in the text. The standard-siren determinations are omitted as they are too wide for the plot. Figure courtesy of Pablo Lemos.

25.3.2 *Supernovae as cosmological probes*

Empirically, the peak luminosity of SNe Ia can be used as an efficient distance indicator (*e.g.*, Ref. [31]), thus allowing cosmology to be constrained via the distance–redshift relation. The favorite theoretical explanation for SNe Ia is the thermonuclear disruption of carbon–oxygen white dwarfs. Although not perfect 'standard candles,' it has been demonstrated that by correcting for a relation between the light-curve shape, color, and luminosity at maximum brightness, the dispersion of the measured luminosities can

be greatly reduced. There are several possible systematic effects that may affect the accuracy of the use of SNe Ia as distance indicators, *e.g.*, evolution with redshift and interstellar extinction in the host galaxy and in the Milky Way.

In the late 1990s two major studies, the Supernova Cosmology Project and the High-z Supernova Search Team, found evidence for an accelerating Universe [32], interpreted as due to a cosmological constant or a dark energy component. When combined with the CMB data (which indicate near flatness, *i.e.*, $\Omega_{\rm m} + \Omega_\Lambda \simeq 1$), the best-fit values were $\Omega_{\rm m} \simeq 0.3$ and $\Omega_\Lambda \simeq 0.7$. Most results in the literature are consistent with the $w = -1$ cosmological constant case. The leading sample currently is the Pantheon+ compilation [33]. This set of 1550 spectroscopically-confirmed SNe Ia gives $\Omega_{\rm m} = 0.334 \pm 0.018$ (stat+sym) for an assumed flat ΛCDM model, while in combination with the CMB, for a flat wCDM model these data give $w = -0.98^{+0.2}_{-0.3}$ [34]. Future experiments (*e.g.* DES year 5 SNIa) will refine constraints on the cosmic equation of state $w(z)$.

25.3.3 *Cosmic microwave background*

The physics of the CMB is described in detail in the CMB chapter in this volume. Before recombination, the baryons and photons are tightly coupled, and the perturbations oscillate in the potential wells generated primarily by the dark matter perturbations. After decoupling, the baryons are free to collapse into those potential wells. The CMB carries a record of conditions at the time of last scattering, often called primary anisotropies. In addition, it is affected by various processes as it propagates towards us, including the effect of a time-varying gravitational potential (the integrated Sachs-Wolfe effect), gravitational lensing, and scattering from ionized gas at low redshift.

The primary anisotropies, the integrated Sachs–Wolfe effect, and the scattering from a homogeneous distribution of ionized gas, can all be calculated using linear perturbation theory. Available codes include `CAMB` and `CLASS` [9], the former widely used embedded within the analysis package `CosmoMC` [35] and in higher-level analysis packages such as `CosmoSIS` [36], `CosmoLike` [37], and Cobaya [38]. Gravitational lensing is also calculated in these codes. Secondary effects, such as inhomogeneities in the reionization process, and scattering from gravitationally-collapsed gas (the Sunyaev–Zeldovich or SZ effect), require more complicated, and more uncertain, calculations.

The upshot is that the detailed pattern of anisotropies depends on all of the cosmological parameters. In a typical cosmology, the anisotropy power spectrum [usually plotted as $\ell(\ell+1)C_\ell/2\pi$] features a flat plateau at large angular scales (small ℓ), followed by a series of oscillatory features at higher angular scales, the first and most prominent being at around one degree ($\ell \simeq 200$). These features, known as acoustic peaks, represent the oscillations of the photon–baryon fluid around the time of decoupling. Some features can be closely related to specific parameters—for instance, the location in multipole space of the set of peaks probes the spatial geometry, while the relative heights of the peaks probe the baryon density—but many other parameters combine to determine the overall shape.

The 2018 data release from the *Planck* satellite [1] gives the most powerful results to date on the spectrum of CMB temperature anisotropies, with a precision determination of the temperature power spectrum to beyond $\ell = 2000$. The Atacama Cosmology Telescope (ACT) and South Pole Telescope (SPT) experiments extend these results to higher angular resolution, though without full-sky coverage. *Planck* and the polarization-sensitive versions of ACT and SPT give the current state of the art in measuring the spectrum of E-polarization anisotropies and the correlation spectrum between temperature and polarization. These are consistent with models based on the parameters we have described, and provide accurate determinations of many of those parameters [2]. Primordial B-mode polarization has not been detected (although the gravitational lensing effect on B modes has been measured).

The data provide an exquisite measurement of the location of the set of acoustic peaks, determining the angular-diameter distance of the last-scattering surface. In combination with other data this strongly constrains the spatial geometry, in a manner consistent with spatial flatness and excluding significantly-curved Universes. CMB data give a precision measurement of the age of the Universe. The CMB also gives a baryon density consistent with, and at higher precision than, that coming from BBN. It affirms the need for both dark matter and dark energy. It shows no evidence for dynamics of the dark energy, being consistent with a pure cosmological constant ($w = -1$). The density perturbations are consistent with a power-law primordial spectrum, and there is no indication yet of tensor perturbations. The current best-fit for the reionization optical depth from CMB data, $\tau = 0.054$, is in line with models of how early structure formation induces reionization.

Planck also made the first all-sky map of the CMB lensing field, which probes the entire matter distribution in the Universe and adds some additional constraining power to the CMB-only datasets. The recent ACT results [39] demonstrate very well the reconstruction of the mass power spectrum at intermediate redshifts from CMB gravitational lensing. These measurements are consistent with *Planck*, supporting ΛCDM (see more in the CMB chapter).

25.3.4 *Galaxy clustering*

The power spectrum of density perturbations is affected by the nature of the dark matter. Within the ΛCDM model, the power spectrum shape depends primarily on the primordial power spectrum and on the combination $\Omega_{\rm m}h$, which determines the horizon scale at matter–radiation equality, with a subdominant dependence on the baryon density. The matter distribution is most easily probed by observing the galaxy distribution, but this must be done with care since the galaxies do not perfectly trace the dark matter distribution. Rather, they are a 'biased' tracer of the dark matter [40]. The need to allow for such bias is emphasized by the observation that different types of galaxies show bias with respect to each other. In particular, scale-dependent and stochastic biasing may introduce a systematic effect on the determination of cosmological parameters from redshift surveys [41]. Prior knowledge from simulations of galaxy formation or from gravitational lensing data could help to quantify biasing. Furthermore, the observed 3D galaxy distribution is in redshift space, *i.e.*, the observed redshift is the sum of the Hubble expansion and the line-of-sight peculiar velocity, leading to linear and non-linear dynamical effects that also depend on the cosmological parameters. On the largest length scales, the galaxies are expected to trace the location of the dark matter, except for a constant multiplier b to the power spectrum, known as the linear bias parameter. On scales smaller than 20 Mpc or so, the clustering pattern is 'squashed' in the radial direction due to coherent infall, which depends approximately on the parameter $\beta \equiv \Omega_{\rm m}^{0.6}/b$ (on these shorter scales, more complicated forms of biasing are not excluded by the data). On scales of a few Mpc, there is an effect of elongation along the line of sight (colloquially known as the 'finger of God' effect) that depends on the galaxy velocity dispersion.

25.3.4.1 *Baryon acoustic oscillations*

The power spectra of the 2-degree Field (2dF) Galaxy Redshift Survey and the Sloan Digital Sky Survey (SDSS) are well fit by a ΛCDM model and both surveys showed first evidence for baryon acoustic oscillations (BAOs) [42, 43]. When eBOSS is combined with *Planck*, Pantheon Type Ia Supernovae and other probes the result is $w_{\rm p} = -1.020 \pm 0.032$ at the pivot redshift $z_{\rm p} = 0.29$ [29]. Similar results for w were obtained *e.g.* by the WiggleZ survey [44]. Preliminary results from the DESI galaxy redshift survey [45] confirm the detection of the BAOs, in agreement with previous surveys.

25.3.4.2 *Redshift distortion*

There is continuing interest in Kaiser's 'redshift distortion' effect [46]. This distortion depends on cosmological parameters via the perturbation growth rate in linear theory $f(z) = d\ln\delta/d\ln a \simeq \Omega_{\rm m}^{\gamma}(z)$, where $\gamma \simeq 0.55$ for the ΛCDM model and may be different for modified gravity models. By measuring $f(z)$ it is feasible to constrain γ and rule out certain modified gravity models [47, 48]. We note the degeneracy of the redshift-distortion pattern and the geometric distortion (the so-called Alcock–Paczynski effect [49]), *e.g.*, as illustrated by the

WiggleZ survey [50] and eBOSS [29].

25.3.4.3 *Limits on neutrino mass from galaxy surveys and other probes*

Large-scale structure data place constraints on Ω_ν due to the neutrino free-streaming effect [51]. Presently there is no clear detection, and upper limits on neutrino mass are commonly estimated by comparing the observed galaxy power spectrum with a four-component model of baryons, cold dark matter, a cosmological constant, and massive neutrinos. Such analyses also assume that the primordial power spectrum is adiabatic, scale-invariant, and Gaussian. Potential systematic effects include biasing of the galaxy distribution and non-linearities of the power spectrum. An upper limit can also be derived from CMB anisotropies alone, while combination with additional cosmological datasets can improve the results.

The most recent results on neutrino mass upper limits and other neutrino properties are summarized in the Neutrinos in Cosmology chapter in this volume. The latest cosmological data constrain the sum of neutrino masses to be below 0.13 eV [28], consistent with Refs. [2, 29, 39]. Since the lower limit on this sum from oscillation experiments (assuming normal hierarchy) is 0.06 eV it is expected that future cosmological surveys will soon detect effects from neutrino mass. Also, current cosmological datasets are in good agreement with the standard value for the effective number of neutrino species $N_{\rm eff} = 3.044$.

25.3.5 *Clustering in the inter-galactic medium*

It is commonly assumed, based on hydrodynamic simulations, that the neutral hydrogen in the inter-galactic medium (IGM) can be related to the underlying mass distribution. It is then possible to estimate the matter power spectrum from the absorption observed in quasar spectra, the so-called Lyman-α forest. The usual procedure is to measure the power spectrum of the transmitted flux, and then to infer the mass power spectrum. Photo-ionization heating by the ultraviolet background radiation and adiabatic cooling by the expansion of the Universe combine to give a simple power-law relation between the gas temperature and the baryon density. It also follows that there is a power-law relation between the optical depth τ and $\rho_{\rm b}$. Therefore, the observed flux $F = \exp(-\tau)$ is strongly correlated with $\rho_{\rm b}$, which itself traces the mass density. The matter and flux power spectra can be related by a biasing function that is calibrated from simulations. There are two variants of Lyman-alpha analyses: 1-dimensional power spectra from individual lines-of-sight that probe small ($\sim$Mpc) scales; and 3-dimensional Lyman-alpha BAO analyses that measure large-scale correlations (over $\sim$100 Mpc scales) using neighboring quasar lines-of-sight.

The latest BOSS and eBOSS datasets have provided measurements of the BAO scale both in the Lyman-α absorption and in its cross-correlation with quasars at an effective redshift $z = 2.3$ [29, 52]. The results agree within 1.5-σ with the *Planck* CMB flat-Λ estimation for BAO scale. Such measurements will improve with the Dark Energy Spectroscopic Instrument (DESI) and other future spectroscopic surveys. The Lyman-α flux power spectrum has also been used to constrain the nature of dark matter, for example limiting the amount of warm dark matter [53].

25.3.6 *Weak gravitational lensing*

Images of background galaxies are distorted by the gravitational effect of mass variations along the line of sight. Deep gravitational potential wells, such as galaxy clusters, generate 'strong lensing' leading to arcs, arclets, and multiple images, while more moderate perturbations give rise to 'weak lensing.' Weak lensing is now widely used to measure the mass power spectrum in selected regions of the sky (see Ref. [54] for reviews). Since the signal is weak, the image of deformed galaxy shapes (the 'shear map') must be analyzed statistically to measure the power spectrum, higher moments, and cosmological parameters. There are various systematic effects in the interpretation of weak lensing, *e.g.*, due to atmospheric distortions during observations, the redshift distribution of the background galaxies (usually depending on the accuracy of photometric redshifts), the intrinsic correlation of galaxy shapes, and non-linear modeling uncertainties.

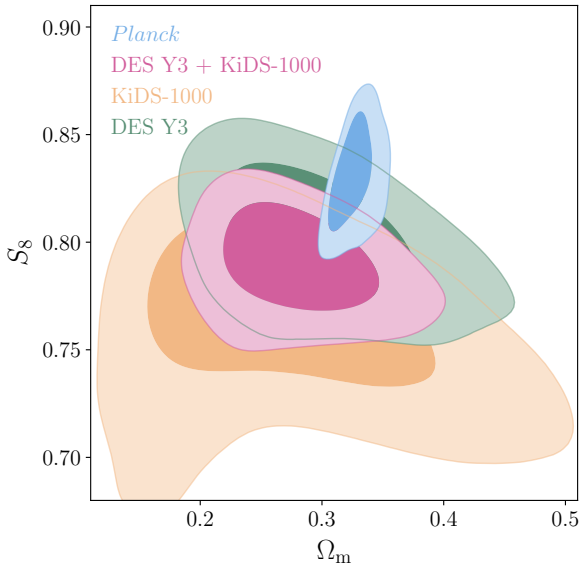

Figure 25.2: Marginalized posterior contours (inner 68% confidence level, outer 95% confidence level) in the $\Omega_{\rm m}$–S_8 plane. The plot shows KiDS weak lensing alone, DES Y3 weak lensing alone, DES and KiDS combined, and *Planck* CMB. Figure courtesy of Alexandra Amon and the DES and KiDS collaborations.

Weak-lensing measurements from the Kilo-Degree Survey (KiDS) [55], the Subaru Hyper-Suprime-Cam (HSC) [56], and DES [57] have constrained the clumpiness parameter $S_8 \equiv \sigma_8(\Omega_{\rm m}/0.3)^{0.5}$. Each of these surveys has yielded S_8 lower than that derived from *Planck*. Figure 25.2 shows the $\Omega_{\rm m}$–S_8 constraints derived from a joint KiDS/DES analysis [58] versus the CMB constraint from *Planck*, where the tension is significantly reduced, to 1.7σ, as compared to previous analyses. Results from weak lensing from DES, combined with other probes, are described in the next section.

25.3.7 *Other probes*

Other probes that have been used to constrain cosmological parameters, but that are not presently competitive in terms of accuracy, are the integrated Sachs-Wolfe effect [59,60], the number density or composition of galaxy clusters [61], and galaxy peculiar velocities that probe the mass fluctuations in the local Universe [62].

25.4 Bringing probes together

Although it contains two ingredients—dark matter and dark energy—which have not yet been verified by laboratory experiments, the ΛCDM model is almost universally accepted by cosmologists as the best description of the present data. The approximate values of some of the key parameters are $\Omega_{\rm b} \simeq 0.05$, $\Omega_{\rm c} \simeq 0.25$, $\Omega_\Lambda \simeq 0.70$, and a Hubble constant $h \simeq 0.70$. The spatial geometry is very close to flat (and usually assumed to be precisely flat), and the initial perturbations Gaussian, adiabatic, and nearly scale-invariant.

The most powerful data source is the CMB, which on its own supports all these main tenets. Values for some parameters, as given in Ref. [2], are reproduced in Table 25.1. These particular results presume a flat Universe. The constraints are somewhat strengthened by adding additional datasets, BAO being shown in the Table as an example, though most of the constraining power resides in the CMB data. Similar constraints at lower precision were previously obtained by the *WMAP* collaboration, and more recently by SPT.

If the assumption of spatial flatness is lifted, it turns out that the primary CMB on its own constrains the spatial curvature fairly weakly, due to a parameter degeneracy in the angular-diameter distance. However, inclusion of other data readily re-

Table 25.1: Parameter constraints reproduced from Ref. [2] (Table 2, column 5), with some additional rounding. Both columns assume the ΛCDM cosmology with a power-law initial spectrum, no tensors, spatial flatness, a cosmological constant as dark energy, and the sum of neutrino masses fixed to 0.06 eV. Above the line are the six parameter combinations actually fit to the data ($\theta_{\rm MC}$ is a measure of the sound horizon at last scattering); those below the line are derived from these. The first column uses *Planck* primary CMB data plus the *Planck* measurement of CMB lensing. This column gives our present recommended values. The second column adds in data from a compilation of BAO measurements described in Ref. [2]. The perturbation amplitude $\Delta^2_{\mathcal{R}}$ (denoted $A_{\rm s}$ in the original paper) is specified at the scale $0.05\,{\rm Mpc}^{-1}$. Uncertainties are shown at 68% confidence.

	Planck TT,TE,EE+lowE+lensing	+BAO
$\Omega_{\rm b}h^2$	0.02237 ± 0.00015	0.02242 ± 0.00014
$\Omega_{\rm c}h^2$	0.1200 ± 0.0012	0.1193 ± 0.0009
$100\,\theta_{\rm MC}$	1.0409 ± 0.0003	1.0410 ± 0.0003
$n_{\rm s}$	0.965 ± 0.004	0.966 ± 0.004
τ	0.054 ± 0.007	0.056 ± 0.007
$\ln(10^{10}\Delta^2_{\mathcal{R}})$	3.044 ± 0.014	3.047 ± 0.014
h	0.674 ± 0.005	0.677 ± 0.004
σ_8	0.811 ± 0.006	0.810 ± 0.006
$\Omega_{\rm m}$	0.315 ± 0.007	0.311 ± 0.006
Ω_Λ	0.685 ± 0.007	0.689 ± 0.006

moves this degeneracy. Simply adding the *Planck* lensing measurement, and with the assumption that the dark energy is a cosmological constant, yields a 68% confidence constraint on $\Omega_{\rm tot} \equiv \sum \Omega_i + \Omega_\Lambda = 1.011 \pm 0.006$ and further adding BAO makes it 0.9993 ± 0.0019 [2]. Results of this type are normally taken as justifying the restriction to flat cosmologies.

One derived parameter that is very robust is the age of the Universe, since there is a useful coincidence that for a flat Universe the position of the first peak is strongly correlated with the age. The CMB data give 13.797 ± 0.023 Gyr (assuming flatness). This is in good agreement with the ages of the oldest globular clusters and with radioactive dating.

The baryon density $\Omega_{\rm b}$ is now measured with high accuracy from CMB data alone, and is consistent with and more precise than the determination from BBN. The value quoted in the Big-Bang Nucleosynthesis chapter in this volume is $\Omega_{\rm b}h^2 = 0.0220 \pm 0.0004$.

While Ω_Λ is measured to be non-zero with very high confidence, there is no evidence of evolution of the dark energy density. As described in the Dark Energy chapter in this volume a combination of CMB, SN, RSD, and BAO measurements, assuming a flat Universe, yield $w = -1.03 \pm 0.03$ [28], consistent with the cosmological constant case $w = -1$. Allowing more complicated forms of dark energy weakens the limits.

The data provide strong support for the main predictions of the simplest inflation models: spatial flatness and adiabatic, Gaussian, nearly scale-invariant density perturbations. But it is disappointing that there is no sign of primordial gravitational waves; combining *Planck* and *WMAP* with BICEP2/Keck Array BK18 data (plus BAO data to help constrain $n_{\rm s}$) gives a 95% confidence upper limit of $r < 0.036$ at the scale $0.05\,{\rm Mpc}^{-1}$ [63]. The density perturbation spectral index is clearly required to be less than one by current data, though the strength of that conclusion can weaken if additional parameters are included in the model fits.

Tests have been made for various types of non-Gaussianity, a particular example being a parameter $f_{\rm NL}$ that measures a quadratic contribution to the perturbations. Various non-Gaussian shapes are possible (see Ref. [64] for details), and current constraints on the popular 'local', 'equilateral', and 'orthogonal' types (combining CMB temperature and polarization data) are $f_{\rm NL}^{\rm local} = -1 \pm 5$, $f_{\rm NL}^{\rm equil} = -26 \pm 47$, and $f_{\rm NL}^{\rm ortho} = -38 \pm 24$, respectively (these may appear weak, but prominent non-Gaussianity requires the product $f_{\rm NL}\Delta_{\mathcal{R}}$ to be large, and $\Delta_{\mathcal{R}}$ is of order 10^{-5}). Clearly none of these give any indication of primordial non-Gaussianity.

While the above results come from the CMB alone, other probes are becoming competitive (especially when considering more complex cosmological models), and so the combination of data from different sources is of growing importance. We note that it has become fashionable to combine probes at the level of power-spectrum data vectors, taking into account nuisance parameters in each type of measurement. Discussions on 'tension' in resulting cosmological parameters depend on the statistical approaches used. Commonly the cosmology community works within the Bayesian framework, and assesses agreement amongst data sets with respect to a model via Bayesian evidence, essentially the denominator in Bayes' theorem.

As an example of results, combining DES Y3 (position–position clustering, galaxy–galaxy lensing, and weak lensing shear) with *Planck*, BAO, and RSD measurements from eBOSS, and Type Ia supernovae from the Pantheon dataset compilation, has shown the datasets to be mutually compatible and yields very tight constraints on cosmological parameters: $S_8 \equiv \sigma_8(\Omega_{\rm m}/0.3)^{0.5} = 0.812 \pm 0.008$ and $\Omega_{\rm m} = 0.306^{+0.004}_{-0.005}$ in ΛCDM, and $w = -1.03 \pm 0.03$ in wCDM [28] matching the constraint in Ref. [29]. The combined measurement of the Hubble constant within ΛCDM gives $H_0 = 68.0^{+0.4}_{-0.3}\ {\rm km\,s^{-1}\,Mpc^{-1}}$, still leaving substantial tension with the SH0ES measurement described earlier. Future analyses and the next generation of surveys will test for deviations from ΛCDM, for example epoch-dependent $w(z)$ and modifications to General Relativity.

25.5 Outlook for the future

The concordance model is now well-established, and there seems little room left for any dramatic revision of this paradigm. A measure of the strength of that statement is how difficult it has proven to formulate convincing alternatives.

Should there indeed be no major revision of the current paradigm, we can expect future developments to take one of two directions. Either the existing parameter set will continue to prove sufficient to explain the data, with the parameters subject to ever-tightening constraints, or it will become necessary to deploy new parameters. The latter outcome would be very much the more interesting, offering a route towards understanding new physical processes relevant to the cosmological evolution. There are many possibilities on offer for striking discoveries, for example:

- the cosmological effects of a neutrino mass may be unambiguously detected, shedding light on fundamental neutrino properties;
- detection of primordial non-Gaussianities would indicate that non-linear processes influence the perturbation generation mechanism;
- detection of variation in the dark energy density (*i.e.*, $w \neq -1$) would provide much-needed experimental input into its nature.

These supply more than enough motivation for continued efforts to test the cosmological model and improve its accuracy. Over the coming years, there are a wide range of new observations that will bring further precision to cosmological studies. Indeed, there are far too many to mention them all here, and so we highlight just a few areas.

The CMB observations will improve in several directions. A current frontier is the study of polarization, for which power spectrum measurements have now been made by several experiments. Detection of primordial B-mode anisotropies is the next major goal and a variety of projects are targeting this, though theory gives little guidance as to the likely signal level. Future CMB projects that are approved include the Simons Observatory and *LiteBIRD*.

An impressive array of cosmology surveys are already operational, under construction, or proposed, including the ground-based Hyper Suprime Camera (HSC) and Rubin-LSST imaging surveys, spectroscopic surveys such as DESI, and space missions *Euclid* (succesfully launched in July 2023) and the *Roman* Space Telescope.

An exciting area for the future is radio surveys of the redshifted 21-cm line of hydrogen. Because of the intrinsic narrowness of this line, by tuning the bandpass the emission from narrow redshift slices of the Universe will be measured to extremely high redshift, probing the details of the reionization process at redshifts up to perhaps 20, as well as measuring large-scale features such as the BAOs. LOFAR and CHIME are the first instruments able to do this and have begun operations. In the longer term, the Square Kilometre Array (SKA) will take these studies to sophisticated levels.

The development of the first precision cosmological model is a major achievement. However, it is important not to lose sight of the motivation for developing such a model, which is to understand the underlying physical processes at work governing the Universe's evolution. From that perspective, progress has been much less dramatic. For instance, there are many proposals for the nature of the dark matter, but no consensus as to which is correct. The nature of the dark energy remains a mystery. Even the baryon density, now measured to an accuracy of a percent, lacks an underlying theory able to predict it within orders of magnitude. Precision cosmology may have arrived, but at present many key questions remain, to motivate and challenge the cosmology community.

26. Neutrinos in Cosmology

Revised August 2023 by J. Lesgourgues (TTK, RWTH) and L. Verde (ICC, U. of Barcelona; ICREA, Barcelona).

26.1 Standard neutrino cosmology

Neutrinos leave detectable imprints on cosmological observations that can then be used to constrain neutrino properties. This is a great example of the remarkable interconnection and interplay between nuclear physics, particle physics, astrophysics and cosmology (for general reviews see *e.g.*, [1–4]). Present cosmological data are already providing constraints on neutrino properties not only complementary but also competitive with terrestrial experiments; for instance, upper bounds on the total neutrino mass have shrinked by a factor of about 20 in the past two decades. Forthcoming cosmological data may soon provide key information, not obtainable in other ways like *e.g.*, a measurement of the absolute neutrino mass scale.

A relic neutrino background pervading the Universe (the Cosmic Neutrino background, CνB) is a generic prediction of the standard hot Big Bang model (see Big Bang Nucleosynthesis – Chap. 24 of this *Review*). While it has not yet been detected directly, it has been indirectly confirmed by the accurate agreement of predictions and observations of: *a*) the primordial abundance of light elements (see Big Bang Nucleosynthesis – Chap. 24) of this *Review*; *b*) the power spectrum of Cosmic Microwave Background (CMB) anisotropies (see Cosmic Microwave Background – Chap. 29 of this *Review*); and *c*) the large-scale clustering of cosmological structures. Within the hot Big Bang model such good agreement would fail dramatically without a CνB with properties matching closely those predicted by the standard neutrino decoupling process (*i.e.*, involving only weak interactions).

We will illustrate below that cosmology is sensitive to the following neutrino properties: their density, related to the number of active (*i.e.*, left-handed, see Neutrino Mass, Mixing, and Oscillations - Chap. 14 of this *Review*) neutrino species, and their masses. At first order, cosmology is sensitive to the total neutrino mass, but is blind to the mixing angles and CP violation phase as discussed in Neutrino Mass, Mixing, and Oscillations (Chap. 14 of this *Review*). This makes cosmological constraints nicely complementary to measurements from terrestrial neutrino experiments.

The minimal cosmological model, ΛCDM, currently providing a good fit to most cosmological data sets (with the exception of some data in tension, discussed in The Cosmological Parameters Chap. 25 of this *Review*), assumes that the only massless or light (sub-keV) relic particles since the Big Bang Nucleosynthesis (BBN) epoch are photons and active neutrinos. Extended models with light sterile neutrinos, light thermal axions or other light relics – sometimes referred to as "dark radiation"– would produce effects similar to, and potentially degenerate with, those of active neutrinos. Thus neutrino bounds are often discussed together with limits on such scenarios. In case of anomalies in cosmological data, it might not be obvious to discriminate between interpretation in terms of active neutrinos with non-standard decoupling, additional production mechanisms, non-standard interactions, etc., or in terms of some additional light particles. Such extensions have been explored as a possible way to resolve the H_0 tension between late and early Universe determinations [5–8], but are not widely favoured [9–11].

Hence neutrino density and mass bounds can be derived under the assumption of no additional massless or light relic particles, and the neutrino density measured in that way provides a test of standard (*i.e.*, involving only weak interactions) neutrino decoupling.

In that model, the three active neutrino types thermalize in the early Universe, with a negligible leptonic asymmetry. Then they can be viewed as three propagating mass eigenstates sharing the same temperature and identical Fermi-Dirac distributions, thus with no visible effects of flavour oscillations. Neutrinos decouple gradually from the thermal plasma at temperatures $T \sim 2\,\mathrm{MeV}$. In the instantaneous neutrino decoupling limit, *i.e.*, assuming that neutrinos were fully decoupled at the time when electron-positrons annihilate and release entropy in the thermal bath, the neutrino-to-photon density ratio between the time of electron-positron annihilation and the non-relativistic transition of neutrinos would be given by

$$\frac{\rho_\nu}{\rho_\gamma} = \frac{7}{8} N_{\rm eff} \left(\frac{4}{11}\right)^{4/3} , \qquad (26.1)$$

with $N_{\rm eff} = 3$, and the last factor comes from the fourth power of the temperature ratio $T_\nu/T_\gamma = (4/11)^{1/3}$ (see Big Bang Cosmology – Chap. 22 in this *Review*). In the above formula, $N_{\rm eff}$ is called the effective number of neutrino species because it can be viewed as a convenient parametrisation of the relativistic energy density of the Universe beyond that of photons, in units of one neutrino in the instantaneous decoupling limit. Precise simulations of neutrino decoupling and electron-positron annihilation, taking into account flavor oscillations, provide precise predictions for the actual phase-space distribution of relic neutrinos [12–18]. These distributions differ from the instantaneous decoupling approximation through a combination of a small shift in the photon temperature and small flavor-dependent non-thermal distortions, all at the percent level. The final result for the density ratio ρ_ν/ρ_γ in the relativistic regime can always be expressed as in Eq. (26.1), but with a different value of $N_{\rm eff}$. The most recent analyses, that includes the effect of neutrino oscillations with the present values of the mixing parameters, an improved calculation of the collision terms and the most recent results on plasma thermodynamics QED corrections, give[1] $N_{\rm eff} = 3.044$ [16, 17]. The precise number density ratio n_ν/n_γ can also be derived from such studies, and is important for computing the ratio $\Omega_\nu h^2/\sum_i m_i$ (ratio of the physical density of neutrinos in units of the critical density to the sum of neutrino masses) in the non-relativistic regime. Once neutrinos are decoupled, their momentum redshifts like $p \propto 1/a$ but, due to the absence of interactions, their phase-space distributions remain constant when expressed in terms of the comoving momentum $q = pa$, even when they become non-relativistic.

The neutrino temperature today, $T_\nu^0 \simeq 1.7 \times 10^{-4}\,\mathrm{eV} \simeq 1.9\,\mathrm{K}$, is smaller than at least two of the neutrino masses, since the two squared-mass differences are $|\Delta m^2_{31}|^{1/2} > |\Delta m^2_{21}|^{1/2} > T_\nu^0$ (see Neutrino mass, Mixing, and oscillations – Chap. 14 of this *Review*). Thus at least two neutrino mass eigenstates are non-relativistic today and behave as a small "hot" fraction of the total dark matter (they cannot be all the dark matter, as explained in Chap. 27 in this *Review*). This fraction of hot dark matter can be probed by cosmological experiments, for two related reasons, as we now describe.

First, neutrinos are the only known particles behaving as radiation at early times (during the CMB acoustic oscillations) and dark matter at late times (during structure formation), which has consequences on the background evolution. Neutrinos become non-relativistic when their mass is equal to their average momentum, given for any Fermi-Dirac-distributed particle by $\langle p \rangle = 3.15\,T$. Thus the redshift of the non-relativistic transition is given by $z_i^{\rm nr} = m_i/(3.15\,T_\nu^0) - 1 = m_i/[0.53\,\mathrm{meV}] - 1$ for each eigenstate of mass m_i, giving for instance $z_i^{\rm nr} = 110$ for $m_i = 60\,\mathrm{meV}$, corresponding to a time deep inside the matter-dominated regime. Second, until the non-relativistic transition, neutrinos travel at the speed of light, and later on they move at a typical velocity $\langle v_i/c \rangle = 3.15\,T_\nu(z)/m_i = 0.53(1+z)\,\mathrm{meV}/m_i$, which is several orders of magnitude larger than that of the dominant cold (or even of possibly warm) dark matter component(s). This brings their characteristic diffusion scale, called the "free-streaming length", to cosmological relevant values, with consequences on gravitational clustering and the growth of structure.

Once neutrinos are non-relativistic, their energy density is given by $\rho_\nu \simeq \sum m_i n_i$. Since the number densities n_i are equal to each other (up to negligible corrections coming from flavour effects in the decoupling phase), the total mass $\sum m_\nu = m_1 + m_2 + m_3$ can be factorized out. It is possible that the lightest neutrino is still relativistic today, in which case this relation is slightly incorrect, but given that the total density is always strongly dominated by that of non-relativistic neutrinos, the error made is completely

[1] The last effects that potentially require some further checks in order to fully settle the fourth significant digit in $N_{\rm eff}$ are temperature QED corrections; according to [18], the final result might be closer to 3.043 than to 3.044.

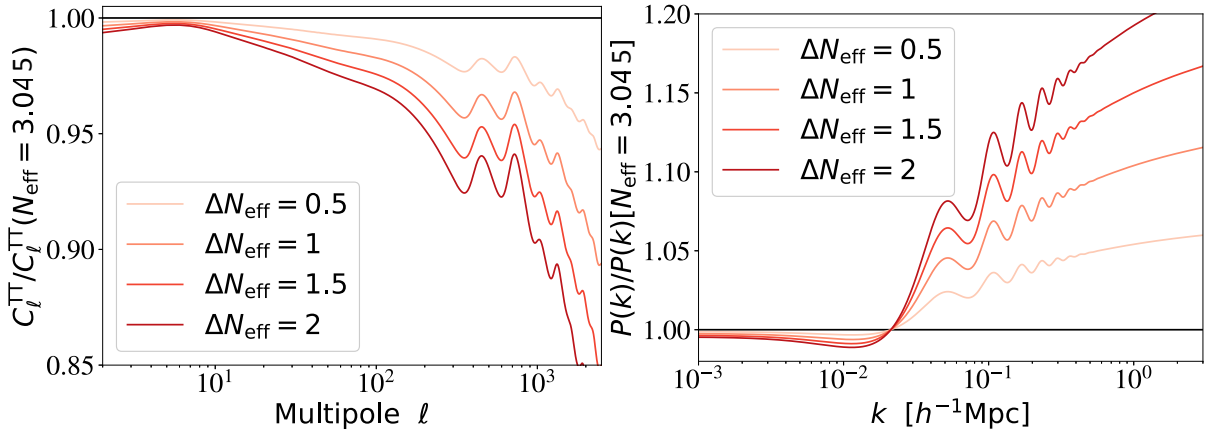

Figure 26.1: Ratio of the CMB C_ℓ^{TT} (left, including lensing effects) and matter power spectrum $P(k)$ (right, computed for each model in units of $(h^{-1}\mathrm{Mpc})^3$) for different values of $\Delta N_{\rm eff} \equiv N_{\rm eff} - 3.044$ over those of a reference model with $\Delta N_{\rm eff} = 0$. In order to minimize and better characterise the effect of $N_{\rm eff}$ on the CMB, the parameters that are kept fixed are $\{z_{\rm eq},\, z_\Lambda,\, \omega_{\rm b},\, \tau\}$ and the primordial spectrum parameters. Fixing $\{z_{\rm eq},\, z_\Lambda\}$ is equivalent to fixing the fractional density of total radiation, of total matter and of cosmological constant $\{\Omega_{\rm r}, \Omega_{\rm m}, \Omega_\Lambda\}$ while increasing the Hubble parameter as a function of $N_{\rm eff}$. The statistical errors on the C_ℓ are $\sim 1\%$ for a band power of $\Delta\ell = 30$ at $\ell \sim 1000$. The error on $P(k)$ is estimated to be of the order of 5%.

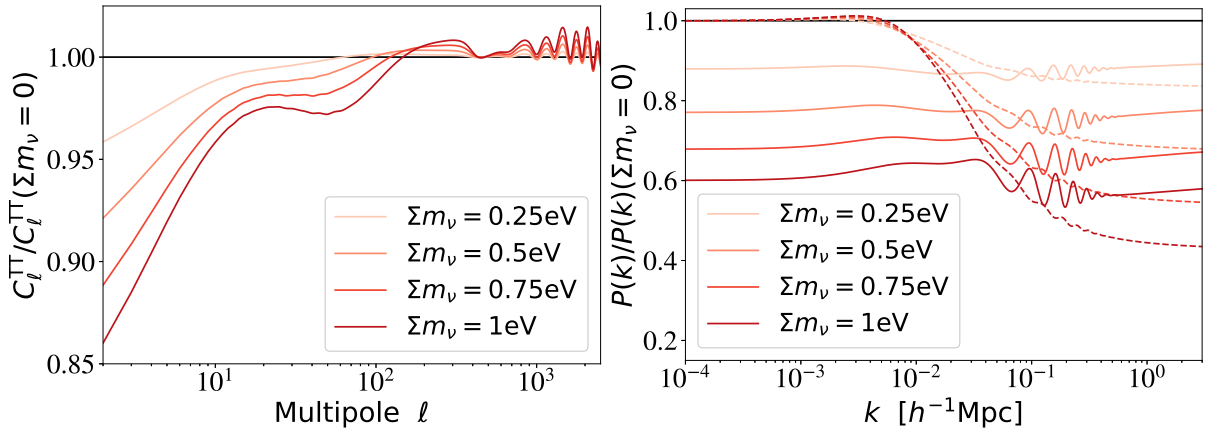

Figure 26.2: Ratio of the CMB C_ℓ^{TT} and matter power spectrum $P(k)$ (computed for each model in units of $(h^{-1}\mathrm{Mpc})^3$) for different values of $\sum m_\nu$ over those of a reference model with massless neutrinos. In order to minimize and better characterise the effect of $\sum m_\nu$ on the CMB, the parameters that are kept fixed are $\omega_{\rm b}$, $\omega_{\rm c}$, τ, the angular scale of the sound horizon $\theta_{\rm s}$ and the primordial spectrum parameters (solid lines). This implies that we are increasing the Hubble parameter h as a function of $\sum m_\nu$. For the matter power spectrum, in order to single out the effect of neutrino free-streaming on $P(k)$, the dashed lines show the spectrum ratio when $\{\omega_{\rm m}, \omega_{\rm b}, \Omega_\Lambda\}$ are kept fixed. For comparison, the error on $P(k)$ is of the order of 5% with current observations, and the fractional C_ℓ errors are of the order of $1/\sqrt{\ell}$ at low ℓ.

negligible. Using the expression for n_i/n_γ obtained from precise neutrino decoupling studies [16, 17], and knowing n_γ from the measurement of the CMB temperature, one can compute ρ_ν^0, the total neutrino density today,[2] in units of the critical density $\rho_{\rm crit}^0$:

$$\Omega_\nu = \frac{\rho_\nu^0}{\rho_{\rm crit}^0} = \frac{\sum m_\nu}{93.12 h^2\ \mathrm{eV}}\,, \qquad (26.2)$$

and the total neutrino average number density today: $n_\nu^0 = 339.5\ \mathrm{cm}^{-3}$ [19]. Here h is the Hubble constant in units of 100 km s^{-1} Mpc^{-1}.

26.2 Effects of neutrino properties on cosmological observables

As long as they are relativistic, *i.e.*, until some time deep inside the matter-dominated regime for neutrinos with a mass $m_i \ll 3.15\, T_\nu^{\rm eq} \sim 1.5\,\mathrm{eV}$ (see Big Bang Cosmology, Chap. 22 in this *Review*), neutrinos enhance the density of radiation: this effect is parameterised by $N_{\rm eff}$ and can be discussed separately from the effect of the mass that will be described later in this section. Increasing $N_{\rm eff}$ impacts the observable spectra of CMB anisotropies and matter fluctuations through background and perturbation effects.

26.2.1 *Effect of* $N_{\rm eff}$ *on the CMB*

The background effects depend on what is kept fixed when increasing $N_{\rm eff}$. If the densities of other species are kept fixed, a higher $N_{\rm eff}$ implies a smaller redshift of radiation-to-matter equality, with very strong effects on the CMB spectrum: when the amount of expansion between radiation-to-matter equality and photon decoupling is larger, the CMB peaks are suppressed. This effect is not truly characteristic of the neutrino density, since it can be produced by varying several other parameters. Hence, to characterise the effect of $N_{\rm eff}$, it is more useful and illuminating to enhance the density of total radiation, of total matter and of Λ by exactly the same amount, in order to keep the redshift of radiation-to-matter equality $z_{\rm eq}$ and matter-to-Λ equality z_Λ fixed [20–22]. The primordial spectrum parameters, the baryon

[2] The value 93.12 eV applies to the limit of large masses, in which $\rho_\nu^0 = \sum m_i n_i^0$ and neutrinos are degenerate in mass [19]. This number would be larger by $\sim$0.1% in the limit of minimal normal hierarchy (or smaller by $\sim$0.06% for minimal inverted hierarchy), due the lighest mass state(s) being still relativistic today and to flavor-dependent non-thermal distortions in the neutrino phase-space distributions.

density $\omega_{\rm b} \equiv \Omega_{\rm b} h^2$ and the optical depth to reionization τ can be kept fixed at the same time, since we can simply vary $N_{\rm eff}$ together with the Hubble parameter h with fixed $\{\omega_{\rm b}, \Omega_{\rm c}, \Omega_\Lambda\}$. The impact of such a transformation is shown in Fig. 26.1 for the CMB temperature spectrum C_ℓ^{TT} (defined in Chap. 29 in this *Review*) and for the matter power spectrum $P(k)$ (defined in Chap. 22 in this *Review*) for several representative values of $N_{\rm eff}$. These effects are within the reach of cosmological observations given current error bars, as discussed in Section 26.3.1 (for instance, with the *Planck* satellite data, the statistical error on the C_ℓ's is of the order of one per cent for a band power of $\Delta\ell = 30$ at $\ell \sim 1000$).

With this transformation, the main background effect of $N_{\rm eff}$ is an increase in the diffusion scale (or Silk damping scale, see Cosmic Microwave Background – Chap. 29 in this *Review*) at the time of decoupling, responsible for the decrease in C_ℓ^{TT} at high ℓ, plus smaller effects coming from a slight increase in the redshift of photon decoupling [20–22]. At the level of perturbations, a higher $N_{\rm eff}$ implies that photons feel gravitational forces from a denser neutrino component; this tends to decrease the acoustic peaks (because neutrinos are distributed in a smoother way than photons) and to shift them to larger scales / smaller multipoles (because photon perturbations traveling at the speed of sound in the photon-baryon fluid feel some dragging effect from neutrino perturbations travelling at the speed of light) [20, 22, 23]. The effect of increasing $N_{\rm eff}$ on the polarization spectrum features are the same as on the temperature spectrum: an increased Silk damping, and a shift in the acoustic peak amplitude and location - the latter effect is even more clear in the polarization spectrum, in which the location of acoustic peaks does not get further influenced by a Doppler effect like for temperature. The combination of these effects is truly characteristic of the radiation density parameter $N_{\rm eff}$ and cannot be mimicked by other parameters; thus $N_{\rm eff}$ can be accurately measured from the CMB alone. However, there are correlations between $N_{\rm eff}$ and other parameters. In particular, we have seen (Fig. 26.1) that in order to minimise the effect of $N_{\rm eff}$ on the CMB spectrum, one should vary h at the same time, hence there is a correlation between $N_{\rm eff}$ and h, which implies that independent measurements reducing the error bar on h also reduce that on $N_{\rm eff}$. Note that this correlation is not equivalent to a perfect degeneracy, so both parameters can be constrained with CMB data alone.

26.2.2 *Effect of $N_{\rm eff}$ on the matter spectrum*

We have discussed the effect of increasing $N_{\rm eff}$ while keeping $z_{\rm eq}$ and $\omega_{\rm b}$ fixed, because the latter two quantities are very accurately constrained by CMB data. This implies that $\omega_{\rm c}$ increases with $N_{\rm eff}$, and that the ratio $\omega_{\rm b}/\omega_{\rm c} = \Omega_{\rm b}/\Omega_{\rm c}$ decreases. However, the ratio of baryonic-to-dark matter has a strong impact on the shape of the matter power spectrum, because until the time of decoupling of the baryons from the photons, CDM experiences gravitational collapse, while baryons are kept smoothly distributed by photon pressure and affected by acoustic oscillations. The decrease of $\Omega_{\rm b}/\Omega_{\rm c}$ following from the increase of $N_{\rm eff}$ gives more weight to the most clustered of the two components, namely the dark matter one, and produces an enhancement of the small-scale matter power spectrum and a damping of the amplitude of baryon acoustic oscillations (BAOs), clearly visible in Fig. 26.1 (right plot). The scale of BAOs is also slightly shifted by the same neutrino dragging effect as for CMB peaks [20, 26].

The increase in the small-scale matter power spectrum is also responsible for a last effect on the CMB spectra: the CMB last scattering surface is slightly more affected by weak lensing from large-scale structures. This tends to smooth the maxima, the minima, and the damping scale of the CMB spectra [27].

26.2.3 *Effect of neutrino masses on the CMB*

Neutrino eigenstates with a mass $m_i \ll 0.6\,{\rm eV}$ become non-relativistic after photon decoupling. They contribute to the non-relativistic matter budget today, but not at the time of equality or recombination. If we increase the neutrino mass while keeping fixed the density of baryons and dark matter ($\omega_{\rm b}$ and $\omega_{\rm c}$), the early cosmological evolution remains fixed and independent of the neutrino mass, until the time of the non-relativistic transition. Thus one might expect that the CMB temperature and polarization power spectra are left invariant. This is not true for four reasons.

First, the neutrino density enhances the total non-relativistic density at late times, $\omega_{\rm m} = \omega_{\rm b} + \omega_{\rm c} + \omega_\nu$, where $\omega_\nu \equiv \Omega_\nu h^2$ is given as a function of the total mass $\sum m_\nu$ by Eq. (26.2). The late background evolution impacts the CMB spectrum through the relation between scales on the last scattering surface and angles on the sky, and through the late ISW effect (see Cosmic Microwave Background – Chap. 29 of this *Review*). These two effects depend respectively on the angular diameter distance to recombination, $d_A(z_{\rm rec})$, and on the redshift of matter-to-Λ equality. Increasing $\sum m_\nu$ tends to modify these two quantities. By playing with h and Ω_Λ, it is possible to keep one of them fixed, but not both at the same time. Since the CMB measures the angular scale of acoustic oscillations with exquisite precision, and is only loosely sensitive to the late ISW effect due to cosmic variance, we choose in Fig. 26.2 to play with the Hubble parameter in order to maintain a fixed scale $d_A(z_{\rm rec})$. With such a choice, an increase in neutrino mass comes together with a decrease in the late ISW effect explaining the depletion of the CMB spectrum for $l \leq 20$. The fact that both $\sum m_\nu$ and h enter the expression of $d_A(z_{\rm rec})$ implies that measurements of the neutrino mass from CMB data are strongly correlated with h. Second, the non-relativistic transition of neutrinos affects the total pressure-to-density ratio of the Universe, and causes a small variation of the metric fluctuations. If this transition takes place not too long after photon decoupling, this variation is observable through the early ISW effect [22,28,29]. It is responsible for the dip seen in Fig. 26.2 for $20 \leq \ell \leq 200$. Third, when the neutrino mass is higher, the CMB spectrum is less affected by the weak lensing effect induced by the large-scale structure at small redshift. This is due to a decrease in the matter power spectrum described in the next paragraphs. This reduced lensing effect is responsible for most of the oscillatory patterns visible in Fig. 26.2 (left plot) for $\ell \geq 200$. Fourth, the neutrinos with the smallest momenta start to be non-relativistic earlier than the average ones. The photon perturbations feel this through their gravitational coupling with neutrinos. This leads to a small enhancement of C_l^{TT} for $\ell \geq 500$, hardly visible on Fig. 26.2 because it is balanced by the lensing effect.

26.2.4 *Effect of neutrino masses on the matter spectrum*

The physical effect of neutrinos on the matter power spectrum is related to their velocity dispersion. Neutrinos free-stream over large distances without falling into small potential wells. The free-streaming scale is roughly defined as the distance travel by neutrinos over a Hubble time scale $t_{\rm H} = (a/\dot{a})$, and approximates the scale below which neutrinos remain very smooth. On larger scales, they cluster in the same way as cold dark matter. The power spectrum of total matter fluctuations, related to the squared fluctuation $\delta_{\rm m}^2$ with $\delta_{\rm m} \equiv \delta_{\rm b} + \delta_{\rm c} + \delta_\nu$, gets a negligible contribution from the neutrino component on small scales, and is reduced by a factor $(1 - 2f_\nu)$, where $f_\nu = \omega_\nu/\omega_{\rm m}$. Additionally, on scales below the free-streaming scale, the growth of ordinary cold dark matter and baryon fluctuations is modified by the fact that neutrinos contribute to the background density, but not to the density fluctuations. This changes the balance between the gravitational forces responsible for clustering, and the Hubble friction term slowing it down. Thus the growth rate of CDM and baryon fluctuations is reduced [30]. This results today in an additional suppression of the small-scale linear matter power spectrum by approximately $(1 - 6f_\nu)$. These two effects sum up to a factor $(1 - 8f_\nu)$ [31] (more precise approximations can be found in [2, 22]). The non-linear spectrum is even more suppressed on mildly non-linear scales [3, 32–36].

This effect is often illustrated by plots of the matter power spectrum ratio with fixed parameters $\{\omega_{\rm m}, \omega_{\rm b}, \Omega_\Lambda\}$ and varying f_ν, *i.e.*, with the CDM density adjusted to get a fixed total dark matter density [2, 22, 31] (see Fig. 26.2, right plot, dashed lines). This transformation does not leave the redshift of equality $z_{\rm eq}$ invariant, and has very large effects on the CMB spectra. If one follows the logic of minimizing CMB variations and fixing $z_{\rm eq}$ like in the previous paragraphs, the increase in $\sum m_\nu$ must take place together with an increase of h, which tends to suppress the large-

Table 26.1: Summary of $N_{\rm eff}$ constraints.

	Model	$N_{\rm eff}$	Ref.

scale power spectrum, by approximately the same amount as the neutrino free-streaming effect [37]. In that case, the impact of neutrino masses on the matter power spectrum appears as an overall amplitude suppression, which can be seen in Fig. 26.2 (right plot, solid lines). The oscillations on intermediate wavenumbers come from a small shift in the BAO scale [37]. This global effect is not degenerate with a variation of the primordial spectrum amplitude $A_{\rm s}$, because it only affects the matter power spectrum, and not the CMB spectra. However, the amplitude of the CMB temperature and polarization spectrum is given by the combination $A_{\rm s}e^{-2\tau}$. Hence a measurement of τ is necessary in order to fix $A_{\rm s}$ from CMB data, and avoid a parameter degeneracy between $\sum m_\nu$ and $A_{\rm s}$ [37–39].

A few of the neutrino mass effects described above –free-streaming scale, early ISW– depend on individual masses m_i, but most of them depend only on the total mass through f_ν – suppression of the matter power spectrum, CMB lensing, shift in angular diameter distance–. Because the latter effects are easier to measure, cosmology is primarily sensitive to the total mass $\sum m_\nu$ [40, 41]. The possibility that future data sets might be able to measure individual masses or the mass hierarchy, despite systematic errors and parameter degeneracies, an active area of investigation [42–48].

26.3 Cosmological Constraints on neutrino properties

In this review we focus on cosmological constraints on the abundance and mass of ordinary active neutrinos. Several stringent but model-dependent constraints on non-standard neutrinos (*e.g.*, sterile neutrinos, active neutrinos with interactions beyond the weak force, unstable neutrinos with invisible decay, etc.) can also be found in the literature.

We highlight that cosmological constraints on neutrino properties are always obtained within the framework of a ΛCDM model or simple and popular extensions of this model as spelled out in the following subsections. In light of the emergence of cosmological tensions and especially the so-called Hubble tension which has now reached the $\sim 5\sigma$ level (see Chap. 25 of this *Review*), it is important to bear in mind the following considerations. Inconsistent measurements should not be combined: bounds obtained from combination of discrepant data sets should be considered with extreme caution. Additionally, the constraints reported below assume that the solution of the H_0 tension –whatever that may be– leaves the interpretation of the adopted probes unaffected.

26.3.1 *Neutrino abundance*

Table 26.1 shows a list of constraints on $N_{\rm eff}$ obtained with several combination of data sets. 'Pl18' denotes the *Planck* 2018 data, composed of a high-ℓ temperature+polarization likelihood (TT,TE,EE), low-ℓ polarization (low E) and CMB lensing spectrum likelihood (lensing) based on lensing extraction from quadratic estimators [24]. 'BAO' refers to measurements of the BAO scale (and hence of the angular diameter distance) described in detail in the references given in the table.

Within the framework of a 7-parameter cosmological model (ΛCDM+$N_{\rm eff}$), the constraint on $N_{\rm eff}$ from the *Planck* 2018 data release [TT,TE,EE+lowE] is $N_{\rm eff} = 2.92^{+0.36}_{-0.37}$ (95%CL). This number is perfectly compatible with the prediction of the standard neutrino decoupling model, $N_{\rm eff} = 3.044$, and can be viewed as a proof of self-consistency of the cosmological model.

The bounds can be tightened by adding information on the low-redshift background expansion from BAOs. Finally one may also add information from large-scale structure (LSS), *i.e.*, on the growth rate and clustering amplitude of matter as a function of scale, although LSS data are not very constraining for the $N_{\rm eff}$ parameter. The second result quoted in Table 26.1 shows that the $N_{\rm eff}$ bound tightens slightly when adding BAO information from the BOSS galaxy survey plus LSS information from the *Planck* CMB lensing spectrum. Adding more recent data on BAOs and redshift-space distortions (RSDs) from the eBOSS galaxy survey [49] only provides a very marginal improvement of the bounds [54]. All combinations of *Planck* 2018 data with BAO and/or LSS data return measurements consistent with the standard expectation.

The situation is different with the inclusion of low-redshift measurements of H_0 with distance ladders (DLs) [55,56], now reaching a 5.7σ tension with *Planck* in the ΛCDM framework. As explained in Section 26.2, the positive correlation between $N_{\rm eff}$ and h means that inclusion of the H_0 measurement would tend to push $N_{\rm eff}$ to higher values. However, the high values of $N_{\rm eff}$ that would potentially reconcile the measured CMB or BAO peak scale with the Hubble parameter suggested by DLs, $H_0 \sim 73$ km/s/Mpc, are excluded by the measurement of the damping tail of the CMB temperature spectrum, either by *Planck* itself (given the previously quoted $N_{\rm eff}$ bounds) or by more recent and independent small-scale CMB data sets (as shown e.g. in [57]). Thus, the $N_{\rm eff}$ extension to the ΛCDM model does not reduce the tension significantly, and the combination of *Planck* and DL data does not return any meaningful constraint on $N_{\rm eff}$ in this context. It is currently unclear whether a resolution of the Hubble tension would require a departure from the ΛCDM (or ΛCDM+$N_{\rm eff}$) model [11, 58–62].

As long as DL data are not included, the error bars on $N_{\rm eff}$ degrade mildly when the data are analysed in the context of more extended cosmological scenarios. Adding only the total neutrino mass as an 8th free parameter has a negligible impact on the bounds. The authors of Ref. [25] take a more extreme point of view and fit a 12-parameter model to Pl18[TT,TE,EE+lowE+lensing] data; they obtain $N_{\rm eff} = 2.95 \pm 0.24$ (68% CL), showing that it is very difficult with current cosmological data to accommodate shifts of more than 0.5 from the standard $N_{\rm eff}$ value, and to obtain good fits with, for instance, a fourth (sterile) thermalized neutrino. This is interesting since the anomalies in some oscillation data could be interpreted as evidence for at least one sterile neutrino with a large mixing angle, which would need to be thermalised unless non-standard interactions come into play [5]. In other words, cosmology disfavours the explanation of the oscillations anomalies in terms of extra neutrinos if they are thermalized.

However, if a resolution to the Hubble tension requires a departure from the ΛCDM model or its most simple extensions, the situation is more open. In the presence of new physical ingredients (such as, e.g., non-standard interactions, exotic dark matter candidates, non-minimal dark energy properties or modified gravity), it is in principle conceivable that $N_{\rm eff}$ reaches larger values. However, to date, none of these ingredients has been shown to fully solve the Hubble tension and reconcile CMB, BAO, DL, and supernovae data.

26.3.2 *Are they really neutrinos, as expected?*

While a value of $N_{\rm eff}$ significantly different from zero (at more than 15σ) and consistent with the expected number 3.044 yields a powerful indirect confirmation of the CνB, departures from standard $N_{\rm eff}$ could be caused by any ingredient affecting the early-time expansion rate of the Universe. Extra relativistic particles (either decoupled, self-interacting, or interacting with a dark sector), a background of gravitational waves, an oscillating scalar

Table 26.2: Summary of $\sum m_\nu$ constraints.

field with quartic potential, departures from Einstein gravity, or large extra dimensions are some of the possibilities for such ingredients. In principle one could even assume that the cosmic neutrino background never existed or has decayed (like in the "neutrinoless Universe" model of [63]) while another dark radiation component is responsible for $N_{\rm eff}$. At least, cosmological data allow to narrow the range of possible interpretations of $N_{\rm eff} \simeq 3$ to the presence of decoupled relativistic relics like standard neutrinos. Indeed, free-streaming particles leave specific signatures in the CMB and LSS spectra, because their density and pressure perturbations, bulk velocities and anisotropic stress also source the metric perturbations. These signatures can be tested in several ways.

A first approach consists of introducing a self-interaction term in the neutrino equations [6, 7]. Ref. [8] finds that current CMB and BAO data are compatible with no self-interactions. The upper limit to the effective coupling constant $G_{\rm eff}$ for a Fermi-like four-fermions interaction at 95% confidence is $\log_{10}(G_{\rm eff}{\rm MeV}^2) < -1.47$ for Pl18+BAO [11]. Note however that neutrino self-interactions as strong as $\log_{10}(G_{\rm eff}{\rm MeV}^2) \simeq -1.4$ could reconcile CMB temperature and BAO data with the direct H_0 measurement of Ref [64], but such interactions seem to be hardly compatible with BBN, laboratory constraints [10] and CMB polarization [9, 11].

A second approach consists of introducing two phenomenological parameters, $c_{\rm eff}$ and $c_{\rm vis}$ (see *e.g.*, [65–67]): $c^2_{\rm eff}$ generalizes the linear relation between isotropic pressure perturbations and density perturbations, while $c^2_{\rm vis}$ modifies the neutrino anisotropic stress equation. While relativistic free-streaming species have $(c^2_{\rm eff}, c^2_{\rm vis}) = (1/3, 1/3)$, a perfect relativistic fluid would have $(c^2_{\rm eff}, c^2_{\rm vis}) = (1/3, 0)$. Other values do not necessarily refer to a concrete model, but make it possible to interpolate between these limits. *Planck* data, alone or in combination with galaxy clustering, strongly suggests $(c^2_{\rm eff}, c^2_{\rm vis}) = (1/3, 1/3)$ [68–70].

Finally, Ref. [23] (resp. [26]) shows that current data are precise enough to detect the "neutrino drag" effect mentioned in Sec. 26.2 through the measurement of the CMB peak (resp. BAO) scale. These findings show that current cosmological data are able to detect not just the average density of some relativistic relics, but also their anisotropies.

26.3.3 *Neutrino masses*

Table 26.2 shows a list of constraints on $\sum m_\nu$ obtained with several combinations of data sets. The acronyms 'Pl18' and 'BAO' have been described in the previous subsection, while 'ACT' refers to CMB observations from the Atacama Cosmology Telescope [50], 'RSD' to redshift-space distortions from the eBOSS galaxy survey [49], 'Shape' to the shape parameter of the matter power spectrum measured by the BOSS (eBOSS) galaxy redshift survey [51, 71–73], 'Lyman-α' to the one-dimensional flux power spectrum of eBOSS quasars [52], 'SN' to the Type Ia supernovae compilation of [74], 'DES-Y1' to the weak lensing and galaxy auto- and cross-correlation measured by the Dark Energy Survey (DES) using Year 1 data [75], and 'DES-Y3' for the same quantity estimated from DES Year 3 data [53].

Given that most determinations of $N_{\rm eff}$ are compatible with the standard prediction, $N_{\rm eff} = 3.044$, it is reasonable to adopt this value as a theoretical prior and to investigate neutrino mass constraints in the context of a minimal 7-parameter model, ΛCDM+$\sum m_\nu$. Under this assumption, the most robust constraints come from *Planck* 2018 temperature and polarization data alone: $\sum m_\nu < 0.26\,$eV (95%CL) [24]. Among the four effects of neutrino masses on the CMB spectra described before, current bounds are dominated by the first and the third effects (modified late background evolution, and distortions of the temperature and polarization spectra through weak lensing).

Adding measurements of the BAO scale is crucial, since the determination of the angular diameter distance at small redshift allows us to break parameter degeneracies, for instance between $\sum m_\nu$ and h. The combination of Pl18[TT,TE,EE+lowE] with the most recent BAO measurements, including the eBOSS Data Release 16 (DR16), gives $\sum m_\nu < 0.13\,$eV (95%CL) [49]. Supernovae data are less constraining than BAO data for the neutrino mass determination.

Because the parameter correlation between $\sum m_\nu$ and H_0 is negative, the inclusion of DL data would tend to provide stronger bounds on neutrino masses. However, like for $N_{\rm eff}$, such bounds would not be meaningful, since they would arise from a combination of discrepant data sets. Thus, to constrain neutrino masses, it is once more crucial to understand whether the Hubble tension arises from unmodeled aspects that have no effect on the current treatment and interpretation of the datasets adopted here or new physical ingredients.

Taking the former point of view, it is interesting to add LSS data sets, sensitive also to the small-scale suppression of the matter power spectrum due to neutrino free-streaming, although most of the constraining power for current data sets comes from the constraints on the expansion history and growth-history signals [76]. The inclusion of CMB lensing data from *Planck* 18 improves the CMB-only bound only by a small amount, but the inclusion of higher resolution CMB lensing maps from ACT [50] brings the limit down to 0.12 eV. To get an even stronger bound, one can add data from the eBOSS survey, which infers the growth rate of structures from RSDs. The addition of BAO and RSD measurements from eBOSS tightens the bound down to $\sum m_\nu < 0.10\,$eV (95%CL) [49]. Further including information about the large-scale shape ('Shape') of the power spectrum, BOSS+eBOSS data alone give $\sum m_\nu < 0.40\,$eV (95%CL) with a BBN prior on ω_b, while *Planck*+BOSS+eBOSS give $\sum m_\nu < 0.082$ eV (95% CL) [51]. A similar bound arises from the most recent Lyα forest data from BOSS combined with *Planck* and BAO data, giving $\sum m_\nu < 0.087$ eV (95% CL). Such bounds already challenge the

inverted hierarchy mass scheme, which predicts $\sum m_\nu \geq 0.11\,\mathrm{eV}$ (e.g., [47] and refs. therein).

It should however be noticed that DES prefers a lower σ_8 value than the *Planck* best fit, relaxing the bound to $\sum m_\nu < 0.12\,\mathrm{eV}$ (95%CL) [49] when using Year 1 data in combination with eBOSS and other datasets (Pl18+BAO+RSD+SN+DES). Using Year 3 data and a similar combination, the DES collaboration obtains $\sum m_\nu < 0.13\,\mathrm{eV}$ (95%CL) [53]. Notice however that the DES analysis adopts a theory prior $\sum m_\nu \geq 0.06\mathrm{eV}$ while other constraints only assume $\sum m_\nu \geq 0$. For a direct comparison, the combined constraint of reference [49] can be recomputed with the same theory prior and becomes $\sum m_\nu < 0.13$ eV (95%CL).

Leaving aside DL measurements, one finds that upper bounds on neutrino masses become weaker when other data are analysed in the context of extended cosmological models, but only by a small amount. Floating $N_{\rm eff}$ instead of fixing it to 3.044 has no significant impact on the neutrino mass bounds reported in the previous paragraphs. Even in the extreme case considered by Ref. [25], with 12 free cosmological parameters, one can see in Table 26.2 that the bound from *Planck* 2018 (without lensing) + BAO increases from 0.13 eV to 0.52 eV (95% CL) only. This shows that current cosmological data are precise enough to disentangle the effect of several extended cosmological parameters, and that neutrino mass bounds are becoming increasingly robust.

One should stress again that if the explanation of DL measurements requires a cosmological scenario with new – and yet unkown – physical ingredients, the current neutrino mass bounds may in principle be shifted or relaxed. However, in the absence of working scenarios that convincingly explain the Hubble tension without raising other tensions, we do not at the moment have any framework for quoting alternative mass bounds and assessing their model dependence.

26.4 Future prospects and outlook

The cosmic neutrino background has been detected indirectly at very high statistical significance. Direct detection experiments are now being planned, *e.g.*, at the Princeton Tritium Observatory for Light, Early Universe, Massive-neutrino Yield (PTOLEMY) [77]. The detection prospects crucially depend on the exact value of neutrino masses and on the enhancement of their density at the location of the Earth through gravitational clustering in the Milky Way and its sub-halos – an effect however expected to be small [78–81].

Over the past few years the upper limit on the sum of neutrino masses has become increasingly stringent, first indicating that the mass ordering is hierarchical and recently putting the inverted hierarchy under pressure and favouring the normal hierarchy (although quantitative estimates of how disfavoured the inverted hierarchy is vary depending on assumptions, see *e.g.* [44, 46, 47, 82–84]) which has consequences for planning future double beta-decay experiments. However, these bounds rely on the ΛCDM model or its most simple extensions, and thus, on the assumption that a resolution of the Hubble tension with DL measurements does not affect the modeling and interpretation of the data sets adopted here. If this is not the case, a shift of paradigm might be required, potentially leading to weaker neutrino density and mass bounds.

Neutrino mass and density bounds are expected to keep improving significantly over the next years, thanks to new LSS experiments like DESI [85], Euclid [86], LSST [87], SPHEREx [88] and SKA [89], in combinations with new CMB experiments like Simons Observatory [90], CMB-S4 [91] or LiteBird [92]. If the ΛCDM model is confirmed, and if neutrinos have standard properties, the total neutrino mass should be detected at the level of at least 3–4σ even at the minimum level allowed by oscillations. This is the conclusion reached by several independent studies, using different dataset combinations (see *e.g.*, [39, 93–98]). One should note that at the minimum level allowed by oscillations $\sum m_\nu \sim 0.06\,\mathrm{eV}$, neutrinos constitute $\sim 0.5\%$ of the Universe matter density, and their effects on the matter power spectrum is only at the 5% level, implying that exquisite control of systematic errors will be crucial to achieve the required accuracy. At this level, the information coming from the power spectrum shape is more powerful than that coming from geometrical measurements (e.g., BAO). But exploiting the shape information, especially on small, mildly non-linear or non-linear scales, requires improved understanding of the non-linear regime, and of galaxy bias for galaxy surveys. The fact that different surveys, different probes, and different data set combinations have enough statistical power to reach this level, offers a much needed redundancy and the possibility to perform consistency checks which in turns helps immensely with the control of systematic errors and in making the measurement robust. Using the entire Universe as a particle detector, the on-going and future observational efforts hold the exciting prospect to provide a measurement of the sum of neutrino masses and possibly indication of their mass hierarchy.

27. Dark Matter

Revised August 2023 by L. Baudis (Zurich U.) and S. Profumo (UC Santa Cruz).

27.1 The case for dark matter

Modern cosmological models invariably include an electromagnetically close-to-neutral, non-baryonic matter species with negligible velocity from the standpoint of structure formation, generically referred to as "cold dark matter" (CDM; see The Big-Bang Cosmology—Sec. 22 of this *Review*). For the benchmark ΛCDM cosmology adopted in the Cosmological Parameters—Sec. 25 of this *Review*, the DM accounts for 26.4% of the critical density in the universe, or 84.4% of the total matter density. The nature of only a small fraction, between at least 0.5% (given neutrino oscillations) and at most 1.6% (from combined cosmological constraints), of the non-baryonic matter content of the universe is known: the three Standard Model neutrinos (see the Neutrino Masses, Mixing, and Oscillations—Sec. 14 of this *Review*)). The fundamental makeup of the large majority of the DM is, as of yet, unknown.

Assuming the validity of General Relativity, DM is observed to be ubiquitous in gravitationally collapsed structures of size ranging from the smallest known galaxies [1] to galaxies of size comparable to the Milky Way [2], to groups and clusters of galaxies [3]. The mass-to-light ratio is observed to saturate at the largest collapsed scales to a value indicative, and close to, what inferred from other cosmological observations for the universe as a whole [4]. In such collapsed structures, the existence of DM is inferred directly using tracers of mass enclosed within a certain radius such as stellar velocity dispersion, rotation curves in axisymmetric systems, the virial theorem, gravitational lensing, and measures of the amount of non-dark, i.e. baryonic, mass such as stellar number counts and tracers of gas density such as X-ray emission [5]. The global DM abundance as determined from cosmological probes is discussed in Sec. 22.

The picture of structure formation in modern cosmology heavily relies on, and can be considered an independent and exceptionally strong motivation for, DM. Baryonic density fluctuations at CMB decoupling are observed to be at most on the order of $\delta\rho_b/\rho_b|_{\rm rec} \approx 10^{-5}$; since density perturbations grow linearly with the scale factor in the linear regime, absent any other matter fluid, one would predict that

$$\delta\rho_b/\rho_b|_{\rm today} \approx \frac{\delta\rho_b/\rho_b|_{\rm rec}}{a_{\rm rec}} \approx 10^{-2}, \qquad (27.1)$$

at odds with the observed highly non-linear structures in the universe, $\delta\rho_b/\rho_b|_{\rm obs} \gg 1$. The presence of a dominant non-relativistic ("cold") pressure-less matter component decoupled from the thermal bath well before recombination allows instead for the prediction of a matter power spectrum in remarkable agreement with observations [6].

Assuming deviations of gravitational interactions on large scales from general relativity or from its Newtonian limit, certain effects, attributed in the standard scenario to DM, can be explained by modified gravity [7]. Usually such theories mimic the effects otherwise attributed to DM on a limited range of scales, but fail globally, and especially at the largest scales. Key issues that at present appear highly problematic in the framework of theories of modified gravity without DM include (i) predicting the correct spectrum of density perturbations, (ii) predicting the observed anisotropy power spectrum of the CMB, and (iii) explaining weak lensing and X-ray observations of merging clusters such as 1E 0657-558 (the "Bullet" cluster) [8]. The inferred relative speed of gravitational and electromagnetic radiation in GW170817 additionally excludes a significant swath of modified theories of gravity where the two speeds (of gravitational and electromagnetic waves) differ [9].

27.2 Properties of dark matter candidates

Electric charge: The "darkness" of DM can be quantified based on constraints from the CMB and large-scale structure: if the DM is charged, or "milli-charged" (for instance via a kinetic mixing with a dark photon field, producing an effective suppressed coupling to the visible photon field), it might impact the baryon-photon plasma during recombination; in turn, DM density fluctuations can be suppressed by radiation pressure and photon diffusion, additionally altering the baryon acoustic peak structure. [10] finds that the most stringent constraints stem from the requirement that the DM be completely decoupled from the baryon-photon plasma at recombination, yielding a maximal "milli-electric" charge, in units of the electron charge, of $3.5\times10^{-7}(m_{\rm DM}/1\ {\rm GeV})^{0.58}$ for $m_{\rm DM} > 1$ GeV, and of $4.0\times10^{-7}(m_{\rm DM}/1\ {\rm GeV})^{0.35}$ for $m_{\rm DM} < 1$ GeV. Limits also exist from structure formation on how optically dark and dissapationaless the DM should be.

Self-interactions: Observations of merging clusters [8] and of the ellipticity of certain galaxies as inferred from X-rays [11] constrain the level of DM-DM self interactions. The figure of merit is the ratio of the DM-DM cross section and the DM mass [12] (see Ref. [13] for a review), $\sigma_{\rm DM-DM}/m_{\rm DM} < 0.47\ {\rm cm}^2/{\rm g} \simeq 0.84$ barn/GeV at 95% C.L.. Assuming a velocity dependence in $\sigma_{\rm DM-DM}$, "self-interacting DM" has been advocated as a possible solution to certain possible small-scale structure issues in the standard non-collisional ($\sigma_{\rm DM-DM} \simeq 0$) setup [13, 14] (see Sec. 27.4).

Mass: Lower Limits: Model-independent lower limits for very small DM masses are due to quantum effects: for fermionic DM particles, the phase-space density $f(\vec{x},\vec{p})$ is bounded from above due to Pauli's exclusion principle, $f < gh^{-3}$, with g the number of internal degrees of freedom and h Planck's constant; observations of the velocity dispersion (or, equivalently, measures of the enclosed mass) and physical density in dwarf galaxies, lead to a lower limit on fermionic DM masses, sometimes known as the Tremaine-Gunn limit [15]. Using the Fornax dwarf, Ref. [16] finds $m_F > 70$ eV. More stringent limits can be drawn from Lyman-α observations, although such limits depend on the thermal history of the DM. In the case of bosonic DM, the Compton wavelength of an ultra-light species might erase small-scale structure, in conflict with CMB and large-scale structure [17], Lyman-α observations [18,19], and measurements of high-redshift galaxy luminosity functions and the Milky Way satellite luminosity function [20–22]: these observations indicate that $m_B \gtrsim 10^{-22}$ eV.

Mass: Upper Limits: General upper limits exist on the mass of the DM constituent from the stability against tidal disruption of structures immersed in DM halos, such as galactic disks and globular clusters, and of individual small galaxies. The most stringent limits can be derived using wide halo binaries [23] and the stability of the star cluster within Eridanus II [24]. Such limits constrain an individual, point-like DM constituent, assuming it makes up 100% of the DM, to be lighter than around 5 $M_\odot$. (Notice that the mass limits discussed here do not assume any specific production mechanism, and do not depend on the observed cosmological DM density).

Stability: The DM lifetime must be long compared to cosmological timescales [25].

27.3 Genesis of dark matter

The generation of DM in the early universe can proceed via thermal or non-thermal production, or both, or it may result from a particle-antiparticle asymmetry.

Freeze-out: The process of chemical decoupling from the high-temperature, high-density thermal bath (freeze-out) as a paradigm for particle production in the early universe is both a predictive and a successful one. The possibility that just like light elements, neutrinos, and CMB photons, particle DM also originated from a thermal decoupling process has thus garnered significant attention.

A particle species *chemically* decouples when the rate Γ for the species' number-changing processes drops below the Hubble rate H. Rough estimates for the abundance of relics can be obtained by (i) calculating the freeze-out (i.e. "decoupling") temperature $T_{\rm f.o.}$, corresponding to $H(T_{\rm f.o.}) \sim \Gamma(T_{\rm f.o.})$, (ii) equating the comoving number density at freeze-out and today, eventually (iii) obtaining the physical density of relic particles today. This procedure assumes that entropy is conserved between $T_{\rm f.o.}$ and today, an assumption that could well be violated, especially for

heavy relics that decouple early, for instance by entropy injection episodes [26]. Notice also that the freeze-out calculation strongly depends on the assumed background cosmology, and changes e.g. if the early universe is not radiation-dominated around DM decoupling.

The calculation of the freeze-out relic abundance hinges on a Boltzmann equation relating the Liouville operator to the collision operator acting on the phase space density. Under a variety of simplifying assumptions including homogeneity and isotropy, it is possible to reduce the relevant equation for the number density n of a single species pair-annihilating with particles in the thermal bath via 2-to-2 processes to

$$\frac{dn}{dt} - 3Hn = -\langle\sigma v\rangle \left(n^2 - n_{\rm eq}^2\right), \qquad (27.2)$$

where $\langle\sigma v\rangle$ is the thermally-averaged pair-annihilation cross section times relative velocity (see Ref. [27]), and $n_{\rm eq}$ is the equilibrium number density. Relics for which the freeze-out temperature is much larger than the particle mass (and thus that freeze-out as ultra-reltivistic) are called *hot* relics; if the opposite is true, the relic is instead considered *cold*.

A straightforward calculation shows that to leading order the frozen-out density of *hot* relics is *linearly proportional to the relic particle mass*. The comoving number density $Y = n/s$, where s is the entropy density, for a hot relic is approximately given by its equilibrium value,

$$Y_{\rm f.o.} \simeq Y_{\rm eq} \simeq 0.278 \frac{g_{\rm eff}}{g_{*s}}, \qquad (27.3)$$

where $g_{\rm eff}$ is the relic's effective number of degrees of freedom, and g_{*s} is the number of entropic relativistic degrees of freedom, both calculated at $T_{\rm f.o.}$. The resulting relic abundance, assuming an iso-entropic expansion, is

$$\Omega_{\rm hot}h^2 = \frac{mY_{\rm f.o.}s_0h^2}{\rho_c} \simeq \frac{m}{93\ {\rm eV}}, \qquad (27.4)$$

with s_0 the entropy density today, and with the latter equality holding for the case of SM neutrinos, with a freeze-out temperature around 1 MeV (which enters in the final relic abundance through the degrees of freedom dependence on the right-hand-side of Eq. (27.3)).

For *cold* relics, the leading-order dependence of the relic abundance on the DM particle properties is an *inverse proportionality relation to the pair-annihilation cross section*,

$$\Omega_{\rm cold}h^2 \simeq 0.1 \left(\frac{x_{\rm f.o.}}{20}\right) \left(\frac{10^{-8}\ {\rm GeV}^{-2}}{\sigma_{\rm DM+DM\leftrightarrow anything}}\right), \qquad (27.5)$$

where $x \equiv m_{\rm DM}/T$. In turn, the freeze-out temperature is approximately given by the solution to the equation

$$\sqrt{x}\cdot e^{-x} = \left(m_{\rm DM}\cdot M_P\cdot\sigma_{\rm DM+DM\leftrightarrow anything}\right)^{-1}, \qquad (27.6)$$

where $M_P \simeq 2.435\times10^{18}$ GeV is the reduced Planck mass. As a result, $T_{\rm f.o.} \simeq m_{\rm DM}/x_{\rm f.o.}$, with $x_{\rm f.o.}$ a number between 10 and 50, depending on the cross section, with only a logarithmic dependence on the DM mass. Since for electroweak-scale cross sections and masses $\sigma_{\rm DM+DM} \simeq 10^{-8}$ GeV^{-2}, "weakly-interacting massive particles", or WIMPs have gained exceptional popularity. Notice that Eq. (27.5) bears, however, no connection to the weak scale [28], despite the relation being known as "WIMP miracle".

Numerous scenarios exist, including notably supersymmetry [29,30] and models with universal extra dimensions [31,32] where the relic abundance of the DM is controlled by processes involving a slightly heavier, unstable, co-annihilating species [33]. In this case the calculation of the abundance of the stable species proceeds similarly to what outlined above, with an effective pair-annihilation cross section that captures the effects of co-annihilation replacing the pair-annihilation cross section [30].

Freeze-in: Collisional processes can lead to the production of out-of-equilibrium particles that progressively accumulate over cosmic time, a process sometimes called *freeze-in*. The abundance of the frozen-in particles produced at a given redshift depends on the product of the production rate times the Hubble time at that redshift. Freeze-in generally implies that the lightest observable-sector particles decay to the DM with relatively long lifetimes, giving peculiar signals at colliders (see e.g. [34]). Gravitinos are an example of DM candidates possibly produced via a freeze-in type scenario, albeit the portal coupling is in that case via a higher dimensional, Planck-suppressed operator [35].

Cannibalization and other dark-sector number-changing processes: Thermal processes can drive the abundance of the DM beyond simple 2-to-2 number-changing interactions. For instance, DM can "cannibalize" [36, 37] itself if $n \to 2$ processes exist. In this case, a critical aspect is whether or not the DM sector is in thermal contact with the Standard Model thermal bath. If it is, $n \to 2$ processes can drive the relic abundance, e.g. in the Strongly Interacting Massive Particles (SIMP) scenario [38]. Models exist where the *kinetic decoupling* (i.e. the decoupling from the *thermal equilibrium velocity distribution*) of the two sectors drives the abundance of the DM (elastically decoupling relics, or ELDERs [39]). When the two sectors are not in thermal contact, $n \to 2$ processes heat the DM sector dramatically, rapidly affecting the temperature ratio between the visible and dark sectors [36, 38]. If the relevant cross sections are large enough, and the DM mass light enough, significant effects can arise in structure formation [36].

Non-thermal production: DM production can proceed via processes out of thermal equilibrium ("non-thermal" production). These include DM production via the decay of a "mother" particle [40,41] (or of topological defects [42], moduli [43] etc.) to the DM, or production via gravitational effects.

Asymmetric DM: An enticing alternative possibility for DM production is that of *asymmetric* DM [44,45]: the relic DM abundance arises from an asymmetry between anti-DM and DM. This asymmetry may or may not be related to the baryon-antibaryon asymmetry. If it is, then depending on the model and its thermal history, a relation exists between the mass of the DM and the proton mass. A variety of proposals have been put forward where alternately baryogenesis is explained from a DM sector asymmetry, or vice-versa (see e.g. Ref. [46] for a review).

Primordial Black Holes production: A qualitatively standalone class of DM candidates, primordial black holes (PBHs), arises from entirely different mechanisms from what reviewed above. PBHs are thought to originate from gravitational collapse of large density fluctuations in the early universe [47, 48]. The over-densities could be produced in a variety of ways, such as topological defects like cosmic strings, necklaces or domain walls, curvature fluctuations from a period of ultra-slow-roll, a sound speed "resonance" , an early phase of matter domination, or sub-horizon phenomena including a phase transition and preheating.Albeit the calculation depends on the details of gravitational collapse, the formation time is connected to the PBH mass via $M = \gamma M_{PBH} \simeq 2\times10^5\gamma\left(\frac{t}{1\ {\rm s}}\right)M_\odot$, with $\gamma \simeq (1/\sqrt{3})^3$ during radiation domination [49].

27.4 Density and velocity distribution of dark matter

27.4.1 *Local density and velocity distribution*

The density and distribution of DM in the Milky Way encipher relevant dynamical information about our Galaxy, and are particularly important for direct and indirect detection experiments. The *local density* (ρ_0) is an average over a volume of a few hundred parsecs in the Solar neighbourhood.

To determine the local density from observations, two classes of methods are used [50]. So-called *local measures* rely on the vertical motion of tracer stars in the vicinity of the Sun, while *global measures* extrapolate ρ_0 from the measured rotation curve, with additional assumptions about the Galactic halo shape. Conversely, by comparing the extrapolated local density with the one obtained from local measures, one can constrain the local shape of the Milky Way halo. A major source of uncertainty on ρ_0 is the contribution of baryons (stars, gas, stellar remnants) to the local dynamical mass. For instance, the motion of tracer stars used in local measures is dictated by the total potential generated by

baryons and DM, and a robust baryonic census must be available to infer the additional contribution from DM. Recent determinations from global methods lie in the range $(0.2-0.6)\,\mathrm{GeV/cm^3}$, while new studies of the local DM density from *Gaia* satellite data yield $(0.3-1.5)\,\mathrm{GeV/cm^3}$, depending on the type of stars used in the study.

Other observational quantities that enter in the phase space distribution of DM, and provide constraints on mass models of the Milky Way are the local circular speed v_c and the escape velocity v_{esc}. The local circular speed is measured by various methods, roughly divided into measurements of the Sun's velocity with respect to an object assumed to be at rest with respect to the Galactic centre or direct measurements of the local radial force. These methods yield values of $v_c = (218-246)\,\mathrm{km/s}$. A recent estimate of the escape velocity, defined as the speed above which objects are not gravitationally bound to our galaxy, is v_{esc}=533^{+54}_{-41} km/s [51] (see also the more recent estimate in [52] of v_{esc}=$484.6^{+17.8}_{-7.4}$ km/s, which is not in tension with the value we use).

The local velocity distribution of DM particles can not be measured directly at present, and is mostly derived from simulations. In general, experiments use the simplest, so-called *Standard Halo Model (SHM)* for their data analysis. It assumes an isotropic, isothermal sphere of DM particles with a density profile of $\rho(r) \propto r^{-2}$, for which the velocity distribution is Maxwellian, with a velocity dispersion $\sigma_v = v_c/\sqrt{2}$. This distribution, which formally extends to infinity, is truncated at v_{esc} [53]. Earlier high resolution, dark-matter-only simulations found velocity distributions that markedly deviated from a Maxwell-Boltzmann distribution and in addition revealed components above the dominant smooth distribution, including narrow spikes due to tidal streams. Recent hydrodynamical simulations of Milky Way-like galaxies including baryons, which have a non-negligible effect on the DM distribution in the Solar neighbourhood, find velocity distributions that are indeed close to Maxwellian, arguing that the SHM is a good approximation.

Ultimately the goal is to determine the velocity distribution from observations (for example by studying the motion of stars that share the same kinematics as the DM), and the *Gaia* satellite data offers a unique opportunity to study the various stellar populations. Recently it was revealed that the local stellar halo has two components: a quasi-spherical, weakly rotating structure with metal-poor stars, and a flattened, radially anisotropic structure of metal-rich stars, which arose due to accretion of a large $(10^{11-12}\,\mathrm{M_\odot})$ dwarf galaxy around (8-10)$\times 10^9$ y ago [54]. The expectation is that the local DM halo shows a similar bimodal structure, and first velocity distributions of the two components - using the stellar populations as tracers - were inferred in [55]. In Ref. [56], an updated halo model is introduced: it includes the anisotropic structure seen in the *Gaia* data and provides an analytic expression for the velocity distribution. The value of the local DM density is updated to $(0.55\pm0.17)\,\mathrm{GeV/cm^3}$, where the 30% error accounts for the systematics. The circular rotation and the escape speeds are updated to $v_c = (233\pm3)\,\mathrm{km/s}$ and v_{esc}=528^{+24}_{-25} km/s. The former is in agreement with a new Bayesian estimation of the circular velocity using Gaia DR3, of $v_c = (233\pm7)\,\mathrm{km/s}$ [57]. With Gaia DR3, new stellar streams are being discovered, some of these likely originating from the disruption and merger of dwarf galaxies. The study of the velocities of such streams will allow for increasingly improved constraints on both the DM subhalo density profiles and the velocity distributions.

27.4.2 *Small-scale challenges*

The ΛCDM framework is tremendously successful at explaining the observed large-scale structures of the Universe (corresponding to distances $\geq$1 Mpc, the typical inter-galactic distance), as well as the main properties of galaxies that form within DM haloes, see the comprehensive review in Ref. [58]. The observed large-scale structure is consistent with point-like, cold DM particles that interact purely via the gravitational force. However, in the past decades, observations at scales below $\sim$1 Mpc, where structure formation becomes strongly nonlinear, turned out more problematic to be described within the ΛCDM model. The main *small-scale challenges* are known as: the missing satellites problem, the cusp-core problem and the too-big-to-fail problem. Initially these issues, which are not all independent of one another, arose by comparing theoretical predictions from dark-matter-only simulations to observation. While their most likely solutions are in dissipative, baryonic physics (such gas cooling, star formation, supernovae feedback), see the recent reviews in Ref. [59, 60], the small-scale problems could in addition call for a modification or an extension of the ΛCDM paradigm. Most importantly, the ever increasing amount of data on the satellites of the MW and M31 are used to constrain alternative DM models.

The missing satellites problem: High-resolution cosmological simulations of DM haloes the size of the MW predict hundreds or thousands of subhaloes with masses that are in principle large enough to allow for galaxy formation ($> 10^7\,\mathrm{M_\odot}$). Yet less than $\sim$100 satellite galaxies with masses down to $\sim$300 $\mathrm{M_\odot}$ are known to orbit our galaxy within 300 kpc. Galaxies in the field show a similar under-abundance. One solution could be that galaxy formation becomes increasingly inefficient as the halo mass drops, and thus the smallest DM haloes have naturally failed to form galaxies. Progress in both observations and theoretical modeling of observable properties of dwarf galaxies show that there is very scant evidence for a "missing satellite problem" [60]. Nonetheless, additional, related strong tensions remain, including the *diversity of observed rotation curves* [61] and the *unexpected alignment of satellite planes*, the latter issue possibly solved by high-precision simulations tracking inflow along filaments of the cosmic web [62].

The cusp-core problem: The mass density profiles of DM haloes in ΛCDM simulations rise steeply at small radii, $\rho(r) \propto r^{-\gamma}$, with $\gamma \simeq 0.8-1.4$. This is in contrast to the observed density profiles of many low-mass galaxies (albeit not all), the rotation curves of which are best fit with constant-density cores, $\gamma \simeq 0-0.5$. A related issue is that simulations predict more DM than measured in the central regions of galaxies (also known as the central density problem). A likely solution is that baryonic feedback modifies the structure of DM haloes. Hydrodynamic simulations which include the effects of baryons on galaxy formation have shown that baryonic feedback (e.g., supernova-driven blowouts) can erase the central cusps and produce core-like density profiles. Surveys of satellites of hundreds of galaxies similar to the Milky Way, such as SAGA [63], will likely provide important observational information.

The too-big-to-fail problem: This problem is related to the fact that the dark matter halos of the largest observed Milky Way satellites are typically much smaller than those of the most massive subhalos of simulated Milky Way-like halos. DM haloes of such masses are thought to be too massive to have failed to form stars (hence the name of the problem), especially if lower-mass subhaloes are capable of doing so. A similar issue is present in Andromeda and in field galaxies outside the Local Group. Possible solutions include lowering the mass assumed for the Milky Way host halo, or baryonic effects including tidal stripping and larger-than-expected inner cores [60]. Other issues relate to the origin of ultra-faint galaxies, and the opposite problem of dwarf galaxies with very little dark matter given their stellar mass; there exist proposed solutions to both challenges, including the "bullet dwarf" scenario of Ref. [64].

The solutions that were briefly mentioned above do not require modifications to the ΛCDM framework. Other solutions involve either modifications of linear theory predictions (via the nature of the DM particle, e.g., Warm DM - WDM) or modifications of nonlinear predictions (via DM models that involve a self-interaction of DM particles - SIDM). WDM models postulate particles with masses at the keV-scale, and the observed number of dark-matter-dominated satellites is used to set a lower limit on the number of subhaloes in the MW and thus a lower limit on the particle's mass [59]. Current constraints are in the range $m_{WDM} > (1.6-2.3)\,\mathrm{keV}$. Cosmological simulations with SIDM find that $\sigma/m_{SIDM} \simeq$(0.5-10) $\mathrm{cm^2/g}$ can alleviate the cusp-core and too-big-to-fail problems, giving rise to DM cores in dwarf galaxies with sizes of (0.3-1.5) kpc [13]. Galaxy clusters provide important constraints, and their large central DM densities pre-

fer models with $\sigma/m_{\rm DM} \lesssim 0.1\,{\rm cm}^2/{\rm g}$ [65]. Thus, if SIDM is to solve the small-scale CDM problems and obey the constraints observed on the scales of clusters, σ must depend on the velocity of the particle: it must increase as the rms speed of the particle decreases from the scale of clusters ($v \sim 10^3$ km/s) to the scale of dwarf galaxies ($v \sim 10$ km/s).

27.5 Dark matter models

Particle DM model building is deeply intertwined with the question of the nature of physics beyond the Standard Model (BSM) of particle physics[1]. Directions in this area have followed a few strategies, including, but not limited to

(1) pursuing DM candidates embedded in frameworks that include solutions to other open issues in particle physics, for example WIMPs in connection with electroweak-scale new physics that addresses the hierarchy problem, such as supersymmetry (see the Supersymmetry reviews Sec. 88 and 88); axions in connection with frameworks that address the strong CP problem (see Axions and Other Similar Particles—Sec. 90); sterile neutrinos in connection with the problem of neutrino masses and mixing (see the Neutrino Masses, Mixing, and Oscillations—Sec. 14); or (2) *ad hoc*, or *bottom-up* models built with the intent of addressing or explaining a putative experimental (e.g. particle physical anomalies) or observational (e.g. astronomical) signal.

WIMPs: The WIMP paradigm has been a preferred framework chiefly because it often arises in beyond the Standard Model scenarios that address the hierarchy problem whilst also providing a simple mechanism to explain the observed relic abundance via the "WIMP miracle" described above. Perhaps the most notable example of a framework containing a paradigmatic WIMP is the minimal supersymmetric extension to the Standard Model, if the lightest supersymmetric particle is a neutralino (the mass eigenstate resulting from the mixing of the supersymmetric partners to the Higgses and to the SU(2) and hypercharge gauge bosons, and, possibly, of additional singlet scalars); purely SU(2) sneutrinos have long been ruled out by direct detection, but with suitable mixing with "inert" (gauge-singlet) sneutrinos they can also play the role of WIMP candidates. For more details see the the Supersymmetry—Sec. 88 and 89 in this *Review*. Other nonsuperysmmetric WIMP models include models with a Higgs or Z (or Z') portal, universal extra dimensions [32], and other models with extra (warped or flat) dimensions, little Higgs theories, technicolor and composite Higgs theories, among others (see e.g. the review in [66]).

Axions and axion-like particles: Axions are an especially compelling example of a broad category of DM candidates encompassing very light scalar or pseudoscalar fields. The QCD axion provides a solution to the strong CP problem, and is at present a viable DM candidate (see Sec. 90 for details on motivations, production mechanisms, and detection prospects for the QCD axion). Ultra-light, bosonic DM generally implies the imprint of quantum effects on macroscopic scales (hence the name of *wave* or *fuzzy* DM). Specifically, some of the small-scale issues mentioned in sec. 27.4 can be addressed if the de Broglie wavelength of the DM, of mass m_a and velocity v_a,

$$\frac{\lambda}{2\pi} = \frac{\hbar}{m_a v_a} \simeq 1.9\ {\rm kpc} \left(\frac{10^{-22}\ {\rm eV}}{m_a}\right)\left(\frac{10\ {\rm km/s}}{v_a}\right) \qquad (27.7)$$

is comparable to the size of the smallest observed gravitationally collapsed structures, roughly, for a self-gravitating system of mass M, a scale $r \simeq GM/v^2$. The typical expectation is the formation of a soliton-like core in the DM density profile of size λ, thus inversely proportional to the DM mass, with an upper limit on the central density of around

$$\rho_s \lesssim 7\ M_\odot/{\rm pc}^3 \left(\frac{m_a}{10^{-22}\ {\rm eV}}\right)^6 \left(\frac{M}{10^9\ M_\odot}\right) \qquad (27.8)$$

for a halo of virial mass M. Additionally, wave DM predicts that halos lighter than around $10^7 (m_a/10^{-22}\ {\rm eV})^{-3/2} M_\odot$ should not exist [67], and that the number of halos in the local universe with a mass at or less $10^9 (m_a/10^{-22}\ {\rm eV})^{-4/3} M_\odot$ [68] be significantly depleted, addressing in part the too big to fail and missing satellite problems (see Sec. 27.4 above). Light bosonic DM is necessarily produced non-thermally [69], and the connection with the visible sector need not, but might, exist.

Dark photons: Light *vector* bosons such as a "dark photon" V with a mass below $m_V < 2m_e$, can be cosmologically stable (depending upon its kinetic mixing coupling with the visible photon) and be a viable DM candidate. Light dark photons can be produced in the early universe through scattering or annihilation via processes such as $\gamma e^\pm \to V e^\pm$ or $e^+e^- \to V\gamma$, or via resonant photon-dark photon conversion, or from a condensate seeded by inflationary perturbations [70], or from a misalignment mechanism similar to the one commonly invoked for axion production; constraints on the parameter space stem from a combination of direct detection experiments, where the dark photon is absorbed and leads to a large ionization signal, from stellar cooling constraints from the Sun, horizontal branch stars, and red giants, and from CMB and the diffuse radiation from the $V \to 3\gamma$ decay mode. More broadly, light dark (pseudo-)scalars and vectors can be best constrained with experiments that rely on their wave-like behaviour and/or on their possible "portal" with the visible sector. A broad assortment of experiments is sensitive to the range of masses between 10^{-22} eV and 10^{-2} eV. Among these experimental efforts, the lowest masses are probed by torsion balance experiments [71, 72], atom interferometry [73], comagnetometers [74, 75], and even gravitational wave detectors [76]; at increasing masses, if the light bosons couple electromagnetically, they can generate effective currents which are detectable with different apparata depending on the relevant, mass-dependent target frequency. The experimental portfolio includes the broadband axion search ABRACADABRA [77,78], the LC resonator DM Radio [79], lumped-element LC resonators [80], and cavity resonators such as HAYSTAC [81] and ADMX [82] .

Sterile Neutrinos: Sterile (gauge-singlet) neutrinos, assumed to share a Dirac mass term with ordinary, $SU(2)_L$-active neutrinos, have long been considered viable DM candidates [83]. The mostly-sterile mass eigenstate participates in $SU(2)_L$ interactions via a mixing parameter $\theta \ll 1$ that controls much of the particle's phenomenology. In particular, the sterile neutrino possesses an inverse-lifetime on the order of $\tau^{-1} \sim G_F^2 m_\nu^5 \theta^2$, forcing the mixing to not exceed

$$\theta < 3.3 \times 10^{-4} \left(\frac{10\ {\rm keV}}{m_\nu}\right)^5 \qquad (27.9)$$

in order for the lifetime to exceed the age of the universe. While the main decay channel is to three active neutrinos, observationally the radiative decay mode to one neutrino plus a photon is much more relevant, giving rise to a quasi-monochromatic photon line at half the sterile neutrino mass. A recent tentative signal at 3.5 keV was reported from stacked observations of clusters of galaxies, individual clusters [84, 85], and the Galactic center [86] with both the XMM and Chandra X-ray observatories. The signal however was not detected in a large sample of galaxies and groups of galaxies [87] and dwarf galaxies [88], and especially Draco [89], shedding strong doubts on its sterile neutrino decay origin. Future observations with increased energy resolution might conclusively pinpoint the origin of the 3.5 keV emission [90].

Models with rich dark sectors: The absence of any conclusive signals from DM as a particle thus far motivates the hypothesis that the DM be charged under some new "hidden" dark-sector force, an idea that dates back many decades [91], including in the guise of "mirror DM" (more recently in the context of "neutral naturalness"). Top-down motivation for hidden-sector DM comes from string theory [92], although TeV-scale BSM framework such as supersymmetry and composite Higgs models can also naturally accommodate hidden sectors [93]. Although no coupling of the visible sector to the hidden sector need exist in principle, there are a few reasons to expect it [94].The mass scale for hidden-sector DM is broader than, but overlapping with, that for WIMPs (this latter being limited to roughly between a few GeV and a few TeV). In particular, while some motivation exists for electroweak-scale

[1] Notice that this includes the case of PBHs, as successful formation of the correct number density of PBHs involves new ingredients beyond standard cosmology and particle physics

hidden sectors, light, sub-GeV hidden sectors have a strong theoretical underpinning, and offer novel detection avenues and opportunities. The phenomenology of hidden-sector DM depends primarily on the nature of the force and its force carrier. The most-widely considered cases are (pseudo-)scalar and (axial-)vector mediators. Among the structures for the mediators' coupling to the visible sector, renormalizable "portals" include the $H^\dagger H$ operator, through Lagrangian terms of the type $(\mu\phi + \lambda\phi^2)H^\dagger H$, coupling to the hypercharge field strength $B^{\mu\nu}$ via kinetic mixing, $\epsilon' B_{\mu\nu} F'^{\mu\nu}$, and the "neutrino" portal, $y_n LHN$, where L is the lepton doublet of any generation, N is a right-handed neutrino, H is the SM Higgs doublet, and y_n the Yukawa coupling. Other possibilities are for instance a vector mediator directly coupled to SM fermions charged under its corresponding symmetry [95], or a Z' associated to $\mathrm{U}(1)_{B-L}$.Additional possibilities, arising for instance from vector couplings to anomalous global symmetries of the SM like baryon or lepton number, also exist [94]. The accelerator program necessary to probe hidden-sector DM often involves small-scale colliders and fixed-target experiments, with experiments utilizing missing energy and momentum offering the best sensitivity. Beam-dump experiments can test large ranges of DM-mediator couplings as long as mediators decay or scatter inside the detector (see e.g. the recent review [96]). Such experiments can also probe dark sectors with light vectors coupled to visible matter besides gauge kinetic mixing: an instance are neutrino trident scattering used to place bounds on e.g. $L_\mu - L_\tau$ Z' gauge bosons. Being virtually unconstrained, the phenomenology of dark sectors can be arbitrarily rich, with possibilities ranging from dark non-Abelian gauge interactions creating non-trivial self-interacting and/or particle number-changing dynamics, to models of "dynamical" DM, with multi-component, unstable DM candidates and a time-variable effective total DM abundance and equation of state [97].

27.6 Laboratory detection of dark matter

Laboratory searches for DM particles can be roughly classified in direct detection experiments, axion searches (see Axions and Other Similar Particles—Sec. 90), and searches at accelerators and colliders.

27.6.1 *Searches at Accelerators and Colliders*

Various searches for dark matter have been carried out by the CMS and ATLAS collaborations at the LHC in *pp* collisions [98–102]. In general, these assume that dark matter particles escape the detector without interacting leading to significant amounts of missing energy and momentum.

Searches for DM with the LHC and other colliders have targeted DM models that interact with the SM via Higgs or Z boson exchange, effective field theories with heavy mediators, UV-complete models such as supersymmetry, models with long-lived particles, and models with rich dark sectors. The experimental program correspondingly includes searches for invisible-particle production mediated by a SM boson, generic searches for invisible particles produced via new particle mediators, and specific searches for complete models.

There are a variety of types of signals for DM, as noted by Ref. [98]:

(a) the imbalance in the transverse momentum in an event due to the presence of DM particles, produced together with one Standard Model particle,

(b) a bump in the di-jet or di-lepton invariant mass distributions, or

(c) an excess of events in the di-jet angular distribution, produced by a dark matter mediator. No signal for DM has been observed in the LHC experiments so far. Instead, limits are set on masses, couplings, and cross-sections. The latter can be compared, generally in a model-dependent way, with direct detection experiments.

Searches strategies are designed to optimize signal-to-noise by selecting search-specific cuts: a model-independent instance is initial-state electromagnetic or strong-interaction radiation plus missing transverse energy. Collider searches for DM inform, and are informed, by DM searches through direct or indirect detection (see below), and, if possible, by the inferred thermal relic DM abundance. The collider searches alone cannot prove that a discovery is of dark matter.

In the latter category, searches for DM with the LHC and other colliders have targeted DM models that interact with the SM via Higgs or Z boson exchange, effective field theories with heavy mediators, UV-complete models such as supersymmetry, models with long-lived particles, and models with rich dark sectors. The experimental program correspondingly includes searches for invisible-particle production mediated by a SM boson, generic searches for invisible particles produced via new particle mediators, and specific searches for complete models. Searches strategies are designed to optimize signal-to-noise by selecting specific search-specific cuts: a model-independent instance is initial-state electromagnetic or strong-interaction radiation plus missing transverse energy.

New fixed-target experiments are increasingly probing lighter, sub-GeV dark sectors; thermal, or quasi-thermal relics (such as asymmetric, SIMP, ELDER DM models) provide sharp, largely model-independent experimental targets in the case of direct annihilation to Standard Model particles; even "secluded" annihilation to dark-sector particles can be probed with fixed-target experiments, albeit with some model-dependent caveats. Accelerator searches provide unique ways to test light DM models in that they present a lower dependence on the DM particle nature, that could e.g. drive suppressed velocity-dependent direct detection cross sections, and on kinematic thresholds that can similarly suppress rates with other search strategies; additionally, accelerator searches offer opportunities to explore dark sectors in greater detail than other search strategies [94].

Experimental approaches to explore scenarios with a light DM χ and mediator A' include (i) searches for missing mass in exclusive reactions such as $e^+e^- \to \gamma(A'\chi\bar{\chi})$ or $e^-p \to e^-p(A'\chi\bar{\chi})$, (ii) missing momentum/energy, e.g. in fixed-target reactions such as $eZ \to eZ(A'\chi\bar{\chi})$, (iii) electron and proton beam dump, where the DM particle is detected from scattering in a downstream detector after being produced in the beam dump, (iv) direct dark photon searches, when the mediator cannot decay to the dark matter, $m_{A'} < 2m_\chi$. Current facilities actively probing the methods listed above include APEX and HPS and JLab, MiniBooNE at Fermilab, NA64 at CERN, and TREK at J-PARC. Future experiments that will eventually contribute to covering the mentioned thermal targets include Belle-II at KEK, MAGIX at MESA, PADME at LNF, SHIP at CERN, VEPP3 at BINP, BDX at JLab, COHERENT at ORNL, DarkLight at JLab, LDMX at SLAC or JLab, MMAPS at Cornell, SBN at Fermilab, and SeaQuest [94].

27.6.2 *Direct detection formalism*

Direct detection experiments mostly aim to observe elastic or inelastic scatters of Galactic DM particles with atomic nuclei, or with electrons in the detector material. Predicted event rates assume a certain mass and scattering cross section, as well as a set of astrophysical parameters: the local density ρ_0, the velocity distribution $f(\vec{v})$, and the escape velocity v_{esc} (see Sec. 27.4).

Interactions with atomic nuclei: For DM scattering off nuclei, the differential scattering rate R as a function of nuclear recoil energy E_R is

$$\frac{dR(E_R,t)}{dE_R} = N_T \frac{\rho_0}{m_{\mathrm{DM}}} \int_{v>v_{min}} v f(\vec{v}+\vec{v}_E(t)) \frac{d\sigma(E_R,v)}{dE_R} d^3v, \tag{27.10}$$

where N_T is the number of target nuclei, m_{DM} is the mass of the DM particles, $v = |\vec{v}|$ is the speed of the particle in the experiment's rest frame, $f(\vec{v}+\vec{v}_E(t))$ is the velocity distribution in the Earth's frame, v_{min} is the minimum speed of the DM particles that can cause a recoil energy E_R and σ is the scattering cross section on the nucleus [29, 120]. For elastic scattering, the minimum velocity is $v_{min} = (m_N E_R/2m_r^2)^{1/2}$, with m_N being the mass of the nucleus, and $m_r = (m_N m_{\mathrm{DM}})/(m_N + m_{\mathrm{DM}})$ the reduced mass of the nucleus-DM system. In case of inelastic scattering, the minimum speed becomes $v_{min} = (m_N E_R/2m_r^2)^{1/2} + E^*/(2m_N E_R)^{1/2}$, with the nuclear excitation energy E^*, for part of the kinetic energy of the incoming particle will be spent on exciting the nucleus. The prompt de-excitation energy, if observed

Table 27.1: Best constraints from direct detection experiments on the SI (at high >5 GeV and low < 5 GeV masses) and SD DM-nucleon couplings.

Experiment	Target	Fiducial mass [kg]	Cross section [cm^2]	DM mass [GeV]	Ref.
Spin independent high mass (>5 GeV)

in addition to the nuclear recoil energy, will boost the region-of-interest to higher energies [121].

If one assumes the standard, leading order spin-independent (SI) and spin-dependent (SD) interactions, which couple to the charge/mass and spin of the nucleus, respectively, the differential cross-section is proportional to the inverse squared speed of the DM particle, $d\sigma/dE_R \propto v^{-2}$, and the dependence on the velocity distribution can be expressed as:

$$g(v_{min}, t) = \int_{v>v_{min}} \frac{f(\vec{v} + \vec{v}_E(t))}{v} d^3v. \quad (27.11)$$

This functions allows for the comparison of various experimental results independently of the underlying velocity distribution [122], for a given DM mass. The time-integrated differential cross section is the sum of the SI and SD contributions:

$$\frac{d\sigma(E_R, v)}{dE_R} = \frac{m_N}{2m_r^2 v^2} \left(\sigma_0^{SI} F_{SI}^2(E_R) + \sigma_0^{SD} F_{SD}^2(E_R) \right), \quad (27.12)$$

where $F^2(E_R)$ are the nuclear form factors and σ_0 the cross-sections in the limit of zero momentum transfer. Since the incoming particle velocity is $v/c \sim 10^{-3}$, the nuclear recoil energy is at most tens of keV (much smaller than typical nuclear binding energies per nucleon), and the momentum transfer $q = (2m_N E_R)^{1/2} \sim \mathcal{O}(10 - 100)$ MeV. This implies that $1/q$ can be of the same order as nuclear radii $R \sim A^{1/3}$ fm, and that nuclei are not point-like from the perspective of a DM particle. The cross sections will thus involve nuclear form factors. These were calculated in [123] and [124] for the SI and SD case, respectively, for specific target nuclei, while the cross sections are often expressed in terms of single-nucleon cross sections and effective couplings of the DM particle to protons and neutrons. In the SI case, all the nucleons in the nucleus contribute coherently to the cross-section (under the assumption of isospin independence in the DM couplings). Dominant sources of uncertainty are the nucleon sigma terms, especially for Higgs-dominated interactions, where the couplings are proportional to the quark masses. An overview is presented in Ref. [125]. For SD scattering, the nuclear spin contents due to the protons and neutrons must be considered.

The interactions of DM particles with nuclei can be treated in a non-relativistic effective field theory (NR-EFT) approach, which considers more general DM scenarios based on the lowest-order, four-field operators that describe the couplings to nucleons. These operators, which correspond to different types of interactions between the DM and quark fields, can be momentum- and velocity-dependent, and might be leading when momentum-independent interactions are suppressed, or even vanish in the limit of zero momentum [126, 127]. In Ref. [127, 128] all 15 operators (arising from 20 possible bilinear combinations between the DM and nucleon fields) which obey Galilean-invariance, T-symmetry and are Hermitian are written out up to quadratic order in q, and the nuclear response functions evaluated in shell-model calculations for DM targets made of F, Na, Ge, I and Xe isotopes. The connection to particle physics within the context of *simplified DM models* is made in Ref. [129, 130], where the simplified models assume a single DM particle with one mediator which couples it to quarks. More recently the DM-nucleus scattering was also analysed in the framework of chiral effective field theory (Ch-EFT), a low-energy effective theory of QCD, which allows for a consistent derivation of the nuclear responses beyond the leading-order expressions [131, 132]. Ch-EFT preserves the QCD symmetries, and predicts DM couplings to two nucleons (e.g., when the hypothetical particle couples to a virtual pion exchanged between the nucleons). It also provides a power counting that suggests a hierarchy of the various NR-EFT operators, which is however approximate given that the couplings between the DM and the Standard Model fields are not known. The generalized SI structure factors for spin-1/2 and spin-0 DM particles and various isotopes of F, Si, Ar, Ge and Xe employed in direct detection experiments are provided in Ref. [132].

Scattering off bound electrons and absorption: For DM particle masses below the GeV-scale, most searches for DM-nucleus scattering rapidly lose sensitivity, due to energy thresholds around a few 100 eV - few keV. As an example, a light DM particle

with a mass of 100 MeV and $v \propto 10^{-3}c$ will induce a nuclear recoil energy of about 0.5 eV in a target made of argon. Another strategy is to search for DM scattering off bound electrons, allowing for all of the kinetic energy (50 eV in the above case) to be transferred to the material [133]. The leading possibilities are ionisation, excitation, and molecular dissociation processes, which typically require energies of (1-10) eV, and thus allow to probe scattering of DM particles with masses down to the $\mathcal{O}$(MeV) range.

For a bound electron with binding energy E_B DM particle masses of $m_{\rm DM} \geq 250\,{\rm keV} \times {\rm E_B}/1$ eV can in principle be probed. The signal depends on the material, and can consist of one or more electrons (in semiconductors, noble liquids, graphene), one or more photons (in scintillators) or phonons (in superconductors and superfluids) and quasiparticles (in superconductors). As an example, the differential event rate for ionization in atoms is given by:

$$\frac{dR_{ion}}{d\ln E_R} = N_T \frac{\rho_0}{m_{\rm DM}} \frac{d\langle\sigma_{ion} v\rangle}{d\ln E_R}, \tag{27.13}$$

where E_R is the recoil energy transferred to the electron, $\langle\sigma_{ion} v\rangle$ is the thermally averaged ionization cross section and N_T is the number of target atoms per unit mass. The cross-section is related to the non relativistic DM-electron elastic scattering cross-section (σ_e):

$$\frac{dR_{ion}}{d\ln E_R} = \frac{6.2}{A}\left(\frac{\rho_0}{0.4\,{\rm GeV\,cm^{-3}}}\right)\left(\frac{\sigma_e}{10^{-40}{\rm cm^2}}\right)\left(\frac{10\,{\rm MeV}}{m_{\rm DM}}\right) \times \frac{d\langle\sigma_{ion} v\rangle/d\ln E_R}{10^{-3}\sigma_e}\,\frac{\rm events}{\rm kg\,d} \tag{27.14}$$

Predicted differential rates in various materials (He, Ar, Ge, Xe) and for different particle masses are shown in [133], together with cross section sensitivities as a function of mass and expected background rates from neutrinos. More recently, rates of electronic transitions induced by DM-electron scattering on Xe, Si and Ge for spin 0, spin 1/2, and spin 1 DM models were calculated in [134]. The code `EXCEED-DM` (extended calculation of electronic excitations for direct detection of dark matter) can compute DM-electron interaction rates with inputs from a variety of *ab initio* electronic structure calculations [135].

Two classes of DM candidates, axion-like-particles (ALPs) and dark (or hidden) photons (see Sec. 27.5), can be absorbed in a target material by interactions with bound electrons via the axioelectric effect, which is analogous to the photoelectric effect: a boson is absorbed by a bound electron, which is then ejected from the atom [70,136,137]. The dark photon arises in extensions of the SM by a new massive or massless U(1)' field, coupled to the SM $\mathrm{U}(1)_Y$ via a kinetic mixing term κ, see Sec. 27.5. The absorption cross-section of a massive, NR particle m_V with coupling $e' = e\kappa$ to electrons is (in natural units, and for energies $E_V \ll m_e$)

$$\sigma_{abs} = \frac{\alpha'}{\alpha}\left(\frac{E_V}{2m_e}\right)^2 \sigma_{pe}, \tag{27.15}$$

where σ_{pe} is the photoelectric cross-section, and an analogue to the electromagnetic fine structure constant α is introduced, $\alpha' = (e\kappa)^2/4\pi$. The rate per atom is

$$R \simeq \frac{\rho_0}{m_V} \times \kappa^2 \sigma_{pe}. \tag{27.16}$$

Since the kinetic energy of the dark photon is negligible compared to its rest energy, a mono-energetic peak at its mass is expected in the spectrum of a direct detection experiment. Dark photons with a thermally generated abundance are excluded by direct detection experiments [70], however non-thermal mechanisms (e.g., via perturbations during inflation) could create the relic abundance, see Section 27.3.

Similarly to axions, ALPs arise in the spontaneous breaking of a global symmetry, and are phenomenologically described by a mass m_a and a decay constant f_a. Unlike for QCD axions, however, there is no strict relation between m_a and f_a. The coupling strength to electrons with mass m_e is parameterised by $g_{ae} = 2m_e/f_a$, and the absorption cross section of a particle with incoming velocity v_a is related to the cross-section for the photoelectric effect as

$$\sigma_{abs} v_a \simeq \frac{3E_a^2}{4\pi\alpha f_a^2}\sigma_{pe} = \frac{3g_{ae}^2}{4\pi\alpha}\left(\frac{E_a}{2m_e}\right)^2 \sigma_{pe}. \tag{27.17}$$

As in the case of the dark photon, the signature is a mono-energetic peak at the mass of the particle, broadened by the energy resolution of the detector. Constraints on the couplings of ALPs and dark photons to electrons from direct detection experiments in m_a and m_V mass ranges from $\sim (1 - 10^4)$ eV were derived in Ref. [138, 139], and compared to indirect limits from anomalous energy losses in the Sun, in red-giant and horizontal-branch stars. For a detailed discussion of axion and ALP searches, we refer to the *Axion* review.

27.6.3 *Current and future direct detection technologies*

Direct detection experiments aim to observe the small (keV-scale and below) and rare (fewer than ∼1 event/(kg y)) signals which are induced by DM particle scatters in a detector, mostly in the form of ionisation, scintillation or lattice vibrations. A majority of experiments detects more than one signal, which allows to distinguish between scattering off of electrons (electronic recoils, ER) and off of atomic nuclei (nuclear recoils, NR). A 3D position resolution is required to define central detector regions (or fiducial volumes) with low background rates from surrounding materials, and the distinction between single- versus multiple-scatters rejects a significant fraction of backgrounds, given that DM will scatter at most once. We refer to [140,141] for recent reviews of the field.

Specific signatures: For NRs, the shape of the differential recoil spectrum is exponentially falling with recoil energy, and depends on the mass of the particle and on the nuclear mass. Unless $m_{\rm DM} \gg m_N$, $m_{\rm DM}$ can in principle be determined from the measured recoil spectrum, where multiple targets will provide tighter constraints [142]. The Earth's motion through the MW induces a seasonal variation of the total event rate and a forward-backward asymmetry in a directional signal [143, 144]. The annual modulation is due to the Earth's motion in the Galactic rest frame, which is a superposition of the Earth's rotation around the Sun and the Sun's rotation around the Galactic center. Since the Earth's orbital speed is much smaller than the Sun's speed, the expected amplitude of the modulation is $\simeq 5\%$. In the SHM, the period is one year, and the phase is 150 d (June 2), when both speeds add up maximally. This expectation is modified for different DM distributions, e.g. in the case of sub-structures such as clumps and streams [145, 146] and a DM disc [147]. In addition, the modulation changes phase at a specific recoil energy (known as crossing-energy) [148], which depends on the DM and nuclear mass, allowing to in principle determine $m_{\rm DM}$ if low energy thresholds can be achieved. A powerful signature is provided by the ability to detect the axis and direction of the recoiling nucleus. Since the DM flux in the laboratory frame is peaked in the direction of motion of the Sun towards the constellation Cygnus, the recoil spectrum is peaked in the opposite direction. The observation of such a dipole feature would provide a 'smoking-gun' evidence for DM, where the forward-backward rates can differ by a factor of ∼10, depending on the energy threshold. Ref. [149] provides a review of the theoretical framework and of the discovery reach of directional detectors.

Backgrounds, including neutrinos: Early direct detection experiments employing low-background Ge spectrometers featured background levels around 2 events/(kg d keV), while the latest generation of liquid Xe experiments reduced this noise by almost five orders of magnitude, to 4×10^{-5} events/(kg d keV). In liquid xenon detectors, the measured ER spectra at low energies are for the first time dominated by solar *pp* neutrino interactions, second-order weak decays, as well as ^{214}Pb β-decays from radon mixed with the xenon. Other backgrounds are due to the radioactivity of detector components, followed by cosmic muons and their secondaries such as fast neutrons. The cosmic and environmental radiation are suppressed by going deep underground and surrounding the experiments with appropriate shielding structures (mainly large water Cherenkov detectors for the current and

next-generation detectors). Activation of materials via cosmic-ray interactions produce long-lived radio-nuclides (e.g., ^{39}Ar, ^{60}Co, ^{68}Ge, ^{32}Si, etc), while long-lived, human-made isotopes (^{85}Kr, ^{137}Cs, etc) can mix with detector materials or generate surface backgrounds. For details, we refer to *Section 36.6* of this *Review*.

The final backgrounds are due to the irreducible neutrino flux from the Sun, the atmosphere and the diffuse supernovae background [150]. Solar pp-neutrinos start dominating the electronic recoil background due to elastic neutrino-electron scatters, at a level of $\sim (10-25)$ events/(t y) below energies of $\sim$100 keV, while coherent elastic neutrino-nucleus scatters (CEνNS) from ^{8}B solar neutrinos will induce up to $\sim 10^3$ events/(t y) for high-A targets, at nuclear recoil energies below $\sim$few keV. Nuclear recoils from atmospheric neutrinos and the diffuse supernovae neutrino background will yield event rates in the range $(1-5)$ events/(100 t y), depending on the detector material. In general, ^{8}B and atmospheric neutrinos will impact light ($\leq$6 GeV) and heavy (100 GeV and above) DM searches for cross sections on nucleons below $\sim 10^{-45}$ cm^2 and $\sim 10^{-49}$ cm^2, respectively. The precise cross-sections where neutrinos constitute a dominant background strongly depend on the systematic uncertainties on the neutrino flux normalisation for each source [151]. For very low energy thresholds to nuclear recoils, e.g. 10-30 eV in Ge and Si detectors, CEνNS due to the ^{7}Be neutrino flux become relevant for exposures of $\sim$50 kg y [152]. For DM searches with electron recoils via DM-electron scattering and dark photon or ALP absorption, solar neutrinos will also limit the sensitivity to DM masses in the range $\sim$(1-10^3) MeV and $\sim$(1-10^3) eV, respectively, for large exposures $\sim$1 t y, as shown in Ref. [153].

Solid-state cryogenic detectors: Current experiments using the bolometric technique (see *Section 36.5* of this *Review*), together with either charge or light readout, are SuperCDMS (Si, Ge) at Soudan (until 2015) and SNOLAB (in construction), EDELWEISS (Ge) at the Laboratoire Souterrain de Modane (LSM) and CRESST ($CaWO_4$, Al_2O_3, Si, $LiAlO_2$) at the Laboratori Nazionali del Gran Sasso (LNGS). These experiments are optimised for low-mass DM searches, and can probe WIMP masses down to $\sim$0.03 GeV. CRESST operated a 0.35-g thin wafer Si detector and reached a 10-eV energy threshold, probing DM masses in the range (115–500) MeV, improving existing limits by up to a factor 20 for masses below 160 MeV. CDMSlite operated detectors at higher bias voltages to amplify the phonon signals produced by drifting charges and thus have access to light DM around 1.5 GeV. A reanalysis of the CDMSlite data using the Migdal effect allowed to exclude new parameter space for WIMP-nucleon cross-sections down to 30 MeV [113]. The goal at SNOLAB is to probe the (0.05–5) GeV region down to cross sections of $\sim 10^{-44}$ cm^2. Much smaller, gram-scale versions of cryogenic detectors can have single-charge resolution and thus probe low-mass DM via inelastic electron recoils. A SuperCDMS single-charge sensitive Si detector placed upper limits on DM interacting with electrons for masses between (0.5–10^4) MeV, as well as on dark photon kinetic mixing for dark photon masses in the range (1.5–40) eV. With Ge crystals operated at Soudan, SuperCDMS constrained dark photons and ALPs in the mass range 40 eV to 500 keV.

Germanium ionisation detectors operated at 77 K can reach sub-keV energy thresholds and low backgrounds, but lack the ability to distinguish electronic from nuclear recoils. The CDEX-10 experiment at the China Jinping Underground Laboratory (CJPL) uses p-type, point-contact Ge detectors operated in liquid nitrogen to probe DM masses down to 3 GeV. It also reported constraints on the kinetic mixing of dark photons in the mass range (0.1–4.0) keV. The $0\nu\beta\beta$-decay experiments Majorana Demonstrator and GERDA have obtained constraints on the couplings of ALPs and dark photons to electrons, with masses between (6-100) keV and (60-1000) keV, respectively. The Majorana Demonstrator improved laboratory constraints on solar axion masses between (1.2–100) eV, setting limits on the axion-photons coupling of $g_{a\gamma} < 1.45 \times 10^{-9}$ GeV^{-1}(95% CL).

Noble liquids: Liquid argon (LAr) and liquid xenon (LXe) are employed as DM targets, while R&D on liquid helium is ongoing. We refer to Ref. [154] for a review of the liquid noble gas detector technology in low-energy physics, as well to *Section 36.4* of this *Review*. At present the best constraints on DM-nucleus interactions come from multi-tonne experiments using xenon: the LZ experiment at SURF, PandaX-4T at CJPL and XENONnT at LNGS. These experiments probe particle masses down to $\sim$6 GeV (when using both light and charge signals) and the SI DM-nucleon cross section down to 9.2×10^{-48} cm^2 (at 36 GeV). LAr experiments employ pulse shape discrimination (PSD) that allows for distinguishing between ER and NR events, at the expense of higher energy thresholds than in LXe. The DarkSide-50 TPC at LNGS (until 2019) sets a minimum upper limit on the SI, DM-nucleon cross-section of 6×10^{-43} cm^2 at 10 GeV, while the single-phase experiment DEAP-3600 at SNOLAB constrains the SI cross-section to values below 3.9×10^{-45} cm^2 at 100 GeV.

In noble liquids, sub-GeV DM particles can be searched for by observing inelastic, ER processes following a low-energy nuclear recoil: excitation and ionisation of the recoiling atom (the hypothetical Migdal effect) and a bremsstrahlung photon [155]. As an example, LUX and XENON1T constrained DM particle masses between (0.3–5) GeV via bremsstrahlung photons and Migdal electrons. Even lower masses are accessible when using the amplified, charge signal only, at the expense of giving up discrimination between ERs and NRs. XENON1T probed particle masses down to 60 MeV, while DarkSide-50 published constraints on WIMP masses as low as 40 MeV. DM masses at the MeV-scale can also be probed by exploiting the scattering off electrons. PandaX-4T presented light DM searches with ionisation signals, with NR and ER energy thresholds of 0.77 keV and 0.07 keV, obtaining leading constraints in the mass range 40 MeV–100 GeV and 100 MeV–10 GeV for a heavy and light mediator, respectively [156]. DarkSide-50 set limits in the mass range $(16-56)$ MeV and above 80 MeV for a heavy and light mediator, respectively [157]. Noble liquids TPCs also search for solar axions, galactic ALPs and dark photons. XENONnT set upper limits on the axion-electron coupling of 2×10^{-12} in the mass range $(10^{-6}$–1) eV for solar axions, and probes couplings between $(1-2)\times10^{-14}$ in the mass range (1–10) keV for galactic ALPs [158]. DarkSide-50 probes ALP masses down to 0.03 keV with couplings in the range $10^{-13}-10^{-14}$ [157].

The next generation of liquefied noble gas detectors are in construction (DarkSide-20k) or at the design and R&D stage (Argo, DARWIN/XLZD, PandaX-xT). These will increase the sensitivity to various DM candidates by 1-2 orders of magnitude, with the ultimate goal of exploring the experimentally accessible parameter space, until the backgrounds from neutrinos will start dominating the event rates.

Room temperature scintillators: Several large DM experiments using high-purity NaI(Tl) crystals are acquiring data in various underground laboratories. Of these, DAMA/LIBRA at LNGS has the highest mass, 250 kg, and the largest exposure: 1.33 t y with an energy threshold of 1 keV and 2.46 t y with an energy threshold of 2 keV. It is the only experiment in the field that reported an annually modulated event rate with a statistical significance of 12.9 σ C.L. (20 annual cycles), with a modulation amplitude around 0.02 events/(kg d keV) in the energy region (1-4) keV. These findings were interpreted as due to DM interactions via nuclear or electronic recoils. The ANAIS experiment at Canfranc operates 112.5 kg of NaI(Tl) scintillators with an energy threshold of 1 keV and a background rate of 3.6 events/(kg d keV) in the (1-6) keV region. A blind analysis of 3 y of data, for an exposure of 314 kg y is consistent with an absence of modulation at 3.3 σ. The COSINE-100 experiment, located at the Yangyang Underground Laboratory in Korea, operates 106 kg of NaI(Tl) crystals in a liquid scintillator, with an energy threshold of keV and a background rate of 3.6 events/(kg d keV). Results from a 173 kg y exposure in the (1-6) keV energy range are consistent, at 68.3%C.L., with both the null hypothesis and DAMA/LIBRA's best fit value in the same energy range. A larger exposure and a reduced energy threshold are required to test DAMA/LIBRA for 3 σ coverage. COSINE-200, under construction at the new, deeper underground laboratory Yemilab, will be a larger experiment with reduced backgrounds. The SABRE experiment plans to operate a total of 50 kg of NaI(Tl) crystals, focussing on reaching a background level of 0.1 events/(kg d keV), an order of magnitude below DAMA/LIBRA. Twin detectors will be installed at

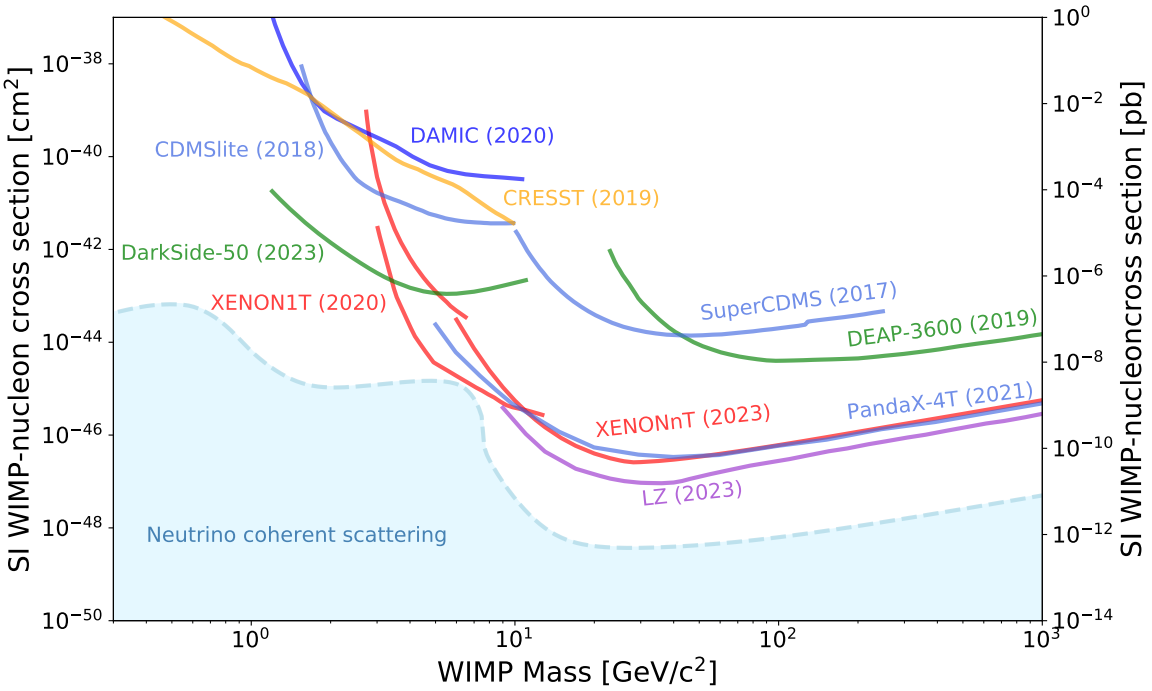

Figure 27.1: Upper limits on the SI DM-nucleon cross section as a function of DM mass.

LNGS and at the Stawell Underground Physics Laboratory in the Southern hemisphere. While a DM-induced signal is expected to have the same phase in both hemispheres, seasonal or site-related effects would show different amplitudes and phases in the twin detectors. The COSINUS experiment, under construction at LNGS, will use NaI crystals operated as cryogenic scintillating calorimeters to differentiate between nuclear and electronic recoils based on the observation of phonon and light signals. The first phase aims for an exposure of 100 kg d, while the second phase aims to achieve, with 1000 kg d, a fully model-independent cross-check of a NR origin of the DAMA/LIBRA signal.

Room temperature ionisation detectors: Silicon charged-coupled devices (CCDs) are employed for low-mass DM searches, as well as for hidden photon searches in the eV-mass range. Ionisation events induced in bulk silicon of high-resistivity, fully depleted CCDs are observed with charge resolutions around 1-2 e^- and extremely low leakage currents, at the level of few e^- mm^{-2}d^{-1}. The position of an energy deposit is reconstructed in 3 dimensions and the particle type (electron, neutron, muon, α-particles, etc) is reconstructed based on the recorded track pattern.

The DAMIC experiment at SNOLAB yielded new constraints on DM-electron scattering, and on the hidden-photon kinetic mixing parameter in the mass range (1-30) eV with an exposure of 7.6 kg d and on low-mass WIMPs with an exposure of 11 kg d. The SENSEI projects employs the skipper technology to achieve single-electron sensitivity. A run with a 2 g detector in the MINOS cavern at Fermilab yielded world-leading constraints on DM-electron scattering for a large range of sub-GeV dark matter masses. The skipper technology is also employed in the next stage of the DAMIC programme, DAMIC-M at LSM, which plans for a kg-size mass. The goal is to achieve thresholds of 2-3 electrons and to probe the DM-nucleon cross-section down to few$\times10^{-43}$cm^2 around 2-3 GeV and the DM-electron cross section down to 2×10^{-41}cm^2 at 10 MeV mass. DAMIC-M has operated first CCDs at LSM and achieved constraints on sub-GeV DM particles interacting with electrons in the mass range (0.53-1000) MeV, for an exposure of 85.23 g d.

The NEWS-G collaboration operates spherical proportional counters filled with a noble gas. Advantages of this technology are the low intrinsic electronic noise and a high amplification gain, allowing for low energy thresholds down to single-electron detection, and the possibility to use different light targets (He, Ne, etc). A 60 cm diameter chamber operated at LSM with a gas mixture of Ne + CH_4 (0.7%) at 3.1 bar, excluded SI, WIMP-nucleon cross sections above 4.4×10^{-37}cm^2 at 0.5 GeV after an exposure of 9.6 kg d with an energy threshold ~100 eV. The next iteration, a 140-cm sphere detector made of very low radioactivity copper (few μBq/kg of ^{238}U and ^{232}Th) has been installed at SNOLAB in 2021. The detector has recently started to acquire physics data, with a predicted background level of (5 ± 2) events/(kg keV d) for sub-keV events.

Superheated liquid detectors: Investigation of the spin-dependent interaction channel calls for target nuclei with uneven total angular momentum. A particularly favourable candidate is ^{19}F, the spin of which is carried mostly by the unpaired proton, yielding a cross-section which is almost a factor of ten higher than of other employed nuclei with spin (e.g., ^{23}Na, ^{73}Ge, ^{127}I, ^{129}Xe, ^{131}Xe). Fluorine is part of the target of experiments using superheated liquids, such as the ones operated by the PICO collaboration. A search in the PICO-60 C_3F_6 bubble chamber at SNOLAB with an exposure of 1404 kg d and an energy threshold of 2.45 keV, yielded the most stringent constraint on the DM-proton SD cross-section at 3.2×10^{-41}cm^2 for a 25 GeV particle mass. In construction at SNOLAB is PICO-500, a detector with 250 l of superheated freon (C_3F_8) contained between two quartz jars inside a pressure vessel filled with mineral oil, itself inside a tank of ultra-pure water.

Directional detectors: Detectors capable of measuring the direction of the recoiling nucleus would unequivocally confirm the Galactic origin of a signal and could probe the region below the neutrino floor [159, 160]. Because nuclear recoils have a range which is about 10 times smaller than the one of Compton recoils of the same energy, gaseous detectors have an excellent intrinsic background rejection if they can measure the range of events precisely. Several directional detectors are presently in operation, where a 1 m^3 detector has a typical mass of a few 100 g and can measure the sense of an incoming nuclear recoil above a few tens of keV. Cygnus is a proto-collaboration which coordinates the R&D efforts for gas based TPCs with 1 keV threshold. One of these is CYGNO, an experiment that aims to build a 1-m drift length gaseous TPC filled with a He:CF_4 60:40 gas mixture at atmospheric pressure and room temperature at LNGS.

A new technique is based on fine-grained nuclear emulsions

(solid-state detectors with silver halide crystals uniformly dispersed in a gelatine film, where each crystal works as a sensor for charged particles), as proposed by the NEWSdm collaboration. These act as target and nanometric tracking device, and the expected NR tracks are sub-μm in size. Due to the small crystal size and larger number density, a superior spatial resolution compared to gaseous detectors is obtained. Simulations show that to reach the neutrino floor, exposures of 10 t y and 100 t y are required if a 30 nm and 50 nm threshold for detecting the track length is reached. This requires further R&D, since current emulsions allow for 100 nm tracking and target masses are around 1 kg, with 10 kg y exposures planned. A proposed approach for the directional detection of sub-GeV DM is to use two-dimensional materials such as monolayer graphene [161], from which the DM particle can eject electrons. Their energy and direction, correlated with the direction of the incoming DM, can be measured for instance with the proposed PTOLEMY experiment.

New techniques: To probe light (sub-GeV) DM particles, either via scatters off electrons or via couplings to phonons, new techniques beyond the ones discussed above are proposed. The DM particle mass that can be accessed in DM-electron scattering in noble liquids and semiconductors is limited by the minimum ionisation/excitation energy and the size of the band gap, respectively (at the ∼eV-scale). To reach lower energy thresholds, materials with smaller band gaps for electron excitations (∼meV), such as superconductors and superfluids, as well as Dirac materials were proposed [162]. These would in principle allow for the detection of keV-scale DM. Other ideas to detect keV-MeV scale DM are to observe NRs in superfluid He, via collective excitation modes in the fluid [163], as realised in HeRALD and DELight, or based on the breaking of chemical bonds between atoms [164].

Even lighter DM, with masses in the meV-eV range, could be detected via absorption on a conduction electron in a superconductor, followed by the emission of an athermal phonon [165]. Another proposed target for light DM are polar materials (for example GaAs, sapphire), which are especially sensitive for scattering through an ultralight dark photon, via excitation of single optical phonons [166]. If an anisotropic crystal such as sapphire is employed, a daily modulation interaction rate could be established [167]. A new class of detectors for bosonic DM, based on resonant absorption onto a gas of small polyatomic molecules, is proposed in [168]. The DM would effectively act as a laser that resonantly excites transitions in molecules when its mass closely matches the transition energy. While DM with SI couplings can efficiently excite phonons, it has been shown in [169] that if DM couples to the electron spin, magnon excitations (quanta of collective spin wave excitations) in materials with magnetic dipole order may also offer a promising detection avenue. Yet another approach for sub-GeV DM is to employ superconducting nanowires as both target and sensor, and first bounds on DM-electron interactions were placed from a 4.3 ng tungsten-silicide prototype with a 0.8 eV energy threshold and an exposure of 8.8×10^{-14} kg y [170].

The detection of light DM via collective excitations in condensed matter systems and other methods is a rapidly evolving field, and a growing area of research at the interface of DM physics, condensed matter and materials science. We refer to Ref. [171,172] for discussions of some of these new directions and models. Critical challenges are to detect these very small energy depositions, and to reliably asses the background noise.

Table 27.1 summarises the most stringent constraints on the DM-nucleon SI and SD cross-sections, and Figure 27.1 shows the best constraints for SI couplings in the cross-section versus DM mass parameter space, above masses of 0.3 GeV.

27.7 Astrophysical detection of dark matter

DM as a microscopic constituent can have measurable, macroscopic effects on astrophysical systems. Indirect DM detection refers to the search for the annihilation or decay debris from DM particles, resulting in detectable species, including especially gamma rays, neutrinos, and antimatter particles. The production rate of such particles depends on (i) the annihilation (or decay) rate (ii) the density of pairs (respectively, of individual particles) in the region of interest, and (iii) the number of final-state particles produced in one annihilation (decay) event. In formulae, the rate for production of a final state particle f per unit volume from DM annihilation can be cast as

$$\Gamma_f^A = c\frac{\rho_{\rm DM}^2}{m_{\rm DM}^2}\langle\sigma v\rangle N_f^A, \tag{27.18}$$

where $\langle\sigma v\rangle$ indicates the thermally-averaged cross section for DM annihilation times relative velocity [27], calculated at the appropriate temperature, $\rho_{\rm DM}$ is the physical density of DM, and N_f^A is the number of final state particles f produced in one individual annihilation event. The constant c depends on whether the DM is its on antiparticle, in which case $c = 1/2$, or if there is a mixture of DM particles and antiparticles (in case there is no asymmetry, $c = 1/4$). The analog for decay is

$$\Gamma_f^D = \frac{\rho_{\rm DM}}{m_{\rm DM}}\frac{1}{\tau_{\rm DM}}N_f^D, \tag{27.19}$$

with the same conventions for the symbols, and where $\tau_{\rm DM}$ is the DM's lifetime.

Gamma Rays: DM annihilation to virtually any final state produces gamma rays: emission processes include the dominant two-photon decay mode of neutral pions resulting from the hadronization of strongly-interacting final states; final state radiation; and internal bremsstrahlung, the latter two including, possibly, the emission of massive gauge or Higgs bosons subsequently producing photons via their decay products. Similarly, neutrinos are produced from charged pion decay and from radiative processes. The flux of gamma rays and neutrinos is calculated integrating the rate Γ_f per steradian (simply meaning, for isotropic emission, $\Gamma_f/(4\pi)$) along the line of sight within the appropriate angular region (the *differential* flux is obtained in the same way by simply replacing N_f with the differential flux at production, at the appropriate redshift in the case of cosmologically distant sources),

$$\phi_f = \int_{\Delta\Omega} d\Omega \int_{\rm l.o.s.} dl \frac{\Gamma_f}{4\pi}. \tag{27.20}$$

It is customary to factor out, in the expression for the rate, a *particle physics* factor, depending upon the DM particle mass and its annihilation or decay rate, and an *astrophysical* factor, which only depends on the observational target. The latter is sometimes denoted with $J_{\Delta\Omega}(\psi)$ with ψ indicating the direction of the line of sight. Although different conventions are in use, a common choice is to define

$$J_{\Delta\Omega}(\psi) = \int_{\Delta\Omega}\int_{\rm l.o.s.(\psi)} \rho_{\rm DM}^2(l,\Omega)\; dl d\Omega. \tag{27.21}$$

For a target with uniform density ρ and radius r at a distance $d \gg r$, such that the target is entirely within the solid angle $\Delta\Omega$,

$$J \simeq \frac{4\pi r^3 \bar{\rho}_{\rm DM}^2}{3d^2}. \tag{27.22}$$

Searches for gamma-ray emission from DM annihilation have focused on targets chosen based on a variety of considerations, primarily intended to maximize signal to noise. Nearby dwarf spheroidal galaxies contain very small amounts of gas, and do not host any significant astrophysical background at gamma-ray or X-ray frequencies, and are thus an optimal target choice for DM searches. An accurate determination of the DM density profile in these objects results in somewhat large systematics when deriving constraints from the non-observation of emission from DM; future optical surveys will help pinpoint with greater accuracy stellar kinematics and thus reduce such uncertainty; a second target is the inner region of the Milky Way: while nearby and potentially hosting a large density of DM, the Galactic center region is however very bright at almost any wavelength, making the extraction of a signal highly problematic; nearby clusters of galaxies are also known to host significant astrophysical emission, but are potentially ideally suited to constrain DM decay. Finally, putative nearby DM clumps are also a possible source of a bright DM signal (albeit from an unknown direction), as is the annihilation of DM in all halos at all redshifts.

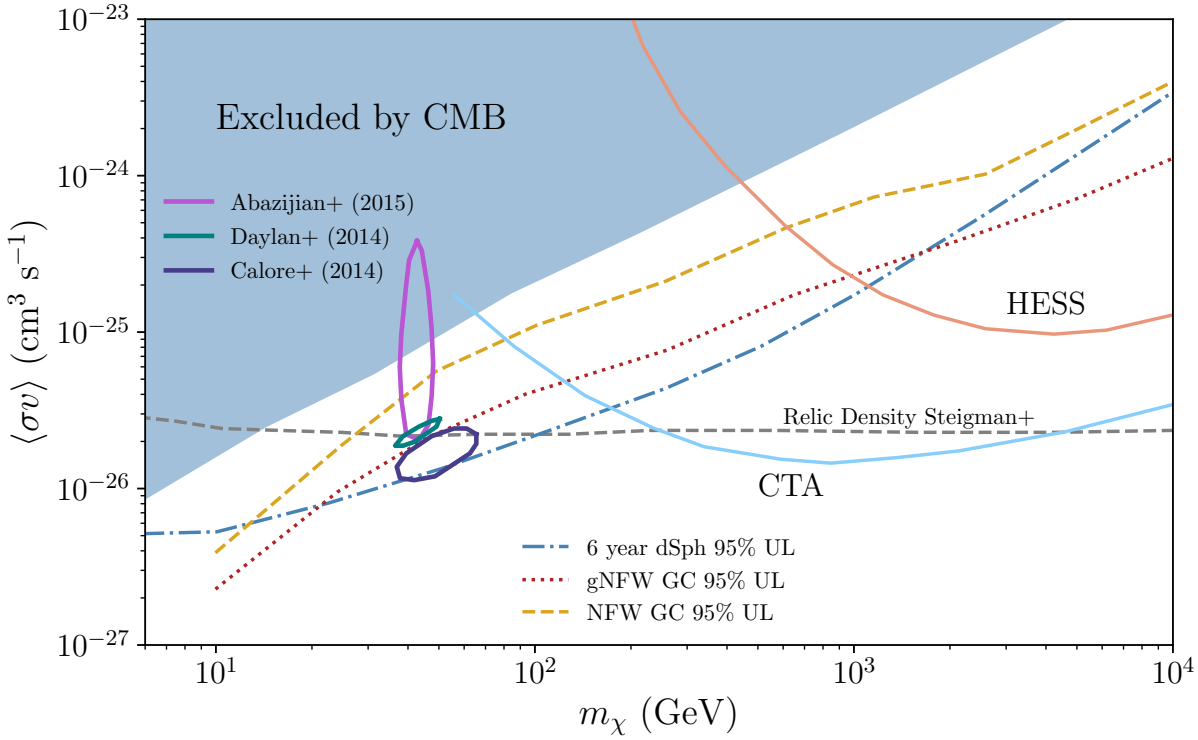

Figure 27.2: Upper limits and projected sensitivity from CTA on the pair-annihilation rate versus the DM mass from gamma-ray and CMB observations (figure courtesy of Logan Morrison).

DM annihilation and decay can lead to striking spectral features. Since the process happens typically at very low particle velocities, if the DM pair-annihilates e.g. to two photons or two neutrinos, the final-state particles will be nearly monoenergetic, with an energy close to the DM particle mass and a width proportional to the DM velocity in units of c (if a $\gamma\gamma$ line is present electroweak symmetry also implies a $Z\gamma$ line, if kinematically allowed). No astrophysical processes are known to produce lines at gamma-ray or neutrino energies in the GeV and above (with, perhaps, the possible exception of cold pulsar winds [173]) making this channel virtually background-free. At lower energy, lines are expected from radiative decay modes of candidates such as sterile neutrinos (see Sec. 27.5).DM annihilation or decay can lead to additional spectral features besides lines. These include (one or more) "boxes" [174], produced by boosted final states decaying to monochromatic photons (such as e.g. neutral pions), or combinations thereof. Processes occurring at higher redshift can distort these spectral features by smearing them to lower energies. Neglecting gamma-ray attenuation, the flux of gamma rays from all redshift can be cast as

$$\frac{dN_\gamma}{dE_\gamma}(E_\gamma) = \frac{c}{8\pi}\int \frac{\langle\sigma v\rangle\rho_{\rm DM}(z)dz}{H(z)(1+z)^3 m^2_{\rm DM}}\left(\frac{dN_\gamma}{dE'}\right)_{E'=E_\gamma(1+z)}. \quad (27.23)$$

While the calculation of the differential spectrum of gamma rays from a given final state f, dN^f_γ/dE_γ, is carried out using numerical tools, such as PYTHIA [175] that reproduce hadronization and particle decay for masses well above a few GeV, in the sub-GeV range gamma-ray production follows primarily from meson decay and radiative processes well outside the range of applicability of the Altarelli-Parisi splitting function. The MeV gamma-ray range will soon be probed with forthcoming satellites [176]. Recently a code that provides the expected gamma-ray spectrum for sub-GeV DM, `Hazma`, has become available [177].

Observations with the Fermi Large Area Telescope (LAT) and with ground-based facilities such as HESS, VERITAS, MAGIC, and HAWC have provided an unprecedented picture of the gamma-ray sky ideally suited to look for a signal from DM annihilation or decay for DM particles from a few GeV mass up to several TeV. The LAT has provided some of the most stringent constraints to-date on DM pair-annihilation for a variety of annihilation final states, chiefly from stacked observations of nearby satellite dwarf spheroidal galaxies [178]. Excesses of gamma rays over the expected diffuse and point-source background have been claimed, most importantly from the direction of the inner Galaxy, where a signal from DM annihilation might be especially bright [179,180]. The nature of this excess is quite controversial: while the morphology and spectrum fall within what expected for a standard WIMP with a mass of a few tens of GeV [181], unresolved point sources, including especially an (expected) population of millisecond pulsars (MSPs) have been advocated as a possible plausible counterpart [182]. Statistical methods to discriminate between DM and MSPs have been utilized [183,184], but recent studies indicate that such results might not be conclusive [185]. Large uncertainties in the Galactic diffuse background emission model are additionally known to exist, and possible plague the morphological and spectral information [186, 187].Other notable potential gamma-ray excesses include a diffuse emission from the Andromeda galaxy (M31) [188–190], possibly in excess of what expected from cosmic-ray models [191]; and a diffuse emission at 511 keV energy in the inner Galaxy from Integral-SPI observations [192]; such emission has known astrophysical counterparts [193], as well as several proposed DM explanations (e.g. [194]).

While DM annihilation and decay typically occurs at low velocities, the possibility of "boosted" DM has also been considered [195]. In this case, the DM particle might dominantly pair-annihilate to a lighter dark species, which does interact with Standard Model particle, and could be detected with neutrino telescopes or direct detection experiments. Future facilities that promise to widen the reach of gamma-ray searches for DM include especially the Cherenkov Telescope Array (CTA), see fig. 27.2.

Neutrinos: DM can be captured in celestial bodies in significant amounts, depending on the DM scattering cross section off of nucleons, the DM mass, and the DM flux incident on the celestial body of interest. For DM masses at or around the GeV scale, evaporation from the celestial body plays an important role [196]. If enough DM accumulates, DM annihilation inside the celestial body can then lead to the production of Standard Model parti-

cles. Such particles can heat up the body, if they lose most of their energy before escaping. Utilizing models for heat production in planets, or stellar interior models in the case of stars, constraints can be put on DM particle properties. Of note are constraints from anomalous warming of cold planets such as Uranus [197], alterations to the stellar structure or the Sun's seismic activity [198], and anomalous Earth heat flow [199]. Alternately, DM annihilation in celestial bodies can result in the production of particles that can escape the body. Within the Standard Model, the only such instance is annihilation to neutrinos, but, similarly to the boosted DM case the DM can annihilate to a (stable or unstable) dark-sector particles, whose decay or interactions can be detected on Earth [200,201]. For direct annihilation to neutrinos, given the lower limit on the DM mass from evaporation, the typical neutrino energies usually exceed the energy of neutrinos from the Sun, the best target for this type of searches, making this a virtually background-free DM search. Significant neutrino fluxes can only be achieved, however, if near-equilibration is reached between the capture and annihilation rates. In turn, this requires large-enough DM-nucleon scattering cross sections, to-date very close to the limits from direct detection (see sec. 27.6). Only spin-dependent cross section, and capture in the Sun usually provide large-enough neutrino fluxes. IceCube and ANTARES searches for an anomalous flux of high-energy neutrinos from the Sun yielded null results, which can be interpreted as constraints on spin-dependent nucleon-DM interactions under the assumption of equilibration and of specific annihilation final states [202,203]. Lower-threshold detectors, including DeepCore [204] and PINGU [205], can produce interesting limits on lower-mass DM candidates above the evaporation threshold.

Cosmic-ray Antimatter: Stable charged particles produced by decays of products of, or directly from DM annihilation or decay, populate the cosmic radiation and are a prime target for indirect DM searches. To maximize signal to noise, searches focus on relatively rare particle species, such as positrons, antiprotons, and antinuclei. While in certain models the production of particles and antiparticles is not symmetric [206], generally DM annihilation or decay produces as many particles as antiparticles in the final state. Charged particles produced by DM propagate and lose energy prior to reaching detectors. The transport of charged particles is customarily carried out in the context of diffusion models such as the Galactic "leaky box" setup, see e.g. [207]. While progress in constraining the uncertain propagation and energy-loss processes has been steady with improved data from new detectors such as PAMELA [208] and AMS-02 [209], the calculation of the particle flux at Earth from that at production suffers from significant uncertainties [207].

An excess of high-energy positrons over the standard secondary production from inelastic cosmic-ray interactions has been firmly established by several experiments, most recently and with the highest statistics by AMS-02 [210]. The excess has been ascribed to DM annihilation, although strong constraints from the non-observation of corresponding anomalies in other channels, such as antiprotons and gamma rays, and the peculiar spectral shape, force DM models to be quite convoluted (see e.g. [211]). Alternately, excess *primary* positrons can be produced in the magnetosphere of nearby pulsars [212, 213]. This latter explanation was questioned in [214] in connection with the detection of a TeV halo around two candidate pulsars, leading to the determination of a highly suppressed diffusion coefficient within the pulsar nebula; with such low diffusion coefficient, positrons from the pulsars would not contribute significantly to the flux at Earth; Ref. [215], however, showed that likely the diffusion coefficient is not constant, and that if it increases outside the nebula, as expected from other cosmic-ray measurements, pulsars can still be considered as the counterpart to the positron excess. Other explanations for the excess, albeit somewhat controversial, and increasingly constrained by data, also exist [216, 217].

The antiproton spectrum in the cosmic radiation as measured by AMS-02 [209] also exhibits features that might be considered as excess flux between 10 and 20 GeV, and energies above 100 GeV [218], which have been interpreted as possible signal of DM annihilation; more realistically, however, systematic uncertainties in the antiproton production cross section, in cosmic-ray transport, reacceleration at high energy and, at low energy, solar modulation make it extremely difficult to assess the robustness of the excesses [219, 220].

Antinuclei such as anti-deuterium and anti-helium could also form as a result of DM annihilation or decay. While baryon number conservation forces the typical kinetic energy of antinuclei produced in inelastic cosmic-ray processes to large values, antinuclei arising from hadronization of DM-initiated jets have low energy, offering optimal signal-to-noise when a low-energy cut on the antinucleus kinetic energy is used [221–225]. Specific detector designs have been developed to single out low-energy cosmic-ray antinuclei (e.g. $E < 0.25$ GeV/nucleon in the case of the General Antiparticle Spectrometer, or GAPS [226]). The detection of even a single antinucleus would have considerable importance as a possible sign of new physics [227].

Multi-wavelength studies: Electrons and positrons from DM lose energy quite efficiently, radiating at a variety of wavelengths. This *secondary* radiative emission presents spectral and morphological features that might provide an important additional indirect detection channel. The most efficient energy loss mechanisms for high-energy electrons and positrons are inverse Compton (IC) up-scattering of background photons, and synchrotron radiation in the presence of magnetic fields. Depending on the DM mass, the emitted light from synchrotron peaks at MHz-GHz frequencies, while the IC emission at X-ray to gamma-ray frequencies, depending on the energy of the background radiation, typically ranging from CMB photons up to starlight photons [228–230]. The calculation of the secondary emission from DM entails both solving the transport of the electrons and positrons from DM, and for the radiative emission; codes exist that perform these calculations for certain astrophysical environments [231–233], with diffusion playing an increasingly critical role in smaller and smaller structures such as dwarf galaxies [229]. It has been demonstrated that for large magnetic fields and for certain final states, the synchrotron emission is more constraining than the gamma-ray emission [234].

Stellar Physics: Microscopic properties of the DM can meaningfully alter, and thus be constrained by, several astrophysical environments, from planets and stars, up to the universe as a whole. DM particles light enough to be produced in collisional processes inside stars, with typically temperatures in the keV, or supernovae, with energy scales in the MeV, lead to an additional energy-loss mechanism, if capable of escaping the system. If this is the case, the increased needed energy output would also result in an increased neutrino flux, leading to constraints on the masses and couplings of the DM, see e.g. [235] for a comprehensive review. DM annihilation can even have fueled early stages of stellar evolution, perhaps with measurable consequences [236]. DM capture in neutron stars could lead to the collapse of the star into black holes; the existence of neutron stars in DM-rich environments can thus be used to constrain the mass and interaction cross section of DM with nucleons [237] and even relatively light, but stable, primordial black holes [238].

Cosmology: Energy injection from DM processes in the early universe, as well as the contribution of DM to the effective relativistic degrees of freedom, are severely constrained from data on Big Bang Nucleosynthesis (see Sec. 24 in this *Review*) and on the energy and anisotropy power spectrum of the CMB (see Sec. 29). Codes exist that perform the calculation of the constraints on particle DM models [177, 239].

PBH Detection: Macroscopic DM candidates can gravitationally perturb structure and compromise the stability of, for instance, globular clusters such as Eridanus II [24], and/or disrupt wide binaries [240]. This constrains the maximal mass of a macroscopic DM candidate to not much more than 5 $M_\odot$ [240] (see also [24]). In the specific case or primordial black holes, strong constraints also stem from the acceleration of charged particles around and after recombination, with significant effects on the CMB [241], albeit a lively debate exists over the accretion efficiency around such objects at high redshift [242,243]. Whether or not PBH in the solar-mass range can be 100% of the DM is therefore disputed at present. Other effects produced by macroscopic,

massive DM candidates are the microlensing of stars [244, 245] and quasars [246], femtolensing of gamma-ray bursts [247], and neutron star capture [238]. It is important to note that recently constraints from both microlensing and femtolensing have been corrected after the realization of important finite-size source and wave effects [245, 248, 249], leaving a substantial window, at PBH masses $10^{17} \lesssim M_{\rm BH}/{\rm g} \lesssim 10^{21}$ where PBH can be 100% of the DM. Light black holes, $M_{\rm BH} \lesssim 10^{17}$ g, are also constrained by the non-detection of products of evaporation [250]; future MeV gamma-ray detectors are slated to significantly improve such constraints and to enable the direct detection of Hawking radiation [251]. If evaporation shuts down at or near the Planck scale, Planck-scale relic PBH are generally expected to carry electric charge and to be detectable with direct detection and neutrino experiments, or with paleo-detectors [252].

28. Dark Energy

Revised August 2023 by D.H. Weinberg (Ohio State U.) and M. White (UC Berkeley; LBNL).

28.1 Repulsive Gravity and Cosmic Acceleration

In the first modern cosmological model, Einstein [1] modified his field equation of General Relativity (GR), introducing a "cosmological term" that enabled a solution with time-independent, spatially homogeneous matter density $\rho_{\rm m}$ and constant positive space curvature. Although Einstein did not frame it this way, one can view the "cosmological constant" Λ as representing a constant energy density of the vacuum [2], whose repulsive gravitational effect balances the attractive gravity of matter and thereby allows a static solution. After the development of dynamic cosmological models [3, 4] and the discovery of cosmic expansion [5], the cosmological term appeared unnecessary, and Einstein and de Sitter [6] advocated adopting an expanding, homogeneous and isotropic, spatially flat, matter-dominated Universe as the default cosmology until observations dictated otherwise. Such a model has matter density equal to the critical density, $\Omega_{\rm m} \equiv \rho_{\rm m}/\rho_{\rm c} = 1$, and negligible contribution from other energy components [7].

By the mid-1990s, the Einstein-de Sitter model was showing numerous cracks, under the combined onslaught of data from the cosmic microwave background (CMB), large-scale galaxy clustering, and estimates of the matter density, the expansion rate (H_0), and the age of the Universe. As noted in a number of papers from this time, introducing a cosmological constant offered a potential resolution of many of these tensions, yielding the most empirically successful version of the inflationary cold dark matter scenario. In the late 1990s, supernova surveys by two independent teams provided direct evidence for accelerating cosmic expansion [8, 9], establishing the cosmological constant model (with $\Omega_{\rm m} \simeq 0.3$, $\Omega_\Lambda \simeq 0.7$) as the preferred alternative to the $\Omega_{\rm m} = 1$ scenario. Shortly thereafter, CMB evidence for a spatially flat Universe [10, 11], and thus for $\Omega_{\rm tot} \simeq 1$, cemented the case for cosmic acceleration by firmly eliminating the free-expansion alternative with $\Omega_{\rm m} \ll 1$ and $\Omega_\Lambda = 0$. Today, the accelerating Universe is well established by multiple lines of independent evidence from a tight web of precise cosmological measurements.

As discussed in the Big Bang Cosmology article of this *Review* (Sec. 22), the scale factor $R(t)$ of a homogeneous and isotropic Universe governed by GR grows at an accelerating rate if the pressure $p < -\frac{1}{3}\rho$ (in $c = 1$ units). A cosmological constant has $\rho_\Lambda =$ constant and pressure $p_\Lambda = -\rho_\Lambda$ (see Eq. 22.10), so it will drive acceleration if it dominates the total energy density. However, acceleration could arise from a more general form of "dark energy" that has negative pressure, typically specified in terms of the equation-of-state-parameter $w = p/\rho$ ($= -1$ for a cosmological constant). Furthermore, the conclusion that acceleration requires a new energy component beyond matter and radiation relies on the assumption that GR is the correct description of gravity on cosmological scales. The title of this article follows the common but inexact usage of "dark energy" as a catch-all term for the origin of cosmic acceleration, regardless of whether it arises from a new form of energy or a modification of GR. Our account here draws on the much longer review of cosmic acceleration in Ref. [12], which provides background explanation and extensive literature references for the discussion in Secs. 28.2 and 28.3.

Below we will use the abbreviation ΛCDM to refer to a model with cold dark matter, a cosmological constant, inflationary initial conditions, standard radiation and neutrino content, and a flat Universe with $\Omega_{\rm tot} = 1$ (though we will sometimes describe this model as "flat ΛCDM" to emphasize this last restriction). We will use wCDM to denote a model with the same assumptions but a free, constant value of w. Models with the prefix "o" (*e.g.*, `owCDM`) allow non-zero space curvature.

28.2 Theories of Cosmic Acceleration

28.2.1 *Dark Energy or Modified Gravity?*

A cosmological constant is the mathematically simplest, and perhaps the physically simplest, theoretical explanation for the accelerating Universe. The problem is explaining its unnaturally small magnitude, as discussed in Sec. 22.4.7 of this *Review*. An alternative (which still requires finding a way to make the cosmological constant zero or at least negligibly small) is that the accelerating cosmic expansion is driven by a new form of energy such as a scalar field [13] with potential $V(\phi)$. The energy density and pressure of the field $\phi(\mathbf{x})$ take the same forms as for inflationary scalar fields, given in Eq. (22.52) of the Big Bang Cosmology article. In the limit that $\frac{1}{2}\dot\phi^2 \ll |V(\phi)|$, the scalar field acts like a cosmological constant, with $p_\phi \simeq -\rho_\phi$. In this scenario, today's cosmic acceleration is closely akin to the epoch of inflation, but with radically different energy and timescale.

More generally, the value of $w = p_\phi/\rho_\phi$ in scalar field models evolves with time in a way that depends on $V(\phi)$ and on the initial conditions $(\phi_i, \dot\phi_i)$; some forms of $V(\phi)$ have attractor solutions in which the late-time behavior is insensitive to initial values. Many forms of time evolution are possible, including ones where w is approximately constant and broad classes where w "freezes" towards or "thaws" away from $w = -1$, with the transition occurring when the field comes to dominate the total energy budget. If ρ_ϕ is even approximately constant, then it becomes dynamically insignificant at high redshift, because the matter density scales as $\rho_{\rm m} \propto (1+z)^3$. "Early dark energy" models are ones in which ρ_ϕ is a small but not negligible fraction (*e.g.*, a few percent) of the total energy throughout the matter- and radiation-dominated eras, tracking the dominant component before itself coming to dominate at low redshift.

Instead of introducing a new energy component, one can attempt to modify gravity in a way that leads to accelerated expansion [14]. One option is to replace the Ricci scalar $\mathcal{R}$ with a function $\mathcal{R} + f(\mathcal{R})$ in the gravitational action [15]. Other changes can be more radical, such as introducing extra dimensions and allowing gravitons to "leak" off the brane that represents the observable Universe (the "DGP" model [16]). The DGP example has inspired a more general class of "galileon" and massive gravity models. Constructing viable modified gravity models is challenging, in part because it is easy to introduce theoretical inconsistencies (such as "ghost" fields with negative kinetic energy), but above all because GR is a theory with many high-precision empirical successes on solar system scales [17]. Modified gravity models typically invoke screening mechanisms that force model predictions to approach those of GR in regions of high density or strong gravitational potential. Screening offers potentially distinctive signatures, as the strength of gravity (*i.e.*, the effective value of $G_{\rm N}$) can vary by order unity in environments with different gravitational potentials.

More generally, one can search for signatures of modified gravity by comparing the history of cosmic structure growth to the history of cosmic expansion. Within GR, these two are linked by a consistency relation, as described below (Eq. (28.2)). Modifying gravity can change the predicted rate of structure growth, and it can make the growth rate dependent on scale or environment. In some circumstances, modifying gravity alters the combinations of potentials responsible for gravitational lensing and the dynamics of non-relativistic tracers (such as galaxies or stars) in different ways (see Sec. 22.4.7 in this *Review*), leading to order unity mismatches between the masses of objects inferred from lensing and those inferred from dynamics in unscreened environments.

At present there are no fully realized and empirically viable modified gravity theories that explain the observed level of cosmic acceleration. The constraints on $f(\mathcal{R})$ models now force them so close to GR that they cannot produce acceleration without introducing a separate dark energy component [18]. The DGP model is empirically ruled out by several tests, including the expansion history, the integrated Sachs-Wolfe effect, and redshift-space distortion measurements of the structure growth rate [19]. The near-simultaneous arrival of gravitational waves and electromagnetic signals from the neutron star merger event GW170817, which shows that gravitational waves travel at almost exactly the speed of light, is a further strong constraint on modified gravity theories [20]. The elimination of models should be considered an important success of the program to empirically test theories of cosmic acceleration. However, it is worth recalling that there was no fully realized gravitational explanation for the precession of Mercury's orbit prior to the completion of GR in 1915, and the fact that no complete and viable modified gravity theory exists

today does not mean that one will not arise in the future. In the meantime, we can continue empirical investigations that can tighten restrictions on such theories or perhaps point towards the gravitational sector as the origin of accelerating expansion.

28.2.2 *Expansion History and Growth of Structure*

The main line of empirical attack on dark energy is to measure the history of cosmic expansion and the history of matter clustering with the greatest achievable precision over a wide range of redshift. Within GR, the expansion rate $H(z)$ is governed by the Friedmann equation (see the articles on Big Bang Cosmology and Cosmological Parameters—Secs. 22 and 25 in this *Review*). For dark energy with an equation of state $w(z)$, the cosmological constant contribution to the expansion, Ω_Λ, is replaced by a redshift-dependent contribution. The evolution of the dark energy density follows from Eq. (22.10),

$$\Omega_{\rm de}\frac{\rho_{\rm de}(z)}{\rho_{\rm de}(z=0)} = \Omega_{\rm de}\exp\left[3\int_0^z [1+w(z')]\frac{dz'}{1+z'}\right] = \Omega_{\rm de}(1+z)^{3(1+w)}, \quad (28.1)$$

where the second equality holds for constant w. If $\Omega_{\rm m}$, $\Omega_{\rm r}$, and the present value of $\Omega_{\rm tot}$ are known, then measuring $H(z)$ pins down $w(z)$. (Note that $\Omega_{\rm de}$ is the same quantity denoted $\Omega_{\rm v}$ in Sec. 22, but we have adopted the 'de' subscript to avoid implying that dark energy is necessarily a vacuum effect.)

While some observations can probe $H(z)$ directly, others measure the distance-redshift relation. The basic relations between angular diameter distance or luminosity distance and $H(z)$ are given in Ch. 22 —and these are generally unaltered in time-dependent dark energy or modified gravity models. For convenience, in later sections, we will sometimes refer to the comoving angular diameter distance, $D_{\rm A,c}(z) = (1+z)D_{\rm A}(z)$.

In GR-based linear perturbation theory, the density contrast $\delta(\mathbf{x},t) \equiv \rho(\mathbf{x},t)/\bar\rho(t) - 1$ of pressureless matter grows in proportion to the linear growth function $G(t)$ (not to be confused with the gravitational constant $G_{\rm N}$), which follows the differential equation

$$\ddot G + 2H(z)\dot G - \frac{3}{2}\Omega_{\rm m}H_0^2(1+z)^3 G = 0\ . \quad (28.2)$$

To a good approximation, the logarithmic derivative of $G(z)$ is

$$f(z) \equiv -\frac{d\ln G}{d\ln(1+z)} \simeq \left[\Omega_{\rm m}(1+z)^3\frac{H_0^2}{H^2(z)}\right]^\gamma\ , \quad (28.3)$$

where $\gamma \simeq 0.55$ for relevant values of cosmological parameters [21]. In an $\Omega_{\rm m} = 1$ Universe, $G(z) \propto (1+z)^{-1}$, but growth slows when $\Omega_{\rm m}$ drops significantly below unity. One can integrate Eq. (28.3) to get an approximate integral relation between $G(z)$ and $H(z)$, but the full (numerical) solution to Eq. (28.2) should be used for precision calculations. Even in the non-linear regime, the amplitude of clustering is determined mainly by $G(z)$, so observations of non-linear structure can be used to infer the linear $G(z)$, provided one has good theoretical modeling to relate the two.

In modified gravity models the growth rate of gravitational clustering may differ from the GR prediction. A general strategy to test modified gravity, therefore, is to measure both the expansion history and the growth history to see whether they yield consistent results for $H(z)$ or $w(z)$.

28.2.3 *Parameters*

Constraining a general history of $w(z)$ is nearly impossible, because the dark energy density, which affects $H(z)$, is given by an integral over $w(z)$, and distances and the growth factor involve a further integration over functions of $H(z)$. Oscillations in $w(z)$ over a range $\Delta z/(1+z) \ll 1$ are therefore extremely difficult to constrain. It has become conventional to phrase constraints or projected constraints on $w(z)$ in terms of a linear evolution model,

$$w(a) = w_0 + w_{\rm a}(1-a) = w_{\rm p} + w_{\rm a}(a_{\rm p} - a), \quad (28.4)$$

where $a \equiv (1+z)^{-1}$, w_0 is the value of w at $z = 0$, and $w_{\rm p}$ is the value of w at a "pivot" redshift $z_{\rm p} \equiv a_{\rm p}^{-1} - 1$, where it is best constrained by a given set of experiments. For typical data combinations, $z_{\rm p} \simeq 0.5$. This simple parameterization can provide a good approximation to the predictions of many physically motivated models for observables measured with percent-level precision. A widely used "Figure of Merit" (FoM) for dark energy experiments [22] is the projected combination of errors $[\sigma(w_{\rm p})\sigma(w_{\rm a})]^{-1}$. Ambitious future experiments with 0.1–0.3% precision on observables can constrain richer descriptions of $w(z)$, which can be characterized by principal components.

There has been less convergence on a standard parameterization for describing modified gravity theories. Deviations from the GR-predicted growth rate can be described by a deviation $\Delta\gamma$ in the index of Eq. (28.3), together with an overall multiplicative offset relative to the $G(z)$ expected from extrapolating the CMB-measured fluctuation amplitude to low redshift. However, these two parameters may not accurately capture the growth predictions of all physically interesting models. Another important parameter to constrain is the ratio of the gravitational potentials governing space curvature and the acceleration of non-relativistic test particles. The possible phenomenology of modified gravity models is rich [23], which enables many consistency tests but complicates the task of constructing parameterized descriptions.

The more general set of cosmological parameters is discussed elsewhere in this *Review* (Sec. 25), but here we highlight a few that are particularly important to the dark energy discussion.

- The dimensionless Hubble parameter $h \equiv H_0/100\ {\rm km\,s^{-1}\,Mpc^{-1}}$ determines the present day value of the critical density and the overall scaling of distances inferred from redshifts.
- $\Omega_{\rm m}$ and $\Omega_{\rm tot}$ affect the expansion history and the distance-redshift relation.
- The sound horizon $r_{\rm s} = \int_0^{t_{\rm rec}} c_{\rm s}(t)dt/a(t)$, the comoving distance that pressure waves can propagate between $t = 0$ and recombination, determines the physical scale of the acoustic peaks in the CMB and the baryon acoustic oscillation (BAO) feature in low-redshift matter clustering [24].
- The amplitude of matter fluctuations, conventionally represented by the quantity $\sigma_8(z)$, scales the overall amplitude of growth measures such as weak lensing or redshift-space distortions (discussed in the next section).

Specifically, $\sigma_8(z)$ refers to the rms fluctuation of the matter overdensity $\rho/\bar\rho$ in spheres of radius $8\,h^{-1}$Mpc, computed from the linear theory matter power spectrum at redshift z, and σ_8 on its own refers to the value at $z = 0$ (just like our convention for $\Omega_{\rm m}$).

While discussions of dark energy are frequently phrased in terms of values and errors on quantities like $w_{\rm p}$, $w_{\rm a}$, $\Delta\gamma$, and $\Omega_{\rm tot}$, parameter precision is the means to an end, not an end in itself. The underlying goal of empirical studies of cosmic acceleration is to address two physically profound questions:

- 1. Does acceleration arise from a breakdown of GR on cosmological scales or from a new energy component that exerts repulsive gravity within GR?
- 2. If acceleration is caused by a new energy component, is its energy density constant in space and time, as expected for a fundamental vacuum energy, or does it show variations that indicate a dynamical field?

Substantial progress towards answering these questions, in particular any definitive rejection of the cosmological constant "null hypothesis," would be a major breakthrough in cosmology and fundamental physics.

28.3 Observational Probes

We briefly summarize the observational probes that play the greatest role in current constraints on dark energy. Further discussion can be found in other articles of this *Review*, in particular Secs. 25 (Cosmological Parameters) and 29 (The Cosmic Microwave Background), and in Ref. [12], which provides extensive references to background literature. Recent observational results from these methods are discussed in Sec. 28.4.

28.3.1 *Methods, Sensitivity, Systematics*

Cosmic Microwave Background Anisotropies: Although CMB anisotropies provide limited information about dark energy on their own, CMB constraints on the geometry, matter content, and radiation content of the Universe play a critical role in dark energy studies when combined with low-redshift probes. In particular, CMB data supply measurements of $\theta_{\rm s} = r_{\rm s}/D_{\rm A,c}(z_{\rm rec})$, the angular size of the sound horizon at recombination, from the angular location of the acoustic peaks, measurements of $\Omega_{\rm m}h^2$ and $\Omega_{\rm b}h^2$ from the heights of the peaks, and normalization of the amplitude of matter fluctuations at $z_{\rm rec}$ from the amplitude of the CMB fluctuations themselves. The comoparison of the acoustic scale to the diffusion damping scale helps to constrain the expansion rate near recombination. *Planck* data yield a 0.18% determination of $r_{\rm s}$, which scales as $(\Omega_{\rm m}h^2)^{-0.25}$ for cosmologies with standard matter and radiation content. The uncertainty in the matter fluctuation amplitude at the epoch of recombination is 0.5%. Secondary anisotropies, including the integrated Sachs-Wolfe effect, the Sunyaev-Zeldovich (SZ, [25]) effect, and weak lensing of primary anisostropies, provide additional information about dark energy by constraining low-redshift structure growth.

Type Ia Supernovae (SN): Type Ia supernovae, produced by the thermonuclear explosions of white dwarfs, exhibit 10–15% scatter in peak luminosity after correction for light curve duration (the time to rise and fall) and color (which is a diagnostic of dust extinction). Since the peak luminosity is not known *a priori*, supernova surveys constrain ratios of luminosity distances $D_{\rm L}(z)$ at different redshifts. If one is comparing a high-redshift sample to a local calibrator sample measured with much higher precision (and distances inferred from Hubble's law), then one essentially measures the luminosity distance in h^{-1}Mpc, constraining the combination $hD_{\rm L}(z)$. With distance uncertainties of 5–8% per well observed supernova, a sample of around 100 SNe is sufficient to achieve sub-percent statistical precision. The percent-level systematic uncertainties in current samples are dominated by uncertainties associated with photometric calibration and dust extinction corrections and modeling the correlations among supernova luminosity, color, light-curve shape, and host galaxy properties. Another potential systematic is redshift evolution of the supernova population itself, which can be tested by analyzing subsamples grouped by spectral properties or host galaxy properties to confirm that they yield consistent results. Recent analyses of large supernova compilations calibrate these systematic uncertainties internally in parallel with cosmological constraints, with an overall error budget that has similar contributions from systematic and statistical uncertainties (e.g., [26]).

Baryon Acoustic Oscillations (BAO): Pressure waves that propagate in the pre-recombination photon-baryon fluid imprint a characteristic scale in the clustering of matter and galaxies, which appears in the galaxy correlation function as a localized peak at the sound horizon scale $r_{\rm s}$, or in the power spectrum as a series of oscillations. Since observed galaxy coordinates consist of angles and redshifts, measuring this "standard ruler" scale in a galaxy redshift survey determines the angular diameter distance $D_{\rm A}(z)$ and the expansion rate $H(z)$, which convert coordinate separations to comoving distances. Errors on the two quantities are correlated, and in existing galaxy surveys the best determined combination is approximately $D_{\rm V}(z) = [czD^2_{\rm A,c}(z)/H(z)]^{1/3}$. As a useful rule of thumb, a survey that fully samples structures at redshift z over a comoving volume V, and is therefore limited by cosmic variance rather than shot noise, measures $D_{\rm A,c}(z)$ with a fractional error of $0.005(V/10\,{\rm Gpc}^3)^{-1/2}$ and $H(z)$ with a fractional error 1.6–1.8 times higher. The most precise BAO measurements to date come from large galaxy redshift surveys probing $z < 0.8$, and these will be extended to higher redshifts by ongoing and future projects. At redshifts $z > 2$, BAO can also be measured in the Lyman-α forest of intergalactic hydrogen absorption towards background quasars, where the fluctuating absorption pattern provides tens or hundreds of samples of the density field along each quasar sightline. For Lyman-α forest BAO, the best measured parameter combination is more heavily weighted towards $H(z)$ because of strong redshift-space distortions that enhance clustering in the line-of-sight direction. Radio intensity mapping, which maps large-scale structure in redshifted 21-cm hydrogen emission without resolving individual galaxies, offers a potential route to measuring BAO over large volumes at relatively low cost, but the technique is still under development. Photometric redshifts in optical imaging surveys can be used to measure BAO in the angular direction, though the typical distance precision is a factor of 3–4 lower compared to a well sampled spectroscopic survey of the same area, and angular BAO measurements do not directly constrain $H(z)$. BAO distance measurements complement SN distance measurements by providing absolute rather than relative distances (with precise calibration of $r_{\rm s}$ from the CMB) and by having greater achievable precision at high redshift thanks to the increasing comoving volume available. Theoretical modeling suggests that BAO measurements from even the largest feasible redshift surveys will be limited by statistical rather than systematic uncertainties.

Weak Gravitational Lensing: Gravitational light bending by a clustered distribution of matter shears the shapes of higher redshift background galaxies in a spatially coherent manner, producing a correlated pattern of apparent ellipticities. By studying the weak lensing signal for source galaxies binned by photometric redshift (estimated from broad-band colors), one can probe the history of structure growth. "Cosmic shear" weak lensing uses the correlation of source ellipticities to deduce the clustering of intervening matter. "Galaxy-galaxy lensing" (GGL) uses the correlation between a shear map and a foreground galaxy sample to measure the average mass profile around the foreground galaxies, which can be combined with galaxy clustering to constrain total matter clustering. For a specified expansion history, the predicted signals scale approximately as $\sigma_8\Omega_{\rm m}^{\alpha}$, with $\alpha \simeq 0.3$–0.5. The predicted signals also depend on the distance-redshift relation, so weak lensing becomes more powerful in concert with SN or BAO measurements that can pin this relation down independently. The most challenging systematics are shape measurement biases, biases in the distribution of photometric redshifts, and intrinsic alignments of galaxy orientations that could contaminate the lensing-induced signal. Weak lensing of CMB anisotropies is an increasingly powerful tool, in part because it circumvents many of these observational and astrophysical systematics. Predicting the large-scale weak lensing signal is straightforward in principle, but the number of independent modes on large scales is small, and the inferences are therefore dominated by sample variance. Exploiting small-scale measurements, for tighter constraints, requires modeling the effects of complex physical processes such as star formation and feedback on the matter power spectrum. Strong gravitational lensing can also provide constraints on dark energy, either through time delay measurements that probe the absolute distance scale, or through measurements of multiple-redshift lenses that constrain distance ratios. The primary uncertainty for strong lensing constraints is modeling the mass distribution of the lens systems.

Clusters of Galaxies: Like weak lensing, the abundance of massive dark-matter halos probes structure growth by constraining $\sigma_8\Omega_{\rm m}^{\alpha}$, where $\alpha \simeq 0.3$–0.5. These halos can be identified as dense concentrations of galaxies or through the signatures of hot (10^7–10^8 K) gas in X-ray emission or SZ distortion of the CMB. The critical challenge in cluster cosmology is calibrating the relation $P(M_{\rm halo}|O)$ between the halo mass as predicted from theory and the observable O used for cluster identification. Measuring the stacked weak lensing signal from clusters has emerged as a promising approach to achieve percent-level accuracy in calibration of the mean relation, which is required for clusters to remain competitive with other growth probes. This method requires accurate modeling of completeness and contamination of cluster catalogs, projection effects on cluster selection and weak lensing measurements, and possible baryonic physics effects on the mass distribution within clusters.

Redshift-Space Distortions (RSD) and the Alcock-Paczynski (AP) Effect: Redshift-space distortions of galaxy clustering, induced by peculiar motions, probe structure growth by constraining the parameter combination $f(z)\sigma_8(z)$, where $f(z)$ is the growth rate defined by Eq. (28.3). Uncertainties in theoretical modeling of nonlinear gravitational evolution and the non-linear bias between the galaxy and matter distributions currently limit application of the

Table 28.1: A selection of major dark-energy experiments, based on Ref. [27]. Abbreviations in the "Data" column refer to optical (Opt) or near-infrared (NIR) imaging (I) or spectroscopy (S). For spectroscopic experiments, the "Spec-z" column lists the primary redshift range for galaxies (gals), quasars (QSOs), or the Lyman-α forest (LyαF). Abbreviations in the "Methods" column are weak lensing (WL), clusters (CL), supernovae (SN), baryon acoustic oscillations (BAO), and redshift-space distortions (RSD).

Project	Dates	Area/deg^2	Data	Spec-z Range	Methods

method to large scales (comoving separations $r \gtrsim 10\,h^{-1}$Mpc or wavenumbers $k \lesssim 0.2h\,\mathrm{Mpc}^{-1}$). A second source of anisotropy arises if one adopts the wrong cosmological metric to convert angles and redshifts into comoving separations, a phenomenon known as the Alcock-Paczynski effect [28]. Demanding isotropy of clustering at redshift z constrains the parameter combination $H(z)D_\mathrm{A}(z)$. The main challenge for the AP method is correcting for the anisotropy induced by peculiar velocity RSD.

Low Redshift Measurement of H_0: The value of H_0 sets the current value of the critical density $\rho_\mathrm{c} = 3H_0^2/8\pi G_\mathrm{N}$, and combination with CMB measurements provides a long lever arm for constraining the evolution of dark energy. The challenge in conventional H_0 measurements is establishing distances to galaxies that are "in the Hubble flow," *i.e.*, far enough away that their peculiar velocities are small compared to the expansion velocity $v = H_0 d$. This can be done by building a ladder of distance indicators tied to stellar parallax on its lowest rung, or by using gravitational-lens time delays or geometrical measurements of maser data to circumvent this ladder.

28.3.2 *Dark Energy Experiments*

Most observational applications of the above methods now take place in the context of large cosmological surveys, for which constraining dark energy and modified gravity theories is a central objective. Table 28.1 lists a selection of recent, ongoing, and planned dark-energy experiments, taken originally from the Snowmass 2013 Dark Energy Facilities review [27], which focused on projects in which the U.S. has either a leading role or significant participation. References and links to further information about these projects can be found in Ref. [27]. We have adjusted some of the dates in this Table relative to those in Ref. [27] and added the European-led KiloDegree Survey (KiDS). Dates in the Table correspond to the duration of survey observations, and the final cosmological results frequently require 1–3 years of analysis and modeling beyond the end of data taking. We are now at an exciting phase in which most of the "Stage III" experiments (in the parlance of Ref. [29]) have completed observations and in some cases final analysis, and the more powerful "Stage IV" experiments are underway or beginning operations in the near future.

Beginning our discussion with imaging surveys, the Dark Energy Survey (DES) observed 1/8 of the sky to a depth roughly 2 magnitudes deeper than the Sloan Digital Sky Survey (SDSS), enabling weak lensing measurements with much greater statistical precision, cluster measurements calibrated by weak lensing, and angular BAO measurements based on photometric redshifts. With repeated imaging of selected fields, DES identified thousands of Type Ia SNe, which together with spectroscopic follow-up data enabled significant improvements for supernova (SN) cosmology. Cosmological results from weak lensing and galaxy clustering analyses of the 3-year (Y3) DES data set are presented in Ref. [30]. The first cosmological results from the DES supernova survey are presented in Ref. [31], and DES supernovae are incorporated into the Pantheon+ compilation analyzed in Ref. [26]. KiDS carried out an optical imaging survey of about 1000 deg^2, with cosmology results from weak lensing and galaxy clustering reported in Refs. [32, 33]. The Subaru Hyper-Suprime Camera (HSC) collaboration is surveying about 1500 deg^2 with greater depth and sharper image quality than DES; cosmology results from the 3-year HSC data set are presented in Refs. [34, 35]. Beginning in the mid-2020s, the Legacy Survey of Space and Time (LSST) of the Vera Rubin Observatory (VRO) will scan the southern sky to SDSS-like depth every four nights. The co-added data from LSST's decade-long primary survey will provide deep multiband imaging over a wide area, enabling weak lensing, cluster, and photometric BAO studies from billions of galaxies. Additionally, LSST time-domain monitoring will identify and measure light curves for thousands of Type Ia SNe per year.

Turning to spectroscopic surveys, the Baryon Oscillation Spectroscopic Survey (BOSS) and its successor eBOSS used fiber-fed optical spectrographs to map the redshift-space distributions of millions of galaxies and quasars. These 3-dimensional maps enable BAO and RSD measurements, and Lyman-α forest spectra of high-redshift quasars extend these measurements to redshifts $z > 2$. As discussed below, the eBOSS Collaboration has now published BAO and RSD analyses from the final data sets of the BOSS and eBOSS programs. The Dark Energy Spectroscopic Instument (DESI) follows a strategy similar to BOSS/eBOSS but on a much grander scale, using a larger telescope (4-m versus 2.5-m) and a much higher fiber multiplex (5000 versus 1000) to survey an order-of-magnitude more galaxies. DESI began full operations in May 2021, and in its first two years it has measured well over 20 million redshifts; at least 40 million redshifts are expected by the survey end. A new Prime Focus Spectrograph (PFS) for the Subaru telescope will enable the spectroscopic component of SuMIRE, starting in 2024, with the large telescope aperture and wavelength sensitivity that extends to the near-infrared (NIR) allowing it to probe a higher redshift galaxy population than DESI, over a smaller area of sky.

Compared to ground-based observations, space observations afford higher angular resolution and a far lower NIR sky background. The *Euclid* mission and the *Nancy Grace Roman Space Telescope* (formerly *WFIRST*) will exploit these advantages, con-

ducting large area imaging surveys for weak lensing and cluster studies and slitless spectroscopic surveys of emission-line galaxies for BAO and RSD studies. *Roman* will also incorporate an imaging and spectrophotometric supernova (SN) survey, extending to redshift $z \simeq 1.7$. One can roughly characterize the difference between the *Euclid* and *Roman* dark-energy experiments as "wide versus deep," with currently planned survey areas of 15,000 deg^2 and 2200 deg^2, respectively. For weak lensing shape measurements, *Euclid* uses a single wide optical filter, while *Roman* will use three NIR filters. The *Euclid* galaxy redshift survey will cover a large volume at relatively low space density, while the *Roman* survey will provide denser sampling of structure in a smaller volume. *Euclid* was launched successfully in July 2023 and has released first light images; it will begin its 6.5-year main mission survey in late 2023. *Roman* is scheduled for launch in late 2026 or early 2027, and details of its cosmology surveys will likely evolve before operations begin. There are numerous synergies among the LSST, *Euclid*, and *Roman* dark energy programs, as discussed in Ref. [36].

28.4 Current Constraints on Expansion, Growth, and Dark Energy

The last decade has seen dramatic progress in measurements of the cosmic expansion history and structure growth, leading to much tighter constraints on the parameters of dark energy models. CMB data from the *WMAP* and *Planck* satellites and from higher resolution ground-based experiments have provided an exquisitely detailed picture of structure at the recombination epoch and CMB-based measures of low-redshift structure through lensing and SZ cluster counts. Cosmological supernova samples have increased in size from tens to thousands, with continuous coverage from $z = 0$ to $z \simeq 1.4$, alongside major improvements in data quality, analysis methods, and detailed understanding of local populations. BAO measurements have advanced from the first detections to 1–2% precision at multiple redshifts, with increasingly sophisticated methods for testing systematics, fitting models, and evaluating statistical errors. Advances in X-ray, SZ, and weak-lensing observations of large samples of galaxy clusters allow a multi-faceted approach to mass calibration, improving statistical precision but also revealing sources of astrophysical uncertainty. Cluster constraints have been joined, and for the present superseded, by precise matter-clustering constraints from cosmic-shear weak lensing and galaxy-galaxy lensing, and by redshift-space distortion measurements that probe different aspects of structure growth at (presently) lower precision. The precision of low-redshift H_0 measurements has sharpened from the roughly 10% error of the *HST* Key Project [37] to claimed precision as high as 1–2% in recent analyses.

As an illustration of current measurements of the cosmic expansion history, Fig. 28.1 compares distance-redshift measurements from SN and BAO data to the predictions for a flat Universe with a cosmological constant. SN cosmology relies on compilation analyses that try to bring data from different surveys probing distinct redshift ranges to a common scale. Here we use the "joint light curve analysis" (JLA) sample of Ref. [39], who carried out a careful intercalibration of the 3-year Supernova Legacy Survey (SNLS3, [41]) and the full SDSS-II Supernova Survey [3] data in combination with several local supernova samples and high-redshift supernovae from *HST*. For illustration purposes, we have binned the JLA data in redshift and plotted the diagonal elements of the covariance matrix as error bars, and we have converted the SN luminosity distances to an equivalent comoving angular diameter distance. Because the peak luminosity of a fiducial SN Ia is an unknown free parameter, the SN distance measurements could all be shifted up and down by a constant multiplicative factor; cosmological information resides in the relative distances as a function of redshift. The normalization used here corresponds to a Hubble parameter $h = 0.674$.

For the BAO data points in Fig. 28.1 we have used the compilation in Table 3 (the "BAO-only" row) from the summary cosmology paper by the eBOSS collaboration [40], where one can find references for the original data sources. The individual BAO measurements come (in order of increasing redshift) from the SDSS-II main galaxy sample and from luminous red galaxies, emission line galaxies, and quasars mapped by BOSS and eBOSS. The two highest redshift points, both with an effective $z \approx 2.3$, come from the auto-correlation of the Lyman-α forest in high-redshift ($z > 2$) quasars from BOSS and eBOSS and from the cross-correlation of the Lyman-α forest with the quasars themselves. The BAO measurements are converted to absolute distances using the sound horizon scale $r_s = 147.09$ Mpc from *Planck* 2018 CMB data, whose 0.18% uncertainty is small compared to the current BAO measurement errors. For the $z = 0.15$ and $z = 1.5$ data points we have converted values of D_V to $D_{A,c}$, while for other redshifts we use the $D_{A,c}$ determinations measured directly by the transverse BAO scale. The galaxy and Lyman-α forest analyses also measure $H(z)$ at the same redshifts, providing further leverage on expansion history that is not captured in Fig. 28.1.

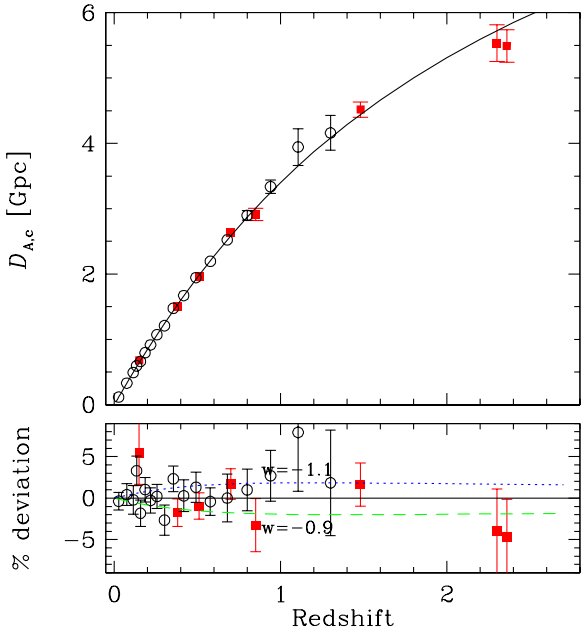

Figure 28.1: Distance-redshift relation measured from Type Ia SNe and BAO compared to the predictions (black curve) of a flat ΛCDM model with $\Omega_m = 0.315$ and $h = 0.674$, the best-fit parameters inferred from *Planck* CMB data [38]. Circles show binned luminosity distances from the JLA SN sample [39], multiplied by $(1+z)^{-1}$ to convert to comoving angular diameter distance. Red squares show BAO distance measurements from the SDSS-II, BOSS, and eBOSS surveys as compiled in Ref. [40]. The lower panel plots residuals from the ΛCDM prediction, with dashed and dotted curves that show the effect of changing w by ±0.1 while all other parameters are held fixed. Note that the SN data points can be shifted up or down by a constant factor to account for freedom in the peak luminosity, while the BAO points are calibrated to 0.2% precision by the sound horizon scale computed from *Planck* data. The errors on the BAO data points are approximately independent, but not entirely so. In the upper panel, error bars are plotted only at $z > 0.7$ to avoid visual confusion. The two Lyman-α forest data points are slightly offset from their effective redshift of $z = 2.33$ for clarity.

The plotted cosmological model has $\Omega_m = 0.315$ and $h = 0.674$, the best-fit values from *Planck* (TT+TE+EE+lowE+lensing) assuming $w = -1$ and $\Omega_{tot} = 1$ [38]. The SN, BAO, and CMB data sets, probing a wide range of redshifts with radically different techniques, are for the most part mutually consistent with the predictions of a flat ΛCDM cosmology. This consistency has held steady or improved as the measurements themselves have improved over the past decade. Dotted and dashed curves in the lower panel of Fig. 28.1 show the effect of changing w by ±0.1 with all other parameters held fixed, which leads to significantly worse agreement with the data. However, such a single-parameter com-

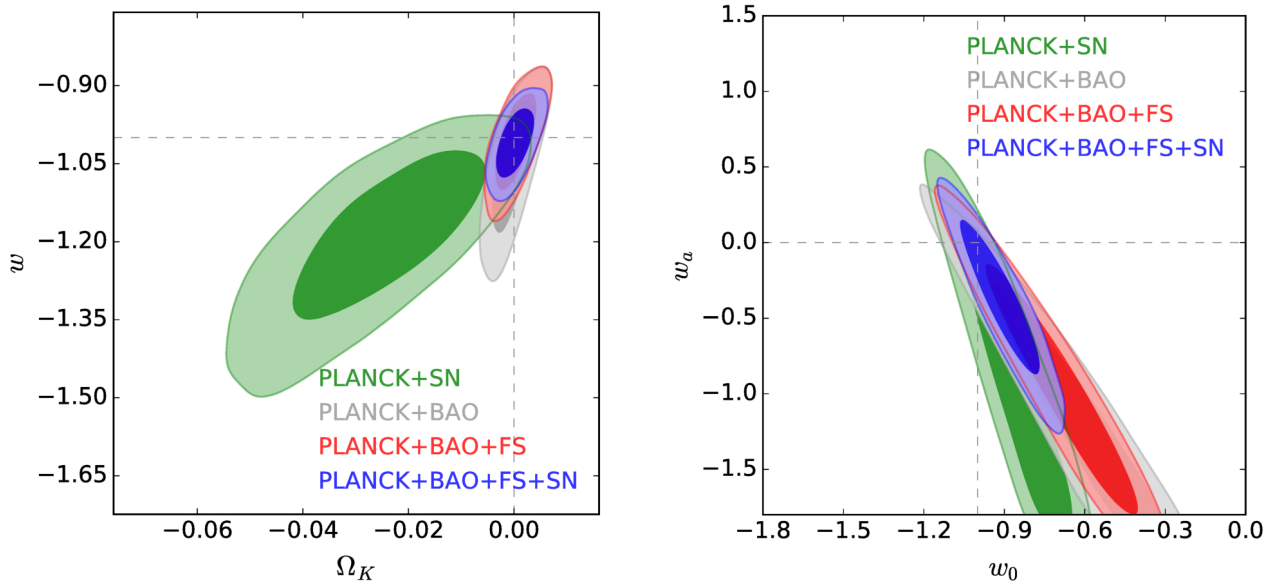

Figure 28.2: Constraints on dark energy model parameters from combinations of CMB, BAO, galaxy clustering, and supernova (SN) data, taken from Ref. [42]. The left panel shows 68% and 95% confidence contours in the `owCDM` model, with constant equation-of-state parameter w and non-zero space curvature $\Omega_K \equiv 1 - \Omega_{\rm tot}$. Green and gray contours show the combination of *Planck* CMB data with SN or BAO data, respectively. Red contours combine CMB, BAO, and the full shape (FS) of redshift-space galaxy clustering. Blue contours add SN data to this combination. The right panel shows confidence contours for the same data combinations in the $\mathtt{w_0w_aCDM}$ model, which assumes a flat Universe and an evolving equation of state with $w(a) = w_0 + w_{\rm a}(1-a)$.

parison does not capture the impact of parameter degeneracies or the ability of complementary data sets to break them, and if one instead forced a match to CMB data by changing h and $\Omega_{\rm m}$ when changing w then the predicted BAO distances would diverge at $z = 0$ rather than converging there. The recent Pantheon+ compilation [43] comprises more than 1500 spectroscopically confirmed Type Ia supernovae from 18 different samples, including those in the JLA. With higher statistical precision and reduced systematic uncertainties, a joint fit of Pantheon+ with CMB and BAO data remains fully compatible with a flat ΛCDM model [26]. Other good representations of recent observational constraints on the cosmic expansion history include Fig. 4 of Ref. [26] for SNIa and Fig. 2 of Ref. [40] for BAO.

Fig. 28.2, taken from Ref. [42], presents constraints on models that allow a free but constant value of w with non-zero space curvature (`owCDM`, left panel) or the evolving equation of state of Eq. (28.4) in a flat Universe ($\mathtt{w_0w_aCDM}$, right panel). Green contours show constraints from the combination of *Planck* 2015 CMB data and the JLA supernova sample. Gray contours show the combination of *Planck* with BAO measurements from BOSS, 6dFGS [44], and SDSS-II [45]. Red contours adopt a more aggressive analysis of the BOSS galaxy data that uses the full shape (FS) of the redshift-space power spectrum and correlation function, modeled via perturbation theory, in addition to the measurement of the BAO scale itself. The full shape analysis improves the constraining power of the data, primarily because measurement of the Alcock-Paczynski effect on sub-BAO scales helps to break the degeneracy between $D_{\rm A,c}(z)$ and $H(z)$. Blue contours show constraints from the full combination of CMB, BAO+FS, and SN data. Supernovae provide fine-grained relative distance measurements with good bin-by-bin precision at $z < 0.7$ (see Fig. 28.1), which is complementary to BAO for constraining redshift evolution of w. In both classes of model, the flat ΛCDM parameters ($w = w_0 = -1$, $\Omega_K = w_{\rm a} = 0$) lie within the 68% confidence contour. Many recent papers feature constraint diagrams analogous to Fig. 28.2, and the constraints within this parameter space have tightened moderately with new data while remaining consistent with flat ΛCDM.

The precision on dark energy parameters depends, of course, on both the data being considered and the flexibility of the model being assumed. For `wCDM`, Ref. [40] find $w = -1.026 \pm 0.033$ using *Planck* CMB data, BAO measurements from SDSS-II and BOSS/eBOSS, and SN measurements from the Pantheon compilation. With the addition of eBOSS RSD data and DES weak lensing and galaxy clustering measurements, they constrain a more flexible model ($\mathtt{ow_0w_aCDM}$) that allows non-zero curvature and an evolving equation-of-state (Eq. 28.4), finding

$$w_{\rm p} = -1.020 \pm 0.032 \tag{28.5}$$

at a pivot redshift $z_{\rm p} = 0.29$, a tight constraint on curvature,

$$1 - \Omega_{\rm tot} = -0.0023 \pm 0.0022\ , \tag{28.6}$$

but only a loose constraint on the evolution parameter,

$$w_{\rm a} = -0.48^{+0.36}_{-0.30}. \tag{28.7}$$

Obtaining a tight constraint on $w_{\rm p}$ in such a flexible cosmological model requires measurements that have complementary sensitivity to its multiple free parameters, and the precision of Eq. (28.5) is a testament to the remarkable improvements in cosmological measurements over the past decade. BAO and FS measurements from DESI will likely supersede those from BOSS/eBOSS in the near future, enabling substantially sharper parameter constraints.

A flat ΛCDM model fit to *Planck* CMB data alone predicts $H_0 = (67.4 \pm 0.5)\ {\rm km\,s^{-1}\,Mpc^{-1}}$ (see Chapter 29 of this *Review*). This prediction and its error bar are sensitive to the assumptions of constant dark energy and a flat Universe. However, by adding BAO and supernova data one can construct an "inverse distance ladder" to measure H_0 precisely, even with a general dark energy model and free curvature [46]. Ref. [40] applies this approach to obtain $H_0 = (68.2 \pm 0.8)\ {\rm km\,s^{-1}\,Mpc^{-1}}$. As discussed in Sec. 25.3.1 of this *Review*, some recent measurements from low-redshift data yield higher values of H_0. For example, Ref. [47] uses a distance ladder based on Cepheid calibration of Type Ia supernova luminosities to find $H_0 = (73.0 \pm 1.0)\ {\rm km\,s^{-1}\,Mpc^{-1}}$, in strong tension with cosmologically inferred values. However, calibrations based on tip-of-the-red-giant-branch (TRGB) distances give lower H_0, consistent with the cosmological values [48].

The tension in H_0 could reflect some combination of statistical flukes and systematic errors in one or more of the data sets employed in these analyses. However, if the resolution lies in new physics rather than measurement errors, then this is probably physics that operates in the *pre-recombination* Universe, rescaling the BAO standard ruler in a way that shifts the ΛCDM and

inverse-distance-ladder values upward. Models with extra relativistic degrees of freedom or dark energy that is dynamically significant in the early Universe can achieve this effect by increasing the early expansion rate, but they are tightly constrained by the damping tail of CMB anisotropies and by the shape of the galaxy power spectrum. These constraints will sharpen significantly with the next generation of CMB experiments, which will improve measurements of polarization anisotropies in the damping tail. A finely tuned model in which early dark energy decays rapidly after recombination can mitigate the tension between CMB data and local H_0 measurements [49], though it still prefers H_0 values below those of Ref. [47]. Numerous theory papers have examined possible physical solutions to the H_0 tension, all of which involve significant modifications to the ΛCDM scenario.

The amplitude of CMB anisotropies is proportional to the amplitude of density fluctuations present at recombination, and by assuming GR and a specified dark energy model one can extrapolate the growth of structure forward to the present day to predict σ_8. Probes of low-redshift structure yield constraints in the (σ_8, Ω_m) plane, which can be summarized in terms of the parameter combination $S_8 \equiv \sigma_8(\Omega_m/0.3)^{0.5}$. As discussed in earlier editions of this *Review*, many weak-lensing and cluster studies to date yield S_8 values lower than those predicted for *Planck*-normalized ΛCDM.

Fig. 28.3, taken from Ref. [50], illustrates the current state-of-play on S_8. (Similar figures with different selections of data can be found in many recent papers and in the previous edition of this *Review*.) The topmost point represents the predicted value and 1σ uncertainty, $S_8 = 0.830 \pm 0.014$, based on a flat ΛCDM model normalized to *Planck* CMB anisotropies. The next two points illustrate a different treatment of the *Planck* data or an alternative CMB data combination. The next four points, in red, illustrate values of S_8 measured from weak lensing of the CMB, again assuming flat ΛCDM. Although the background being lensed is the CMB, this is still a measurement of low-redshift clustering; for multipoles $\ell > 100$ roughly half of the expected signal comes from structure at $z < 2$ and nearly all from $z < 10$ [51].

The remaining points, in blue, represent galaxy-based measurements that probe structure at $z \approx 0.2$–0.8, lower than the peak of the CMB-lensing kernel. The first four come from analyses of the DES, KiDS, and HSC weak lensing surveys, using cosmic shear and galaxy-galaxy lensing combined with galaxy clustering. The three points labeled CX come from cross-correlation of galaxies with CMB lensing maps, which measures the galaxy-matter cross-correlation without using optical weak lensing data. The point labeled GC (fourth from bottom) is inferred from RSD analysis of eBOSS galaxies. Details and references can be found in Sec. 3.4 of Ref. [50].

It is evident from Fig. 28.3 that CMB lensing measurements of S_8 (red points) are in good agreement with predictions based on primary CMB anisotropy (green points), but S_8 values measured from weak lensing at lower redshifts are consistently lower than this prediction (blue points, excluding the GC point derived from RSD). The discrepancy with any individual measurement is only 1–2σ, but the significance is higher if one treats the points derived from separate surveys as statistically independent. For instance, after averaging the two HSC measurements, an unweighted mean of the six low redshift lensing measurements in Fig. 28.3 yields $S_8 = 0.759 \pm 0.009$, where the 1σ error is simply the dispersion of the measurements divided by $\sqrt{N-1} = \sqrt{5}$. With this estimate, the $+3\sigma$ bound $S_8 = 0.786$ lies just below the -3σ bound of the *Planck* prediction, $S_8 = 0.788$. However, several or all of these measurements could be affected by a common systematic error, such as the modeling of galaxy intrinsic alignments or the modeling of structure on non-linear scales. Furthermore, the RSD measurement, which probes similar redshifts with a physically distinct observable, gives a much higher S_8 value, though with an uncertainty large enough to accommodate both the CMB-based prediction and the low-z weak lensing measurement.

The tension between the ΛCDM prediction of S_8 and low redshift weak lensing measurements has persisted through several cycles of this *Review*, without getting obviously stronger or obviously weaker. The sharpest conflicts arise in analyses that extend to non-linear scales and thus have the highest statistical precision, but these analyses are also the most susceptible to modeling uncertainties such as the impact of baryonic dissipation and feedback on the mass distribution. If the tension suggested by Fig. 28.3 represents a true deviation between the clustering growth extrapolated forward from the early Universe and the clustering of matter at late times, then it is difficult to explain by changing the dark energy equation of state because the expansion history is already well constrained by BAO and SN data. Instead, such a deviation might point towards modified gravity, decaying dark matter, or coupling between dark matter and dark energy.

Progress in understanding this tension should come from several directions. Unified analyses of multiple weak lensing data sets are now testing consistency and highlighting the influence of analysis choices on cosmological results [52, 53]. Final data from DES and HSC will have better statistical power, which improves the internal calibration of systematic nuisance parameters and affords greater precision at the larger scales that are easier to model. Improved CMB lensing maps will allow better cross-correlation measurements (the CX points in Fig. 28.3), which avoid some of the main systematics affecting optical weak lensing. DESI data will soon allow the first RSD-based measurements of structure growth at the 1–2% level, which will show whether the low matter clustering amplitude suggested by weak lensing data is also apparent in galaxy peculiar velocities. In modified gravity models these two methods of constraining structure can yield inconsistent results because they respond to different combinations of metric components, but either consistency or inconsistency would provide valuable guidance. Finally, if there is truly a 5–10% discrepancy between CMB-normalized ΛCDM predictions and low-redshift clustering, it should be measured at high statistical significance in *Euclid* weak lensing data and, subsequently, in LSST and *Roman* data.

28.5 Summary and Outlook

Figure 28.2 focuses on model parameter constraints, but to describe the observational situation it is more useful to characterize the precision, redshift range, and systematic uncertainties of the basic expansion and growth measurements. At present, supernova surveys constrain distance ratios at the 1–2% level in redshift bins of width $\Delta z = 0.1$ out to $z \approx 0.8$, with larger but still interesting error bars out to $z \simeq 1.3$. Estimated systematic uncertainties are comparable to statistical uncertainties and include effects of photometric calibration, dust reddening, host-galaxy correlations, and possible evolution of the SN population. BAO surveys have measured the angular diameter distance $D_{A,c}(z)$ and the expansion rate $H(z)$ over the range $0 < z < 2.5$, calibrated to absolute units using the CMB-based value of the sound horizon r_s. For $D_{A,c}(z)$, the final analyses of BOSS/eBOSS achieve precision of 1.6–1.8% in three overlapping redshift bins from luminous galaxies at $z = 0.2 - 1.0$, 2.6% from quasars at $z \approx 1.5$, and 2.9% from the Lyman-α forest at $z \approx 2.3$. For $H(z)$, the precision at the same redshifts is 2.6–3.0%, 4.1%, and 2.1%, respectively. SDSS, DES, KiDS, and HSC have used combinations of weak lensing and galaxy clustering to measure the parameter combination $S_8 = \sigma_8(\Omega_m/0.3)^{0.5}$ with estimated precision of 2–4%, and the cross-correlation of galaxy distributions with CMB lensing maps achieves comparable precision. These estimates account for identified systematic uncertainties, but the measurements and modeling are challenging, and it is possible that the systematics are underestimated. Our simple average of these measurements, treating them as independent and using their dispersion as an empirical estimate of uncertainty, yields an error on the mean of 1.1%. The statistical power of these weak lensing surveys is concentrated at $z \approx 0.2$–0.8, and they provide useful constraints at lower precision on redshift evolution over this range and on individual values of Ω_m and σ_8. RSD measurements constrain the similar parameter combination $f(z)\sigma_8(z)$, but they do not yet have precision competitive with that of weak lensing measurements. Distance-ladder estimates of H_0 now span a small range, using overlapping data but distinct treatments of key steps. Individual studies quote uncertainties as small as 1–2%, with similar statistical and systematic contributions.

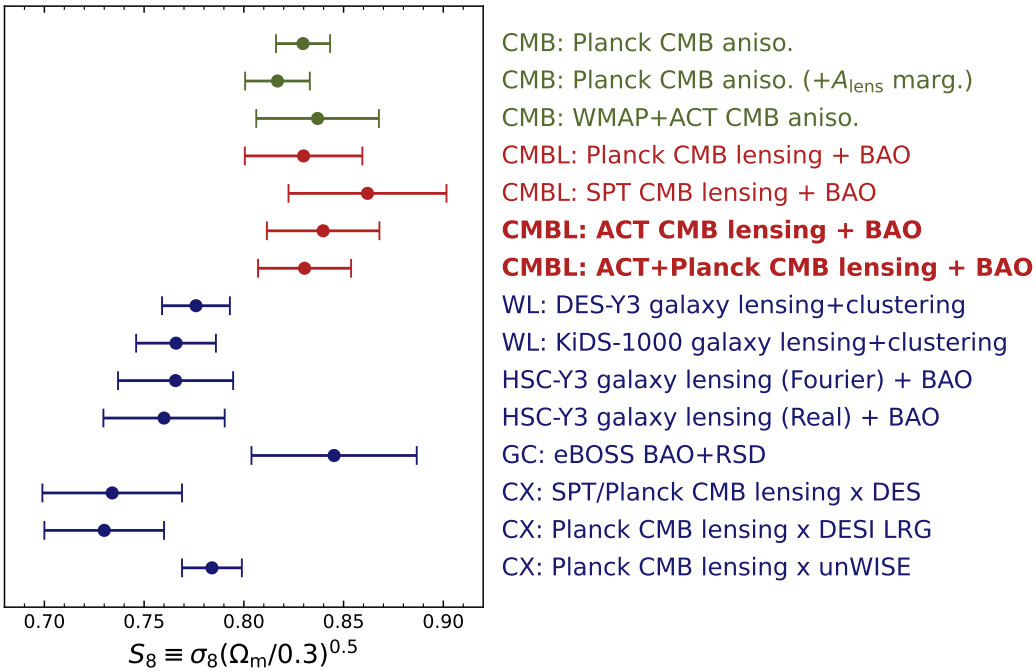

Figure 28.3: Predicted values of $S_8 \equiv \sigma_8(\Omega_m/0.3)^{0.5}$ from a CMB-normalized ΛCDM model (green points), compared to observational estimates from CMB lensing (red points), from optical weak lensing surveys (first four blue points), from galaxy clustering RSD (blue GC point), and from cross-correlation of galaxies with CMB lensing maps (blue CX points). The predictions (green) are extrapolated forward from primary CMB anisotropy measurements that measure structure at $z \approx 1100$. CMB lensing (red) is most sensitive to structure at $z \approx 1-2$, while the galaxy-based data (blue) probe structure at $z \approx 0.2$–0.8. Taken from Ref. [50].

Planck data and higher resolution ground-based experiments now measure CMB anisotropies with exquisite precision; for example, CMB measurements now constrain the physical size of the BAO sound horizon to 0.2% and the angular scale of the sound horizon to 0.01%. A flat ΛCDM model with standard radiation and neutrino content can fit the CMB data and the BAO and SN distance measurements to within their estimated uncertainties. The value of H_0 implied by this model disagrees with recent Cepheid+SNIa distance-ladder measurements of H_0 at a $\sim 5\sigma$ level. This disagreement persists in models that allow non-zero curvature and low redshift evolution of $w(z)$, provided one assumes standard pre-recombination physics to compute the sound horizon r_s. The discrepancy could reflect underestimated systematic uncertainties in the Cepheid-based H_0 estimate, or it could be a sign of new physics in the early Universe that rescales r_s. Improved parallax data from *HST* and *Gaia*, discovery of new SNIa in nearby galaxies, and observing programs on the *James Webb Space Telescope* (*JWST*) are all allowing improvements and systematics checks in the Cepheid distance ladder. It will be equally important to bring the TRGB calibration method to a comparable level of precision and systematics control, and to understand any differences between the Cepheid and TRGB distance scales. Polarization measurements of the CMB damping tail from ground-based experiments will provide increasingly strong constraints on resolutions of the H_0-tension that invoke novel pre-recombination physics.

Extrapolating forward from the CMB anisotropies measured by *Planck* predicts a low redshift value of S_8 that is higher than recent estimates from weak gravitational lensing and galaxy clustering. Comparing the *Planck* central value to the simple average of recent experiments discussed in Sec.28.4 implies a difference of 9.3%: $S_8 = 0.830 \pm 0.014$ versus $S_8 = 0.759 \pm 0.009$. This disagreement could reflect a common systematic that biases several of the weak lensing analyses in the same direction, and it would be weakened if the *Planck* S_8 value were high because of an unlucky statistical fluctuation or a residual systematic. If real, this discrepancy could point towards modified gravity, decaying dark matter, or coupling between dark matter and dark energy.

There are numerous directions for progress over the next several years. Analyses of the final weak lensing data sets from KiDS, HSC, and DES will yield tighter statistical constraints and more complete understanding of systematic uncertainties. Cross-correlation of galaxy maps with higher signal-to-noise CMB lensing maps will provide independent clustering measurements that avoid many of the systematics of optical weak lensing. Collectively these efforts could achieve an unambiguous determination of the amplitude of low redshift matter clustering at the 1–2% level.

The DESI redshift survey already exceeds the size of the SDSS and BOSS/eBOSS surveys, with a factor of ~ 10 increase expected by the end of the 5-year program. DESI will enable the first high precision BAO measurements of expansion history at $z \approx 0.7$–1.4, as well as improved BAO measurements at $z < 0.7$ from denser galaxy samples and at $z > 2$ from much larger Lyman-α forest samples. DESI will also enable the first percent-level measurements of structure growth through RSD. The BAO measurements will complement increasingly precise measurements of the relative distance scale at $z < 1$ from supernova compilations that include the final data from DES. Large galaxy samples will also enable more powerful applications of the Alcock-Paczynski effect and parameter measurements based on voids or higher order clustering statistics.

Euclid, LSST, and *Roman* provide another major leap in observational capabilities. LSST will be the ultimate ground-based optical weak-lensing experiment, measuring several billion galaxy shapes over 20,000 deg^2 of the southern hemisphere sky, and it will detect and monitor many thousands of SNe per year. *Euclid* and *Roman* also have weak lensing as a primary science goal, taking advantage of the high angular resolution and extremely stable image quality achievable from space. Both missions plan large spectroscopic galaxy surveys, which will provide better sampling at high redshifts than DESI or Subaru PFS because of the lower infrared sky background above the atmosphere. *Roman* is also designed to carry out what should be the ultimate supernova cosmology experiment, with deep, high resolution, near-IR observations and the stable calibration achievable with a space platform.

The 2020s will also see dramatic advances in CMB lensing from the Simons Observatory and, potentially, CMB-S4 and/or a space-based probe; cross-correlation with galaxy surveys allows precise tomographic studies of clustering as a function of redshift. While the measurement goals of these next generation facilities overlap, the history of precision cosmology demonstrates the crucial importance of pursuing these measurements with multiple experiments that have distinct challenges and complementary strengths, and with analysis teams that develop ideas independently. The ensemble of experiments will produce cosmological constraints that are much tighter and much more robust to systematic uncertainties than any one of them could achieve individually.

If the anomalies suggested in Fig. 28.3 are real, then these experiments will map out their redshift, scale, and environment dependence in great detail, providing detailed empirical constraints on dynamical dark energy or modified gravity models. If these tensions dissipate with improved measurements, then the experiments of the 2020s will achieve much more stringent tests of the ΛCDM paradigm, with the potential to reveal deviations that are still within the statistical uncertainties of current data. The critical clue to the origin of cosmic acceleration could also come from a surprising direction, such as laboratory, solar-system, or gravitational-wave tests that challenge GR, time variation of fundamental "constants," or anomalous behavior of gravity in some astronomical environments. Experimental advances along these multiple axes could confirm today's relatively simple, but frustratingly incomplete, "standard model" of cosmology, or they could force yet another radical revision in our understanding of energy, or gravity, or the spacetime structure of the Universe.

29. Cosmic Microwave Background

Revised August 2023 by D. Scott (U. of British Columbia) and G.F. Smoot (HKUST; UC Berkeley; LBNL; DIPC; Paris U.).

29.1 Introduction

The energy content in electromagnetic radiation from beyond our Galaxy is dominated by the cosmic microwave background (CMB), discovered in 1965 [1]. Its spectral distribution is well described by a blackbody function with $T = 2.7255\,\mathrm{K}$, which is a principal pillar of the hot Big Bang model for the Universe, with the lack of any observed deviations from a Planckian spectrum constraining physical processes over cosmic history at redshifts $z \lesssim 10^7$ (see earlier versions of this review).

The key information in the CMB sky is extracted from the observed angular variation of its temperature (or intensity) correlations, and to a growing extent polarization [2]. After the first detection of CMB anisotropies by the Cosmic Background Explorer (*COBE*) satellite in 1992 [3], there has been intense activity to map the sky at increasing levels of sensitivity and angular resolution by ground-based and balloon-borne measurements. These were joined in 2003 by the first results from NASA's Wilkinson Microwave Anisotropy Probe (*WMAP*) [4], which were improved upon by analyses of data added every 2 years, culminating in the 9-year results [5]. In 2013 we had the first results [6] from the third generation CMB satellite, ESA's *Planck* mission [7], which were enhanced by results from the 2015 *Planck* data release [8,9], and then the final 2018 *Planck* data release [10,11]. Additionally, CMB anisotropies have been extended to smaller angular scales by ground-based experiments, particularly the Atacama Cosmology Telescope (ACT) [12] and the South Pole Telescope (SPT) [13]. Together these observations have led to a stunning confirmation of the 'Standard Model of Cosmology.' In combination with other astrophysical data, the CMB anisotropy measurements place quite precise constraints on a number of cosmological parameters, and have launched us into an era of precision cosmology. With more than half a century of study of the CMB, the program to map temperature anisotropies is effectively wrapping up, and attention is increasingly focussing on polarization measurements, which promise further tests of fundamental physics.

29.2 CMB Spectrum

It is well-known that the spectrum of the microwave background is very precisely that of blackbody radiation, whose temperature evolves with redshift as $T(z) = T_0(1+z)$ in an expanding Universe. As a direct confirmation of its cosmological origin, this relationship has been tested by measuring the strengths of emission and absorption lines in high-redshift systems (*e.g.*, Ref. [14]).

Measurements of the spectrum are consistent with a blackbody distribution over more than three decades in frequency (there is a claim by ARCADE [15] of a possible unexpected extragalactic emission signal at low frequency, but the interpretation is debated [16]). All viable cosmological models predict a very nearly Planckian spectrum to within the current observational limits. Because of this, measurements of deviations from a blackbody spectrum have received little attention in recent years, with only a few exceptions. However, that situation will likely change as proposed experiments [17] are built that have the potential to dramatically improve early Universe energy release constraints. It now seems feasible to probe spectral distortion mechanisms that are *required* in the standard picture, such as those arising from the damping and dissipation of relatively small-scale primordial perturbations, or the average effect of inverse Compton scattering. A more ambitious goal would be to reach the precision needed to detect the residual lines from the cosmological recombination of hydrogen and helium and hence to test whether conditions at $z \gtrsim 1000$ accurately follow those in the standard picture [18].

29.3 Description of CMB Anisotropies

Observations show that the CMB contains temperature anisotropies at the 10^{-5} level and polarization anisotropies at the 10^{-6} (and lower) level, over a wide range of angular scales. These anisotropies are usually expressed using a spherical harmonic expansion of the CMB sky:

$$T(\theta,\phi) = \sum_{\ell m} a_{\ell m} Y_{\ell m}(\theta,\phi) \tag{29.1}$$

(with the linear polarization pattern written in a similar way using the so-called spin-2 spherical harmonics). Increasing angular resolution requires that the expansion goes to higher multipoles. Because only very weak phase correlations are observed in the CMB sky and no preferred direction is seen, the vast majority of the cosmological information is found in the temperature 2-point function, *i.e.*, the variance as a function only of angular separation. Equivalently, the anisotropy power per unit $\ln \ell$ is $\ell \sum_m |a_{\ell m}|^2 / 4\pi$.

29.3.1 *The Monopole*

The CMB has a mean temperature of $T_\gamma = 2.7255 \pm 0.0006\,\mathrm{K}$ (1σ) [19], which can be considered as the monopole component of CMB maps, a_{00}. Because all mapping experiments involve difference measurements, they are insensitive to this average level; monopole measurements can only be made with absolute temperature devices, such as the FIRAS instrument on the *COBE* satellite [20]. The measured kT_γ is equivalent to $0.234\,\mathrm{meV}$ or $4.60 \times 10^{-10}\, m_e c^2$. A blackbody of the measured temperature has a number density $n_\gamma = (2\zeta(3)/\pi^2)\, T_\gamma^3 \simeq 411\,\mathrm{cm}^{-3}$, energy density $\rho_\gamma = (\pi^2/15)\, T_\gamma^4 \simeq 4.64 \times 10^{-34}\,\mathrm{g\,cm}^{-3} \simeq 0.260\,\mathrm{eV\,cm}^{-3}$, and a fraction of the critical density $\Omega_\gamma \simeq 5.38 \times 10^{-5}$.

29.3.2 *The Dipole*

The largest anisotropy is in the $\ell = 1$ (dipole) first spherical harmonic, with amplitude $3.3621 \pm 0.0010\,\mathrm{mK}$ [10]. The dipole is interpreted to be the result of the Doppler boosting of the monopole caused by the Solar System motion relative to the nearly isotropic blackbody field, as broadly confirmed by measurements of the radial velocities of local galaxies (*e.g.*, Ref. [21]); the intrinsic (non-Doppler) part of the signal is expected to be 2 orders of magnitude smaller (and fundamentally difficult to distinguish). The motion of an observer with velocity $\beta \equiv v/c$ relative to an isotropic Planckian radiation field of temperature T_0 produces a Lorentz-boosted temperature pattern

$$\begin{aligned} T(\theta) &= T_0(1-\beta^2)^{1/2}/(1-\beta\cos\theta) \\ &\simeq T_0 \left[1 + \beta\cos\theta + \left(\beta^2/2\right)\cos 2\theta + \mathrm{O}\left(\beta^3\right)\right]. \end{aligned} \tag{29.2}$$

At every point in the sky, one observes a blackbody spectrum, with temperature $T(\theta)$. The spectrum of the dipole has been confirmed to be the differential of a blackbody spectrum [22]. At higher order there are additional effects arising from aberration and from modulation of the anisotropy pattern, which have also been observed [23].

The implied velocity for the Solar System barycenter is $v = 369.82 \pm 0.11\,\mathrm{km\,s}^{-1}$, assuming a value $T_0 = T_\gamma$, towards $(l,b) = (264.021^\circ \pm 0.011^\circ, 48.253^\circ \pm 0.005^\circ)$ [10]. This Solar System motion implies a velocity for the Galaxy and the Local Group of galaxies relative to the CMB of $v_{\mathrm{LG}} = 620 \pm 15\,\mathrm{km\,s}^{-1}$ towards $(l,b) = (271.9^\circ \pm 2.0^\circ, 29.6^\circ \pm 1.4^\circ)$ [10]; most of the error comes from uncertainty in the velocity of the Solar System relative to the Local Group.

The dipole is a frame-dependent quantity, and one can thus determine the 'CMB frame' (in some sense this is a special frame) as that in which the CMB dipole would be zero. Any velocity of the receiver relative to the Earth and the Earth around the Sun is removed for the purposes of CMB anisotropy studies, while our velocity relative to the Local Group of galaxies and the Local Group's motion relative to the CMB frame are normally removed for cosmological studies. The dipole is now routinely used as a primary calibrator for mapping experiments, either via the time-varying orbital motion of the Earth, or through the cosmological dipole measured by satellite experiments.

29.3.3 *Higher-Order Multipoles*

The variations in the CMB temperature maps at higher multipoles ($\ell \geq 2$) are interpreted as being mostly the result of density

perturbations in the early Universe, manifesting themselves at the epoch of the last scattering of the CMB photons. In the hot Big Bang picture, the expansion of the Universe cools the plasma so that by a redshift $z \simeq 1100$ (with little dependence on the details of the model), the hydrogen and helium nuclei can bind electrons into neutral atoms, a process usually referred to as 'recombination' [24]. Before this epoch, the CMB photons were tightly coupled to the charged baryons, while afterwards they could freely stream towards us. By measuring the $a_{\ell m}$s we are thus learning directly about physical conditions in the early Universe.

A statistically-isotropic sky means that all ms are equivalent, *i.e.*, there is no preferred axis, so that the temperature correlation function between two positions on the sky depends only on angular separation and not orientation. Together with the assumption of Gaussian statistics (*i.e.*, no correlations between the modes), the 2-point function of the temperature field (or equivalently the power spectrum in ℓ) then fully characterizes the anisotropies. The power summed over all ms at each ℓ is $(2\ell+1)C_\ell/(4\pi)$, where $C_\ell \equiv \left\langle |a_{\ell m}|^2 \right\rangle$. Thus, averages of $a_{\ell m}$s over m can be used as estimators of the C_ℓs to constrain their expectation values, which are the quantities predicted by a theoretical model. For an idealized full-sky observation, the variance of each measured C_ℓ (*i.e.*, the variance of the variance) is $[2/(2\ell+1)]C_\ell^2$. This sampling uncertainty (known as 'cosmic variance') comes about because each C_ℓ is χ^2 distributed with $(2\ell+1)$ degrees of freedom for our observable volume of the Universe. For fractional sky coverage, $f_{\rm sky}$, this variance is increased by $1/f_{\rm sky}$ and the modes become partially correlated.

It is important to understand that theories predict the expectation value of the power spectrum, whereas our sky is a *single* realization. Hence, the cosmic variance is an unavoidable source of uncertainty when constraining models; it dominates the scatter at lower ℓs, while the effects of instrumental noise and resolution dominate at higher ℓs [25].

Theoretical models generally predict that the $a_{\ell m}$ modes are Gaussian random fields to high precision, matching the empirical tests, *e.g.*, standard slow-roll inflation's non-Gaussian contribution is expected to be at least an order of magnitude below current observational limits [26]. Although non-Gaussianity of various forms is possible in early Universe models, tests show that Gaussianity is an extremely good simplifying approximation [27]. The only current indications of any non-Gaussianity or statistical anisotropy are some relatively weak signatures at large scales, seen in both *WMAP* [28] and *Planck* data [29], but not of high enough significance to reject the simplifying assumption. Nevertheless, models that deviate from the inflationary slow-roll conditions can have measurable non-Gaussian signatures. So while the current observational limits make the power spectrum the dominant probe of cosmology, it is worth noting that higher-order correlations are tools for constraining otherwise viable theories.

29.3.4 *Angular Resolution and Binning*

There is no one-to-one conversion between multipole ℓ and the angle subtended by a particular spatial scale projected onto the sky. However, crudely speaking, a single spherical harmonic $Y_{\ell m}$ corresponds to angular variations of $\theta \sim \pi/\ell$. CMB maps contain anisotropy information from the size of the map (or in practice some fraction of that size) down to the beam-size of the instrument, σ (the standard deviation of the beam, in radians). One can think of the effect of a Gaussian beam as rolling off the power spectrum with the function $\mathrm{e}^{-\ell(\ell+1)\sigma^2}$.

For less than full sky coverage, the ℓ modes become correlated. Hence, experimental results are usually quoted as a series of 'band powers,' defined as estimators of $\ell(\ell+1)C_\ell/2\pi$ over different ranges of ℓ. Because of the strong foreground signals in the Galactic plane, even 'all-sky' surveys, such as *WMAP* and *Planck*, involve a cut sky. The amount of binning required to obtain uncorrelated estimates of power also depends on the map size.

29.4 Cosmological Parameters

The current 'Standard Model' of cosmology contains around 10 free parameters, only six of which are required to have non-null values (see The Cosmological Parameters—Sec. 25 of this *Review*). The basic framework is the Friedmann-Robertson-Walker (FRW) metric (*i.e.*, a Universe that is approximately homogeneous and isotropic on large scales), with density perturbations laid down at early times and evolving into today's structures (see Big-Bang cosmology—Sec. 22 of this *Review*). The most general possible set of density variations is a linear combination of an adiabatic density perturbation and some isocurvature perturbations. Adiabatic means that there is no change to the entropy per particle for each species, *i.e.*, $\delta\rho/\rho$ for matter is $(3/4)\delta\rho/\rho$ for radiation. Isocurvature means that the set of individual density perturbations adds to zero, for example, matter perturbations compensate radiation perturbations so that the total energy density remains unperturbed, *i.e.*, $\delta\rho$ for matter is $-\delta\rho$ for radiation. These different modes give rise to distinct (temporal) phases during growth, with those of the adiabatic scenario being fully consistent with the data. Models that generate mainly isocurvature type perturbations (such as most topological defect scenarios) are not viable. However, an admixture of the adiabatic mode with up to 1.7% isocurvature contribution (depending on details of the mode) is still allowed [30].

29.4.1 *Initial Condition Parameters*

Within the adiabatic family of models, there is, in principle, a free function describing the variation of comoving curvature perturbations, $\mathcal{R}(\mathbf{x}, t)$. The great virtue of $\mathcal{R}$ is that it is constant in time on super-horizon scales for a purely adiabatic perturbation. There are physical reasons to anticipate that the variance of these perturbations will be described well by a power law in scale, *i.e.*, in Fourier space $\left\langle |\mathcal{R}|_k^2 \right\rangle \propto k^{n_{\rm s}-4}$, where k is wavenumber and $n_{\rm s}$ is the spectral index as usually defined. So-called 'scale-invariant' initial conditions (meaning gravitational potential fluctuations that are independent of k) correspond to $n_{\rm s} = 1$. In inflationary models [31] (see Inflation—Sec. 23 of this *Review*), perturbations are generated by quantum fluctuations, which are set by the energy scale of inflation together with the slope and higher derivatives of the inflationary potential. One generally expects that the Taylor series expansion of $\ln \mathcal{R}_k(\ln k)$ has terms of steadily decreasing size. For the simplest models, there are thus two parameters describing the initial conditions for density perturbations, namely the amplitude and slope of the power spectrum. These can be explicitly defined, for example, through

$$\mathcal{P}_{\mathcal{R}}^2 \equiv k^3 \left\langle |\mathcal{R}|_k^2 \right\rangle / 2\pi^2 \simeq A_{\rm s}\, (k/k_0)^{n_{\rm s}-1}\,, \qquad (29.3)$$

with $A_{\rm s} \equiv \mathcal{P}_{\mathcal{R}}^2(k_0)$ and $k_0 = 0.05\,\mathrm{Mpc}^{-1}$, say. There are other equally valid definitions of the amplitude parameter (see also Secs. 22, 23, and 25 of this *Review*), and we caution that the relationships between some of them can be cosmology-dependent. In slow-roll inflationary models, this normalization is proportional to the combination $V^3/(V')^2$, for the inflationary potential $V(\phi)$. The slope $n_{\rm s}$ also involves V'', and so the combination of $A_{\rm s}$ and $n_{\rm s}$ can constrain potentials.

Inflation generates tensor (gravitational wave) modes, as well as scalar (density perturbation) modes. This property introduces another parameter, measuring the amplitude of a possible tensor component, or equivalently the ratio of the tensor to scalar contributions. The tensor amplitude is $A_{\rm t} \propto V$, and thus one expects a larger gravitational wave contribution in models where inflation happens at higher energies. The tensor power spectrum also has a slope, often denoted $n_{\rm t}$, but since this seems unlikely to be measured in the near future (and there is also a consistency relation with tensor amplitude), it is sufficient for now to focus only on the amplitude of the gravitational wave component. It is most common to define the tensor contribution through r, the ratio of tensor to scalar perturbation spectra at some fixed value of k (*e.g.*, $k = 0.002\,\mathrm{Mpc}^{-1}$ or $k = 0.05\,\mathrm{Mpc}^{-1}$, although it was historically defined in terms of the ratio of contributions at $\ell = 2$). Different inflationary potentials will lead to different predictions, *e.g.*, for 50 e-folds, $\lambda\phi^4$ inflation gives $r = 0.32$ and $m^2\phi^2$ inflation gives $r = 0.16$ (both now strongly disfavored by the data), while other models can have arbitrarily small values of r. In any case, whatever the specific definition, and whether they come from inflation or something else, the 'initial conditions' give rise to a minimum of three parameters, $A_{\rm s}$, $n_{\rm s}$, and r.

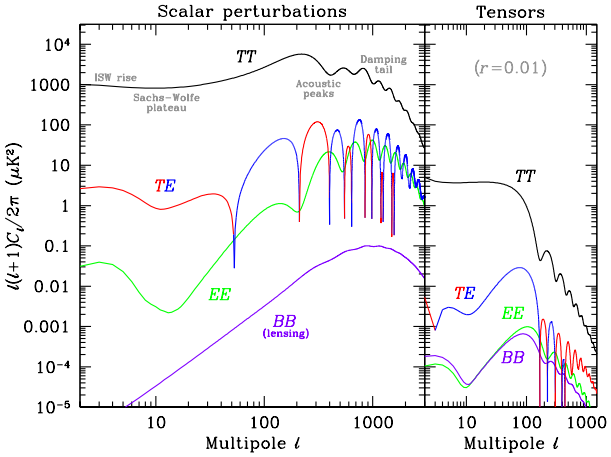

Figure 29.1: Theoretical CMB anisotropy power spectra, using the best-fitting ΛCDM model from *Planck*, calculated using `CAMB`. The panel on the left shows the theoretical expectation for scalar perturbations, while the panel on the right is for tensor perturbations, with an amplitude set to $r = 0.01$ for illustration. Note that the horizontal axis is logarithmic here. For the well-measured scalar TT spectrum, these regions, each covering roughly a decade in ℓ, are labeled as in the text: the ISW rise; Sachs-Wolfe plateau; acoustic peaks; and damping tail. The TE cross-correlation power spectrum changes sign, indicated here by plotting the absolute value, but switching color for the negative parts.

29.4.2 *Background Cosmology Parameters*

The FRW cosmology requires an expansion parameter (the Hubble constant, H_0, often represented through $H_0 = 100\,h\,\mathrm{km\,s^{-1}Mpc^{-1}}$) and several parameters to describe the matter and energy content of the Universe. These are usually given in terms of the critical density, *i.e.*, for species 'x,' $\Omega_\mathrm{x} \equiv \rho_\mathrm{x}/\rho_\mathrm{crit}$, where $\rho_\mathrm{crit} \equiv 3H_0^2/8\pi G$. Since physical densities $\rho_\mathrm{x} \propto \Omega_\mathrm{x}h^2 \equiv \omega_\mathrm{x}$ are what govern the physics of the CMB anisotropies, it is these ωs that are best constrained by CMB data. In particular, CMB observations constrain $\Omega_\mathrm{b}h^2$ for baryons and $\Omega_\mathrm{c}h^2$ for cold dark matter (with $\rho_\mathrm{m} = \rho_\mathrm{c} + \rho_\mathrm{b}$ for the matter sum).

The contribution of a cosmological constant Λ (or other form of dark energy, see Dark Energy—Sec. 28) is usually included, together with a parameter that quantifies the curvature, $\Omega_K \equiv 1 - \Omega_\mathrm{tot}$, where $\Omega_\mathrm{tot} = \Omega_\mathrm{m} + \Omega_\Lambda$. The radiation content, while in principle a free parameter, is precisely enough determined by the measurement of T_γ that it can be considered fixed, making a $< 10^{-4}$ contribution to Ω_tot today.

Astrophysical processes at relatively low redshift can also affect the C_ℓs, with a particularly significant influence during reionization. The Universe became reionized at some redshift z_i, long after recombination, affecting the CMB when it passed through the integrated Thomson-scattering optical depth:

$$\tau = \int_0^{z_\mathrm{i}} \sigma_\mathrm{T} n_\mathrm{e}(z) \frac{dt}{dz} dz, \qquad (29.4)$$

where σ_T is the Thomson cross-section, $n_\mathrm{e}(z)$ is the number density of free electrons (which depends on astrophysics), and dt/dz is fixed by the background cosmology. In principle, τ could be determined from the small-scale matter power spectrum, together with the physics of structure formation and radiative feedback processes; however, because this is a sufficiently intractable calculation, in practice τ needs to be considered as a free parameter.

Thus, we have eight basic cosmological parameters, namely A_s, n_s, r, h, $\Omega_\mathrm{b}h^2$, $\Omega_\mathrm{c}h^2$, Ω_tot, and τ. One can add additional parameters to this list, particularly when using the CMB in combination with other data sets. The next most relevant ones might be: $\Omega_\nu h^2$, the massive neutrino contribution; w ($\equiv p/\rho$), the equation of state parameter for the dark energy; and $dn_\mathrm{s}/d\ln k$, measuring deviations from a constant spectral index. To these 11 one could of course add further parameters describing additional physics, such as details of the reionization process, features in the initial power spectrum, a sub-dominant contribution of isocurvature modes, *etc.*

As well as these underlying parameters, there are other (dependent) quantities that can be obtained from them. Such derived parameters include the actual Ωs of the various components (*e.g.*, Ω_m), the variance of density perturbations at particular scales (*e.g.*, σ_8), the angular scale of the sound horizon (θ_*), the age of the Universe today (t_0), the age of the Universe at recombination, reionization, *etc.* (see The Cosmological Parameters—Sec. 25).

29.5 Physics of Anisotropies

The cosmological parameters affect the anisotropies through the well understood physics of the evolution of linear perturbations within a background FRW cosmology. There are very effective, fast, and publicly-available software codes for computing the CMB temperature, polarization, and matter power spectra, *e.g.*, `CMBFAST` [32], `CAMB` [33], and `CLASS` [34]. These have been tested over a wide range of cosmologies and are considered to be accurate to much better than the 1% level [35], so that numerical errors are less than 10% of the parameter uncertainties for *Planck* [6].

For pedagogical purposes, it is easiest to focus on the temperature anisotropies, before moving to the polarization power spectra. A description of the physics underlying the C_ℓ^{TT}s can be separated into four main regions (the first two combined below), as shown in the top left part of Fig. 29.1.

29.5.1 *The ISW Rise, $\ell \lesssim 10$, and Sachs-Wolfe Plateau, $10 \lesssim \ell \lesssim 100$*

The horizon scale (or more precisely, the angle subtended by the Hubble radius) at last scattering corresponds to $\ell \simeq 100$. Anisotropies at larger scales have not evolved significantly, and hence directly reflect the 'initial conditions.' Temperature variations are $\delta T/T = -(1/5)\mathcal{R}(\mathbf{x}_\mathrm{LSS}) \simeq (1/3)\delta\phi/c^2$, where $\delta\phi$ is the perturbation to the gravitational potential, evaluated on the last-scattering surface (LSS). This is a result of the combination of gravitational redshift and intrinsic temperature fluctuations, and is usually referred to as the Sachs-Wolfe effect [36].

Assuming that a nearly scale-invariant spectrum of curvature (and corresponding density) perturbations was laid down at early times (*i.e.*, $n_\mathrm{s} \simeq 1$, meaning equal power per decade in k), then $\ell(\ell+1)C_\ell \simeq$ constant at low ℓs. This predicted near-flatness is hard to see unless the multipole axis is plotted logarithmically (as in Fig. 29.1, and part of Fig. 29.2).

Time variation of the potentials (*i.e.*, time-dependent metric perturbations) at late times leads to an upturn in the C_ℓs in the lowest several multipoles; any deviation from a total equation of state $w = 0$ has such an effect. So the dominance of the dark energy at low redshift (see Dark Energy—Sec. 28) makes the lowest ℓs rise above the plateau. This is usually called the integrated Sachs-Wolfe effect (or ISW rise), since it comes from the line integral of $\dot{\phi}$; it has been confirmed through correlations between the large-angle anisotropies and large-scale structure [37]. Specific models can also give additional contributions at low ℓ (*e.g.*, perturbations in the dark-energy component itself [38]), but typically these are buried in the cosmic variance.

In principle, the mechanism that produces primordial perturbations could generate scalar, vector, and tensor modes. However, the vector (vorticity) modes decay with the expansion of the Universe. The tensors (transverse trace-free perturbations to the metric) generate temperature anisotropies through the integrated effect of the locally-anisotropic expansion of space. Since the tensor modes also redshift away after they enter the horizon, they contribute only to angular scales above about 1° (see Fig. 29.1). Hence, some fraction of the low-ℓ signal could be due to a gravitational wave contribution, although small amounts of tensors are essentially impossible to discriminate from other effects that might raise the level of the plateau. Nevertheless, the tensors *can* be distinguished using polarization information (see Sec. 29.7).

29.5.2 *The Acoustic Peaks,* $100 \lesssim \ell \lesssim 1000$

On sub-degree scales, the rich structure in the anisotropy spectrum is the consequence of gravity-driven acoustic oscillations occurring before the atoms in the Universe became neutral [39]. Perturbations inside the horizon at last scattering were able to evolve causally and produce anisotropy at the last-scattering epoch, which reflects this evolution. The frozen-in phases of these sound waves imprint a dependence on the cosmological parameters, which gives CMB anisotropies their great constraining power.

The underlying physics can be understood as follows. Before the Universe became neutral, the proton-electron plasma was tightly coupled to the photons, and these components behaved as a single 'photon-baryon fluid.' Perturbations in the gravitational potential, dominated by the dark-matter component, were steadily evolving. They drove oscillations in the photon-baryon fluid, with photon pressure providing most of the restoring force and baryons giving some additional inertia. The perturbations were quite small in amplitude, $\mathcal{O}(10^{-5})$, and so evolved linearly. That means each Fourier mode developed independently, and hence can be described as a driven harmonic oscillator, with frequency determined by the sound speed in the fluid. Thus, the fluid density underwent oscillations, giving time variations in temperature. These combine with a velocity effect, which is $\pi/2$ out of phase and has its amplitude reduced by the sound speed.

After the Universe recombined, the radiation decoupled from the baryons and could travel freely towards us. At that point, the (temporal) phases of the oscillations were frozen-in, and became projected on the sky as a harmonic series of peaks and troughs in power. The main peak is the mode that went through 1/4 of a period, reaching maximal compression. The even peaks are maximal *under*-densities, which are generally of smaller amplitude because the rebound has to fight against the baryon inertia. The troughs, which do not extend to zero power, are partially filled by the Doppler effect because they are at the velocity maxima.

The physical length scale associated with the peaks is the sound horizon at last scattering, which can be straightforwardly calculated. This length is projected onto the sky, leading to an angular scale that depends on the geometry of space, as well as the distance to last scattering. Hence, the angular position of the peaks is a sensitive probe of a particular combination of cosmological parameters. In fact, this characteristic angular scale, θ_*, is the most precisely measured observable, and hence is usually treated as an element of the cosmological parameter set.

One additional effect arises from reionization at redshift $z_{\rm i}$. A fraction of photons (τ) will be isotropically scattered at $z < z_{\rm i}$, partially erasing the anisotropies at angular scales smaller than those subtended by the Hubble radius at $z_{\rm i}$. This corresponds typically to ℓs above about 10, depending on the specific reionization model. The acoustic peaks are therefore reduced by a factor $e^{-2\tau}$ relative to the plateau.

These acoustic peaks were a clear theoretical prediction going back to about 1970 [40]. One can think of them as a snapshot of stochastic standing waves. Since the physics governing them is simple and their structure rich, one can see how they encode extractable information about the cosmological parameters. Their empirical existence started to become clear around 1994 [41], and the emergence, over the following decade, of a coherent series of acoustic peaks and troughs is a triumph of modern cosmology. This picture has received further confirmation with the detection in the power spectrum of galaxies (at redshifts $z \lesssim 1$) of the imprint of these same acoustic oscillations in the baryon component [42], as well as through detection of the expected oscillations in CMB polarization power spectra (see Sec. 29.7).

29.5.3 *The Damping Tail,* $\ell \gtrsim 1000$

The recombination process is not instantaneous, and this imparts a thickness to the LSS. This leads to a damping of the anisotropies at the highest ℓs, corresponding to scales smaller than that subtended by this thickness. One can also think of the photon-baryon fluid as having imperfect coupling, so that there is diffusion between the two components, and hence the amplitudes of the oscillations decrease with time. These effects lead to a damping of the C_ℓs, sometimes called 'Silk damping' [43], which cuts off the anisotropies at multipoles above about 2000. So, although in principle it is possible to measure to ever smaller scales, this becomes increasingly difficult in practice.

29.5.4 *Gravitational Lensing Effects*

CMB gravitational lensing is caused by structures at lower redshift along the line of sight to the LSS. Photon paths are deflected by the lensing potential ϕ, such that $T(\hat{n}) \rightarrow T(\hat{n} + \nabla\phi)$. Typical deflections are around 2 arcmin, but coherent over scales of a degree or so. Lensing preserves surface brightness, which means that a uniform temperature field would be unaffected; however, since there are anisotropies, then several distinct effects can be identified. The C_ℓs are convolved with a smoothing function in a calculable way, partially flattening the peaks and troughs, generating a power-law tail at the highest multipoles, and complicating the polarization signal [44] (see Sec. 29.7.3). Additionally, the effect of lensing on the CMB can be detected through the 4-point function, which correlates temperature gradients and small-scale anisotropies, enabling a map of the lensing potential to be constructed [45],

Lensing is important because it gives an independent estimate of $A_{\rm s}$, breaking the parameter combination $A_{\rm s}e^{-2\tau}$ that is largely degenerate in the temperature anisotropy power spectra. Lensing is an example of a 'secondary effect,' *i.e.*, the processing of anisotropies due to relatively nearby structures (see Sec. 29.9.2). Galaxies and clusters of galaxies give several such effects; all are expected to be of low amplitude, but are increasingly important at the highest ℓs. Such effects carry additional cosmological information (about evolving gravitational potentials in the low-redshift Universe) and are receiving more attention as experiments push to higher sensitivity and angular resolution. The lensing power spectrum (see Sec. 29.8) can potentially constrain dark-energy evolution, while future measurements at high ℓ are a particularly sensitive probe of the sum of the neutrino masses [46].

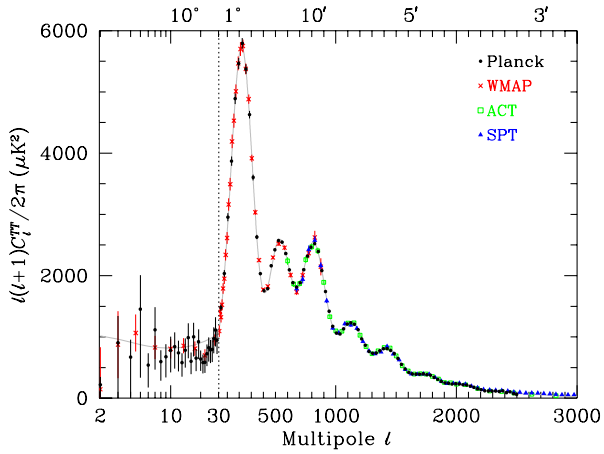

Figure 29.2: CMB temperature anisotropy band-power estimates from the *Planck*, *WMAP*, ACT, and SPT experiments. Note that the widths of the multipole bands vary between experiments and have not been plotted. This figure represents only a selection of the most recent available experimental results, and some points with large error bars have been omitted. At the higher multipoles these band-powers involve subtraction of particular foreground models, and so proper analysis requires simultaneous fitting of CMB and foregrounds over multiple frequencies. The horizontal axis here is logarithmic for the lowest multipoles, to show the Sachs-Wolfe plateau, and linear for the other multipoles. The acoustic peaks and damping region are very clearly observed, with no need for a theoretical line to guide the eye; however, the curve plotted is the best-fit *Planck* ΛCDM model.

29.6 Current Temperature Anisotropy Data

Steady improvement in CMB data quality has led to the present-day cosmological model. The most robust constraints currently available come from *Planck* satellite [47, 48] data (together with constraints from non-CMB cosmological data sets), although

smaller-scale results from the ACT [49] and SPT [50] experiments are beginning to add useful constraining power. We plot power spectrum estimates from these experiments in Fig. 29.2, along with *WMAP* data [5] for comparison (see previous versions of this review for data from earlier experiments). Independent experimental data show consistency, both in maps and in derived power spectra (up to systematic uncertainties in the overall calibration for some experiments). This makes it clear that systematic effects are largely under control.

The band-powers shown in Fig. 29.2 are in very good agreement with a 'ΛCDM' model. As described earlier, several (at least seven) of the peaks and troughs are quite apparent. The original papers present the details on how these estimates were made, on the band-power correlation strengths, and on the information needed for their proper interpretation.

29.7 CMB Polarization

Thomson scattering of an anisotropic radiation field also generates linear polarization and the CMB is predicted to be polarized, at the level of roughly 5% of the temperature anisotropies [51]. Polarization is a spin-2 field on the sky, and the algebra of the modes in multipole space is strongly analogous to spin-orbit coupling in quantum mechanics [52]. The linear polarization pattern can be decomposed in a number of ways, with two quantities required for each pixel in a map, often given as the Q and U Stokes parameters. However, the most intuitive and physical decomposition is a geometrical one, splitting the polarization pattern into a part that comes from a divergence (often referred to as the 'E mode') and a part with a curl (called the 'B mode') [53]. More explicitly, the modes are defined in terms of second derivatives of the polarization amplitude, with the Hessian for the E modes having principal axes in the same sense as the polarization, while the B-mode pattern can be thought of as a 45° rotation of the E-mode pattern. Globally one sees that the E modes have $(-1)^\ell$ parity (like the spherical harmonics), while the B modes have $(-1)^{\ell+1}$ parity.

The existence of this linear polarization allows for six different cross-power spectra to be determined from data that measure the full temperature and polarization anisotropy information. Parity considerations make two of these zero, and we are left with four potential observables, C_ℓ^{TT}, C_ℓ^{TE}, C_ℓ^{EE}, and C_ℓ^{BB} (see Fig. 29.1). Because scalar perturbations have no handedness, the B-mode power spectrum can only be sourced by vectors or tensors. Moreover, inflationary scalar perturbations give only E modes, while tensors generate roughly equal amounts of E and B, therefore the determination of a non-zero B-mode signal is a way to measure the gravitational-wave contribution (and thus potentially derive the energy scale of inflation). However, because the signal is expected to be rather weak, one must first eliminate the foreground contributions and other systematic effects down to very low levels. In addition, CMB lensing creates B modes from E modes, further complicating the extraction of a tensor signal.

As with temperature, the polarization C_ℓs exhibit a series of acoustic peaks generated by the oscillating photon-baryon fluid. The main 'EE' power spectrum has peaks that are out of phase with those in the 'TT' spectrum because the polarization anisotropies are sourced by the fluid velocity. The 'TE' part of the polarization and temperature patterns comes from correlations between density and velocity perturbations on the last-scattering surface, which can be both positive and negative, and is of larger amplitude than the EE signal. There is no polarization Sachs-Wolfe effect, and hence no large-angle (low-ℓ) plateau. However, scattering during a recent period of reionization can create a polarization 'bump' at large angular scales.

Because the polarization anisotropies have only a small fraction of the amplitude of the temperature anisotropies, they took longer to detect. The first measurement of a polarization signal came in 2002 from the DASI experiment [54], which provided a convincing detection, confirming the general paradigm, but of low enough significance that it lent no real constraint to models. Despite dramatic progress since then, it is still the case that polarization data mainly support the basic paradigm, while reducing error bars on parameters by only around 20%. However, there are exceptions to this, specifically in the reionization optical depth, and the potential to constrain primordial gravitational waves. Moreover, the situation is expected to change dramatically as more of the available polarization modes are measured.

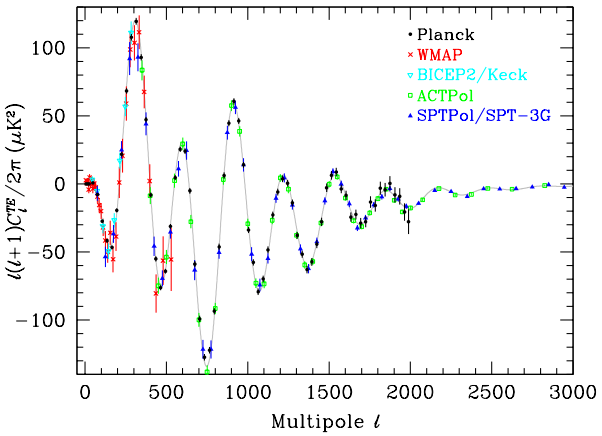

Figure 29.3: Cross-power spectrum band-powers of the temperature anisotropies and E-mode polarization signal from *Planck* (the low multipole data have been binned here), as well as *WMAP*, BICEP2/Keck, ACTPol, and SPTPol/SPT-3G. The curve is the best fit to the *Planck* temperature, polarization, and lensing band-powers. Note that each data point is an average over a band of multipoles, and hence to compare in detail with a model one has to integrate the theoretical curve through the band.

29.7.1 *T–E Power Spectrum*

Because the T and E skies are correlated, one has to measure the TE power spectrum, as well as TT and EE, in order to extract all the cosmological information. This TE signal has now been mapped out extremely accurately by *Planck* [48], and these band-powers are shown in Fig. 29.3, along with those from *WMAP* [55] and BICEP2/Keck [56], with ACTPol [57] and SPTPol/-SPT-3G [58, 59] extending to smaller angular scales. The anti-correlation at $\ell \simeq 150$ and the peak at $\ell \simeq 300$ were the first features to become distinct, but now a whole series of oscillations is clearly seen in this power spectrum (including six or seven peaks and troughs [10]). The measured shape of the cross-correlation power spectrum provides supporting evidence for the general cosmological picture, and also directly constrains the thickness of the last-scattering surface. Because the polarization anisotropies are generated in this scattering surface, the existence of correlations at angles above about a degree demonstrates that there were super-Hubble fluctuations at the recombination epoch. The sign of this correlation also confirms the adiabatic paradigm.

The overall picture of the source of CMB polarization and its oscillations has also been confirmed through tests that average the maps around both temperature hot spots and cold spots [60]. One sees precisely the expected patterns of radial and tangential polarization configurations, as well as the phase shift between polarization and temperature. This leaves no doubt that the oscillation picture is the correct one and that the polarization is coming from Thomson scattering at $z \simeq 1100$.

29.7.2 *E–E Power Spectrum*

Experimental band-powers for C_ℓ^{EE} from *Planck*, *WMAP*, BICEP2/Keck Array [56], ACTPol [57], and SPTPol/SPT-3G [58,59] are shown in Fig. 29.4. Without the benefit of correlating with the temperature anisotropies (*i.e.*, measuring C_ℓ^{TE}), the polarization anisotropies are very weak and challenging to measure. Nevertheless, the oscillatory pattern is now well established and the data closely match the TT-derived theoretical prediction. In Fig. 29.4 one can clearly see the 'shoulder' expected at $\ell \simeq 140$, the first main peak at $\ell \simeq 400$ (corresponding to the first trough in C_ℓ^{TT}), and the series of oscillations that is out of phase with those of the temperature anisotropy power spectrum (including six or seven peaks and troughs [10]).

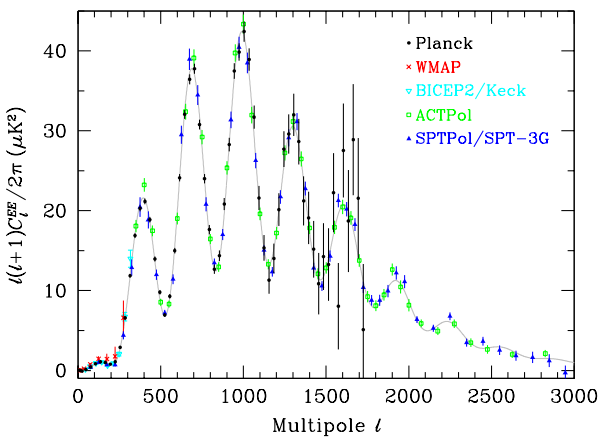

Figure 29.4: Power spectrum of E-mode polarization from *Planck*, together with *WMAP*, BICEP2/Keck, ACTPol, and SPTPol/SPT-3G. Note that some band-powers with larger uncertainties have been omitted and that the unbinned *Planck* low-ℓ data have been binned here. Also plotted is the best-fit theoretical model from *Planck* temperature + polarization + lensing data.

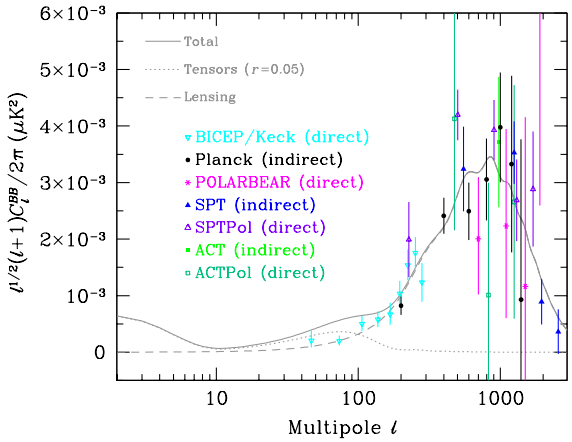

Figure 29.5: Power spectrum of B-mode polarization, including results from the BICEP2/BICEP3/Keck Array combined analysis, *Planck*, POLARBEAR, SPT, and ACT. Note that some of the measurements are direct estimates of B modes on the sky, while others are only sensitive to the lensing signal and come from combining E-mode and lensing potential measurements. Several earlier experiments reported upper limits, which are all off the top of this plot. A logarithmic horizontal axis is adopted here and the y-axis has been divided by a factor of $\sqrt{\ell}$ in order to show all three theoretically expected contributions: the low-ℓ reionization bump; the $\ell \simeq 100$ recombination peak; and the high-ℓ lensing signature. The dotted line is for a tensor (primordial gravitational wave) fraction $r = 0.05$, simply as an example, with all other cosmological parameters set at the best *Planck*-derived values, for which model the expected lensing B modes have also been shown with a dashed line.

Perhaps the most unique result from the polarization measurements is at the largest angular scales ($\ell < 10$) in C_ℓ^{TE} and C_ℓ^{EE}, where there is evidence for an excess signal (not visible in Fig. 29.4) compared to that expected from the temperature power spectrum alone. This is precisely the signal anticipated from an early period of reionization, arising from Doppler shifts during the partial scattering at $z < z_{\rm i}$. The amplitude of the signal indicates that the first stars, presumably the source of the ionizing radiation, formed around $z \simeq 8$ (although the uncertainty is still quite large). This corresponds to a scattering optical depth $\tau \simeq 0.06$, so roughly 6% of CMB photons were re-scattered at the reionization epoch, with the other 94% last scattering at $z \simeq 1100$. However, estimates of the amplitude of this reionization excess have come down since the first measurements by *WMAP* (indicating that this is an extremely difficult measurement to make) and the latest *Planck* results have reduced the value further [11,61].

29.7.3 *B–B Power Spectrum*

The expected amplitude of C_ℓ^{BB} is very small, so measurements of this polarization curl-mode are extremely challenging. The first indication of the existence of the BB signal came from the detection of the expected conversion of E modes to B modes by gravitational lensing, through a correlation technique using the lensing potential and polarization measurements from SPT [62]. However, the real promise of B modes lies in the detection of primordial gravitational waves at larger scales. This tensor signature could be seen either in the 'recombination bump' at around $\ell = 100$ (caused by an ISW effect as gravitational waves redshift away at the last-scattering epoch) or the 'reionization bump' at $\ell \lesssim 10$ (from additional scattering at low redshifts).

Results from the BICEP2 experiment [63] in 2014 suggested a detection of the primordial B-mode signature around the recombination peak. BICEP2 mapped a small part of the CMB sky with the best sensitivity level reached at that time (below 100 nK), but at a single frequency. Higher frequency data from *Planck* indicated that much of the BICEP2 signal was due to dust within our Galaxy, and a combined analysis by the BICEP2, Keck Array, and *Planck* teams [64] indicated that the data are consistent with no primordial B modes. The current constraint from *Planck* data alone is $r < 0.069$ (95% at $k = 0.05\,{\rm Mpc}^{-1}$ [11,61]) using all CMB power spectra, and this limit is reduced to $r < 0.044$ with the inclusion of BICEP2/Keck Array data [61,65]. The most constraining limit is $r < 0.036$ from a combination of BICEP2, Keck Array, and BICEP3 data, using *WMAP* and *Planck* maps to help remove foregrounds [66].

Several experiments are continuing to push down the sensitivity of B-mode measurements, motivated by the enormous importance of a future detection of this telltale signature of inflation (or other physics at the highest energies). A compilation of experimental results for C_ℓ^{BB} is shown in Fig. 29.5, coming from a combination of direct estimates of the B modes (BICEP2/BICEP3/Keck Array [66], POLARBEAR [67], SPTPol [68], and ACTPol [57]) and indirect determinations of the lensing B modes based on estimating the effect of measured lensing on measured E modes (*Planck* [69], SPT [62], and ACT [70]). Additional band-power estimates are expected from these and other experiments in the near future, with the Simons Observatory [71], the so-called 'Stage 4' CMB project [72] and the *LiteBIRD* satellite [73], holding great promise for pushing down to the $r \sim 0.001$ level.

29.8 CMB Lensing Power Spectrum

One further CMB observable is the gravitational lensing deflection, leading to the construction of a map of the lensing potential. The latest *Planck* results [74] give a map that is detected at the $> 40\sigma$ level using a minimum-variance procedure from the 4-point function of temperature and polarization data. From these maps, estimates can be constructed of $C_\ell^{\phi\phi}$, the lensing-potential power spectrum, which is found to be consistent with predictions from the best-fit temperature and polarization model. Recent results from ACT give a power spectrum that has a similar overall signal-to-noise ratio [75] and there are also interesting measurements from SPT [76]. Figure 29.6 plots the *Planck*, ACT, and SPT estimates of $C_\ell^{\kappa\kappa}$, the lensing convergence power spectrum, which is proportional to $\ell^2(\ell+1)^2$ times the potential power spectrum $C_\ell^{\phi\phi}$.

We can think of each sky pixel as possessing three independent quantities that can be measured, namely T, E, and ϕ (and potentially B, if that becomes detectable). Determining the constraining power comes down to counting $Y_{\ell m}$ modes [77], as well as appreciating that some modes help to break particular parameter degeneracies. We have only scratched the surface of CMB lensing so far, and it is expected that future small-scale experiments will

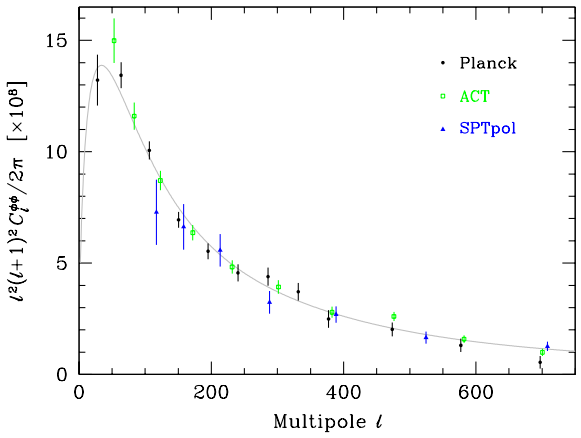

Figure 29.6: Power spectrum measurements for CMB lensing, including selected results from *Planck*, ACT, and SPT. The quantity plotted is the (dimensionless) potential power spectrum, scaled by $\ell^2(\ell+1)^2$ and multiplied by a factor of 10^8 to make the numbers more manageable. Some less reliable measurements have not been plotted. The best-fit *Planck* ΛCDM spectrum is plotted as a gray line.

be able to extract more of the cosmological information. Further constraints can also be derived on the lower-redshift Universe by cross-correlating CMB lensing with other cosmological tracers of large-scale structure. Additionally, small-scale lensing, combined with E-mode measurements, can be used to 'delens' CMB B-mode data, which will be important for pushing down into the $r \lesssim 0.01$ regime [78].

29.9 Complications

There are a number of issues that complicate the interpretation of CMB anisotropy data (and are considered to be *signal* by many astrophysicists), some of which we sketch out below.

29.9.1 *Foregrounds*

The microwave sky contains significant emission from our Galaxy and from extragalactic sources [79]. Fortunately, the frequency dependence of these various sources is in general substantially different from that of the CMB anisotropy signals. The combination of Galactic synchrotron, bremsstrahlung, and dust emission reaches a minimum at a frequency of roughly 100 GHz (or wavelength of about 3 mm). As one moves to greater angular resolution, the minimum moves to slightly higher frequencies, but becomes more sensitive to unresolved (point-like) sources.

At frequencies around 100 GHz, and for portions of the sky away from the Galactic plane, the foregrounds are typically 1 to 10% of the CMB anisotropies. By making observations at multiple frequencies, it is relatively straightforward to separate the various components and determine the CMB signal to the few per cent level. For greater sensitivity, it is necessary to use the spatial information and statistical properties of the foregrounds to separate them from the CMB. Furthermore, at higher ℓs it is essential to carefully model extragalactic foregrounds, particularly the clustering of infrared-emitting galaxies and scattering due to galaxy clusters, which dominate the measured power spectrum as we move into the damping tail.

The foregrounds for CMB polarization follow a similar pattern to those for temperature, but are intrinsically brighter relative to CMB anisotropies. *WMAP* showed that the polarized foregrounds dominate at large angular scales, and that they must be well characterized in order to be discriminated [80]. *Planck* has shown that it is possible to characterize the foreground polarization signals, with synchrotron dominating at low frequencies and dust at high frequencies [81]. On smaller scales there are no strongly-polarized foregrounds, and hence at high multipoles it is in principle easier to measure foreground-free modes in polarization than in temperature. Although foreground contamination will no doubt become more complicated as we push down in sensitivity, making analysis more difficult, for the time being, foreground contamination is not a fundamental limit for CMB experiments.

29.9.2 *Secondary Anisotropies*

With increasingly precise measurements of the primary anisotropies, there is growing theoretical and observational interest in 'secondary anisotropies,' pushing experiments to higher angular resolution and sensitivity. These secondary effects arise from the processing of the CMB due to ionization history and the evolution of structure, including gravitational lensing (which was already discussed) and patchy reionization effects [82]. Additional information can thus be extracted about the Universe at $z \ll 1000$. This tends to be most effectively done through correlating CMB maps with other cosmological probes of structure. Secondary signals are also typically non-Gaussian, unlike the primary CMB anisotropies.

A secondary signal of great current interest is the Sunyaev-Zeldovich (SZ) effect [83], which is Compton scattering ($\gamma e \to \gamma' e'$) of the CMB photons by hot electrons in intergalactic plasma. This creates spectral distortions by transferring energy from the electrons to the photons. It is particularly important for clusters of galaxies, through which one observes a partially Comptonized spectrum, resulting in a decrement at radio wavelengths and an increment in the submillimeter.

The imprint on the CMB sky is of the form $\Delta T/T = y\, f(x)$, with the y parameter being the integral of Thomson optical depth times $kT_e/m_e c^2$ through the cluster, and $f(x)$ describing the frequency dependence. This is simply $x\coth(x/2) - 4$ for a non-relativistic gas (the electron temperature in a cluster is typically a few keV), where the dimensionless frequency $x \equiv h\nu/kT_\gamma$. As well as this 'thermal' SZ effect, there is also a smaller 'kinetic' effect due to the bulk motion of the cluster gas, giving $\Delta T/T \sim \tau(v/c)$, with either sign, but having the same spectrum as the primary CMB anisotropies.

A significant advantage in finding galaxy clusters via the SZ effect is that the signal is largely independent of redshift, so in principle clusters can be found to arbitrarily large distances. The SZ effect can be used to find and study individual clusters, and to obtain estimates of the Hubble constant. There is also the potential to constrain other cosmological parameters, such as the clustering amplitude σ_8 and the equation of state of the dark energy, through counts of detected clusters as a function of redshift. The promise of the method has been realized through detections of clusters purely through the SZ effect by SPT [84], ACT [85], and *Planck* [86]. Results from *Planck* clusters [87] suggest a somewhat lower value of σ_8 than inferred from CMB anisotropies, but there are still systematic uncertainties that might encompass the difference, and a more recent analysis of SPT-detected clusters shows better agreement [88]. Further analysis of scaling relations among cluster properties should enable more robust cosmological constraints to be placed in future, so that we can understand whether this 'tension' might be a sign of new physics.

29.9.3 *Higher-order Statistics*

Although most of the CMB anisotropy information is contained in the power spectra, there will also be weak signals present in higher-order statistics. These can measure any primordial non-Gaussianity in the perturbations, as well as non-linear growth of the fluctuations on small scales and other secondary effects (plus residual foreground contamination of course). There are an infinite variety of ways in which the CMB could be non-Gaussian [26]; however, there is a generic form to consider for the initial conditions, where a quadratic contribution to the curvature perturbations is parameterized through a dimensionless number $f_{\rm NL}$. This weakly non-linear component can be constrained in several ways, the most popular being through measurements of the bispectrum (or 3-point function).

The constraints depend on the shape of the triangles in harmonic space, and it has become common to distinguish the 'local' or 'squeezed' configuration (in which one side is much smaller than the other two) from the 'equilateral' configuration. Other configurations are also relevant for specific theories, such as 'orthogonal' non-Gaussianity, which has positive correlations for

$k_1 \simeq 2k_2 \simeq 2k_3$, and negative correlations for the equilateral configuration. The constraints from the *Planck* team [89] are $f_{\rm NL}^{\rm local} = 1 \pm 5$, $f_{\rm NL}^{\rm equil} = -26 \pm 47$, and $f_{\rm NL}^{\rm ortho} = -38 \pm 24$.

These results are consistent with zero, but are at a level that is now interesting for model predictions. The amplitude of $f_{\rm NL}$ expected is small, so that a detection of $f_{\rm NL} \gg 1$ would rule out all single-field, slow-roll inflationary models. It is still possible to improve upon these *Planck* results, and it certainly seems feasible that a measurement of primordial non-Gaussianity may yet be within reach. *Non*-primordial detections of non-Gaussianity from expected signatures have already been made. For example, the bispectrum and trispectrum contain evidence of gravitational lensing, the ISW effect, and Doppler boosting. For now the primordial signal is elusive, but should it be detected, then detailed measurements of non-Gaussianity will become a unique probe of inflationary-era physics. Because of that, much effort continues to be devoted to honing predictions and measurement techniques, with the expectation that we will need to go beyond the CMB (*e.g.*, 3D galaxy surveys) to dramatically improve the constraints.

29.9.4 *Anomalies*

Several features seen in the *Planck* data [29,60,90] confirm those found earlier with *WMAP* [28], showing mild deviations from a simple description of the sky; these are often referred to as 'anomalies.' One such feature is the lack of power in the multipole range $\ell \simeq 20$–30 [11, 48]. Other examples involve the apparent breaking of statistical anisotropy, caused by alignment of the lowest multipoles, as well as a somewhat excessive cold spot and a power asymmetry between hemispheres. No such feature is significant at more than the roughly 3σ level, and the importance of '*a posteriori*' statistics here has been emphasized by many authors. Since these effects are at large angular scales, where cosmic variance dominates, the results will not increase in significance with more data, although there is the potential for more sensitive polarization measurements to provide independent tests.

29.10 Constraints on Cosmological Parameters

The most striking outcome of the last couple of decades of experimental results is that the standard cosmological paradigm continues to be in very good shape. A large amount of high-precision data on the CMB power spectrum is adequately fit with fewer than 10 free parameters (and only six need non-trivial values). The framework is that of FRW models, which have nearly flat geometry, containing dark matter and dark energy, and with adiabatic perturbations having close to scale-invariant initial conditions.

Within this basic picture, the values of the cosmological parameters can be constrained. Of course, more stringent bounds can be placed on models that cover a restricted parameter space, *e.g.*, assuming that $\Omega_{\rm tot} = 1$ or $r = 0$. More generally, the constraints depend upon the adopted prior probability distributions, even if they are implicit, for example by restricting the parameter freedom or their ranges (particularly where likelihoods peak near the boundaries), or by using different choices of other data in combination with the CMB. As the data become even more precise, these considerations will be less important, but for now we caution that restrictions on model space and choice of non-CMB data sets and priors need to be kept in mind when adopting specific parameter values and uncertainties.

There are some combinations of parameters that fit the CMB anisotropies almost equivalently. For example, there is a nearly exact geometric degeneracy, where any combination of $\Omega_{\rm m}$ and Ω_Λ that provides the same angular-diameter distance to last scattering will give nearly identical C_ℓs. There are also other less exact degeneracies among the parameters. Such degeneracies can be broken when using the CMB results in combination with other cosmological data sets. Particularly useful are complementary constraints from baryon acoustic oscillations, galaxy clustering, the abundance of galaxy clusters, weak gravitational lensing measurements, and Type Ia supernova distances. For an overview of some of these other cosmological constraints, see The Cosmological Parameters—Sec. 25 of this *Review*.

Within the context of a 6-parameter family of models (which fixes $\Omega_{\rm tot} = 1$, $dn_{\rm s}/d\ln k = 0$, $r = 0$, and $w = -1$) the *Planck* results for TT, together with TE, EE, and CMB lensing, yield [11]: $\ln(10^{10} A_{\rm s}) = 3.044 \pm 0.014$; $n_{\rm s} = 0.965 \pm 0.004$; $\Omega_{\rm b}h^2 = 0.02237 \pm 0.00015$; $\Omega_{\rm c}h^2 = 0.1200 \pm 0.0012$; $100\theta_* = 1.04092 \pm 0.00031$; and $\tau = 0.054 \pm 0.007$. Other parameters can be derived from this basic set, including $h = 0.674 \pm 0.005$, $\Omega_\Lambda = 0.685 \pm 0.007$ ($= 1 - \Omega_{\rm m}$) and $\sigma_8 = 0.811 \pm 0.006$ (see also Astrophysical Constants and Parameters—Sec. 2). Somewhat different (although consistent) values are obtained using other data combinations, such as including BAO, supernova, H_0, or weak-lensing constraints (see Sec. 25 of this *Review*). However, the *Planck* results quoted above are currently the best available from CMB data alone. Results from other CMB experiments (*e.g.*, SPT-3G [59]) are consistent and becoming competitive.

The standard cosmological model still fits the data well, with the error bars on the parameters continuing to shrink. Improved measurement of higher acoustic peaks has dramatically reduced the uncertainty in the θ_* parameter, which is now detected at $> 3000\sigma$. The evidence for $n_{\rm s} < 1$ is now at the 8σ level from *Planck* data alone. The value of the reionization optical depth has decreased compared with earlier estimates; it is convincingly detected, but still not at very high significance.

The inferred value of H_0 is smaller than the most precise values derived from the cosmic distance ladder. This parameter tension is discussed more fully in other sections of this *Review*. The CMB anisotropies also provide the most precise estimate of the age of the Universe, with *Planck* giving the value $t_0 = 13.797 \pm 0.023\,{\rm Gyr}$.

Constraints can also be placed on parameters beyond the basic six, particularly when including other astrophysical data sets. Relaxing the flatness assumption, the constraint on $\Omega_{\rm tot}$ is 1.011 ± 0.006. Note that for h, the CMB data alone provide only a very weak constraint if spatial flatness is not assumed. However, with the addition of other data (particularly powerful in this context being a compilation of BAO measurements; see Sec. 25 of this *Review*), the constraints on the Hubble constant and curvature improve considerably, leading to $\Omega_{\rm tot} = 0.9993 \pm 0.0019$ [11].

For $\Omega_{\rm b}h^2$ the CMB-derived value is generally consistent with completely independent constraints from Big Bang nucleosynthesis (see Sec. 24 of this *Review*). Related are constraints on additional neutrino-like relativistic degrees of freedom, which lead to $N_{\rm eff} = 2.99 \pm 0.17$ (including BAO), *i.e.*, no evidence for extra neutrino species.

The tightest published limit on the tensor-to-scalar ratio is $r < 0.036$ (measured at $k = 0.05\,{\rm Mpc}^{-1}$) from BICEP/Keck Array [66]. The detailed limit depends on how other parameters, especially $A_{\rm s}$, $n_{\rm t}$, and $dn_{\rm s}/d\ln k \neq 0$ are restricted. The joint constraints on $n_{\rm s}$ and r allow specific inflationary models to be tested [30,91]. Looking at the $(n_{\rm s}, r)$ plane, this means that $m^2\phi^2$ (mass-term quadratic) inflation is disfavored by the data, as well as $\lambda\phi^4$ (self-coupled) inflation.

The addition of the dark-energy equation of state w adds the partial degeneracy of being able to fit a ridge in (w, h) space, extending to low values of both parameters. This degeneracy is broken when the CMB is used in combination with other data sets, *e.g.*, adding a compilation of BAO and supernova data gives $w = -1.028 \pm 0.031$ [11]. Constraints can also be placed on more general dark energy and modified-gravity models [92]. However, when extending the search space, one needs to be careful not to over-interpret some tensions between data sets as evidence for new physics.

For the reionization optical depth, a reanalysis of *Planck* data in 2016 resulted in a reduction in the value of τ, with the tightest result giving $\tau = 0.055 \pm 0.009$, and the newest analyses giving similar numbers. This corresponds to $z_{\rm i} = 7.8$–8.8 (depending on the functional form of the reionization history), with an uncertainty of ± 0.9 [93]. This redshift is only slightly higher that that suggested from studies of absorption lines in high-z quasar spectra [94] and Ly α-emitting galaxies [95], perhaps hinting that the process of reionization was not as complex as previously suspected. The important constraint provided by CMB polarization, in combination with astrophysical measurements, thus allows us to investigate how the first stars formed and brought about the end of the cosmic dark ages.

29.11 Particle Physics Constraints

CMB data place limits on parameters that are directly relevant for particle physics models. For example, there is a limit on the sum of the masses of the neutrinos, $\Sigma m_\nu < 0.12\,\mathrm{eV}$ (95%) [11] coming from *Planck* together with BAO measurements (although limits are weaker when considering both $N_{\rm eff}$ and Σm_ν as free parameters). This assumes the usual number density of fermions, which decoupled when they were relativistic. The limit is tantalizingly only a factor of a few higher than the minimum value coming from neutrino mixing experiments (see Neutrino Mixings—Secs. 14 and 26). As well as being an indirect probe of the neutrino background, *Planck* data also require that the neutrino fluid has perturbations, *i.e.*, that it possesses a sound speed $c_{\rm s}^2 \simeq 1/3$, as expected [9].

The current suite of data suggests that $n_{\rm s} < 1$, with a best-fitting value about 0.035 below unity. This is already quite constraining for inflationary models, particularly along with r limits. There is no current evidence for running of the spectral index, with $dn_{\rm s}/d\ln k = -0.004 \pm 0.007$ from *Planck* alone [11] (with a similar value when BAO data are included), although this is less of a constraint on models. Similarly, primordial non-Gaussianity is being probed to interesting levels, although tests of simple inflationary models will only come with significant reductions in uncertainty.

The large-angle anomalies, such as the hemispheric modulation of power and the dip in power at $\ell \simeq 20$–30, have the potential to be hints of new physics. Such effects might be expected in a Universe that has a large-scale power cut-off, or anisotropy in the initial power spectrum, or is topologically non-trivial. However, cosmic variance and *a posteriori* statistics limit the significance of these anomalies, absent the existence of a model that naturally yields some of these features (and ideally also predicting other phenomena that can be tested).

Constraints on 'cosmic birefringence' (*i.e.*, rotation of the plane of CMB polarization that generates non-zero TB and EB power) can be used to place limits on theories involving parity violation, Lorentz violation, or axion-photon mixing [96].

It is possible to place limits on additional areas of physics [97], for example annihilating dark matter [9, 9], primordial magnetic fields [98], and time variation of the fine-structure constant [99], as well as the neutrino chemical potential, a contribution of warm dark matter, topological defects, or physics beyond general relativity. Further particle physics constraints will follow as the smaller-scale and polarization measurements continue to improve.

The CMB anisotropy measurements precisely pin down physics at the time of last-scattering, and so any change of physics can be constrained if it affects the relevant energies or timescales. Future, higher sensitivity measurements of the CMB frequency spectrum will push the constraints back to cover energy injection at much earlier times ($\sim 1\,\mathrm{year}$). Comparison of CMB and BBN observables extend these constraints to timescales of order seconds, and energies in the MeV range. And to the extent that inflation provides an effective description of the generation of perturbations, the inflationary observables may constrain physics at GUT-type energy scales.

More generally, careful measurement of the CMB power spectra and non-Gaussianity can in principle put constraints on physics at the highest energies, including ideas of quantum gravity, string theory, extra dimensions, colliding branes, *etc.* At the moment any calculation of predictions appears to be far from definitive. However, there is a great deal of activity on implications of fundamental theories for the early Universe, and hence a chance that there might be observational implications for specific scenarios.

29.12 Fundamental Lessons

More important than the precise values of parameters is what we have learned about the general features that describe our observable Universe. Beyond the basic hot Big Bang picture, the CMB has taught us that:

- the (observable) Universe is very close to isotropic;
- the Universe recombined at $z \sim 1000$ and started to become ionized again at $z \sim 10$;
- the geometry of the Universe is close to flat;
- both dark matter and dark energy are required;
- gravitational instability is sufficient to grow all of the observed large structures in the Universe;
- topological defects were not important for structure formation;
- there were 'synchronized' super-Hubble modes generated in the early Universe;
- the initial perturbations were predominantly adiabatic in nature;
- the primordial perturbation spectrum has a slightly red tilt;
- the perturbations had close to Gaussian (*i.e.*, maximally random) initial conditions.

These features form the basis of the cosmological standard model, ΛCDM, for which it is tempting to make an analogy with the Standard Model of particle physics (see earlier Sections of this *Review*). In comparison, the cosmological model is much further from any underlying 'fundamental theory,' which might ultimately provide the values of the parameters from first principles. Nevertheless, any genuinely complete 'theory of everything' must include an explanation for the values of these cosmological parameters in addition to the parameters of the Standard Model of particle physics.

29.13 Future Directions

Given the significant progress in measuring the CMB sky, which has been instrumental in tying down the cosmological model, what can we anticipate for the future? There will be a steady improvement in the precision and confidence with which we can determine the appropriate cosmological parameters. Ground-based experiments operating at smaller angular scales will continue to place tighter constraints on the damping tail, lensing, and cross-correlations. New polarization experiments at small scales will probe further into the damping tail, without the limitation of extragalactic foregrounds. And polarization experiments at large angular scales will push down the limits on primordial B modes.

Planck, the third generation CMB satellite mission, was launched in May 2009, and produced a large number of papers, including a set of cosmological studies based on the first two full surveys of the sky (accompanied by a public release of data products) in 2013, a further series coming from analysis of the full mission data release in 2015 (eight surveys for the Low Frequency Instrument and five surveys for the High Frequency Instrument), and a third series derived from a final analysis of the 2018 data release, including full constraints from polarization data. *Planck* data currently dominate constraints on models, but that situation will change soon.

A set of cosmological parameters is now known to percent-level accuracy, and that may seem sufficient for many people. However, we should certainly demand more of measurements that describe *the entire observable Universe!* Hence a lot of activity in the coming years will continue to focus on determining those parameters with increasing precision. This necessarily includes testing for consistency among different predictions of the cosmological Standard Model, and searching for signals that might require additional physics.

A second area of focus will be the smaller-scale anisotropies and 'secondary effects.' There is a great deal of information about structure formation at $z \ll 1000$ encoded in the CMB sky. This may involve higher-order statistics and cross-correlations with other large-scale structure tracers, as well as spectral signatures, with many experiments targeting the galaxy cluster SZ effect, for example. The current status of CMB lensing is similar (in terms of total signal-to-noise) to the quality of the first CMB anisotropy measurements by *COBE*, and thus we can expect that experimental probes of lensing will improve dramatically in the coming years. All of these investigations can provide constraints on the dark-energy equation of state, for example, which is a major area of focus for several future cosmological surveys at optical wavelengths. CMB lensing also promises to yield a measurement of the sum of the neutrino masses.

A third direction is increasingly sensitive searches for specific signatures of physics at the highest energies. The most promising

of these may be the primordial gravitational wave signals in C_ℓ^{BB}, which could be a probe of the $\sim 10^{16}$ GeV energy range. There are several experiments underway or being developed that are designed to search for the polarization B modes, with the most ambitious being CMB-S4 on the ground and *LiteBIRD* in space. Additionally, non-Gaussianity holds the promise of constraining models beyond single-field slow-roll inflation.

Anisotropies in the CMB have proven to be the premier probe of cosmology and the early Universe. Theoretically the CMB involves well-understood physics in the linear regime, and is under very good calculational control. A substantial and improving set of observational data now exists. Systematics appear to be under control and are not currently a limiting factor. And so for the next several years we can expect an increasing amount of cosmological information to be gleaned from CMB anisotropies, with the prospect also of some genuine surprises.

30. Cosmic Rays

Revised March 2024 by J. Alvarez-Muñiz (Santiago de Compostela U.), Z. Cao (IHEP Beijing), U.F. Katz (Erlangen U.), P. Mertsch (TTK, RWTH) and C. Spiering (DESY, Zeuthen).

30.1 Theory

Cosmic rays (CRs) are a non-thermal population of particles that pervade the Universe. Their salient characteristics can be inferred from their major observational properties: spectrum, composition and arrival directions. For charged CRs, the energies extend from tens of MeV to close to 1 ZeV, the intensity is $\sim 10^4\,\mathrm{m^{-2}\,s^{-1}\,sr^{-1}}$ above 1 GeV, but the differential spectrum falls steeply with energy E, following a power-law dependence $E^{-\gamma}$. The most striking spectral features are the "knee" at a few PeV where the spectral index γ changes from ~ 2.7 to ~ 3, the "second knee" at ~ 100 PeV with a change to ~ 3.3 and the "ankle" at a few EeV where γ changes to ~ 2.5. The flux is largely suppressed above a few tens of EeV. (More detailed discussion of spectral features can be found below in Secs. 30.2.1 and 30.2.2.) Charged CRs are composed mostly of protons, helium, and other nuclei, as well as electrons, positrons and anti-protons. The arrival directions are mostly isotropic, but below and around the knee interesting $\mathcal{O}(10^{-4}\ldots10^{-3})$ anisotropies due to the distribution of sources and properties of the Galactic magnetic fields have been observed, reaching $\sim\mathcal{O}(10^{-1})$ at the highest energies. Gamma-rays can be resolved into those from astrophysical sources (~ 6660 [36] above 50 MeV, $\sim$ 300 [37, 38] at TeV energies), plus diffuse fluxes of galactic and extra-galactic origin, predominantly showing power-law dependence on energy. The observation of high-energy neutrinos has opened a new window; while the distribution is largely isotropic, evidence for two extra-galactic sources as well as for a contribution from the galactic plane has been found. The energy spectra of charged CRs, diffuse gamma-rays and neutrinos are shown in Fig. 30.1. Combined observations of charged CRs, gamma-rays and neutrinos as well as gravitational waves (see Sec. 21.2.3) allow for valuable insights into the most extreme astrophysical environments and is referred to as multi-messenger astrophysics. Adding the contribution from all species results in the all-particle spectrum. While it was believed for a long-time that it was a featureless power law up to the knee at a few PeV, it has now been recognized that it has much more structure, mirroring the features in the individual species. These features carry important information on the acceleration and transport of CRs.

The energy variables used are kinetic energy E, kinetic energy per nucleon, $E_\mathrm{n} = E/A$ for a particle of mass number A, or rigidity $\mathcal{R} \equiv pc/(Ze)$ (given in units of volt) for a particle of charge number Z, p being the momentum of the particle; the term rigidity refers to the resistance against deflections in a magnetic field B: particles of low (high) rigidity have small (large) gyroradii $r_\mathrm{g} = \mathcal{R}/B$. Kinetic energy is closely related to the experimental signatures of a calorimetric instrument, while rigidity is the most natural one for a spectrometric one. Note also that relativistic nuclei suffer little energy losses and their transport is prescribed by magnetic fields, thus it can only depend on rigidity. The *intensity* J of CRs, also called the diffuse flux, is defined through the differential number $\mathrm{d}N$ of particles with energy in the interval $[E, E+\mathrm{d}E]$, crossing the area $\mathrm{d}A$ from a solid angle $\mathrm{d}\Omega$ in the time $\mathrm{d}t$: $\mathrm{d}N = J\,\mathrm{d}E\,\mathrm{d}A\,\mathrm{d}\Omega\,\mathrm{d}t$. Its isotropic part is related to the differential density $\psi = (4\pi/v)J$, v being the particle speed and to the phase-space density f as $J = p^2 f$. Note that the intensity can be also defined in reference to particle energy per nucleon or rigidity. To stress this, often the intensity is written as $\mathrm{d}J/\mathrm{d}E$, $\mathrm{d}J/\mathrm{d}E_\mathrm{n}$ or $\mathrm{d}J/\mathrm{d}\mathcal{R}$.

In the detection of CRs, two classes of techniques are distinguished [39]. *Direct observations*, see Sec. 30.2.1, make use of the interactions of CRs in particle physics detectors (e.g. trackers, spectrometers and calorimeters). Given the limited exposures of such instruments and the steeply falling spectra, this is currently only realistic below ~ 100 TeV. In *indirect observations*, see Sec. 30.2.2, showers of secondary particles initiated by charged CR interactions in natural materials (e.g. air, water or ice) are detected through fluorescence, air-Cherenkov, water-Cherenkov or scintillation effects. This allows for large instrumented surfaces or volumes. Historically, the two classes of techniques have been employed by two separate communities and we structure the review of charged CRs accordingly. For detection of gamma-rays, direct observations are relevant mostly below hundreds of GeV; for gamma-rays of higher energies and neutrinos of essentially all energies, indirect observations are required.

Charged CRs are deflected by magnetic fields and so generally speaking the observed events do not point back to sources. CRs can however reach the earth from galactic and even cosmological distances. Between hundreds of MeV and at least a few PeV, CRs are believed to be of galactic origin; above a few EeV, the sources are most likely extra-galactic. If CRs with energies in excess of $\sim$ 1 EeV came from sources in the Galactic disk, the angular distribution at Earth would be very anisotropic, which is at variance with observations. And if CRs below $\sim$ 1 PeV were dominantly of extra-galactic origin, this would result in a gamma-ray flux from objects like the Large Magellanic Cloud exceeding observations [40]. Direct and indirect observations therefore also largely refer to galactic/extra-galactic sources, respectively. CRs with energies in excess of 1 EeV are referred to as ultra-high energy cosmic rays (UHECRs).

Sources of non-thermal electromagnetic radiation are routinely observed, see Sec. 30.3, yet the dominant source of locally measured CRs have not been unambiguously identified. Source candidates are typically associated with endpoints of stellar evolution or supermassive black holes that release large amounts of gravitational or rotational energy [41]. In the Galaxy, the prime candidates are supernova remnants [42] where particles can be shock-accelerated by their blast waves [43]. Other candidates are star cluster winds [44,45], stellar wind binaries, micro quasars [46] (a source powered by accretion from a donor star onto a stellar mass black hole) or even the Galactic Center [47]. The candidate sources for extra-galactic CRs are Active Galactic Nuclei (AGN) [48], specifically blazars and radio galaxies, gamma-ray bursts [49], starburst galaxies [50, 51], pulsars [52] and magnetars [53]. These objects exhibit power-law spectra in electromagnetic radiation, albeit in limited wavelength ranges. The acceleration mechanisms considered in the literature are shock acceleration [43], stochastic acceleration [54], and reconnection [55]. A fundamental constraint on the maximum energy, the so-called Hillas criterion [56], follows from the requirement that the gyroradius must be smaller than the source size.

In the Milky Way, the dominant process in CR transport is diffusion as evidenced by the small anisotropies in CR arrival directions and by certain abundance ratios of nuclear species. This diffusive transport bears some resemblance with heat transport in that it smooths the spatial distribution of CRs. However, in contrast to heat transport, CR diffusion is not due to collisions, but interactions with turbulent magnetic fields. Generally, CRs interact "resonantly" with plasma waves, that is they get affected only by waves with a wavelength similar to the gyroradius of the CR particle. If this condition is satisfied, a CR particle will be deflected by the Lorentz force. Many random deflections lead to a random walk in space, that is diffusion [57].

There is a number of other processes contributing to the transport of charged CRs: momentum losses, i.e. radiative losses for electrons and positrons [59], ionization and Coulomb losses for nuclei, electrons and positrons [60]; spallation, that is production of (mostly) lighter nuclei by inelastic collisions of heavier ones; and other inelastic collisions, e.g. the production of light mesons. We note that progress in the study of CR transport is often limited by the nuclear interactions since many cross-sections are poorly known, if at all [61]. The various processes are encoded in the CR transport equation [62], also referred to as the Parker transport equation [63] in the space physics community. This partial differential equation is supplemented by the boundary condition of free escape on the surface of the (often cylindrical) confinement volume. Only in simplified cases can this equation be solved analytically. The most instructive case is the 1D approximation where only the direction perpendicular to the Galactic disk is retained. The solution differs for *primaries*, that is species present and accelerated in the CR sources, and *secondaries*, which are not present in CR sources, but produced by inelastic collisions of primaries in the gaseous disk of

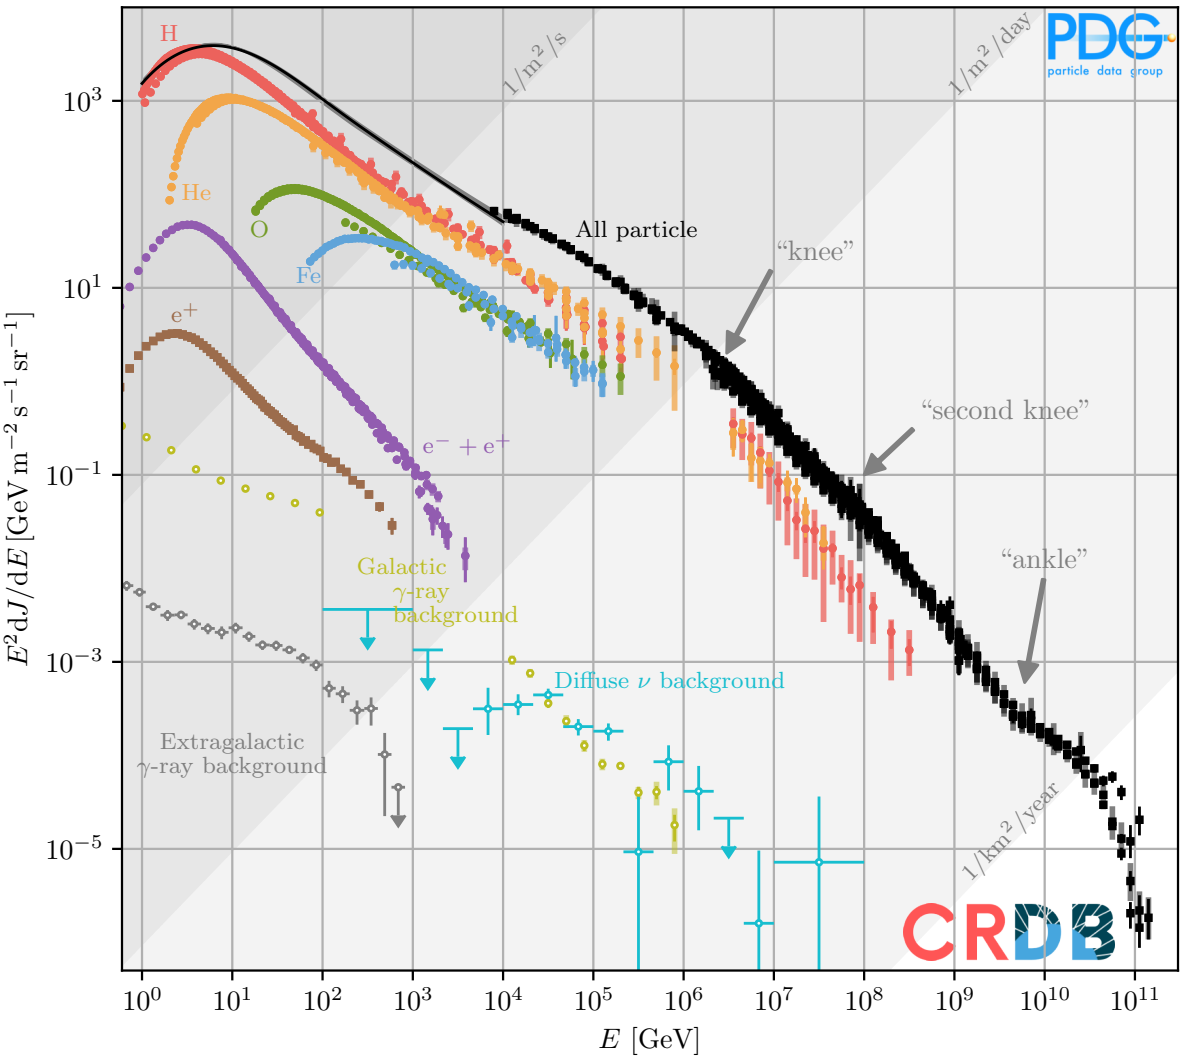

Figure 30.1: The spectrum of cosmic rays (CRs). Shown are measurements of the intensity of charged and neutral CRs, multiplied by kinetic energy squared. The data for the charged CRs [1–30] have been extracted from the Cosmic Ray Database (CRDB) [31]. Below 10^4 GeV, the all-particle spectrum is the sum of spline fits of the most important nuclear species. The diffuse γ-ray fluxes have been extracted from Refs. [32–34], measurements of the diffuse neutrino background from Ref. [35]. Energy-integrated intensities are indicated by the various diagonal lines.

the Galaxy. Diffusion in the Galaxy, characterized by a diffusion coefficient $\kappa(\mathcal{R})$, modifies the source spectrum $q(\mathcal{R})$, resulting in the steady-state spectrum $\psi(\mathcal{R}) \propto q(\mathcal{R})/\kappa(\mathcal{R})$. As the production spectrum of secondaries follows the steady-state spectrum of primaries, $q_2(\mathcal{R}) \propto \psi_1(\mathcal{R})$, the secondary steady-state spectrum is $\psi_2(\mathcal{R}) \propto q_2(\mathcal{R})/\kappa(\mathcal{R}) \propto \psi_1(\mathcal{R})/\kappa(\mathcal{R})$. As $\kappa(\mathcal{R})$ grows with $\mathcal{R}$, secondary spectra $\psi_2(\mathcal{R})$ fall more quickly with rigidity than primary spectra $\psi_1(\mathcal{R})$. Unstable secondaries provide additional constraints on the gas density and residence time of CRs. The solution of the transport equation in more realistic setups requires numerical codes [64–67].

Protons (iron nuclei) with energies in excess of $\sim$ 1 EeV ($\sim$ 26 EeV) in a micro-Gauss magnetic field have gyroradii larger than the typical kiloparsec scales of the Galaxy, thus they cannot be confined. Their directions are however affected by so-called small-angle scattering, both in the Milky Way and possibly outside. As far as their spectrum and composition is concerned, protons and heavier nuclei suffer from inelastic collisions with the CMB and the extra-galactic background light at the highest energies. For protons above 10 EeV, photo-pion production limits the propagation distances to $\sim$ 100 Mpc; for nuclei, heavier ones photo-disintegrate to lighter ones, also limiting their spatial reach. Both processes can lead to a suppression of the flux known as the GZK effect [68, 69] and produce secondary gamma-rays and neutrinos. Other secondary particles include neutral and charged pions, which ultimately decay to photons, electrons, positrons and neutrinos, and electron-positron pairs which can also initiate a cascade of photons and lower energy electrons and positrons. The stable decay products, in particular gamma-rays and neutrinos can be used as an additional diagnostic tool for the study of the origin and transport of UHECRs.

In many astrophysical environments, the energy density of CRs constitutes a significant fraction of the total or is comparable to that of other ingredients. For instance, on galactic scales, the CR energy density is of the same order as that of magnetic fields, radiation fields or the turbulent gas. Due to their pressure, CRs can be dynamically important and shape their environments: Specifically, CRs contribute to the gravitational support of galaxies and can drive galaxy-scale outflows. They ionize neutral gas, thus determining coupling of gas and magnetic fields. CRs can generate turbulence by a variety of streaming instabilities [70, 71], which play a central role in shock acceleration and galactic transport [72]. Finally, CRs also produce diffuse emission through interactions with gas and radiation fields, an additional handle for CR studies.

CRs are also important probes of fundamental physics. If dark

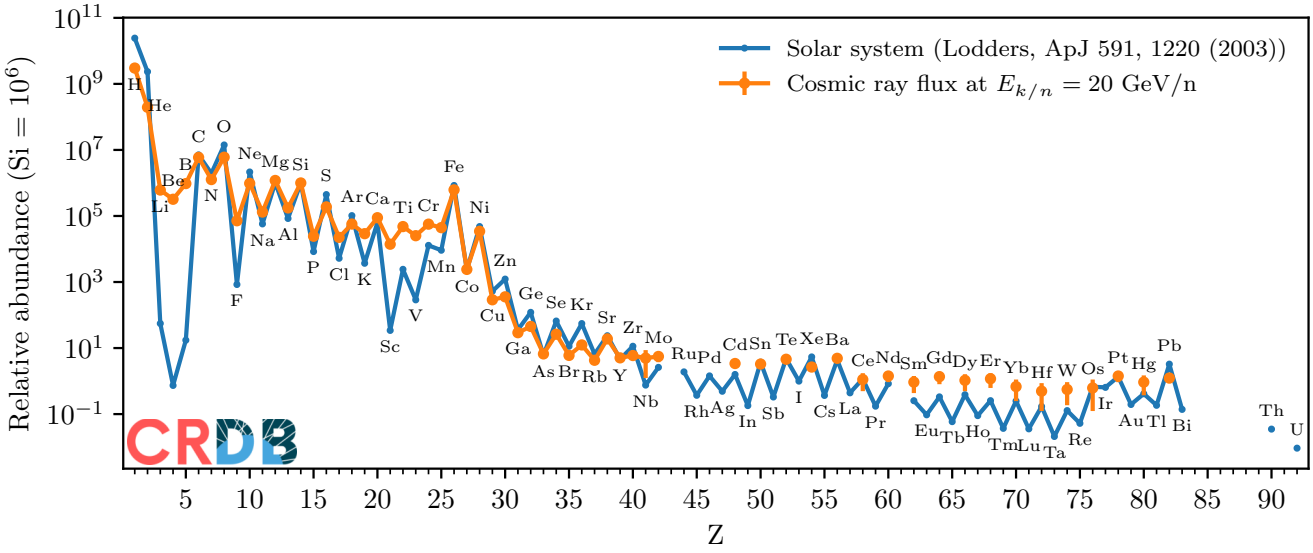

Figure 30.2: CR abundances compared with solar system ones [58]. Modified from [31].

matter has interactions with the Standard Model, the products of self-annihilation or decay of DM particles can potentially be observed (DM, see Sec. 27.7). This is called DM indirect observation. Generically, one would expect similar rates of production of particles and antiparticles whereas astrophysical sources predominantly accelerate matter particles. It is therefore advisable to search for signals in CRs positrons, anti-protons and anti-nuclei [73, 74]. In fact, excesses have been reported of positrons and anti-protons, yet astrophysical pollutions and/or experimental systematic uncertainties can not be excluded. There have also been searches in gamma-rays and neutrinos and a number of studies have indentified an excess of gamma-rays from the Galactic Center that is compatible with DM particles of weak-scale mass and weak annihilation cross-section [75]. Another target for exotic searches in CRs is anti-matter of primordial origin [76]. Most interestingly, the AMS-02 collaboration has claimed $\mathcal{O}(10)$ $\overline{\text{He}}$ candidate events, but whether those are of primordial origin as opposed to instrumental effects is at this point not clear.

30.2 Charged cosmic rays

30.2.1 *Direct observations*

Direct observations [77] cover energies between a few MeV and a few tens of TeV, where CRs must be of Galactic origin. At energies lower than a few MeV, solar energetic particles [78] are dominating the flux; above a few tens of TeV, the fluxes are too low to be observed directly and instead indirect detection techniques [79] need to be used. Besides spectral information, direct observations enable identification of species on an event-by-event basis, certain experiments even provide isotopic discrimination. We present a compilation of direct observations of the most important primary and secondary nuclei in Fig. 30.3. These show broken power-law spectra in rigidity with $J \propto E^{-\gamma}$ in different rigidity ranges. The various changes in spectral slope contain valuable information on the rigidity-dependence of the diffusion coefficient κ and the primary source spectra q_1.

Protons are dominating the CR flux by number and by energy below ~ 10 TeV and their spectrum has been measured with excellent precision. Measurements of the proton spectrum and other primaries are shown in the left panel of Fig. 30.3. Data from the AMS-02 experiment [8] show a $\mathcal{R}^{-2.8}$ spectrum above ~ 10 GeV with a break to $\mathcal{R}^{-2.7}$ at ~ 300 GV. This feature had been observed by PAMELA earlier [2], and also with CREAM and ATIC for heavier nuclei [80, 81]. As a reminder, at energies above a few GeV, the measured spectrum can be interpreted as the ratio of the source spectrum $q(\mathcal{R}) \propto \mathcal{R}^{-\Gamma}$ divided by the diffusion coefficient $\kappa(\mathcal{R}) \propto \mathcal{R}^{\delta}$. Thus a spectral index of $\gamma = \Gamma + \delta \simeq 2.8$ can describe the data. On the basis of proton data alone, the degeneracy between the source spectral index Γ and the spectral index of the diffusion coefficient δ cannot be broken. Also, the break at ~ 300 GV could be a break in the source spectrum or in the diffusion coefficient, but see below. At energies lower than ~ 10 GeV, the spectrum turns over because of energy losses and solar modulation. At energies beyond the reach of AMS-02, both DAMPE and CALET data show a softening at rigidity ~ 10 TV [7, 10], confirming earlier indications [80, 81].

Most of the other primary species, that is helium, carbon, nitrogen, oxygen, neon, magnesium and silicon with the notable exception of iron, also show a spectral break at ~ 300 GV, but their spectra are generally harder than the proton one, e.g. $\gamma_{\text{He}} < \gamma_{\text{p}}$, both below and above the break. Suggested explanations for this difference in spectrum include gradients in the relative circumstellar abundances of protons and heavier nuclei or invoking different source populations for these two groups. At ~ 10 TV a softening break mirrors the feature observed in protons [82]. Above an energy of ~ 100 TeV, elemental information is scarse, but a combined analysis of proton and helium by DAMPE extends to ~ 300 TeV and indicates another spectral hardening [83]. (Note that this data are not included in Fig. 30.3 though.) Such a feature was to be expected to a certain degree in order to connect to the indirect measurements of proton and helium which start at ~ 1 PeV. Note that there exist some 20 % discrepancies between the oxygen and carbon data from AMS-02 [8], CALET [13] and PAMELA experiments [84] in normalization, possibly also in spectral shapes.

Iron constitutes an exception to the otherwise rather similar slopes of primary species heavier than proton. As is also the case for other nuclei, AMS-02 [15] and CALET [16] disagree on the normalization by ~ 20 %, but both measurements of the iron spectrum exhibit spectral shapes different from the oxygen ones. While the ratio of Fe/O could be accommodated if all nuclei traversed the same amount of matter (grammage) between source and observer (the so-called slab model), more realistic models cannot explain the observations [85]. Also, the AMS-02 data on Fe/O are in tension with earlier measurements [86, 87]. Most interestingly, if extrapolated to lower energies, the Fe/O could only be accommodated if solar modulation was negligible.

Measurements of *stable* secondary nuclei contribute two important pieces of information to the standard scenario of galactic CRs: First, their over-abundance in CRs (with respect to solar system values, see Fig. 30.2) indicates diffusion as the primary transport process; and second, their spectral shapes, or rather the difference in spectral shapes between secondaries and primaries allows inference of the diffusion coefficient. Specifically, at energies where energy losses can be ignored for nuclei, that is above a

few GeV, the propagated spectra of primaries $\psi_1(\mathcal{R})$ are approximately $\propto \mathcal{R}^{-2.8\ldots-2.7}$, which is explained as a softening of the sources spectrum $q_1(\mathcal{R})$. Secondaries, however, are produced with a spectrum proportional to the propagated primary spectrum, $q_2(\mathcal{R}) \propto \psi_1(\mathcal{R})$ which also gets further softened by the diffusion coefficient. The difference in spectral index can be clearly seen when comparing primary with secondary spectra. A compilation of such secondary spectra from AMS-02 [8, 88, 89], CALET [90] and PAMELA [84] is shown in the right panel of Fig. 30.3. Lithium, beryllium, boron and fluorine can be identified as almost pure secondaries by their soft spectra. Aluminium, sodium and neon, however, have harder spectra, somewhere intermediate between primaries and secondaries. This can be understood as being due to mixture of softer secondary contribution from spallation in the interstellar medium (ISM) and a harder primary source component. Secondaries also exhibit a hardening break at $\sim 300\,\mathrm{GV}$, but the change in spectral slope is about twice as big [91] when compared to that of the primaries. This fact serves as evidence for the break being due to a change in the rigidity-dependence of the diffusion coefficient, as opposed to a break in the source spectrum [92, 93]. Recently, there have been some claims of excesses in low-energy intensities of Li, F, Al [94], however these claims are somewhat controversial. We note the importance of composition studies for shedding light on cosmic ray origin.

Unstable isotopes with a lifetime similar to the residence time of CRs can be used to study galactic propagation. Among these species, ^{10}Be, ^{26}Al and ^{60}Fe have been studied the most as their rest lifetime is close to the residence time of CRs at GV rigidities. Roughly speaking, the flux ratio of an unstable and a stable secondary that are both produced from similar primary species, reflects the ratio of production cross-section at high energies (where decay is suppressed by time-dilation). On the other hand, at low energies, this ratio is suppressed due to the decay of the unstable species. The transition takes place at energies where the decay time equals the residence time in the Galactic disk. At present, there is limited information on ratios at energies beyond 1 GeV/nucleon where the transition for the ratios of the above mentioned unstable nuclei is expected to take place.

CR electrons are also believed to be accelerated in the preferred candidate sources of nuclei, that is, SNRs. Other source candidates are pulsars and pulsar wind nebulae (PWNe); in the simplest models those also accelerate similar amounts of CR positrons. We show a compilation of the most recent and precise data from AMS-02 [8], CALET [19], DAMPE [17], *Fermi*-LAT [18], H.E.S.S. [95] and PAMELA [96] on CR electrons, positrons and the sum of electrons and positrons in Fig. 30.4. In addition to the processes at work in the propagation of nuclei, electrons suffer significant radiative losses due to synchrotron emission and inverse Compton scattering. In fact, for the parameters determined in the standard scenario, the cooling time is shorter than the residence time above $\sim$ 10 GeV. For the same source spectral index, the spectra are predicted to be softer than those of primary nuclei. Indeed, the observed spectrum is roughly $\propto E^{-3.1}$.

If positrons were only produced by spallation in the interstellar medium, the positron spectrum should be softer than the electron one, however, on the contrary it is markedly harder. Between $\sim 10\,\mathrm{GeV}$ and $\sim 100\,\mathrm{GeV}$ its spectral index γ_{e^+} transitions from 3 to 2.7 before a spectral break or cut-off at a few hundred GeV as shown in Fig. 30.4. The fact that the positron spectrum is harder than the electron one above a few GeV had first been detected by PAMELA [97] after earlier indications. AMS-02 has now measured the spectrum with great precision up to $\sim 1\,\mathrm{TeV}$ [8]. The origin of the harder positron spectrum remains unclear today. After the discovery by PAMELA, there had been hope that this was the long sought for signature of self-annihilation or decay of weakly interacting massive particles (WIMP) dark matter [98]. However, such interpretations are now severely constrained by observations of gamma-rays, anti-protons and the cosmic microwave background (CMB, see Chap. 29). Production of e^+ in pulsars or PWNe is an astrophysical explanation that had been hypothesized long before the PAMELA observations (e.g. [99]). Recently, there have been observations of extended emission of high-energy gamma-rays, so-called gamma-ray halos around PWNe [100], interpreted as evidence of the presence of high-energy electrons and positrons around these objects. Other astrophysical explanations include the production and subsequent acceleration of secondaries in old SNRs [101, 102].

Measurements of the spectra of electrons and positrons are particularly interesting at high energies. Due to the increasingly important radiative losses, the distance to the sources which could significantly contribute to the total flux decreases with energy. Estimates at 1 TeV of this diffusion-loss length are only $\simeq 0.3\,\mathrm{kpc}$. The predicted spectrum therefore becomes rather sensitive to the exact distances and ages of young, nearby sources which manifest as individual bumps in the spectrum. Turning this around, observations can be used to search for young, nearby sources of CRs. At energies above $\sim 1\,\mathrm{TeV}$, only calorimetric observations are currently available which cannot discriminate between electrons and positrons. Observations of the all-electron flux, that is the sum of electron and positron fluxes, find a break at $\sim 1\,\mathrm{TeV}$, displayed in Fig. 30.4. This was first seen by H.E.S.S. [95] and later confirmed by DAMPE [17] and CALET [19]. The break by about one power in energy has been interpreted either as due to a break in the spectrum of a large number of sources, e.g. [104] or as a stochasticity effect from a small population of sources [105].

In the standard scenario of galactic cosmic rays, anti-protons are also produced as secondary particles, but unlike secondary nuclei or electrons and positrons, their production is kinematically suppressed at lower energies. The spectrum of anti-protons observed by PAMELA (Fig. 3 in [106]) and AMS-02 (Fig. 62 in [8]) is close to $E^{-2.8}$, which is somewhat harder than predicted by earlier models. More recent models can accommodate the observations, in part due to a re-evaluation of the production cross-section. Note that there have been claims that the transport parameters obtained when fitting to proton and anti-proton data differ from those obtained by fitting to heavier nuclei [107]. An alternative explanation for the harder anti-proton spectrum is the acceleration of secondaries in old supernova remnants [102, 108]. At energies of a few GeV, there have been claims of an excess in the measured anti-proton spectrum. If interpreted as a sign of dark matter annihilation, such an excess could be explained by a weak-scale particle of mass of a few tens of GeV and annihilation cross-sections close to the thermal relic value. However, the significance of the signal is relatively low if correlations in the cross-section uncertainties and in the measurements are taken into account. Considering the spectra of anti-protons together with protons and positrons, it appears that all three have similar spectral indices between $\sim 10\,\mathrm{GV}$ and $\sim 300\,\mathrm{GV}$. This is rather surprising, given that as secondaries positrons and anti-protons should have spectra softer than the primary protons, due to energy losses and diffusive losses, respectively. In the standard scenario this cannot be explained and thus must be considered a mere coincidence.

The only astrophysical mechanism for production of anti-nuclei like anti-deuterons ($\overline{\mathrm{D}}$) or anti-helium ($^3\overline{\mathrm{He}}$ or $^4\overline{\mathrm{He}}$) is coalescence of anti-nucleons produced in the spallation of primary nuclei in the interstellar medium. Due to kinematics, however, this is significantly suppressed at energies below a few GeV, thus rendering this an interesting channel for searches of dark matter, in particular for relatively light WIMPs with masses of a few GeV or less. The AMS-02 collaboration has reported some ten candidate events of anti-helium, yet the rate of $^3\overline{\mathrm{He}}$ or $^4\overline{\mathrm{He}}$ is incompatible with models of coalescence (e.g. [109]). Currently, the most constraining limits on $\overline{\mathrm{D}}$ are from the BESS balloon flights [110]. This should be improved on by the upcoming GAPS experiment, and also an upgrade of the AMS-02 experiment increasing the acceptance by a factor of three could help clarifying the situation.

Another important observable in the study of CRs are anisotropies, most commonly defined as the relative directional deviation of the CR intensity from the angular average. As the typical anisotropies are at the level of one part in 10^3 or 10^4, high statistics are required. At TeV and PeV energies, only ground-based experiments have enough statistics, yet they cannot constrain the component of the anisotropy that is aligned with the Earth's rotation axis. Traditionally, therefore, only the projection of the true 2D dipole into the equatorial plane has been reported in terms of an amplitude and phase. We show a

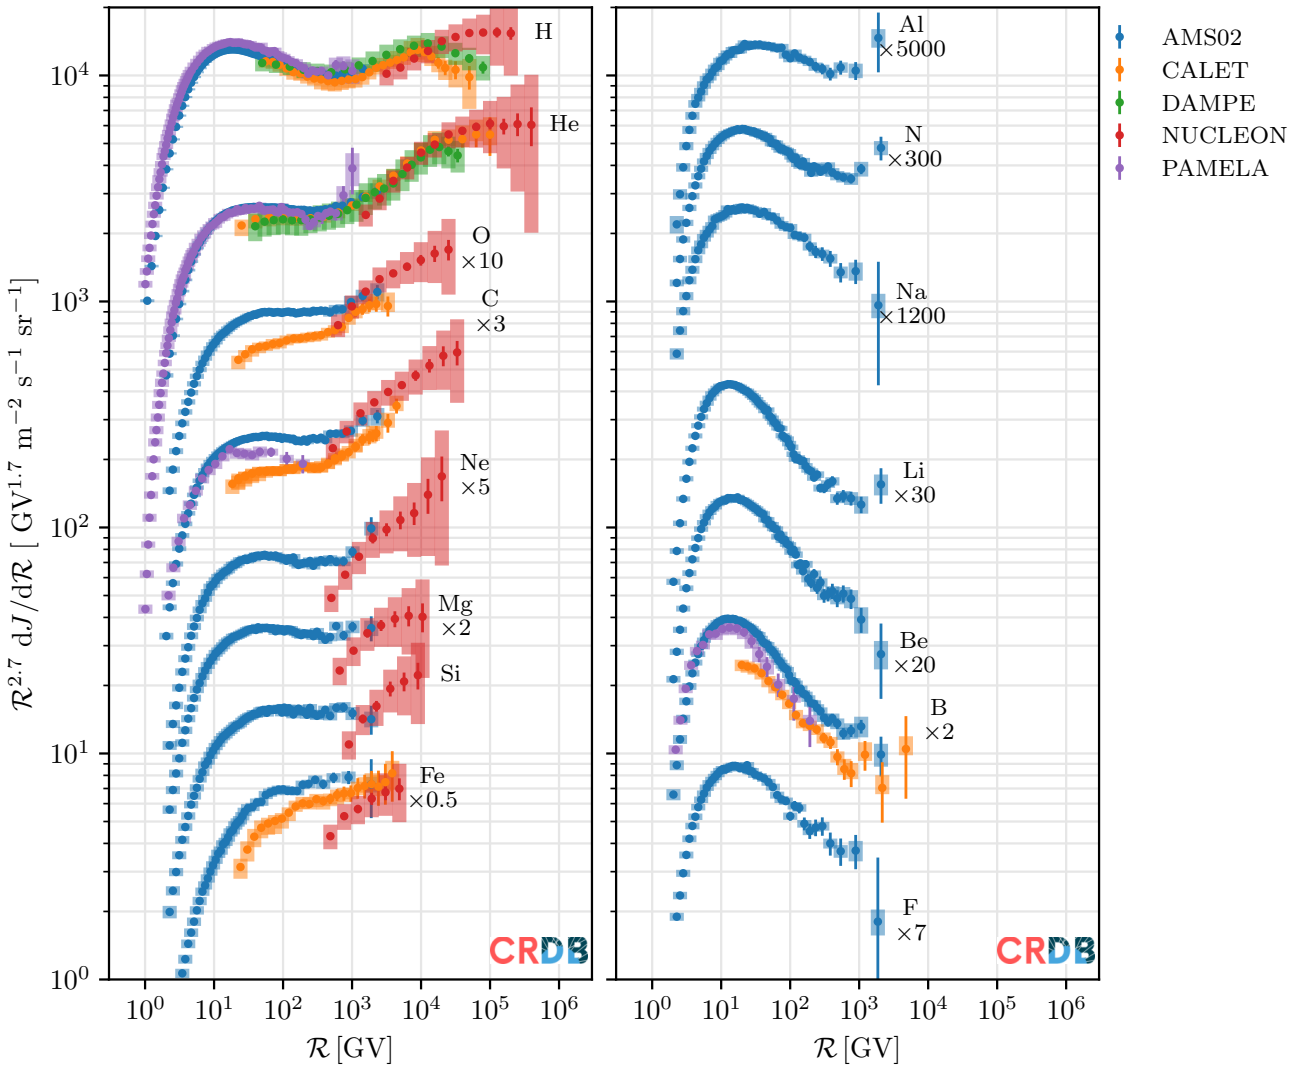

Figure 30.3: Rigidity spectra for a selection of CR nuclei. Primary species are shown in the left panel, (mostly) secondary species in the right panel. The error bars denote the statistical uncertainties, the shaded bars represent the systematic uncertainties. The spectra have been shifted and multiplied by $\mathcal{R}^{2.7}$ to better bring out spectral features. Here, we have constrained ourselves to data from space-borne experiments of the last ten years, that is AMS-02 [8,15,88,89,103], CALET [10,16,82,90], DAMPE [7,13], NUCLEON [5] and PAMELA [2,84]. Data have been extracted from [31].

compilation [31] in Fig. 30.5. The amplitude is at the level of $\simeq 10^{-4}$ at energies of hundreds of GeV and increases to $\simeq 10^{-3}$ at tens of TeV. At ~ 100 TeV there is a dip before the amplitude rises again. Beyond a few PeV upper limits exist at the level of 10^{-2}. The Compton-Getting effect [111,112], that is a dipole anisotropy due to the relative motion of the solar system with respect to the Galactic rest frame has been experimentally confirmed [113]. The phase is relatively constant at a direction of 45° and switches to 250°, which is close to the Galactic Center direction, also around 100 TeV. For a description of anisotropies at the highest energies see Section 30.2.2. In addition, observations of anisotropies on scales smaller than the dipole have been reported (see Ref. [114]). These are not expected in standard diffusion theories that only predict a dipole. The leading explanation is the generation due to the specific realization of the turbulent magnetic field in our Galactic neighbourhood.

30.2.2 *Indirect observations*

In the energy range above $\simeq 1$ PeV the intensity of cosmic rays is so low that it prevents the collection of a statistically significant sample of these particles in a direct manner with detectors carried on balloons or satellites. Instead, cosmic rays are detected indirectly through the cascade of particles they produce in the atmosphere, the so-called extensive air showers (EAS). In this way, cosmic rays up to and even above 100 EeV have been observed [115, 116], corresponding to about a hundred million times larger energy than that achieved by particles accelerated in human-made experiments.

Extensive Air Showers. Extensive air showers (EAS) are cascades of millions to billions of secondary particles initiated by a single primary particle (cosmic ray: proton, neutron or heavier nucleus; photon; or neutrino) of energy E in the atmosphere. Due to the small density of air $\rho \lesssim 10^{-3}\,\mathrm{g\,cm^{-3}}$, the shower develops throughout the whole of the atmosphere, and for a primary particle of 10 EeV has a lateral spread of $\sim 10\,\mathrm{km}^2$ at ground level, hence the name EAS.

When an energetic, $E \gtrsim 1$ PeV, cosmic proton or nucleus interacts with a nucleus of air, it generates between a few and hundreds of secondary particles depending on its energy. On average $\sim 30\% - 40\%$ of the energy of the primary particle is carried by a leading baryon or nucleus. The remaining energy is employed in the creation of ultra-relativistic secondary particles, most of them charged ($\pi^{\pm}$) and neutral (π^0) pions, with a smaller number of hadrons and heavier mesons such as charged and neutral kaons, ρ-mesons, etc. The energy of the primary particle

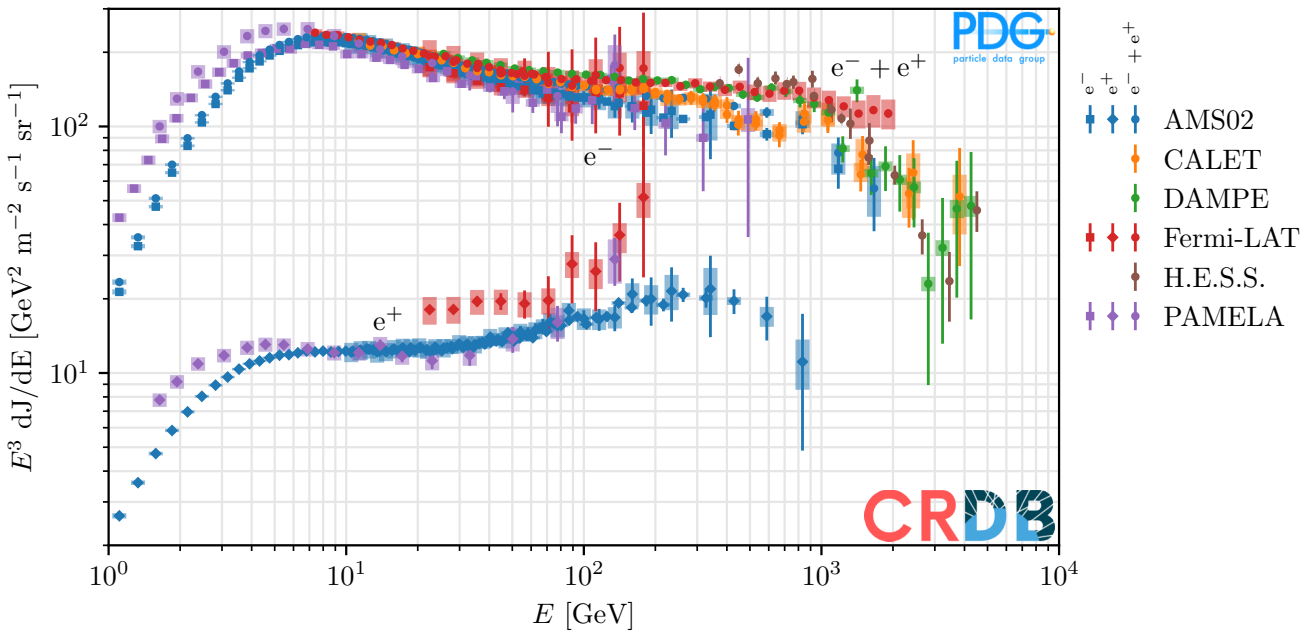

Figure 30.4: Intensities of cosmic ray electrons (squares), positrons (diamonds) and their sum (dots) as a function of kinetic energy E. We have included data from the most recent space experiments AMS-02 [8], CALET [19], DAMPE [17], *Fermi*-LAT [18] and PAMELA [96] as well as from the ground-based H.E.S.S. experiment [95]. The spectra have been multiplied by E^3 to enhance the visibility of the spectral features. Data have been extracted from [31].

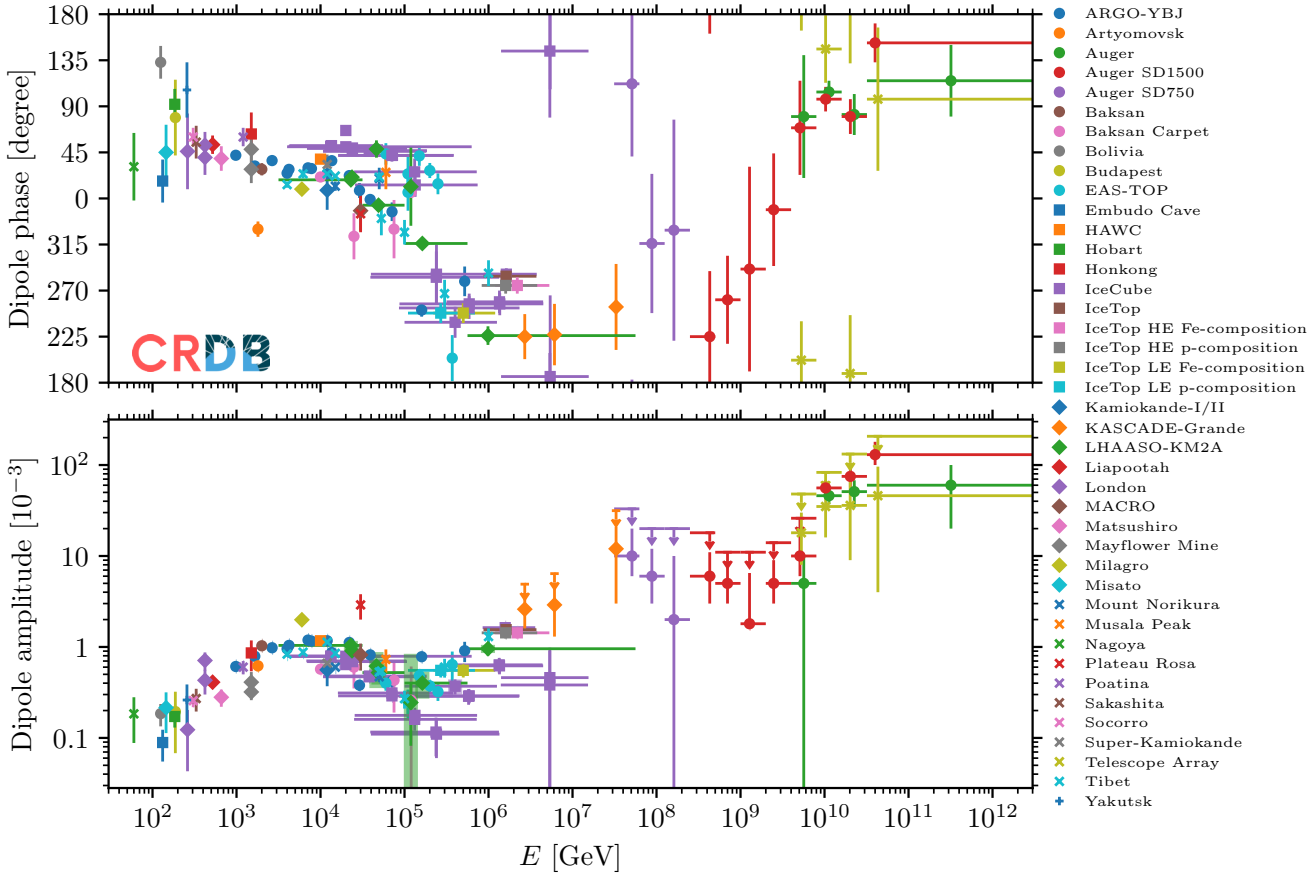

Figure 30.5: Phase and amplitude of the dipole anisotropy in CRs. Modified from Ref. [31].

rapidly degrades into a large number of secondaries that can subsequently interact or decay depending on the nature and energy of the particle and the density of the medium, further contributing to the shower development. If $\pi^{\pm}$ live long enough they can interact with an air nucleus before decaying. At altitudes of a few km where the atmosphere is less dense than at sea level, most $\pi^{\pm}$ with $E_{\pi^{\pm}} \gtrsim 100\,\mathrm{GeV}$ interact while lower energy $\pi^{\pm}$ decay. Interacting $\pi^{\pm}$ along with the leading baryon and other hadrons, form a penetrating core of shower particles constituting the *hadronic component* of the cascade (Fig. 30.6). Charged pions decaying into muons, $\pi^+ \to \mu^+ + \nu_\mu$ and $\pi^- \to \mu^- + \bar{\nu}_\mu$, represent the main contribution to the *muonic component* of the shower (Fig. 30.6), being also responsible for the production of the bulk of the so-called atmospheric neutrinos. Most muons of energies above a few GeV travel through the atmosphere without decaying and reach ground, constituting a penetrating component of the shower. On the other hand, most π^0s, continuously produced in the hadronic core of the shower, do not travel long enough distances to interact with an air nucleus unless their energy is well above 1 EeV. Instead, they decay almost immediately $\pi^0 \to \gamma\gamma$, initiating electromagnetic showers. Neutral pions play a significant role in generating the *electromagnetic component* that forms the majority of the shower (Fig. 30.6). This is composed of e^- and e^+ with a mean energy of 10 MeV as a result of photon pair production, as well as secondary photons from bremsstrahlung. Decaying muons also contribute to the electromagnetic component of the shower. The longitudinal development of the distinct and intertwined shower components, electromagnetic, muonic, and hadronic, is shown in Fig. 30.6. High-energy primary or secondary photons can occasionally photoproduce $\pi^{\pm}$ and initiate a hadronic subcascade resulting in an additional muonic component.

As a cosmic ray shower develops in the atmosphere, the number of particles increases in the longitudinal direction along the shower axis. The amount of matter traversed, X, is measured in units of $\mathrm{g\,cm^{-2}}$. The shower reaches a maximum size of the electromagnetic component $N_{\max}$ at a depth known as $X_{\max}$ (Fig. 30.6). The number of electrons and positrons declines rapidly after maximum when their energy reaches the *critical energy* in air, $\sim 80\,\mathrm{MeV}$, and they lose their remaining energy dominantly through ionization loss. Since neutrinos do not suffer electromagnetic interactions, and high energy muons reach ground level after releasing only a portion of their energy, a fraction of the energy of the primary initiating the shower is not deposited in the atmosphere. This is the so-called *invisible energy* that amounts to $\approx 10\% - 20\%$ of the shower energy for energies above 0.1 EeV, decreasing with the energy of the primary particle initiating the shower and increasing with its mass number [118]. At the same time the shower develops in the transverse or lateral dimension to the shower axis, as shown in Fig. 30.6, mainly due to the transverse momentum in hadronic interactions and multiple Coulomb scattering of e^- and e^+.

Shower development is driven by the particles carrying most of the energy in the forward region of the kinematical phase space of the collisions with air nuclei. Particle production is dominated by non-perturbative QCD which is necessarily treated by using phenomenological approaches. Moreover, particle collisions occurring in the atmosphere at 0.1 EeV are equivalent to center-of-mass energies presently achieved at the LHC, and this energy scales up by a factor of approximately 30 at the highest cosmic ray energies observed. These two facts result in the need for extrapolations both in energy and phase space when modeling hadronic interactions. The cosmic-ray community has developed sophisticated simulation packages such as AIRES [117] and CORSIKA [119] to predict EAS observables as a function of primary energy and mass. These programs adopt models of hadronic interactions such as SIBYLL [120], QGSJET [121] and EPOS [122], tuned to a large data set including recent LHC data. Inferring fundamental properties of the primary particle initiating the shower, most notably its mass, requires the use of these air shower simulations. Large uncertainties remain, both due to theoretical limitations and the lack of data from existing collider experiments. A toy model to describe electromagnetic showers is due to Heitler [123], while for hadronic showers a model was developed by Matthews [124]. These oversimplified models shed light on the relation between the main shower observables and the nature of the primaries and predict that for the electromagnetic component, $N_{\max} \propto E$; $X_{\max} \propto \log E$ and $X_{\max} \propto \log A^{-1}$ with A the mass number of the primary nucleus; while for the muonic component, $N_\mu \propto A^{(1-\beta)} E^{\beta}$ with $\beta \simeq 0.85...0.95$. These important features of air showers constitute the basis for the identification of the primary particle with EAS (see next section). Similar features are also obtained in detailed Monte Carlo simulations of EAS development (Fig. 30.6), and have been observed experimentally.

Shower detection and cosmic-ray reconstruction. EAS have been detected with several techniques. Arrays of conventional particle detectors such as scintillators, water-Cherenkov stations or underground muon detectors, measure the lateral distribution of the shower front at ground, i.e., at a fixed depth. Due to the low cosmic-ray intensity especially at EeV energies (Figs. 30.1 and 30.7), the particle detectors are spread over large areas to compensate for the low flux, separated by distances that range from hundreds of meters to above 1 km. From the times at which the shower front hits several of these particle detectors, the arrival direction of the cosmic ray is measured with an accuracy typically better than $\sim 1^\circ$. Shower arrays measure a shower size parameter, proportional to the number of secondary particles, that can be related to the energy E of the primary particle. With several types of detectors working together, it becomes possible to effectively separate the electromagnetic and muonic components of the shower, thereby providing an estimate of the mass of the primary. The main arrays of particle detectors for EAS observation currently in operation are the surface detector of water-Cherenkov stations of the Pierre Auger Observatory in Argentina [125] spread over a total area of $\sim 3000\,\mathrm{km^2}$, and the Telescope Array (TA) of scintillators in USA ($\sim 700\,\mathrm{km^2}$) [126]. They typically work with almost 100% duty cycle and have measured many properties of the cosmic-ray flux (see next section).

Other arrays can measure the radiation emitted when the shower develops in the atmosphere, namely, optical Cherenkov radiation, fluorescence light, or radio emission in the MHz to GHz frequency range. Cherenkov detectors measure the forward-beamed incoherent emission at optical wavelengths. This can be achieved with arrays of individual elements such as at the Yakutsk [127] and Tunka-133 [128] observatories. A fluorescence telescope can monitor a large volume of the atmosphere and detect the isotropic fluorescence radiation emitted by the nitrogen molecules of air excited by the passage of the charged particles of the shower. The fluorescence radiation is produced in proportion to the energy dissipation and the shower size $N(X)$, allowing a reconstruction of the longitudinal profile of the energy deposit dE/dX of the shower as a function of atmospheric depth X and, in particular, providing a measurement of $X_{\max}$. With the fluorescence detection technique, the atmosphere is used as a calorimeter, with the integral $E_{\mathrm{cal}} = \int (dE/dX) dX$ called the calorimetric energy of the shower. An estimation of the primary energy with the fluorescence detection technique is obtained by adding to E_{cal} a correction to account for the invisible energy introduced above. Fluorescence and optical Cherenkov detectors are limited by operation during clear and moonless nights which reduces their duty cycle to $\simeq 15\%$. The main fluorescence detectors currently in operation are those of the Pierre Auger Observatory [125] and TA [126].

Arrays of detectors of radio emission employ cost-effective elements (antennas) to detect the radiation in the 10's of MHz to GHz produced by the charged particles in the EAS. Radio emission is mainly due to two mechanisms: the transverse current induced by the magnetic field of the Earth that travels at the speed of light along shower axis, and the Askaryan effect i.e the radiation emitted by the excess of negative charge (e^-) that develops in the shower through Compton scattering of shower photons on e^- in the medium, as well as Möller and Bhabha scatterings. The measurement of the radiated energy in radio waves at ground also provides an estimate of the primary energy [129]. In a radio-quiet environment, these detectors can operate with a close to 100% duty cycle, only limited by thunderstorms and heavy rain. The principal arrays of radio antennas currently operating include the Auger Engineering Radio Array (AERA) and the ongoing deploy-

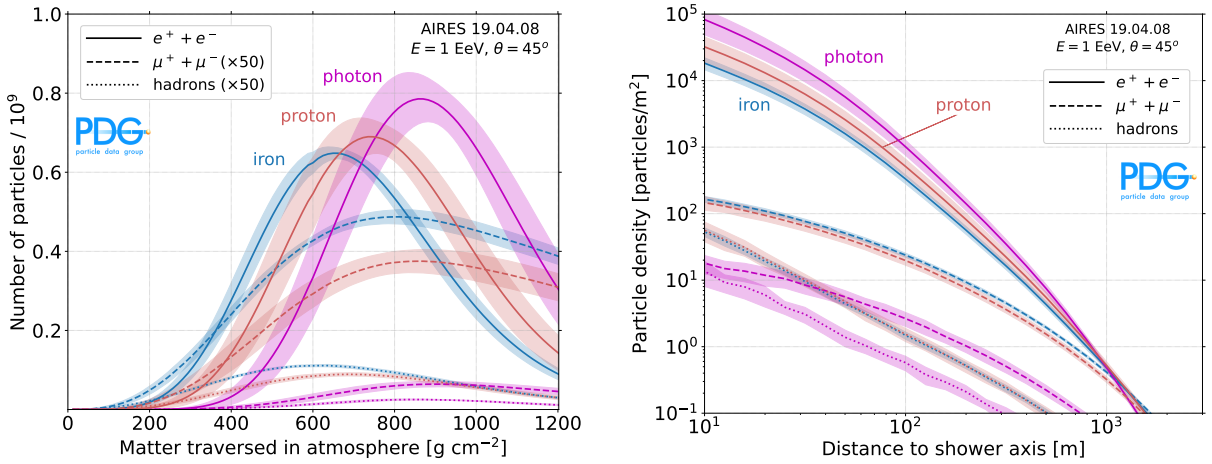

Figure 30.6: Left: Average number of $e^+ + e^-$, $\mu^+ + \mu^-$, and hadrons (lines), and their $\pm 1\,\sigma$ deviation (bands), as a function of matter (in $\mathrm{g\,cm^{-2}}$) crossed in the atmosphere along the shower axis. The profiles are obtained with AIRES simulations [117] of proton, iron and photon-induced extensive air showers of energy $E = 1\,\mathrm{EeV} = 10^{18}\,\mathrm{eV}$ and zenith angle $\theta = 45°$ w.r.t. the vertical to ground (at depth $870\,\mathrm{g\,cm^{-2}}$). Right: Lateral development (perpendicular to shower axis) at ground level of the same components as in the left panel as a function of distance to shower axis.

ment of the AugerPrime Radio Detector at the site of the Pierre Auger Observatory in Argentina [130], the Tunka-Rex [131] and Yakutsk [132] radio extensions in Russia, the LOw Frequency ARray (LOFAR) with its core detector in The Netherlands [133], and the Square Kilometer Array (SKA) in Australia [134].

Combining several types of detectors in the same array has proven very fruitful for increasing the accuracy in event reconstruction and energy calibration. Complementary measurements of the same event are expected to improve the determination of mass composition of the primary flux on an event-by-event basis. Projects under construction exploiting the simultaneous use of several detector kinds include, AugerPrime (water-Cherenkov stations, scintillators, underground muon detectors, fluorescence detectors and radio antennas) [135], TAx4 (scintillators and fluorescence detectors) [136], and the IceCube-Gen2 surface array (scintillators and radio antennas) [137]. Other arrays in the planning stages utilizing radio antennas are GRAND [138] and BEACON [139].

Experimental results. Cosmic rays in the PeV to EeV energy range have been regularly detected for decades, with energies up to $> 100\,\mathrm{EeV}$. Despite the progress made in the field in the last 20 years, the nature and identity of their sources as well as the acceleration mechanisms that boost the particles to these extreme energies remain open questions. The understanding of CRs is mainly derived from analyzing their energy spectrum, several observables sensitive to their primary nature, and their arrival direction distribution. This is a challenging task mainly due to the small flux, with less than 1 particle per $\mathrm{km^2}$ per year above 30 EeV (see Fig. 30.1), but also because the properties of CRs in this energy range can only be inferred indirectly from measurements of the EAS whose description relies on extrapolations of particle physics properties at energies several orders of magnitude above those achieved in terrestrial accelerators. Last but not least, since CRs are charged they are deflected by the galactic and intergalactic magnetic fields and their arrival directions at Earth point back only approximately to their actual sources.

Energy spectrum: The cosmic-ray spectrum observed at Earth (Fig. 30.1, with Fig. 30.7 highlighting the highest energies) can be characterized by a series of power-law functions proportional to $E^{-\gamma}$ with $\gamma \in (\simeq 2.5, \simeq 5.0)$ the spectral index that changes with energy. The production mechanism of CRs, mainly the unknown maximum CR energy achievable, CR composition and spectral index at the sources; the source type and distribution in the Universe; and the propagation through the Galaxy and the intergalactic space, all leave distinct imprints on the spectrum giving rise to several observable features. The differential flux over 5 orders of magnitude in energy is shown in Fig. 30.7. The flux has been multiplied by E^3 to highlight the deviations from a pure power law with a single value of γ. Several features are apparent, namely: a steepening at $\simeq 5\,\mathrm{PeV}$ known as the *knee* (Fig. 30.1); another steepening around 100 PeV dubbed the *second knee*; the *ankle*, a flattening of the spectrum at around 5 EeV; a recently discovered feature corresponding to a further flattening starting at 10 EeV dubbed the *instep*; and the *suppression* of the spectrum starting around 50 EeV. These features are thought to be correlated with the observed changes on the average CR composition (see *Primary composition* below).

Cosmic-ray experiments have systematic differences in their energy scales and this manifests itself in differences in the measured spectrum, not only on the energy axis but also on the normalization when the flux is scaled with a power of the energy. The diagonal uncertainty bars in Fig. 30.7 serve to visualize the impact of these systematic differences on the spectrum. In the energy range above $\sim$ 100 PeV the fluorescence technique is used to determine the primary cosmic-ray energy, with the atmosphere where the EAS develops functioning as a calorimeter. In the two state-of-the-art experiments for UHECRs, the Pierre Auger Observatory and the Telescope Array, a sub-sample of events is recorded simultaneously with the fluorescence (FD) and the surface detector (SD) arrays. With the SD, a shower size parameter is measured and calibrated against the energy measured with the FD. This approach provides a more direct method for determining cosmic-ray energy without relying on simulations. Differences in the energy scale between Auger and TA remain, however, primarily due to the use of different measurements of the amount fluorescence light emitted per unit of energy deposited, and to the different models for the invisible energy in EAS adopted. When these systematic uncertainties are accounted for, the spectra of the Pierre Auger Observatory and TA have been shown to agree within 5%, except in the energy region near the end of the instep feature and at the suppression.

Primary composition: The main observable sensitive to CR composition is the depth in the atmosphere along shower axis (X_{max}) at which the number of particles in the shower is maximum. Observatories capable of detecting Cherenkov and/or fluorescence light induced by the passage of the EAS through the atmosphere, can measure X_{max} on an event-by-event basis. With sufficient statistics, the distributions of X_{max} can be determined from which the average value $\langle X_{\mathrm{max}} \rangle$ and its fluctuations

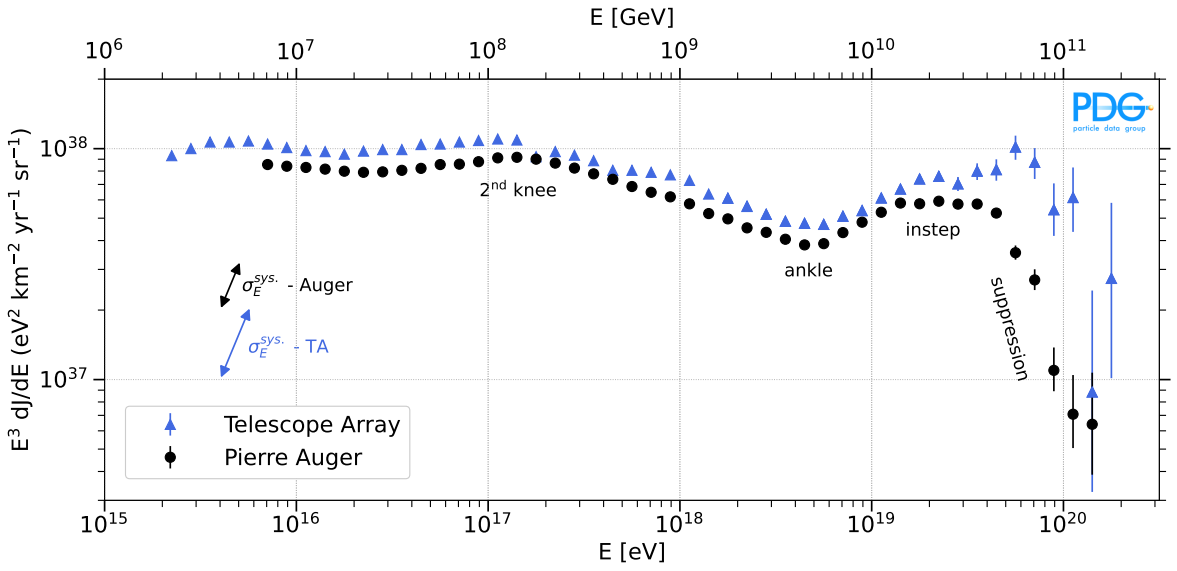

Figure 30.7: Measurements of the all-particle CR flux from Telescope Array (TA) [140] (blue triangles) and the Pierre Auger Observatory [29, 141] (black circles). The direction and magnitude of the systematic uncertainty on the flux due to the energy scale ($\sigma_E^{\rm sys}$) for TA and Auger is indicated by the corresponding arrows. For a comprehensive compilation of measurements see [142].

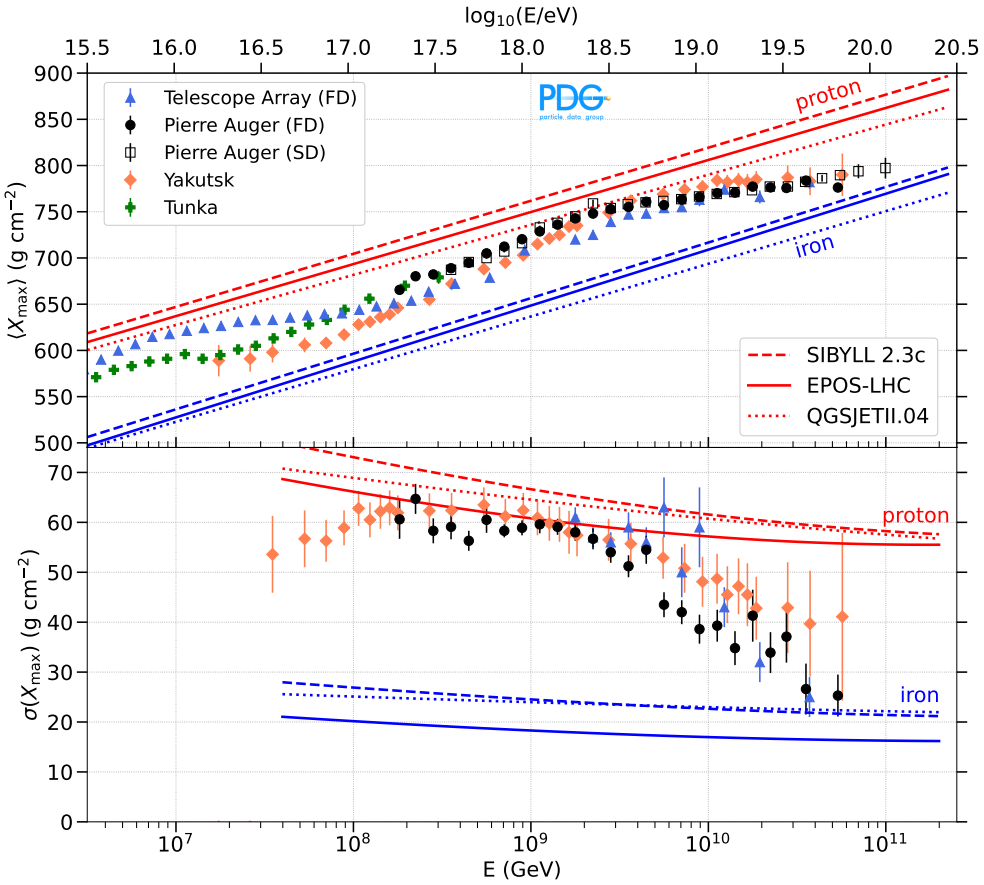

Figure 30.8: Measurements of $\langle X_{\rm max}\rangle$ (top) and $\sigma(X_{\rm max})$ (bottom) obtained by the Telescope Array [143, 144], Pierre Auger Observatory [145, 146], Yakutsk [127] and Tunka [147] UHECR detectors, compared to predictions for proton and iron nuclei using the hadronic models SIBYLL2.3c [148], EPOS-LHC [122] and QGSJET-II.04 [121]. Detection techniques: fluorescence (FD), Cherenkov (Yakutsk, Tunka, and TA below $\simeq$ 1 EeV), and using the surface detector array of the Auger Observatory (SD). For a compilation including experiments using the radio technique see [142] and also [149].

$\sigma(X_{\rm max})$ are obtained. A comparison with the $\langle X_{\rm max}\rangle$ and $\sigma(X_{\rm max})$ as predicted in simulations of EAS for different primaries and energies, as well as fits to the $X_{\rm max}$ distributions lead to the determination of the mean fractions of primary protons, helium, carbon-nitrogen-oxygen and iron in the cosmic-ray flux at Earth. However, the interpretation of any mass-sensitive observable relies on modeling hadronic interactions up to the highest energies where there are no data from terrestrial accelerators, and this introduces a considerable uncertainty in the determination of the mass. Also, due to intrinsic shower-to-shower fluctuations (see Fig. 30.6), an event-by-event determination of the mass of the primaries is not currently possible. Despite these limitations, the measurements presented in Fig. 30.8 alongside the predictions of EAS simulations for proton and iron primaries, reveal a broad trend toward a lighter composition at the knee, within the energy range of a few PeV. This is followed by a gradual rise in the average logarithm of the primary cosmic-ray mass, eventually leading to a heavier composition at around 100 PeV, although notable differences between experiments exist. As the energy increases from 100 PeV up to ~ 2 EeV the measurements point consistently to a predominantly light composition with a large fraction of primary protons. Above that energy, the data from the largest statistical sample of events collected with the FD of the Pierre Auger Observatory indicate that the composition is mixed with the mean mass steadily growing. This observation is further supported by the shower-to-shower fluctuations of $X_{\rm max}$ also shown in Fig. 30.8. Though the data of the Telescope Array seem in apparent tension with this picture, they have been shown to be compatible with the results of the Pierre Auger and Yakutsk Observatories [150] within the current levels of statistics and understanding of systematic uncertainties. In particular, TA data are compatible with the mixed composition inferred by the Pierre Auger Collaboration [142].

The small duty cycle of the fluorescence technique combined with the steeply falling spectrum above $\simeq 50$ EeV prevents a statistically significant determination of the composition in this energy range. Information on the distribution of nuclear masses can be obtained with the surface arrays alone that work with a high duty cycle. Exploiting the arrival times of particles in the SD stations, that are known to contain information on the penetration of the shower in the atmosphere, measurements of $X_{\rm max}$ with the Pierre Auger Observatory were extended up to 100 EeV as shown in Fig. 30.8, after calibration of the mass-sensitivity of the SD with the measurements of $X_{\rm max}$ with FD at lower energy. Other novel methods such as those based on deep learning analysis techniques are also being explored [151]. Additionally, the arrays of radio detectors are also sensitive to $X_{\rm max}$ through the measurement of the shape of the radio emission footprint on the ground induced mainly by the electromagnetic component of the EAS. The radio technique demonstrates considerable potential in this respect and scalability, making it a cost-effective possibility for future UHECR detectors [149, 152].

Arrival directions: Anisotropies in the arrival direction of CRs are a key to discovering their sources. This is in principle feasible if the charges of the CRs and the galactic and extragalactic magnetic fields are well-enough determined. UHECRs are subject to the GZK effect, the energy loss of protons and heavier nuclei in interactions with the cosmic background. This imposes a horizon to possible sources of ~ 250 Mpc for protons and Fe nuclei, but shorter for nuclei in between these two, for instance ~ 5 Mpc for He and ~ 100 Mpc for Si at energies above $\simeq 50$ EeV [153]. Having only a limited range of source distances contributing to the signal makes it potentially feasible to identify sources or infer their properties statistically.

The Pierre Auger Collaboration has discovered a large-scale dipolar anisotropy at energies above 8 EeV with 6.9σ significance [154]. The amplitude of the dipolar anisotropy is $d = 0.073^{+0.010}_{-0.008}$ and the dipole points at a direction that is $\sim 115^\circ$ away from the Galactic Center, evidencing the extragalactic origin of UHECRs above this energy threshold. The dipole direction is not aligned with any obvious individual source, or with the expected CMB dipole, and is instead consistent with the local distribution of stellar mass (2MASS Redshift Survey), after accounting for the deflections expected in the Galactic magnetic field. A compelling feature is the growth of the amplitude of the dipole with energy in agreement with the expectation that particles of higher rigidity are less deflected by magnetic fields. Combining the Pierre Auger Observatory data set in the southern hemisphere and the smaller statistical sample of events from Telescope Array in the north, a full-sky coverage is achieved. The combined results regarding the dipolar anisotropy are compatible with the Pierre Auger Observatory-only results with no evidence of the existence of a quadrupole component. At energies between ~ 10 PeV and ~ 1 EeV the amplitude of the dipole is smaller (Fig. 30.5, bottom panel), but there is a trend for its direction to change from pointing close to the Galactic Center (GC) at low energy towards a direction away from the GC (Fig. 30.5, top panel) in the EeV energy range. This suggests that there is a transition between the galactic and extragalactic origin of UHECRs around the ankle in the spectrum, at a few EeV.

Hints of correlation of arrival direction of UHECRs with potential sources have been confirmed in several analyses [142,154,155]. With data from the Pierre Auger Observatory a 4σ excess of events above 38 EeV was found in a region of angular radius $\simeq 27^\circ$ centered on the radio galaxy Centaurus A (CenA) [154]. The Telescope Array Collaboration has also reported an excess of events with energies above 57 EeV (the so-called *hot spot*) in the northern sky in the direction of R.A. $= 144.0^\circ$, Dec. $= 40.5^\circ$, with a 2.8σ significance and in an angular window of 25° [155]. Correlations with catalogs of potential UHECR sources have also been found. The sky viewed from the Pierre Auger Observatory is better modeled with a $\simeq 10\%$ flux excess in the directions of nearby starburst galaxies with a significance of 3.8σ and an energy threshold of 38 EeV with the correlation driven by the region of CenA where two prominent starburst galaxies are also located [154].

Despite the comprehensive observations made, it remains challenging to definitively ascertain the origin of UHECRs, primarily due to their deviation caused by the insufficiently constrained galactic and extragalactic magnetic fields. However, the constructed CR observatories designed to detect extensive air showers have the potential to also identify neutral particles of comparable energies. These include neutrinos, neutrons, and photons. Such searches can be made provided that methods are devised to separate photon and neutrino-induced EAS from those produced by the more abundant charged CRs, or in the case of neutrons if excesses in the sky are found. No photon or neutrino candidates have been clearly identified in the energy range around and above 100 PeV and upper limits to their flux have been obtained (see Fig. 30.13). UHECR observatories are thus also multi-messenger observatories of neutral particles [156]. These can be combined with gravitational wave detection and conventional radio, optical, X-ray and gamma-ray astronomy to greatly improve our knowledge about the most powerful objects in the Universe, as happened with the discovery of gravitational and electromagnetic radiation from the binary neutron star merger system in 2017 [157], with no neutrinos identified in temporal and spatial coincidence with it [158].

Astrophysical interpretation. A coherent picture of the nature and sources of CRs is emerging from the observations of the spectrum, composition and arrival directions, with many open questions. Cosmic rays below $\simeq 10$ PeV most likely have a galactic origin. The observed dipolar anisotropy in arrival directions imply that above 8 EeV they have their origin in extragalactic sources. One likely scenario is that the transition takes place at a few EeV, a hypothesis supported by the observed phase of the dipolar anisotropy changing around that energy from pointing to near the Galactic Center towards away from it (Fig. 30.5). Cosmic-ray rigidity Ze determines the maximum energy at which different particle species can be accelerated in the sources $E_{\rm max}(Z) = Z \times E_{\rm max}(Z = 1)$. As a consequence, protons would cutoff first in the spectrum, followed by helium, carbon ... up to iron. The observed increase with energy of the mass below the *second knee* could be interpreted as the signature of the end of the Galactic contribution dominating below the *second knee* [159]. As energy increases above a few times 100 PeV, the composition starts to become lighter. This could signify the

emergence of an extragalactic component because no correlation with the densely populated Galactic plane is observed. A combined fit of the Pierre Auger Observatory measurements of the UHECR energy spectrum and composition [160] is compatible with the existence of this extragalactic component along with a second one at higher energy responsible for the sharp change in spectral index at the *ankle* feature in the spectrum at $\simeq 5\,\mathrm{EeV}$. Observations above the ankle suggest that each accelerated nuclear species from protons to iron, dominates in a narrow energy band of the UHECR spectrum produced through a combination of the individual composition peaks. In particular, the *instep* reflects the interplay between the flux contributions of the helium and carbon-nitrogen-oxygen components injected at the source with their distinct cutoff energies, all shaped by nuclear photodisintegration on background light during the propagation. This is consistent with the *suppression* above $\simeq 50\,\mathrm{EeV}$ attributable to the E_{max} reachable at the cosmic accelerators along with the GZK and photodisintegration propagation effects. This comprehensive and unified understanding is continually evolving as additional data accumulates. Multi-messenger observations of the expected secondary neutrino and gamma-ray fluxes, or the lack thereof, will provide valuable constraints.

Hadronic interactions and Extensive Air Showers. EAS detectors probe energy and phase-space regions of hadronic interactions currently not accessible with terrestrial accelerators, although only in a very indirect manner. The tail of the distribution of X_{max} is sensitive to the attenuation length of primary p in the atmosphere, and the inelastic p-air cross-section can be inferred. In this manner, measurements of the p-air cross-section have been obtained at equivalent center-of-mass pp collision energy, $\sqrt{s_{pp}} > 40\,\mathrm{TeV}$, and are in agreement with model predictions within systematic uncertainties [142]. The muonic component in the air shower is generally used as a probe of the hadronic interactions during the shower development. Various measurements of muons with energies in the $\simeq 100\,\mathrm{MeV}$ to $\simeq 10\,\mathrm{GeV}$ range produced in EAS, have revealed that hadronic models of multiparticle production fall short in predicting the observed number of muons above cosmic-ray energies of $\simeq 100\,\mathrm{PeV}$ [161]. On the other hand, the simulated shower-to-shower fluctuations in the muon number that are particularly sensitive to the first hadronic interactions in the shower, are in good agreement with the measurements [162]. This indicates that the shortage in the number of simulated muons builds-up in multiple soft-QCD processes throughout the EAS development rather than being driven by only the first few and highest-energy interactions of the EAS. This constrains possible explanations of the so-called *Muon Puzzle* based on new physics beyond the Standard Model.

30.3 Gamma Rays

There is a well-studied flux of cosmic gamma rays (defined here as having energy greater than 1 MeV) present at the top of the atmosphere. Known as the diffuse gamma-ray flux, it has been measured with multiple space and ground-based instruments across a broad range of energy. On top of the diffuse one, many discrete sources have been found with either a steady gamma-ray flux or variability of many types.

30.3.1 *Observational Instruments: Space borne and Ground based*

Space borne γ-ray detectors, including AGILE [163], DAMPE [164], CALET [165], mainly Fermi-LAT [166], cover the energy range above 10 MeV up to 100 GeV. With the wide Field-of-View (FoV), they effectively survey the whole sky for steady γ-ray sources, and monitor all types of transient phenomena such as flares of Active Galactic Nuclei (AGN) and γ-ray bursts (GRBs). Above 100 GeV, ground-based Imaging Air Cherenkov telescope (IACT) experiments H.E.S.S [167], MAGIC [168], VERITAS [169] and CTA-LST [170] are very effective observational instruments. Using the stereo measurement technique, the IACT arrays achieve the angular resolution of the arrival direction of γ-rays at the level of 3 arc minute which is necessary for the high precision measurements of discrete sources. The small Field-of-View (FoV) of the telescopes and low-operation duty cycle make the all-sky surveys for new sources difficult. Only H.E.S.S scanned the region along the Galactic plane around the Galactic Center [171], as shown in Figure 30.9. Non-imaging Cherenkov light technique is also developed trying to cover wider FoV, e.g. in the TAIGA experiment [172]. The most suitable detectors for all-sky surveys are extensive air shower detector arrays at high altitudes, such as ARGO-YBJ [173], AS$_\gamma$ [174], HAWC [175] and LHAASO [176]. They are operated with very high duty cycle, typically $> 95\%$, have compatible sensitivity for discrete sources to IACT telescopes in much wider FoV in the same energy band, and higher sensitivity at higher energies above 10 TeV. In Table 30.1, the main features of the major facilities in γ-ray astronomy are listed.

30.3.2 *Diffuse Gamma Rays*

The majority of photons detected at high energies are characterized as diffuse emission that is not resolved as discrete sources. The observations of the diffuse emission are mainly carried out by wide FoV detectors, including space missions, OSO-3 [180], SAS-2 [181], COS-B [182], CGRO/EGRET [183], and Fermi-LAT [184] at energies below 1 TeV, and ground-based experiments Milagro [185], H.E.S.S [171], ARGO-YBJ [186], ASγ [187] and LHAASO [33] at energies up to 1 PeV. Evident in Figure 30.9, the dominant component comes from the plane of the Galaxy (i.e., $|b| \lesssim 10^\circ$, and is referred as the Galactic Diffuse Emission (GDE). Precise measurement of the GDE flux strongly depends on the subtraction of the contamination from discrete sources most of which are found spatially extended. With significantly improved sensitivity of source detection, Fermi-LAT and LHAASO largely reduce the contamination by removing the regions associated with known sources. In case of LHAASO, the flux in the Galactic plane with longitudes of $15^\circ < l < 235^\circ$ and latitudes of $|b| < 5^\circ$ is well measured [33].

Three components are expected in GDE, namely γ-rays from the decay of neutral pions produced via inelastic collisions between energetic cosmic ray nuclei and the interstellar medium (ISM); bremsstrahlung radiation of electrons and positrons in ISM; and inverse Compton scattering of electrons and positrons off the interstellar radiation field. Possible annihilation or decay of dark matter (DM) particles might also give rise to diffuse γ-rays particularly in the densest region of the Galaxy. Therefore, GDE serves not only as a very important tool to probe the production, propagation, and interaction of cosmic rays, but also as a route to search for DM in any excess over the expectation, which is based on assumptions of the cosmic-ray spatial distribution, composition, energy spectrum and on the ISM column density along the line-of-sight. The search for DM also depends on the fraction of the contribution by the unresolved dim discrete sources in the GDE. Unfortunately, all of the assumptions have their own large uncertainties at present.

Evidence of an isotropic component of diffuse γ-ray emission, presumably of extragalactically originated, was obtained with the measurement of its spectrum by CGRO/EGRET [188] and Fermi-LAT [189]. The Fermi-LAT spectrum covers the energy range from 0.1 GeV to 820 GeV and is well described by a power-law with an exponential cutoff. It is consistent with a scenario of a discrete source population, such as blazars with power-law spectral shape, dominating the emission and experiencing attenuation due to the extragalactic background light (EBL) [189]. Contributions from the cascade of very-high-energy gamma rays and UHECRs are not ruled out as a fraction of the extragalactic diffuse emission.

30.3.3 *Discrete Gamma Ray Sources*

As a neutral component of cosmic rays, γ-rays directly reach the earth from their sources, thus allowing us to identify the origin of the photons by association with known celestial objects or events. As shown in Figure 30.9, the source-associated contributions are revealed directly by the bright spots whose sizes are due to the point-spread-function (PSF) of the instruments and the intrinsic spatial extensions of the sources. It is also clearly shown that the sources are divided into two groups: *Galactic* and *extragalactic*.

Galactic Sources More than 6600 sources have been found emitting γ-rays in the Milky Way. Most of them have steady photon emissions over a wide energy range above 0.1 GeV up to

Table 30.1: Facilities for γ-ray detection and their specifications in reference *a*) [166], *b*) [177], *c*) [178], *d*) [179], *e*) [170], *f*) [174], *g*) [173], *h*) [175], *i*) [176]. † milli-CU = 10^{-3} Crab Unit.

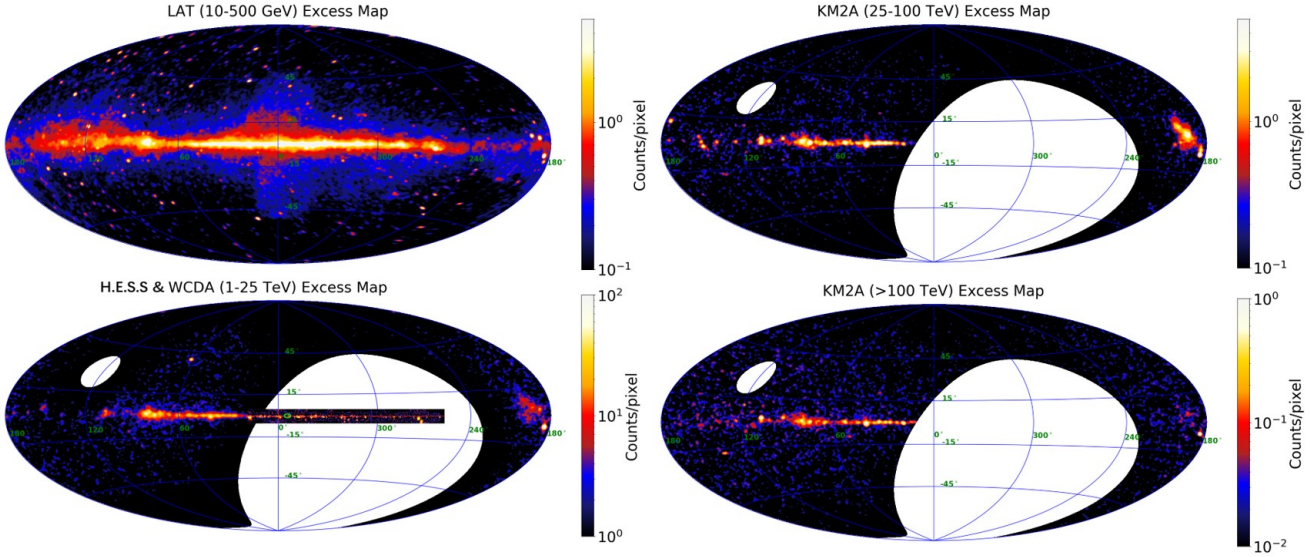

Figure 30.9: The GeV γ-ray sky maps surveyed by Fermi-LAT [184], LHAASO [38] and H.E.S.S [171] from 1 GeV to 100 TeV and above.

2 PeV. 43 of them have emission of γ-rays above 0.1 PeV referred as *PeVatrons* since the parent particles that emitted the photons must be accelerated above 1 PeV on average in the source regions. Variability of the photon fluxes has also been observed from known objects such as pulsars and binary systems or transient phenomena.

A. Sources with steady emissions are the majority of Galactic γ-ray emitters which are well documented in reviews [190], [191], [192] and in γ-ray source catalogs [193] (for $<$ 100 MeV), 4FLGT (for 0.1-300 GeV) by Fermi-LAT [194], TeVCatalog available on-line (http://tevcat.uchicago.edu) and the newly released 1LHAASO (for 1-2000 TeV) by LHAASO [38]. All associations with known celestial objects, such as SNRs, PWNe, young massive-star clusters (YMC) are discussed in the corresponding catalog papers (e.g. individual catalogs collected in http://tevcat.uchicago.edu). Most of the sources, particularly for their high-energy emission above tens of TeV, remain unidentified. Among the identified ones, the Crab [195] and RX J1713-3946 [196] are the most extensively studied objects and constitute paradigmatic examples of PWNe and SNRs.

The Crab has a compact PWN powered by the rotation energy of the pulsar in its heart. Electrons and positrons in the wind are accelerated at the termination shocks and emit γ-rays through synchrotron radiation at energies lower than 0.1 GeV. Simultaneously, accelerated electrons and positrons boost soft background photons, such as those in the cosmic microwave background, to energies well above 1 GeV via inverse Compton scattering. Figure 30.10 shows the spectral energy density (SED) of the Crab nebula with a fit using a simple one-zone leptonic model. It generally describes the radiation of the nebula over energies up to $E_\gamma \sim 1.1$ PeV, implying that electrons and positrons are confined in a small region of $\simeq 0.2\,$pc by a magnetic field of intensity $B \simeq 110\,\mu$G and are accelerated to energies as high as $\simeq 2.3\,$PeV. This requires a surprisingly high acceleration rate, $\eta = \bar{\epsilon}/B = 0.14(B/100\mu\text{G})(E_\gamma/1\text{ PeV})^{1.54}$ PeV, at the level of 15%, where $\bar{\epsilon}$ is projection of the electric field averaged over the particle trajectory. This rate is 3 orders of magnitude higher than that in the normal shock environment such as in SNRs, revealing the existence of a so-called 'extreme accelerator' in the middle of the nebula [195]. The flux of photons above 0.8 PeV indicates some deviation from the pure leptonic scenario implying that a hadronic component might be responsible. It could be a hint of the super PeVatron which may contribute to the Galactic cosmic rays above the knee [195] (see Fig. 30.1).

RX J1713.7-3946 is one of the brightest objects in the TeV sky, and is the first SNR shell to be confirmed as a TeV gamma-ray source [196]. The detailed TeV morphology reveals a shell structure similar to the X-ray observations, indicating that particles are accelerated to very high energy therein. The TeV gamma-ray spectrum extends to nearly 100 TeV. It is not determined yet whether the gamma-rays are produced via Inverse Compton scattering of relativistic electrons (leptonic process), or via neutral pion decay with the pions produced in the inelastic scattering of CR protons with ambient gas (hadronic process) [200]. Nevertheless, the spectral information demonstrates the efficient acceleration of charged particles to energies beyond 100 TeV in this

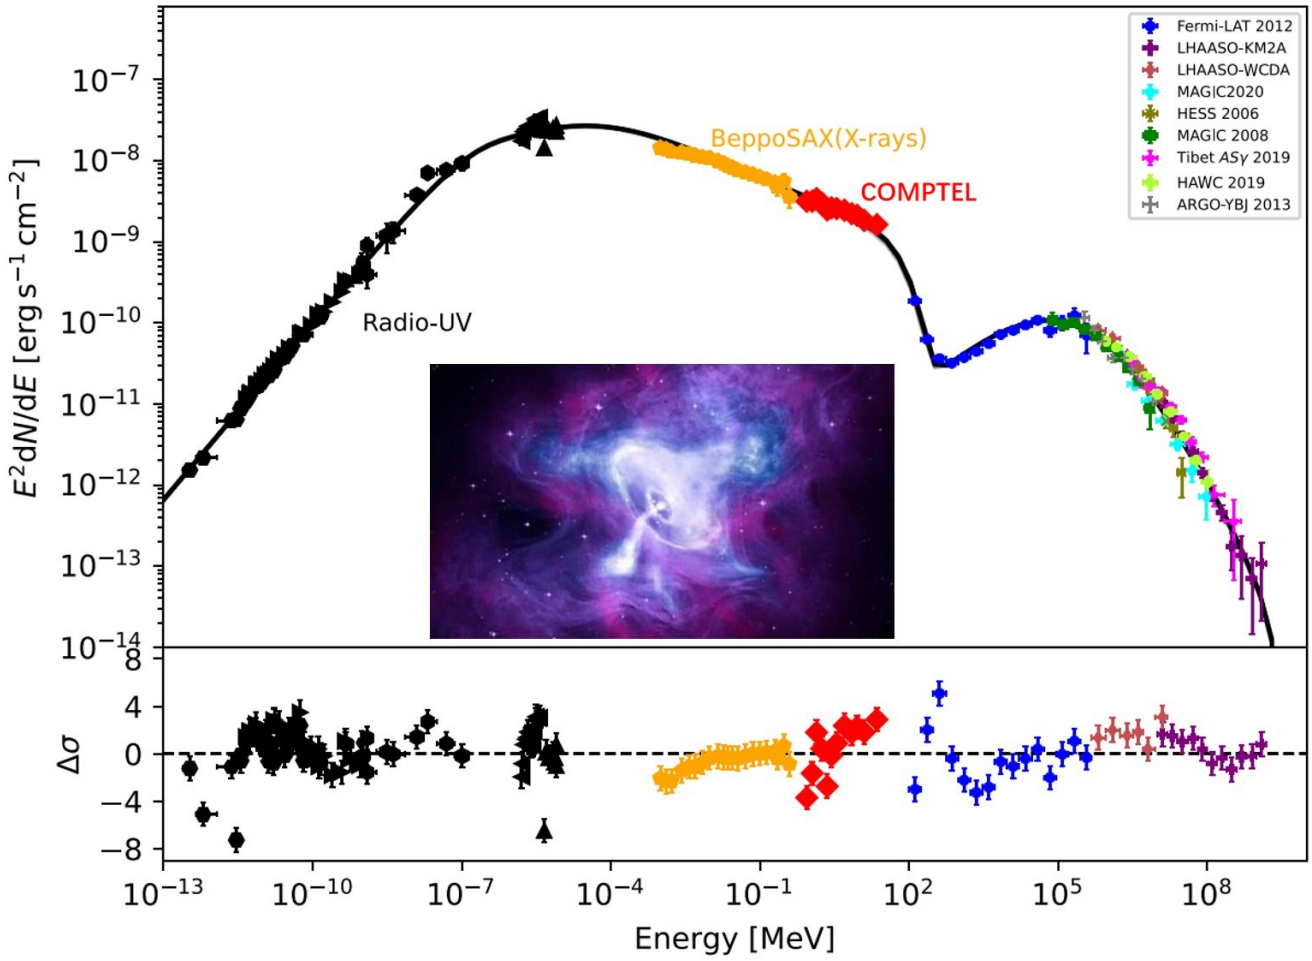

Figure 30.10: Spectral energy density (SED) of photons from the Crab from sub-μeV to 1.1 PeV. Above 1 TeV, data are collected from 7 experiments listed in legend in the upper panel. The lower panel shows the deviation between data and the model based on a widely accepted one-zone leptonic origin in the nebula. Only Fermi-LAT and LHAASO data are shown for simplicity. Inset is the X-ray image of the nebula by Chandra [197].

object. The latest H.E.S.S observations also found that the TeV gamma-ray emission region extends significantly beyond the X-ray emitting shell [201], which may be due to either the escape of particles from the shell or to particle acceleration in the shock precursor region.

B. Variable sources Crab flares, binaries and pulsars are observed in the Galactic γ-ray sky. Their activity varies on timescales from a fraction of one second (pulsars), to days (Crab Nebula, Novae), weeks, months or even years (γ-ray binaries). Various analysis pipelines are developed mainly by the LAT collaboration to search for and monitor γ-ray transients.

The Crab Nebula shows flare activities on a timescale of days [202]. The instability is observed only in GeV band by AGILE and Fermi/LAT. The flaring mechanism is still unclear with a couple of models being under debate.

Each γ-ray binary is composed of a compact object (pulsar or black hole) and a massive star. Their γ-ray emissions characterized by the orbital modulation, with time scales ranging from 3.9 days (LS 5039) to $\sim$ 47 years (PSR J2032+4127). Microquasars are also binary systems that launch powerful jets from the compact objects by accreting matter from their companions. Three microquasars have been detected namely, Cyg X-1, Cyg X-3, and SS 433. They have shown γ-ray activities correlated with orbital motion [203], jet precession [204], X-ray state changes [205], and flares [206]. Eta Carinae is the only colliding wind binary firmly detected, showing orbital modulation in the γ-ray emission in a period of 5.54 years [207].

Pulsars show steady pulsation on their spin periods ranging from several milliseconds to seconds in GeV band [208], thereby qualifying as γ-ray pulsars. Only the Crab and Vela pulsar are pulsating in TeV [209] [210]. PSR J2021+4026 is observed for the γ-ray flux variability on time scales of several years [211], making it the only variable γ-ray pulsar. Many millisecond pulsars themselves are γ-ray pulsars showing periodic variability in milliseconds [212]. γ-ray eclipses and orbital modulations have been detected in several binaries hosting millisecond pulsars, usually on the time scale of hours to days, arising from the intra binary shock between the pulsar wind and stellar wind [213] [214]. Millisecond pulsars could transit between spin-down-powered state and accretion-powered state. Variability in the γ-ray flux is observed accompanying these changes [215].

Novae outbursts have been detected in γ-rays, arising from the particle acceleration at shocks and last for months [216]. RS Ophiuchi is the first nova with its outburst detected in TeV up to 1 month [217].

Extragalactic Sources The majority of extragalactic γ-ray sources are active galactic nuclei (AGN). The fourth catalog of AGNs (4LAC) by LAT for 8 year observations contains 2863 objects located at high Galactic latitudes ($|b| > 10°$) while 344 others were found at lower latitudes [218]. 98% of them are blazars. The blazar population consists of Flat Spectrum Radio Quasars (FSRQs), BL Lac-type objects and unknown types [218]. The Data Release 3 adds 587 more blazars and 4 radio galaxies to the catalog [219]. More than 70 blazars and a few radio galaxies are detected in the very high-energy (VHE) band, namely photon energy greater than 0.1 TeV, by imaging atmospheric Cherenkov

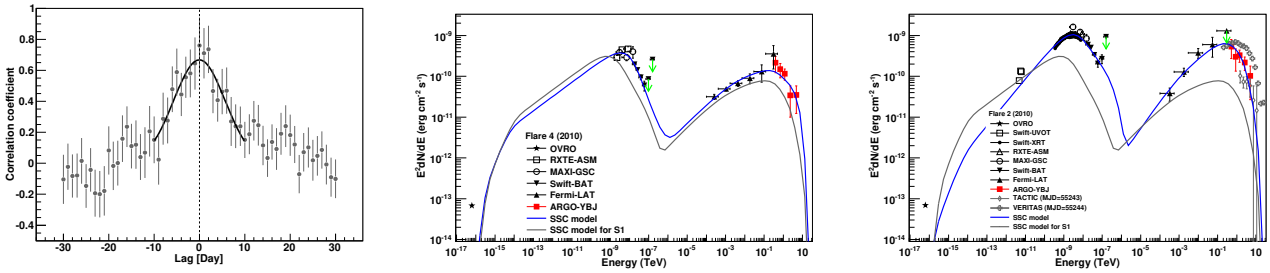

Figure 30.11: The multi wavelength analysis of Mrk 421 involving measurements over wide energy range from radio to TeV γ-ray during 4.5 years when ARGO-YBJ and LAT were operated [198]. The discrete correlation function between the light curves in X-ray band and TeV γ-ray band is calculated and clearly shows no time lag between emissions in the two bands [198] (left panel). The SED significantly changes from steady states (grey solid lines in middle and right panels) to flaring states depending on the strength of flares. Comparing a small flare in the middle panel and a larger one in right panel, the later has harder SED in VHE band [199].

telescopes (IACT) (http://tevcat.uchicago.edu).

Blazars belong to a class of AGN where the jets are oriented at a relatively small angle with respect to the line of sight. This specific viewing angle allows us to observe the emission from those jets with significant Doppler boosting. The photon flux in the jets may enhance significantly with respect to that in quiet states, a phenomenon referred to as blazar flares. They are simultaneously observed over a wide energy band from radio to VHE γ-rays with timescales ranging from a few minutes to year [220] [221]. The broad-band SED of blazars typically shows two humps of non-thermal radiation. The one in the lower energy range from radio to X-rays is generally attributed to synchrotron emission from relativistic electrons and positrons in the jet, while the origin of the hump at higher energies is still under debate. Possible emission mechanisms are the IC scattering of accelerated leptons off low energy photons, which are inside jets or from outside regions [222], or decay of neutral pions produced in collisions of accelerated protons against ambient matter [223], or some combination of the two processes.

The ground-based EAS experiments are suitable γ-ray detectors for monitoring the flares of AGNs with the advantages of large FoV and full duty cycle of operation. The ARGO-YBJ collaboration reported a long-term continuous monitoring of Mrk 421 and Mrk 501 [198, 199, 224], the two brightest blazars in the TeV sky. The γ-ray flux shows a good long-term correlation with that in the X-ray band. HAWC detected the persistent emission from those two AGNs [225]. Recently, the LHAASO collaboration reported eight sources detected at Galactic latitude $|b| > 12°$, among which some are AGNs, including well-known emitters, such as the radio galaxy M87, VER J0521+211 and 1ES 1215+303 [38].

Using data for 4.5 years when ARGO-YBJ and Fermi-LAT simultaneously operated from 2008 to 2013, the ARGO-YBJ collaboration realized the long-term multi wavelength observation of Mrk 421 in all bands of radio, optical, X-ray, GeV, and TeV gamma-rays [198]. The well-known correlation [226] between the photon fluxs in X-ray band and TeV γ-ray band is investigated in a quantitative way, namely the discrete correlation function between the light curves in two energy bands being calculated. No time lag in the scale of days is found(see Figure 30.11). This is regarded as evidence of favoring the one-zone Self-Synchrotron Compton scattering scenario [199].

Flares happened in that time window are systematically analyzed and clear correlation between the strength of flares and features of the SEDs are observed as an example shown in Figure 30.11. Detailed investigation of SEDs implies that various particle acceleration mechanisms, such as relativistic diffusive shock acceleration, might be responsible for different flares. A similar analysis is carried out with data during outbursts of Mrk 501. The SEDs in the VHE band are observed to be harder during flares than that in the quite period. The detection of energetic photons above 10 TeV and the hardness of the SED hint some exceeds over the expectation of one-zone SSC model [224].

Gamma-Ray Bursts (GRBs) GRBs are violent explosions observed in distant galaxies, characterized by a rapid flash of γ-rays lasting from a fraction of a second up to several hundreds of seconds. The emission from GRBs occurs in two stages, namely the prompt emission phase and the afterglow phase, as can be seen in Figure 30.12.

In the second catalog of Fermi/LAT-detected GRBs, covering the first 10 yr of operations, 169 GRBs are detected above 100 MeV [231]. The high-energy emission generally lasts much longer than the prompt keV-MeV emission. The widely discussed scenario for the extended GeV emission is synchrotron radiation by relativistic electrons that are accelerated in shocks resulting from the interaction of the jet with the surrounding medium [232, 233].

VHE emission has been detected from just a few GRBs by IACTs during the afterglow decay phase. MAGIC slewed to the direction of GRB 190114C only $\simeq$ 60 seconds after the trigger and detected photons above 300 GeV from the burst for the first 20 minutes [234]. This VHE emission is explained by inverse Compton up-scattering of synchrotron photons by high energy electrons in the external shock [229], as shown in the right-upper panel of Figure 30.12. Two other events, GRB 180720B and GRB 190829A, were also detected during the afterglow decay phase by H.E.S.S [230, 235], the unexpected SED is shown in the right-lower panel of Figure 30.12.

The brightest-of-all-time GRB 221009A serendipitously occurred within the FoV of LHAASO. More than 64,000 photons (above 0.2 TeV) were detected within the first 3000 seconds by LHAASO-WCDA [228]. The detection covers both the prompt emission phase and the early afterglow in the TeV band, revealing the onset of afterglow emission in the TeV band for the first time, as shown in the left panels of Figure 30.12. In addition, the unprecedented photon statistics of the TeV emission enabled identifying a jet break in the light curve, indicating an opening angle of GRB 221009A of $\sim 0.8°$. This is consistent with the brightest core of a structured jet, explaining the unexpected high isotropic equivalent energy of this GRB. LHAASO-KM2A registered more than 140 photons with energies above 3 TeV from GRB 221009A (to be published). The intrinsic energy spectrum of gamma-rays is well fitted by a power law after correcting for EBL absorption, with the highest energy photon above 13 TeV traveling over a distance with red shift $z \sim 0.152$(TBP).

Tests on Lorentz Invariance Violation (LIV) Tests on LIV are feasible and thus, limits can be set using the highest energetic photons collected from remote sources. Any tiny violation of the invariance leads the fundamental dissipation relation to be rewritten [236] as $E^2 = m^2c^4 + p^2c^2(1 + A_1 pc/M_p c^2 + A_2(pc/M_p c^2)^2 + ...)$, where E, p are the energy and momentum of a particle with the mass m, the M_p is the Plank scale and A_1, A_2 are theoretic parameters of the violation at the first and second order levels. This must lead instability of photons that may decay on their way to the Earth [237]. The first order violation effect due to the decay channel $\gamma \to e^+ + e^-$ has not been found at energies $\sim$5 orders

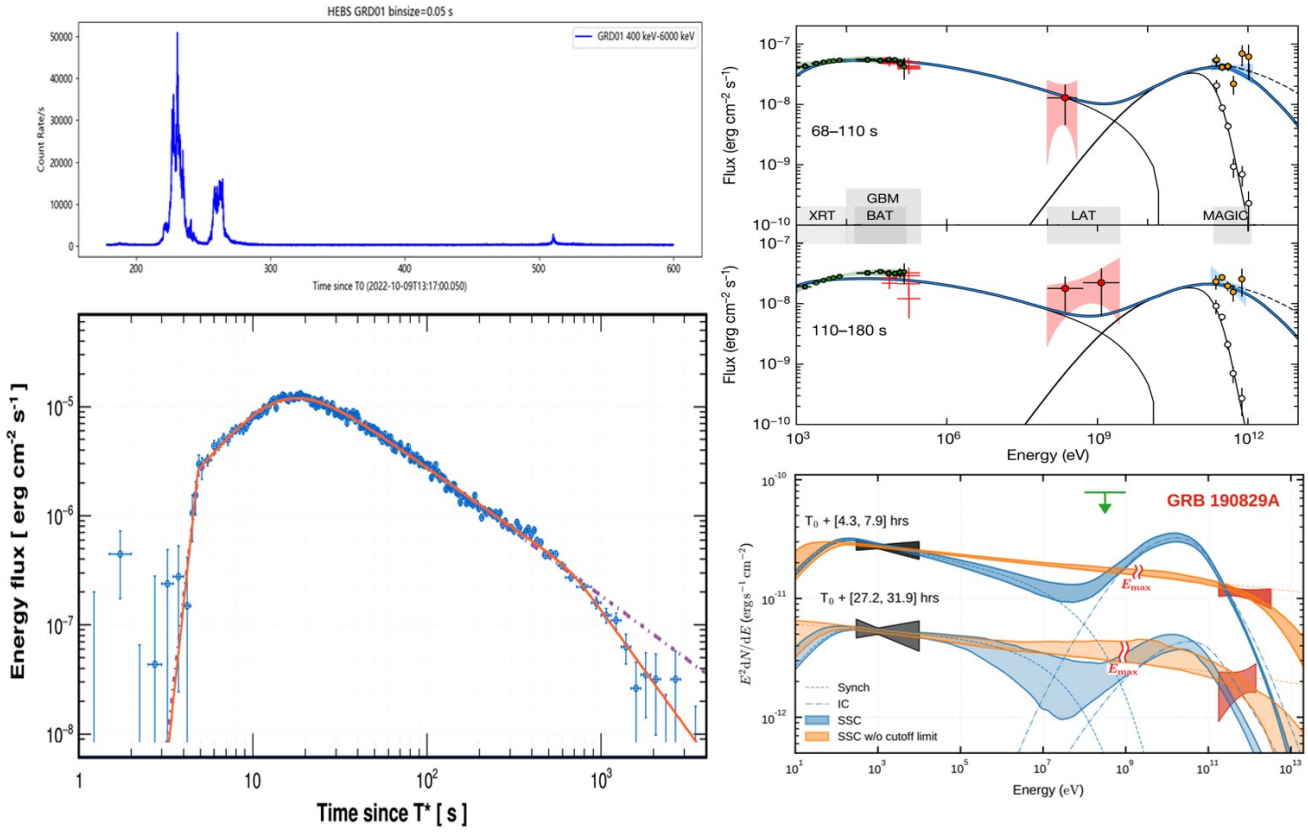

Figure 30.12: The typical multi-wavelength measurement of the light curves of the γ-ray burst GRB 221009A in the GeV band [227] (top left) and in the TeV band [228] (bottom left). The clear different structures of the brightness variation patterns indicate the different origins of the synchrotron radiation and inverse Compton scattering of leptons accelerated by the internal and external shock waves, respectively. The spectral energy distributions of the GRB 190114C and GRB 1908129A, respectively measured by MAGIC [229] (top right) and H.E.S.S [230] (bottom right). The Self-Synchrotron Compton scattering model of the afterglow is marginally supported in the observations covering a wide energy band from X-rays to TeV γ-rays.

of magnitudes higher than the Planck scale, regarded as the null evidence of the quantum gravitational effect. However, the limit due to second-order effect caused by decay channel $\gamma \to 3\gamma$ is still found still ∼3 orders of magnitudes below the Planck scale, using the latest observations of photons up to 1.4 PeV from the Cygnus X direction [238].

30.4 Neutrinos

In contrast to charged particles, neutrinos are not deflected by electromagnetic fields and thus point back to their origin, making them appealing messengers for astronomical observations. In addition, neutrinos of cosmic origin, or produced in the atmosphere of the Earth, allow us to study particle physics in a kinematic regime not accessible to date to accelerator experiments. In the following, we will consider neutrinos with energies at the GeV energy scale and above.

30.4.1 *Production of high-energy neutrinos*

High-energy neutrinos can be produced in hadronic interactions in a variety of astrophysical objects (*astrophysical* or *cosmic* neutrinos), in scattering of extremely energetic protons (p) with the cosmic microwave background (*cosmogenic* neutrinos) and by cosmic-ray interactions in the Earth's atmosphere (*atmospheric* neutrinos). The main production chain is (A denoting atomic nuclei and X a hadronic system)

$$\begin{aligned} p(A) + p(A,\gamma) &\to \pi^{\pm} + X \\ &\text{with subsequent decays} \\ \pi \to \mu\,\nu_\mu \text{ and } \mu &\to e\,\nu_\mu\,\nu_e\ , \end{aligned} \tag{30.1}$$

resulting in a ratio $\nu_e : \nu_\mu : \nu_\tau = 1 : 2 : 0$ (not distinguishing here between ν and $\overline{\nu}$). If the source density is high, muons can lose most of their energy before decaying, yielding a ratio $0 : 1 : 0$ in the extreme case. If protons were kept in the source region by magnetic fields without interacting, and only neutrons could escape and then decay via $n \to p + e^- + \overline{\nu}_e$, the ratio would be $1 : 0 : 0$. Over cosmic distances, flavor mixing turns these ratios to 0.30:0.36:0.34 for the first source scenario (1:2:0), 0.17:0.45:0.37 for the second (0:1:0) and 0.55:0.17:0.28 for the third scenario (1:0:0) [239].

30.4.2 *Measurement methods*

Most experiments targeting high-energy cosmic neutrinos are based on the detection of Cherenkov light induced by charged secondary particles produced in neutrino interactions. This includes underground detectors like Super-Kamiokande with its fiducial volume of $22.5 \times 10^3\,\mathrm{m}^3$ (see Sect. 36.3.1) and underwater/ice detectors like ANTARES, KM3NeT or IceCube, the latter with a volume of $10^9\,\mathrm{m}^3$ (see Sect. 36.3.2). Neutrinos with energies exceeding some tens of PeV can be also detected via the coherent emission of Cherenkov radiation at radio wavelengths in ice or other radio-transparent media (e.g. ANITA or RNO-G, see Sect. 36.3.3). Neutrinos with EeV energies could be identified via extensive air showers starting too deep in the atmosphere to be due to particles with strong or electromagnetic interaction. Alternatively, they could be detected via slightly upward-directed air showers from the decay of tau leptons generated in interactions of Earth-skimming or mountain-traversing ν_τ [249]. These signatures could be observed by cosmic-ray experiments such as the Pierre Auger Observatory [250].

30.4.3 *Diffuse fluxes*

Atmospheric neutrinos The flux of atmospheric neutrinos as measured by different experiments is shown in Fig. 30.13. The production chain for *conventional* atmospheric neutrinos follows eq. (30.1), with an observed ratio $\nu_e : \nu_\mu = 1 : 2$ at energies of

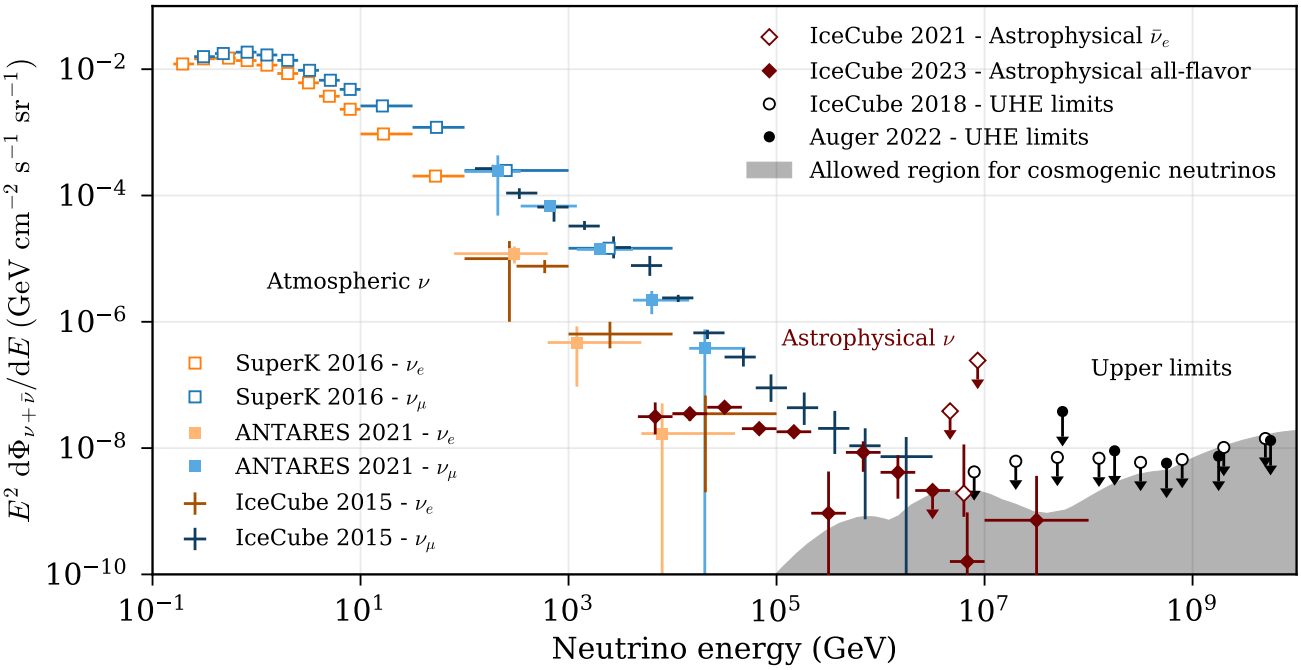

Figure 30.13: Measured energy spectra of atmospheric and cosmic diffuse neutrino fluxes. Experimental limits at highest energy are compared to model predictions for cosmogenic neutrinos [160]. All fluxes are normalized to one flavor ($\nu + \overline{\nu}$), assuming a ratio $\overline{\nu} : \nu = 1$ and, for cosmic neutrinos, a ratio $\nu_e : \nu_\mu : \nu_\tau = 1 : 1 : 1$ at Earth. Data sources: SuperK 2016 [240]; ANTARES 2021 [241]; IceCube 2015 ν_e [242]; IceCube 2015 ν_μ [243]; IceCube 2021 astrophysical $\bar{\nu}_e$ ($\nu + \overline{\nu}$ flux derived from a single candidate event for the Glashow resonance) [244]; IceCube 2023 astrophysical all flavor [35]. The limits at the highest energies are taken from [245] (IceCube) and [246] (Auger). They are shown in the energy bins used for the corresponding analyses and have been adjusted to bin widths of one decade. The region allowed for the expected cosmogenic neutrino fluxes is taken from [247] (see also Fig. 36.10).

a few GeV (where almost all muons decay in the atmosphere), and a ratio below 1 : 10 at TeV energies, where muons reach the ground before decaying. The flux of muon neutrinos with energies below 100 GeV from the lower hemisphere is reduced due to neutrino oscillations, reducing the $\nu_e : \nu_\mu$ ratio at the lowest energies. The flux of ν_e is obtained by subtracting the number of neutral-current muon neutrino interactions (as deduced from the measured charged-current muon neutrino reactions) from the number of contained events without a muon track and converting the resulting E_{ν_e} distribution into the ν_e flux using the differential cross sections for CC and NC ν_e-nucleon scattering. The conventional atmospheric neutrino flux dominates in the GeV to TeV region, following an $E_\nu^{-3.7}$ power law.

Prompt atmospheric neutrinos are produced by the decay of hadrons containing a charm or bottom quark, the production of which is strongly suppressed. Since they are produced early in the air shower and decay before losing energy, however, the energy spectrum of prompt neutrinos is expected to be harder ($E_\nu^{-2.7}$) and to dominate the atmospheric neutrino flux at its highest energies. The corresponding theoretical prediction has large uncertainties related to the cosmic-ray spectrum and mass composition, the model for heavy-flavor production, and the parton distribution functions [251]. At present, experimental measurements only provide upper limits for the prompt flux (see e.g. Fig. 30.14 where the prompt component was fitted to zero).

Diffuse extragalactic neutrino flux In 2013, a diffuse and isotropic flux of neutrinos of astrophysical origin was discovered with the IceCube Neutrino Observatory. The flux was identified with the so-called HESE (high-energy starting events) selection as an excess of neutrino events at high energies over atmospheric neutrinos and a background of misreconstructed atmospheric muons (see Fig. 30.14, for the 7.5-year HESE sample [252]). Similar high-energy excesses were also identified for tracks entering the detector from outside [253], and for fully contained cascade events. Evidence for this flux has meanwhile also been reported by ANTARES [254] and Baikal-GVD [255], albeit with much lower significance. The measured fluxes are consistent with a parameterization as power-law functions proportional to $E_\nu^{-\gamma}$, with the normalization factor and the spectral index γ as parameters. The resulting γ values vary from 2.2 to 2.5 for different event classes covering different energy ranges.

Different production mechanisms result in different neutrino flavor compositions at sources and, after neutrino oscillations over astrophysical distances, at the Earth. An IceCube study of the event topologies [239] slightly favors $\nu_e : \nu_\mu : \nu_\tau = 1 : 2 : 0$ at the source (pion decay according to eq. (30.1) versus 0 : 1 : 0 (damped muons) and disfavors a 1 : 0 : 0 scenario (neutron decay).

A single event with energy 6.05 ± 0.72 PeV has been detected in IceCube [244]. It is compatible with having been generated by the resonant process $\bar{\nu}_e + e^- \to W^- \to$ hadrons at $E_\nu = 6.3$ PeV (Glashow resonance) [256]. A statistically significant observation of the Glashow resonance would reveal the presence of electron antineutrinos in the astrophysical flux and could provide information about their production process: the expected ratio $\bar{\nu}_e : \nu_e$ depends on the mass composition of cosmic-rays and also on the photon density and the magnetic field strength of the source [257].

Cosmogenic neutrinos Cosmogenic neutrinos stem from the decay of charged pions generated in interactions of ultra-high-energy cosmic rays with cosmic microwave (a) and infrared (b) background radiation ($p + \gamma \to n + \pi^+$) [258] and from the decays of neutrons produced in photodisintegration processes [259, 260] (c). The neutrino flux at EeV energies is expected to be dominated by (a) and (c).

Measurement methods and experimental data are described in Sect. 36.3.3. and Fig. 36.10. The expected flux can be estimated from the measured spectrum and composition of charged cosmic rays, using the CMB density and the well measured properties of proton and nuclear interactions with photons at a center-of-mass energy in the GeV range. The current uncertainty of these pre-

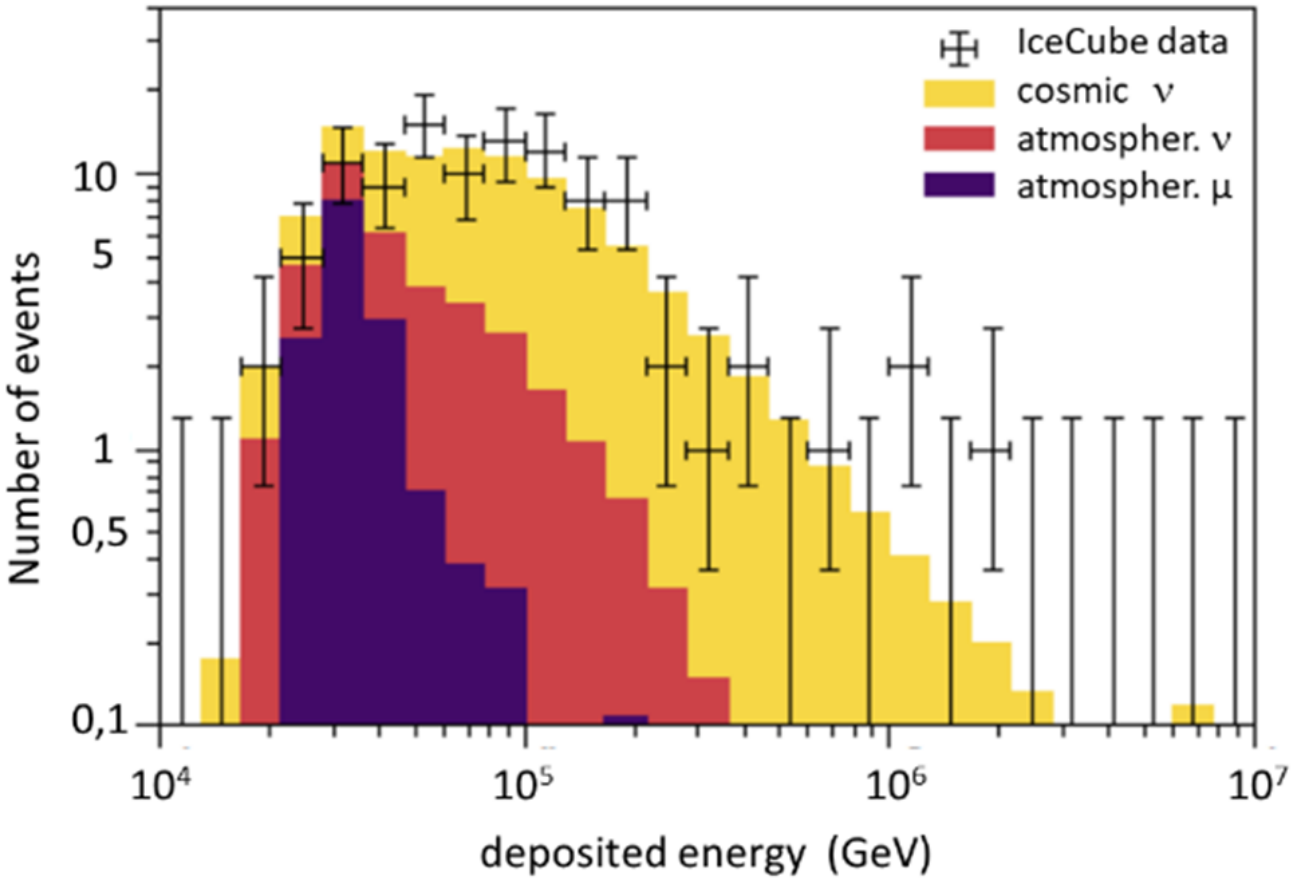

Figure 30.14: Measured (data points) and expected (histograms) distributions of the deposited energy measured in the IceCube detector for events passing the HESE selection, which strongly suppresses down-going atmospheric neutrinos by vetoing accompanying muons. The cosmic neutrino flux has been assumed to follow an unbroken power law in E_ν. Its normalization and spectral index, as well as the normalizations of the conventional and prompt atmospheric neutrino and the atmospheric muon contributions were fitted to the data, where only the region above 60 TeV was used to constrain the cosmic neutrino flux.

dictions exceeds one order of magnitude. Figure 30.13 reproduces the presently tightest limits and compares them to the region for which cosmogenic neutrino fluxes would be consistent with those limits (as of 2019) and cosmic-ray analyses [247].

Neutrinos from the Galactic Plane The Milky Way is an emitter across the electromagnetic spectrum ranging from radio to gamma-rays. A large part of the observed gamma-ray flux is believed to consist of photons from the decays of π^0s produced by cosmic rays colliding with the interstellar medium. The TeV diffuse neutrino flux from the corresponding $\pi^\pm$ decays along the Galactic plane has been estimated with different models, ranging from a simple extrapolation of Fermi-LAT gamma-ray data to higher energies, to more sophisticated approaches (see e.g. [261]).

First hints for a TeV neutrino emission from the Galactic Ridge have been reported by the ANTARES collaboration [262]. IceCube has measured the flux of galactic neutrinos with a significance of 4.5σ against the only-background-hypothesis [248]. Figure 30.15 shows a map of the Galactic plane with the point-by-point pre-trial significance of the IceCube neutrino observations. While the overall signal is consistent with the modeled diffuse emission from the Galactic plane, a significant part could also arise from a population of unresolved point sources. All individual "warm spots", however, are statistically consistent with background fluctuations.

30.4.4 *Neutrinos from astrophysical point sources*

Most point source candidates include Active Galactic Nuclei (AGN). In particular, blazars – AGN that have jets pointing towards the observer – are thought to be likely sources. In 2017, a spatial and temporal correlation was found between a flare of the electromagnetic emission from blazar TXS 0506+056 and the high-energy neutrino event IC170922A, detected by IceCube. An alert was sent to other observatories and a follow-up campaign in multiple wavelengths was started. At the moment of neutrino detection, the blazar was flaring in gamma rays, with an accidental coincidence excluded at the 3σ level [263]. Subsequent analyses of archival data revealed an excess in neutrino events with a significance of 3.5σ with respect to the expected atmospheric background, coincident with the position of TXS 0506+056, albeit not correlated with an electromagnetic flare [264].

In another analysis, the positions of 110 gamma-ray sources selected a priori were analyzed individually for a possible surplus of neutrinos over atmospheric and cosmic background expectations. An excess of 79^{+22}_{-20} neutrinos was found in the direction of the nearby AGN NGC 1068 (not a blazar, but a Seyfert-2 galaxy), at a significance of 4.2σ (see figure 30.16). The excess is spatially consistent with the direction of the strongest clustering of neutrinos in the Northern sky. The inferred flux exceeds the potential TeV gamma-ray flux by at least an order of magnitude [265], suggesting that the sight to the gamma-ray generation region is obscured, as expected for Seyfert-2 galaxies.

Other potential sources include starburst galaxies, galaxy clusters, supernovae remnants (steady emission) as well as Gamma Ray Bursts (GRBs) and Tidal Disruption Events, TDEs (transient emission). Indeed, using data from IceCube and the Zwicky Transient Facility ZTF, hints for a correlation of high-energy muon neutrinos with TDEs have been reported [266].

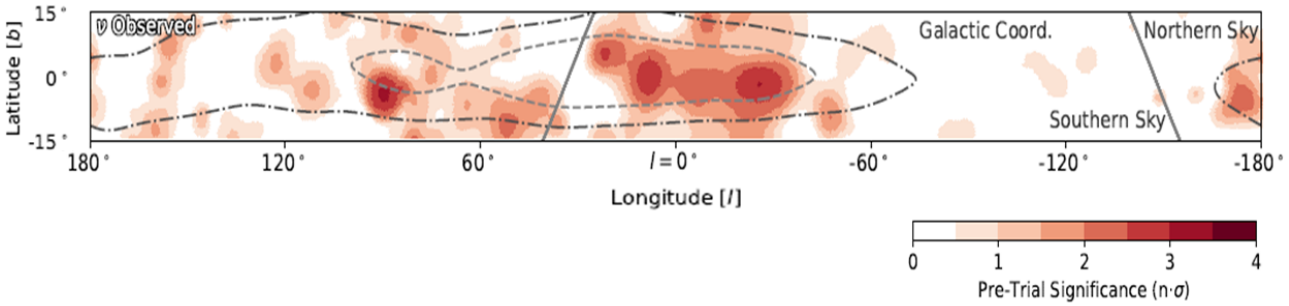

Figure 30.15: The Milky Way plane in neutrinos (Galactic coordinates, with the origin being at the Galactic Center). Shown is the pre-trial significance of the IceCube observations using a cascade neutrino event sample, calculated from an all-sky scan for point-like sources [248]. Contours indicate the regions that contain 20% and 50% of the predicted diffuse neutrino emission according to an extrapolation of Fermi-LAT results. Grey lines indicate the Northern-Southern sky horizon line.

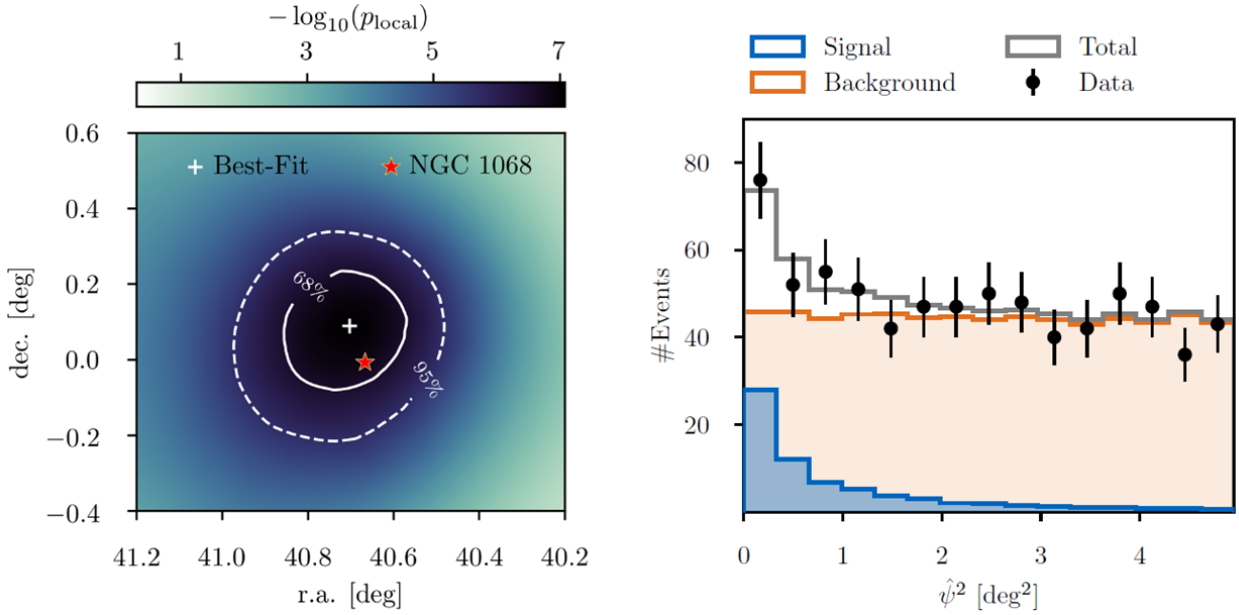

Figure 30.16: Left: The sky region around the most significant spot in the Northern Hemisphere and NGC 1068. Shown is a fine scan of the region around the hottest spot, marked by a white cross. The red circle shows the position of NGC 1068. The solid and dashed contours show the 68% and 95% confidence regions of the hot spot localization. Right: Distribution of the squared angular distance between NGC 1068 and the reconstructed event direction. Figures taken from [265].

30.4.5 *Results on particle physics*

Investigating the attenuation of high-energy neutrinos as a function of energy and their path length through the Earth, the first measurement of the neutrino-nucleon cross section at energies between a few tens of TeV and ≈ 1 PeV (corresponding to center-of-mass energies between a few 100 GeV and about 1.4 TeV) has been achieved [267], giving access in deep-inelastic scattering in a kinematic region currently not accessible to accelerator-based experiments.

The study of atmospheric high-energy neutrinos allows for the investigation of oscillation physics (see Sect. 14) at higher energies and over longer baselines than Earth-bound experiments. Constraints ($\sin^2\theta_{23} = 0.51 \pm 0.050$ and $\Delta m^2_{32} = (2.41 \pm 0.07) \times 10^{-3}\,\text{eV}^2$) have been obtained with IceCube and are compatible with corresponding results from accelerator experiments [268]. Both IceCube and KM3NeT/ORCA are also sensitive to ν_τ appearance [269]. The KM3NeT/ORCA detector (under construction, see Sect. 36.3.2) is furthermore expected to provide sensitivity to the neutrino mass hierarchy.

Also, Beyond-Standard-Model (BSM) physics is being tested. For instance, constraints by IceCube on 2/4 mixing (the fourth state being a sterile neutrino) are comparable to constraints from accelerator experiments [270]. Neutrinos may have BSM interactions, and if the coupling strengths are weak or if heavy mediators are involved, these interactions may only manifest themselves in the HE and UHE neutrino sector. Corresponding constraints from IceCube have been published in [271]. Also, possible oscillation-like effects induced by quantum gravity are investigated [272].

Acknowledgement Many thanks to team members, Prof. Q. Yuan, R.Z. Yang, J. Li, X.Y. Wang, S.Z. Chen and Dr. S.Q. Xi, L. Nie, R.F. Xu, who made substantial contributions to the γ-ray part of this section. We are grateful to C. Haack and L. Schumacher for their invaluable help in producing Fig. 30.13.

Experimental Methods and Colliders

31. Accelerator Physics of Colliders

Revised July 2023 by V. Shiltsev (FNAL) and F. Zimmermann (CERN).

This article provides background for the High-Energy Collider Parameter Tables that follow and some additional information; see in-depth review and a comprehensive list of references in [1]; citations below are limited to widely used textbooks and open access seminal papers and reviews.

31.1 Energy and Luminosity

Collisions of two beams of particles accelerated to high energies $E_{1,2}$ provide access to center-of-mass energies (c.m.e.) $E_{\rm cme} \approx 2\sqrt{E_1 E_2}$, assuming a typically small or zero crossing angle. Most of the 31 colliders that have ever reached the operational stage (seven are operational now) used equal masses and energies of colliding particles, with c.m.e. equal to twice the beam energy $E_{\rm cme} = 2E_{\rm b}$. Other machines collide beams of unequal energies, such as electron-proton or electron-ion colliders, or asymmetric B-factories, that produce new short-lived particles, whose decays are more easily detected and analyzed with a Lorentz boost.

In an accelerator, charged particles gain energy from an electric field, which usually varies in time at a high frequency ranging from 100s of kHz to 10s of GHz. With proper phasing to the RF field over distance l, the energy gain of a particle with charge Ze is proportional to the average accelerating gradient G, i.e. $\Delta E_{\rm b} = ZeGl$. In principle, the highest beam accelerating gradients achieved to date in operational machines or beam test facilities ($G \approx 100$ MV/m in 12 GHz normal-conducting RF cavities and 31.5 MV/m in 1.3 GHz superconducting ones) allow accessing high energies over reasonably long linear accelerators (linacs), but cost considerations often call for minimization of RF acceleration via repeated use of the same RF system which, in that case, would boost the energy in small portions $\Delta E_{\rm b} = ZeV_{\rm RF}$ per turn every time a particle passes through the total cavity voltage $V_{\rm RF}$. Such an arrangement can be realized either in the form of storage-ring circular colliders or also through novel schemes based on, e.g., recirculating linear accelerators (RLAs) with or without energy recovery. Circular colliders are by far the most common; here, the momentum and energy of ultra-relativistic particles are determined by the bending radius inside the dipole magnets, ρ, and by the average magnetic field B of these magnets:

$$p = ZeB\rho \quad \text{or} \quad E_{\rm b}\,[\text{GeV}] = 0.3Z(B\rho)\,[\text{Tm}]\,. \tag{31.1}$$

Such *synchrotron condition* assures approximately constant radius of the beam orbit during acceleration. Transverse focusing by quadrupole magnets is needed to keep particles inside the rather limited space provided by the accelerator beam pipe passing through the magnet apertures. The maximum field of normal-conducting (NC) magnets is about 2 T, due to the saturation of ferromagnetic materials, and, while this is sufficient for lower energy colliders, such as most e^+e^- storage rings, it is not adequate for frontier-energy hadron (or muon) beams, because of the implied need for excessively long accelerator tunnels and prohibitively high total magnet power consumption. The development of superconducting (SC) magnets that employ high electric current carrying Nb-Ti wires cooled by liquid helium below 5 K, opened up the way towards higher fields and to hadron colliders at record energies [2]. For example, the 14 TeV c.m.e. LHC at CERN, uses double-bore SC magnets with a maximum field of 8.3 T at a temperature of 1.9 K, in a tunnel of $C = 26.7$ km circumference (dipole-magnet bending radius $\rho = 2800$ m). The double-bore design allows acceleration of the same particle type in opposite directions and also the operation with different particle species (e.g., protons and heavy ions) in the two apertures, while a single bore magnet implies the use of particles and antiparticles for the collider application. As the production of anti-particles is energy consuming and therefore limited, this concept opens the door to high-performance hadron colliders.

The exploration of rare nuclear and high energy particle physics phenomena requires not only an appropriately high energy, but also a sufficiently large number of detectable reactions. The number of events of interest N_{exp} is given by the product of the cross section of the reaction under study, $\sigma_{\rm exp}$, and the time integral over the instantaneous *luminosity*, $\mathcal{L}$:

$$N_{\rm exp} = \sigma_{\rm exp} \cdot \int \mathcal{L}(t)dt. \tag{31.2}$$

In the Tables, luminosity is stated in the units of $\text{cm}^{-2}\text{s}^{-1}$. The integral on the right is referred to as integrated luminosity $\mathcal{L}_{\rm int}$, and, reflecting the smallness of typical particle-interaction cross-sections is often reported in units of inverse femto- or attobarn, e.g., $1\ \text{ab}^{-1}$=$10^{42}\ \text{cm}^{-2}$. Colliders usually employ bunched beams of particles with approximately Gaussian distributions, and for two bunches containing N_1 and N_2 particles colliding head-on with frequency $f_{\rm coll}$, a basic expression for the luminosity is

$$\mathcal{L} = f_{\rm coll}\frac{N_1 N_2}{4\pi\sigma_x^*\sigma_y^*}\mathcal{F} \tag{31.3}$$

where σ_x^* and σ_y^* characterize the rms transverse beam sizes in the horizontal and vertical directions at the interaction point, and $\mathcal{F}$ is a factor of order 1, that takes into account inefficient geometric overlapping of the beams due to a crossing angle and finite bunch length, and dynamic effects, such as the mutual focusing of the two beam during the collision (see below). Having $n_{\rm b}$ bunches per beam increases the frequency of collisions $f_{\rm coll} = n_{\rm b}f_0$ where f_0 is either the revolution frequency of a circular collider or the repetition rate of a linear one. To achieve a high luminosity, one, therefore, has to maximize the population and number of bunches, either producing these narrowly or focusing them tightly, and colliding them at high frequencies at dedicated locations, where products of their reactions can be registered by particle detectors.

Subsequent sections in this report briefly expand on the beam dynamics behind collider design, comment on the realization of collider performance in a selection of today's facilities, and end with some remarks on future possibilities.

31.2 Beam Dynamics

Given the enormous and highly concentrated power carried by modern high energy particle beams, the main concern of beam dynamics in colliders is stability of motion of i) individual particles in accelerators, ii) single high-intensity beams of many particles moving together, and iii) colliding beams [3–5].

31.2.1 *Single Particle Dynamics*

While a reference particle at the nominal energy proceeds along the design trajectory (reference orbit) mostly determined by transverse magnetic dipole fields, other particles in the bunch are kept close by through the focusing effect of quadrupole fields. Assume that the reference particle carries a right-handed Cartesian coordinate system, with the co-moving z-coordinate pointed in the direction of motion along the reference trajectory, $z = s - vt$ (with v the reference particle velocity, and t time). The independent variable is the distance s of the reference particle along this trajectory, rather than time t, and for simplicity this reference path is taken to be planar. The transverse coordinates are x (horizontal) and y (vertical), where $\{x, z\}$ defines the plane of the reference trajectory.

Several time scales are involved, and this is reflected in the approximations used in formulating the equations of motion. All of today's high-energy colliders are alternating gradient synchrotrons or, respectively, storage rings and the shortest time scale is set by so-called *betatron oscillations*. The linearized equations of motion of a particle displaced from the reference trajectory are:

$$\begin{aligned} &x'' + K_x(s)x = 0\,, y'' + K_y(s)y = 0\,,\ z' = -x/\rho(s)\,,\\ &\text{with}\ \ K_x \equiv \frac{Ze}{p}\frac{\partial B_y}{\partial x} + \frac{1}{\rho^2}\ \text{and}\ K_y \equiv -\frac{Ze}{p}\frac{\partial B_y}{\partial x} \end{aligned} \tag{31.4}$$

where $\rho = p/ZeB_y$ is the radius of curvature due to the field on the reference orbit. The prime denotes d/ds and the Maxwell equation in vacuum $\nabla \times \mathbf{B} = \mathbf{0}$ helps to eliminate $B_x(s)$ using the relation $\partial B_x/\partial y = \partial B_y/\partial x$. In this linear approximation, the vertical magnetic field $B_y(s)$ in the (x, z)-plane contains only

dipole and quadrupole terms, which are treated as static in time, but s-dependent.

The solutions of the Hill's equations (31.4) for x and y with a restoring force periodic in s are those of quasi-harmonic oscillators:

$$x(s) = \sqrt{2J_x\beta_x}\,\cos\psi_x\ ,\quad x'(s) = -\sqrt{\frac{2J_x}{\beta_x}}\,[\alpha_x\cos\psi_x + \sin\psi_x]\ , \tag{31.5}$$

where the *action* J_x is a constant of integration, $\alpha_x = \alpha_x(s) \equiv -(1/2)d\beta_x(s)/ds$, and the envelope of oscillations is modulated by the *beta-function* $\beta_x(s)$. A solution of the same form describes the motion in y. The betatron oscillation phase advances according to $d\psi_x/ds = 1/\beta_x$; that is, $2\pi\beta_x$ also plays the role of a local wavelength of oscillations along the orbit. An extremely important parameter for circular machines is the *tune*, Q_x, which is the number of such oscillations per turn about the closed path:

$$Q_x = \frac{1}{2\pi}\oint d\psi_x = \frac{1}{2\pi}\oint \frac{ds}{\beta_x(s)}. \tag{31.6}$$

While the integer part of the tune $[Q_{x,y}]$ generally characterizes the extent of the focusing lattice, it is the fractional part of the tune $\{Q_{x,y}\}$ that needs to be well defined and controlled by the machine operators in order to stay away from potentially detrimental resonances, which may occur under conditions of $kQ_x + lQ_y = m$, where k, l, and m are integers. For example, for the LHC a combination of horizontal and vertical tunes — also called the *working point* — equal to (Q_x, Q_y)=(64.31, 59.32) has been selected, such that resonances up to the order of $|k|+|l| = 10$ or 12 are avoided. These resonances are driven by high order multipole components of the fields in the magnets, or by self-fields of the beam, or by the electromagnetic fields of the opposite bunch. Normally, the nonlinear components are very weak compared to linear ones, nevertheless, when the nonlinear resonance condition is encountered, the amplitudes of particle oscillations could grow over the beam lifetime, resulting in the escape of the particles to the machine aperture, in the increase of the average beam size, or in both; either of these is highly undesirable phenomena. Careful analysis of nonlinear beam dynamics is instrumental in determining and optimizing the *dynamic aperture*, which is defined as the maximum amplitude of a bounded particle motion.

Neglecting for now all nonlinear effects and usually small $x-y$ coupling, and considering only the linear dynamics, the beta-function is well defined and satisfies the following equation:

$$2\beta_x\beta_x'' - \beta_x'^2 + 4\beta_x^2 K_x = 4\,. \tag{31.7}$$

In a region free of magnetic fields, such as in the neighborhood of a collider interaction point (IP), usually occupied by particle detectors, a symmetric solution of Eq. (31.7) is a parabola:

$$\beta_x(s) = \beta_x^* + \frac{s^2}{\beta_x^*}\,, \tag{31.8}$$

where, in this case, s denotes the longitudinal distance from the IP. The location of the beam waist usually coincides with the IP and corresponds to the minimum value of the beta-function β_x^*; the asterisk is used to indicate IP parameters.

Note that individual quadrupole magnet focuses particles in one plane and defocuses in another, see Eq.(31.4), and a standard way to provide focusing in both planes is to employ an alternating gradient periodic focusing lattice, consisting of a sequence of equally-spaced quadrupoles with a magnetic field gradient equal in magnitude, but alternating in sign ("focusing quadrupole - drift space - defocusing quadrupole - drift space" – known as a *FODO cell*). Eq. (31.7) has stable periodic solutions $\beta_x(s), \beta_y(s)$ in both planes provided that the focal length of the quadrupoles is longer than half the focusing-lens spacing L, i.e., $f = p/(eB_2 l) > L/2$ (where l is the length of a quadrupole magnet, here assumed to be short $l \ll L$, and $B_2 \equiv |\partial B_y/\partial x|$ the quadrupoles' field gradient). In that case, the beta-functions have maxima at the focusing quadrupoles and minima at the defocusing ones, equal to, for example, $\beta_{\max,\min} = (2 \pm \sqrt{2})L$ in the case of $f = L/\sqrt{2}$, which corresponds to a betatron phase advance $\Delta\psi_{x,y} = 90^\circ$ per FODO cell.

Expressing the invariant J_x in terms of $x,\ x'$ yields

$$J_x = \frac{1}{2}\left(\gamma_x x^2 + 2\alpha_x x x' + \beta_x x'^2\right) = \frac{x^2 + (\alpha_x x + \beta_x x')^2}{2\beta_x} \tag{31.9}$$

with $\gamma_x = \gamma_x(s) \equiv (1 + \alpha_x^2(s))/\beta_x(s)$. In a periodic system, these *Courant-Snyder parameters* [6] (frequently referred to as *Twiss parameters*) $\alpha(s)$, $\beta(s)$, $\gamma(s)$ are usually defined by the focusing lattice; in a single pass system such as a linac, the parameters may be selected to match the x-x' distribution of the input beam. For a given position s in the ring, the transverse particle motion in $\{x, x' \equiv dx/ds\}$ phase space describes an ellipse, the area of which is $2\pi J_x$, where the horizontal action J_x is a constant of motion and independent of s. If the interior of that ellipse is populated by an ensemble of non-interacting and non-radiating particles, that area, given the name *emittance*, is constant over the trajectory as well and would only change with energy. In a typical case of the particle's energy change rate being much slower than betatron motion, and considering a Hamiltonian system (i.e., a hadron collider or a linear collider, either without significant synchrotron radiation), the adiabatic invariant $\int p_x dx$ is conserved, and given that for small angles $p_x = x' \cdot \beta\gamma mc^2$, it is common practice to consider an energy-independent *normalized emittance* that is equal to the product of the emittance and relativistic factor $\beta\gamma/\pi$ and denoted by $\varepsilon_{\rm n}$. For a beam with a Gaussian distribution in $\{x, x'\}$, average action value $\langle J_x\rangle$ and standard deviations σ_x, and $\sigma_{x'}$, the definition of the normalized rms emittance is

$$\varepsilon_{{\rm n}x} \equiv \beta\gamma\langle J_x\rangle = \beta\gamma\frac{\sigma_x^2(s)}{\beta_x(s)} = \beta\gamma\frac{\sigma_{x'}^2(s)}{\gamma_x(s)}\,, \tag{31.10}$$

with a corresponding expression for the other transverse direction, y. The angular brackets denote an average over the beam distribution. For 1D Gaussian beam, 95% of the particles are contained within $\{x, x'\}$ phase space area of $6\pi\varepsilon_{\rm n}/(\beta\gamma)$. Normalized beam emittances are conserved over the acceleration cycle in linear, static focusing lattices $K_{x,y}(s)$, and consequently, one would expect the same $\varepsilon_{\rm n}$ at the hadron (or linear) collider top energy as the one coming from the very initial low energy particle source. Unfortunately, that is rarely the case as many time-varying or nonlinear phenomena come into play. In an e^-/e^+ storage ring, the normalized emittance is not preserved during acceleration, but at each energy the beam's equilibrium emittance is determined by the effect of synchrotron radiation as a balance between radiation damping and quantum excitation [7]. In such a ring, for a given accelerator optics, the normalized equilibrium emittance increases with the third power of the beam energy [8].

As for the description of a particle's longitudinal motion, one takes the fractional momentum deviation $\Delta p/p$ from that of the reference particle as the variable conjugate to z. The factors $K_{x,y}$ and ρ in Hill's equations (31.4) are dependent on momentum p, leading to a number of effects: first, the trajectory of off-momentum particles deviates by $\Delta x(s) = D_x(s)(\Delta p/p)$, where the *dispersion function* $D_x(s)$ is determined by the magnetic lattice and is usually positive, periodic, and of the order of $\sim \rho/Q_x^2$. Second, the radius of curvature and orbit path-length C vary with the momentum and, to first order, are characterized by the momentum compaction factor $\alpha_{\rm c}$,

$$\alpha_{\rm c} \equiv \frac{\Delta C/C}{\Delta p/p} = \frac{1}{C}\oint \frac{D_x(s)}{\rho(s)}ds\,, \tag{31.11}$$

which typically is of order $1/Q_x^2$. Energy deviations also result in changes of machine focusing lattice properties and variations of the particle tunes, characterized by the *chromaticity* $Q'_{x,y} \equiv \Delta Q_{x,y}/(\Delta p/p)$. The natural chromaticity due to momentum dependence of the quadrupole focusing is negative and large $\sim -Q_{x,y}$. Corresponding chromatic tune variations can, therefore, become unacceptably large even for relatively small energy deviations $(\Delta p/p) \sim (0.1 - 1)\cdot 10^{-3}$. To assure transverse particle stability, usually, the chromaticity is partially or fully com-

pensated by additional sextupole magnets placed at locations of non-zero dispersion.

Radiofrequency electric fields in s direction provide a longitudinal focusing effect, allowing a stable increase of particle energy. The frequency f_s of such longitudinal *synchrotron oscillations* is (expressed in units of revolution frequency f_0, to become the synchrotron tune Q_s)

$$Q_s \equiv \frac{f_s}{f_0} = \sqrt{\frac{(\alpha_c - 1/\gamma^2) h Z e V_{\rm RF} \sin(\phi_s)}{2\pi\beta c p}} \,, \qquad (31.12)$$

where $h = f_{RF}/f_0$ denotes the RF harmonic number, $V_{\rm RF}$ the RF voltage, and $\phi_s = \cos^{-1}(\Delta E/ZeV_{\rm RF})$ the synchronous phase, with ΔE the average energy loss per turn (e.g. due to synchrotron radiation and impedance). The synchrotron tune Q_s determines the amplitude of longitudinal oscillations for a particle with an initial momentum offset, e.g., the rms bunch length σ_z relates to the rms momentum spread $\delta p/p$ as:

$$\sigma_z = \frac{c(\alpha_c - 1/\gamma^2)}{2\pi Q_s f_0} \left(\frac{\delta p}{p}\right) . \qquad (31.13)$$

Similarly to the case of transverse oscillations, the area of the longitudinal phase space $\{\Delta E, \Delta t\}$, or $\{\gamma\beta\delta p/p = (1/\beta)\Delta\gamma, z = \beta c\Delta t\}$, encircled by a moving particle is an adiabatic invariant, and the corresponding normalized *longitudinal emittance* $\varepsilon_{n,L} = \beta\gamma mc\sigma_z(\delta p/p)$ is a generally conserved quantity in hadron accelerators and also in linear accelerators. In the case of lepton storage rings, synchrotron radiation determines the equilibrium relative momentum spread, which grows linearly with beam energy [7, 8], and the corresponding bunch length follows from Eq. (31.13). In hadron synchrotrons, the longitudinal emittance sometimes is intentionally blown up during acceleration, so as to preserve longitudinal beam stability.

Longitudinal oscillations are the slowest of all the periodic processes which take place in the accelerators. For example, in the LHC, the frequency of synchrotron oscillations at the top energy of 7 TeV is about f_s = 23 Hz, the revolution frequency is f_0 =11.3 kHz, the frequency of betatron oscillations is about $Q_{x,y} f_{\rm rev} \simeq$ 700 kHz and the RF frequency is $f_{\rm RF}$ = 400.8 MHz (h = 35640). It should be noted that longitudinal motion is practically absent in linacs. In the absence of bending dipoles, dispersion $D_x(s)$ is zero and so are the momentum compaction factor α_c and the synchrotron tune Q_s. As a result, ultrarelativistic particles in a linac barely change their relative positions during acceleration despite significant energy spread.

Highest-energy circular colliders face a serious impediment in the form of synchrotron radiation (SR) that causes an energy loss per turn of

$$\Delta E_{\rm SR} = \frac{1}{3\varepsilon_0} \frac{Z^2 e^2 \beta^3 \gamma^4}{\rho} \,, \qquad (31.14)$$

here, ε_0 is the permittivity of vacuum. For electrons and positrons it is equal to $\Delta E_{\rm SR}$ = 88.5 [keV/turn] $E_{\rm b}^4$[GeV]/ρ[m] and requires correspondingly high total RF voltage per turn to replenish the loss. Above a few hundred GeV, the SR energy loss becomes comparable to beam energy $\Delta E_{\rm SR} \sim E_{\rm b}$, which makes circular e^+e^- colliders impractical for c.m.e. above $\sim$ 500 GeV.

Dynamics of the particle spin and sophisticated methods to maintain beam polarization along the acceleration chain, from the polarized sources to collisions, dedicated spin matching procedures to enable self polarization in e^+/e^- storage rings and the *resonant depolarization* method of ultra-precise c.m.e. calibration are described in [9].

31.2.2 *High Intensity Beams*

Ultimate collider luminosity calls for high beam currents $I_{\rm b} = Zef_0 n_{\rm b} N$. Three related major difficulties include growing RF demands to compensate the synchrotron-radiation power loss $P = I_{\rm b}\Delta E_{\rm SR}$ in e^+/e^- beams, the advent of so-called *coherent (*or *collective) beam instabilities*, and growing demands for minimization of radiation due to inevitable particle losses. Many types of single- and multi-bunch instabilities are caused by beam interactions with electromagnetic fields induced by the beam itself due to the *impedance* of the vacuum chambers and RF cavities [4], or caused by unstable clouds of secondary particles, like electrons or ions, which are formed around the circulating beams [10]. These instabilities can develop as quickly as within tens to thousands of turns and need to be controlled. Mechanisms that are routinely employed to avoid coherent instabilities include the use of nonlinear magnets to generate sufficient spread of the tunes and therefore, provide *Landau damping*, fast beam-based transverse and longitudinal feedback systems, and electron/ion clearing (either by weak magnetic or electric fields or by modulation of the primary beam current profile rendering secondaries unstable, or by reducing the yield of secondary electrons via either a special coating or extensive *beam scrubbing* of the vacuum chamber walls).

High current beam operation is sensitive to even minuscule fractional intensity losses caused by particles' scattering at a large angle or with a large energy loss, sufficient for either the particle amplitudes $\sqrt{2J_{x,y}\beta_{x,y}(s)}$, or their dispersive position deviations $\Delta x = D_x(s)(\delta p/p)$ to exceed the available transverse aperture, usually set by collimators (otherwise, by the vacuum chamber and magnet apertures). This can be due to residual vacuum molecules near the beam orbit or Compton scattering off thermal photons, due to Coulomb scattering off other particles within the same bunch (*Touschek effect*), or due to collisions with opposite beam particles and fields, such as inelastic interaction of protons, Bhabha scattering $e^+e^- \to e^+e^-$, or radiative Bhabha scattering $e^+e^- \to e^+e^-\gamma$ (see corresponding chapters in [11]).

Particles can also get lost on the aperture as a result of much slower mechanisms of diffusion caused either by the above processes with smaller scattering amplitudes, but stochastically repeated many times, such as intensity-dependent multiple Coulomb *intrabeam scattering* [12], by external noises such as ground motion or magnetic field fluctuations, or via chaotic mechanisms like Arnold diffusion, modulational diffusion, or resonance streaming in nonlinear fields, enhanced by minor tune modulations. Diffusion leads to a slow evolution of the beam distribution function and appearance of highly unwanted large-amplitude tails and beam emittance growth. The only way to counteract it is to arrange *beam cooling* (damping of particle oscillations). The cooling requires a reaction force opposite to particle momentum arranged such that, on average, the corresponding dissipative particle energy loss is compensated for by external power [13, 14].

In the case of electron or positron storage rings, such cooling occurs naturally due to synchrotron radiation and provides an automatic route to achieve small equilibrium emittances through a balance between radiation damping and excitation of oscillations by random radiation of individual photons. Fast radiation damping allows *top-up injection* of new particles without removing existing ones, a useful method to maximize the integrated luminosity of circular e^+e^- colliders. Synchrotron radiation damping will also be an important cooling mechanism for future energy-frontier hadron colliders, like the proposed FCC-hh and SppC (see below). Four other methods of beam cooling have been developed and successfully employed to attain low emittances, namely *electron cooling* and *stochastic cooling* of heavy particles (ions and antiprotons), *laser cooling* of ion beams, and the *ionization cooling* of muons.

To avoid damage or excessive irradiation of accelerator components so that these remain accessible for maintenance in the tunnel, sophisticated collimation systems are utilized. These systems usually employ a series of targets or primary collimators which scatter the halo particles, and numerous absorbers (sometimes as many as a hundred, which intercept particles in dedicated locations) [15, Ch.9.7]. In the highest energy modern and future colliders, extreme total beam energies $n_{\rm b} N E_{\rm b}$ ranging from MJs to GJs and impacting surface energy densities reaching many GJ/mm^2 pose one of the biggest challenges for high efficiency and robust particle collimation.

31.2.3 *High Luminosity Collisions*

Eq. (31.3) for luminosity can be recast in terms of normalized transverse emittances Eq. (31.10) and the beta-functions β^* at

the IP as:

$$\mathcal{L} = f_0 \gamma n_\mathrm{b} \frac{N^2}{4\pi\sqrt{\varepsilon_{\mathrm{n}x}\beta^*_x\varepsilon_{\mathrm{n}y}\beta^*_y}}\mathcal{F}\,. \quad (31.15)$$

Here, equal bunch populations N are assumed in two Gaussian beams with the same emittances. Naturally, to achieve a high luminosity, one has to maximize the total beam populations $n_\mathrm{b}N$ within the lowest possible emittances, and collide the beams at high frequency at locations where the focusing beam optics provides the lowest possible values of the amplitude functions β^*, the so-called *low-beta insertion*. The latter requires sophisticated systems of strong focusing elements, sometimes occupying quite a significant fraction of the collider's total length. The lowest $\beta^*_{x,y}$ is determined by the maximum field gradients and apertures in the interaction region (IR) magnets and the effectiveness of compensation of chromatic and nonlinear aberrations.

The typical geometric reduction factor is $\mathcal{F} \approx 1$, and it rarely drops below 0.5 for the majority of colliders, unless this is specifically required by physics processes under study. The reduction due to the *hourglass effect* is caused by the increase in transverse beam sizes as one proceeds away from the IP, where $\beta(s)$ grows parabolically, as in Eq. (31.8). For long round bunches the effect scales as $\mathcal{F} \approx \sqrt{\pi}A\exp(A^2)\mathrm{erfc}(A)$, where $A = \beta^*/\sigma_z$. Nonzero beam crossing angles θ_c in the horizontal plane and long bunches (rms bunch length σ_z) will reduce the luminosity, too, by a factor $\mathcal{F} \approx 1/(1+\Phi^2)^{1/2}$, where the parameter $\Phi = \sigma_z \tan(\theta_\mathrm{c}/2)/\sigma^*_x$ is known as the *Piwinski angle*.

One of the most common limits to producing high luminosity arises from electric and magnetic forces of the opposite bunch at the IPs, characterized by a dimensionless *beam-beam parameter* :

$$\xi_{x,y} = \frac{r_0 N \beta^*_{x,y}}{2\pi\gamma\sigma^*_{x,y}(\sigma^*_x + \sigma^*_y)}\,, \quad (31.16)$$

where $r_0 = Z^2e^2/(4\pi\varepsilon_0 mc^2)$ is the classical radius of the colliding particle (with charge Ze and mass m). From Eqs. (31.3) or (31.15) and (31.16), one can note that the path to higher luminosity via higher beam intensity and smaller beam sizes almost automatically calls for a higher beam-beam parameter as $\mathcal{L} \propto \xi$. Cited in the Tables, the beam-beam parameter is roughly equal to the betatron tune shift experienced by small-amplitude particles – positive in the case of opposite charge beams, like e^+e^-, and negative for same charge beams as in pp collisions. Beam-beam forces can lead to coherent effects, such as unstable beam oscillations or blow-up of one beam's size while the other beam remains small or even shrinks (*flip-flop effect*). The tune spread arising from ξ and the nonlinear nature of beam-beam interactions results in strong diffusion along high-order transverse resonances $kQ_x + lQ_y = m$ and, ultimately, in beam size growth and beam losses. Operational experience indicates that the aforementioned effects are tolerable below certain *beam-beam limit* of $\xi_{x,y} \approx 0.003 - 0.012$ in hadron colliders [16], and – due to strong synchrotron radiation damping – an order of magnitude higher one in e^+e^- colliders, with maximum $\xi_{x,y} \approx 0.03 - 0.12$ [17,18]. The accessible beam-beam parameter range can also be restricted by coherent beam-beam instabilities. These various limits translate into a maximum allowed single bunch intensity N and call for an increase of the number of bunches n_b to achieve higher luminosities.

In linear colliders, where each bunch collides only once, with typically much smaller beam size and experiencing much stronger forces, the strength of the collision is measured by the ratio of the rms bunch length σ_z to the beam-beam focal length. This ratio, called *disruption parameter* D_y, is related to ξ_y via $D_y = 4\pi\sigma_z\xi_y/\beta^*_y$. Stronger beam-beam focusing and higher D_y lead to effectively smaller beam sizes and a resulting luminosity enhancement; but it also makes the collisions more sensitive to small offsets, resulting in a *kink instability*. Additional beam-beam effects arising in the collisions at linear colliders are the emission of *beamstrahlung* (synchrotron radiation in the field of the opposing beam), along with e^+e^- pair creation, and depolarization by various mechanisms.

Beamstrahlung is relevant for both linear colliders, where it may significantly degrade the luminosity spectrum, and for future highest-energy circular colliders, where it may limit the beam lifetime, and also increases the energy spread and bunch length of the stored beam. For both types of colliders, the beamstrahlung is mitigated by making the colliding beams as flat as possible at the interaction point ($\sigma^*_x \gg \sigma^*_y$) to lower the beams' EM fields. The photon energy spectrum of the beamstrahlung is characterized by the parameter $\Upsilon = (2/3)\hbar\omega_\mathrm{c}/E_\mathrm{b}$ [19], with $\hbar\omega_\mathrm{c}$ denoting the critical photon energy. The spectrum strongly deviates from the classical synchrotron radiation spectrum for Υ approaching or exceeding 1.

For hadron colliders, two fundamental luminosity limits are the beam lifetime, determined by burn-off in the collisions due to inelastic pp interaction $dN/dt = -\mathcal{L}\sigma_\mathrm{in}$, and the radiation from the collision debris, which may induce "quenches" (transitions to the normal-conducting state) of the superconducting final quadrupole magnets, and, in the long term, affect the equipment lifetime. Another limit on the achievable integrated luminosity in circular colliders is set by the minimum or average turnaround time (the time between the beam abort at the end of a physics fill and the start of the next physics collisions). Achieving practical filling times with many bunches in the collider requires either fast cycling injector machines and/or the top-up injection operation. The latter makes the average luminosity of circular electron-positron colliders approximately equal to the peak luminosity.

31.3 Recent High Energy Colliders

In this and the following section, elaboration is made on various issues associated with some of the recently operating colliders, particularly factors which impact integrated luminosity. Only general references are provided, where further information can be obtained. A more complete list of recent colliders and their parameters can be found in the High-Energy Collider Parameters tables.

31.3.1 *Tevatron*

The first superconducting synchrotron in history, the Tevatron [20] was converted into a proton-antiproton collider in 1985. Its 4.4 T dipole magnets employed Nb-Ti superconducting cable operating at 4.5 K, requiring what was then the world's largest cryogenic system. With $\sqrt{s}$ up to 1.96 TeV it was the highest energy collider for 25 years and delivered more than 12 fb^{-1} of the integrated luminosity to each $p\bar{p}$ detector experiments (CDF and D0) before being shut off in 2011. The route to high integrated luminosity in the Tevatron was governed by the antiproton production rate, the turn-around time to produce another store, and the resulting optimization of store time [21]. The antiproton production complex consisted of three 8 GeV $\bar{p}$ accelerators (the Accumulator, Debuncher, and Recycler – the latter was the first high energy accelerator built with permanent magnets), and employed 25 independent stochastic cooling systems and one pioneering high-energy electron cooling set-up to accumulate up to a record high value of $25{\cdot}10^{10}$ $\bar{p}$ per hour. Despite severe parasitic long-range interactions of the two beams, each consisting of 36 bunches placed on helical orbits by two dozen ±150 kV high-voltage (HV) separators, a total beam-beam tune shift parameter of $n_\mathrm{IP}\xi$ ≈0.025-0.03 was achieved, a record for hadron beams, with $n_\mathrm{IP} = 2$ primary collision points. Other notable advances in the accelerator science and technology included advanced longitudinal beam manipulation techniques of *slip-stacking* and *momentum mining* and the first operational use of *electron lenses* for beam collimation and for compensation of long-range beam-beam effects [22]. The Tevatron ultimately achieved luminosities a factor of 430 higher than the original design specification.

31.3.2 *HERA*

The first lepton-proton collider, the 6.4 km long Hadron-Elektron-Ring-Anlage (HERA) at DESY in Germany [23], operated between 1992 and 2007 and delivered nearly 1 fb^{-1} of integrated luminosity at $\sqrt{s}$ of about 320 GeV to the electron-proton collider experiments H1 and ZEUS [24, Ch.10.5]. It was the first facility to employ both applications of superconductivity: 5 T magnets in the 920 GeV proton ring and SRF accelerating structures to provide about 12 MW of RF power to compensate for synchrotron radiation losses of 30 GeV lepton beams (positrons or

electrons, in a conventional-magnet ring). With proper orbit and optics control, the HERA lepton beam would naturally become transversely polarized to about 60% (within about 40 minutes) thanks to the *Sokolov-Ternov effect*. Special magnets called *spin rotators* were implemented on either side of the collider IPs to produce 30–45% longitudinal polarization at the experiments.

31.3.3 *LEP*

Installed in a tunnel of 26.7 km circumference, LEP [25] was the largest circular e^+e^- collider built so far. LEP was operated from 1989 to 2000 with beam energies ranging from 45.6 to 104.5 GeV. The synchrotron radiation loss per turn reached some 3% of beam energy and it was the total available RF voltage and power, respectively, that determined LEP maximum energy and luminosity of 10^{32} cm^{-2}s^{-1}. At a beam energy of 98 GeV, LEP operated with a beam-beam parameter $\xi \approx 0.083$, i.e., the total beam-beam tune shift for four interaction points was $n_{\rm IP}\xi \approx 0.33$. In the last year of operation, 288 SRF cavities were powered by 36 klystrons with an average power of 0.6 MW each and provided $V_{\rm RF}$= 3.63 GV. Up to about 60 GeV, LEP used resonant depolarization to measure the beam energy with 0.001% accuracy.

31.3.4 *SLC*

Based on an existing 3-km long 2.85 GHz warm RF linac, the SLC [26] was the first and only linear collider. It was operated from 1987 to 1998 with a constant beam energy of 45.6 GeV, up to about 80% electron-beam polarization, quasi-flat beams, a final-focus optics with local chromatic correction based on four interleaved sextupoles and $\beta_y^* \approx 1$ mm. In its last year, SLC achieved a peak luminosity of about 3×10^{30} cm^{-2}s^{-1}, roughly half of the design value. The SLC had a high-efficiency positron source providing 5×10^{12} e^+ per s for 120 Hz injection into the linac. It also employed the *BNS damping* to suppress the single-bunch beam break up instability, and also demonstrated an about 2-fold increase of luminosity from *disruption enhancement* due to the mutual focusing of the colliding electron and positron bunches at the interaction point,

31.4 Presently Operating Colliders

31.4.1 *LHC*

With a beam energy of 6.8 TeV (to be raised to the design value of 7 TeV through consolidation and magnet training), the superconducting Large Hadron Collider [27] presently is the world's highest energy collider. In the latest runs, peak luminosities of up to 2.1×10^{34} cm^{-2}s^{-1} have been achieved at 13 TeV cme - more than twice the design value (the current status is best checked at the Web site [28]). To meet its luminosity goals, the LHC operates with a high beam current of approximately 0.5 A, leading to stored energies of about 330 MJ per beam. Controlled energy deposition and component protection are given a high priority and a sophisticated highly efficient system of more than 100 beam collimators is employed [29]. At the energy of about 7 TeV per particle, synchrotron radiation poses a challenge, as the cryogenic system must remove roughly 7 kW due to synchrotron radiation, intercepted with a specially designed *beamscreen* inside the vacuum chamber, at a temperature of about 5–20 K, to be compared with a temperature of 1.9 K for the magnet cold bore. The elevated temperature allows for a more energy-efficient removal of beam-induced heat. The beamscreen also provides an effective cryo-pump for the vacuum system. When synchrotron-radiation photons hit the beamscreen, they can generate photoelectrons. These photoelectrons, and also any other electrons generated in the vacuum system, e.g. by residual-gas ionization, are accelerated in the electric field of the beam and may multiply via secondary-electron emission, with consequent electron cloud development. To mitigate this issue, the beamscreen is regularly subjected to beam-induced surface conditioning (*scrubbing*), thereby lowering the secondary emission yield. The two proton beams of 2556 bunches spaced by 25 ns are contained in separate pipes throughout most of the circumference and are brought together into a single 130 m long beam pipe at the interaction points. To avoid approximately 30 head-on collisions a small crossing angle of about 0.3 mrad is employed, which reduces the luminosity by about 15%. Still, the bunches moving in one direction experience multiple long-range encounters with the counter-rotating bunches and the resulting perturbations of the particle motion substantially contribute to the beam lifetime reduction. The dominant source of approximately 8 hour characteristic luminosity decay time is proton burn-off due to inelastic pp interaction with $\sigma_{\rm in} \approx 81$ mbarn, corresponding to *pile-up* of up to 50 (number of events per individual bunch crossing). In special physics runs with a few bunches and large β^*, the LHC achieved a head-on beam-beam tune shift of $n_{\rm IP}|\xi| \approx 0.02$ with $n_{\rm IP} = 2$, about twice as high as in regular operation.

The Tables also show the LHC luminosity performance in Pb-Pb collisions, which for the ATLAS and CMS experiments well exceeded the design value, while for the ALICE experiment, the luminosity is *levelled* near the Pb-Pb design value of 10^{27} cm^{-2}s^{-1}. The LHC can also provide Pb-p collisions as it did in 2013 and 2016, and other ion-ion or ion-proton collisions, at different energies.

In the coming years, an ambitious upgrade program, HL-LHC [30], with the accompanying LHC Injectors Upgrade [31], has as its target an order-of-magnitude increase in integrated luminosity through doubling the proton beam current, the utilization of new larger aperture Nb_3Sn superconducting final quadrupoles to allow squeezing the β^* to as low as 10 cm, superconducting compact *crab cavities* and luminosity leveling also for ATLAS and CMS as its key ingredients.

31.4.2 *Electron-Positron Rings*

Asymmetric energies of the two beams allow for the enhancement of B-physics research and for interesting interaction region designs. SuperKEKB operates with 7 GeV electron and 4 GeV positron beams since 2018 and is aiming for luminosities of 8×10^{35} cm^{-2}s^{-1} [32]. By summer 2022, a world record luminosity of 4.7×10^{34} cm^{-2}s^{-1} has been reached, still at rather low beam currents. Vertical beam-beam tune shifts of $\xi_y \approx 0.05$ for the 4 GeV positron beam, and $\xi_y \approx 0.03$ for the 7 GeV electron beam have been achieved. These values are still about a factor of two lower than at the previous KEKB. Since 2020 SuperKEKB operates with a virtual *crab-waist* collision scheme, first developed for the FCC-ee design [33]. The original crab-waist scheme, based on additional sextupole magnets, was earlier implemented at DAΦNE [34]. The general crab-waist concept combines a large Piwinski angle Φ, and an extremely low β_y^* ($\ll \sigma_z$) with the cancellation of the transverse betatron resonances which occur under conditions of $kQ_x + lQ_y = n$, where k, l, n are integers. The latter is achieved by means of existing or additional electromagnetic sextupoles with special betatron phase advances to the collision point [35]. The crab-waist collision scheme has become a design choice for all proposed future e^+e^- circular colliders.

Beside SuperKEKB and DAΦNE, three other e^+e^- ring colliders currently in operation are VEPP-2000 with $\sqrt{s}$ up to 2.0 GeV, BEPC-II with $\sqrt{s}$ up to 4.6 GeV and VEPP-4M with maximum c.m.e. of 12 GeV [1].

31.4.3 *RHIC*

The Relativistic Heavy Ion Collider [36] employs 3.45 T Nb-Ti superconducting magnets, and collides combinations of fully-stripped ions such as H-H ($p-p$), p-Al, p-Au, d-Au, h-Au, Cu-Cu, Cu-Au, Zr-Zr, Ru-Ru, Au-Au, and U-U over a wide energy range. The high charge per particle (+79 for gold, for instance) makes intra-beam scattering of particles within the bunch a special concern, even for seemingly moderate bunch intensities. In 2012, 3-D stochastic cooling was successfully implemented in RHIC [37] and is now routinely used. With stochastic cooling, steady increases in the bunch intensity, and numerous other upgrades, RHIC now operates at 44 times the Au-Au design average luminosity. Unique among high energy colliders, RHIC heavy ions beams cross the *transition energy* $\gamma_{rmt} = 1/\sqrt{\alpha_c}$ during acceleration – see Eqs.(31.11, 31.12) – a point where the derivative with respect to momentum of the revolution period is zero. This period of time is kept as short as allowed by the magnet ramp rate and must be dealt with carefully.

RHIC is also unique in its ability to accelerate and collide polarized proton beams. As proton beam polarization must be maintained from its low-energy source, successful acceleration through

the myriad of depolarizing resonance conditions in high energy circular accelerators has taken years to accomplish [38]. An energy of 255 GeV per proton with 60% final polarization per beam has been realized. As part of a scheme to compensate the head-on beam-beam effect, electron lenses operated routinely during the record high beam-beam parameter polarized proton operation at 100 GeV energy in 2015 [39].

31.5 Future High Energy Colliders and Prospects

Modern nuclear physics and high energy particle physics face critical questions which require next-generation high-energy and high-intensity experiments using hadron-hadron, lepton-lepton, and lepton-proton colliding-beam facilities. Understanding the structure of the proton and neutron directly from the dynamics of their quarks and gluons governed by the quantum chromodynamics calls for new ion-ion and electron-ion colliders. Two types of colliders are generally aspired by the HEP community [40, 41]: i) Higgs factories with a c.m.e. of 240–250 GeV in e^+e^- collisions for precision studies of the Higgs boson ($m_H = 125$ GeV) and exploration of the Higgs sector in greater detail, including measurements of Higgs couplings to fermions and vector bosons, self-coupling, rare decays, mass and width, that can also deliver other electroweak precision physics, e.g. on the Z-pole (91 GeV c.m.e.), at the W-pair threshold (about 160 GeV), and when run as a top quark factory (365–380 GeV); and ii) colliders with c.m.e. levels significantly beyond those of the LHC to explore the energy frontier for potential discoveries through direct searches in pp, $\mu\mu$, and e^+e^- interactions. In addition, precision physics at future high-luminosity factories operating at the τ-charm energy also provides sensitivity to new physics at multi-TeV energies and beyond. A comprehensive review of the future colliders' projects, ideas, and R&D activities can be found in Ref. [1]; Ref. [42] presents comparative analysis of implementation challenges of numerous future HEP collider proposals. Below we only briefly summarize leading collider proposals for construction over the next several decades which rely mostly on currently available technologies, such as normal-conducting (NC) or SC RF and/or NC or SC magnets, some of them requiring reasonable scope and duration mission-oriented development programs, as well as advanced schemes based on plasma acceleration and other innovative ideas. Tentative parameters of some of the colliders discussed, or mentioned, in this section are summarized in Table 31.1 and Table 31.2.

31.5.1 *Ion-Ion and Electron-Ion Colliders*

NICA (Nuclotron-based Ion Collider fAcility) is a new accelerator complex under construction at the Joint Institute for Nuclear Research (JINR, Dubna, Russia) to study properties of hot and dense baryonic matter, strong interactions between quarks and gluons, and spin physics [43]. NICA will provide a variety of beam species, ranging from protons and polarized deuterons to massive gold ions. The 500 m circumference SC magnet based collider is designed for average luminosity in heavy ion and light ion interactions at $\sqrt{s_{NN}}$=4–11 GeV of $1\times10^{27}\mathrm{cm}^{-2}\mathrm{s}^{-1}$ for a variety of nuclei up to $^{197}\mathrm{Au}^{79+}$, and for polarized proton and deuteron collisions at $\sqrt{s}$=12–27 GeV with $\mathcal{L}$=(1–10)$\times10^{31}\mathrm{cm}^{-2}\mathrm{s}^{-1}$. NICA major accelerator challenges include strong intrabeam scattering and space-charge effects which will be mitigated by extensive use of electron and stochastic cooling systems.

The recently announced Electron-Ion Collider (EIC) for nuclear physics research will be built at Brookhaven National Laboratory in the US and arrange collisions between an the reconfigured RHIC with a 41–275 GeV proton beam and a 5-18 GeV electron beam stored in a new ring (eRHIC) [44]. The EIC physics requirements [45], include highly polarized ($P_{e,n}$ ∼70%) electron and nucleon beams (as the precision of measurements of interest scales as $\mathcal{L}P_e^2P_n^2$), a spectrum of ion beams from deuterons to the heaviest nuclei (U or Pb), variable c.m.e. values from $\sqrt{s}$ =20 GeV to 140 GeV, high luminosities of up to 10^{33-34} $\mathrm{cm}^{-2}\mathrm{s}^{-1}$, as well as possibilities of having more than one interaction region. Main accelerator design challenges on the path to the required energy, luminosity, and polarization, include the development of SRF crab-cavities and advanced SC magnets for interaction region focusing, energy-recovery linac (ERL) based electron cooling of hadron beams, essential to attain luminosities two orders of magnitude beyond the predecessor HERA *ep* collider, and high intensity polarized particle sources, augmented by the development of special magnets and operational techniques to preserve the polarization through the acceleration process to the collisions, including swap-out injection.

31.5.2 *Higgs/Electroweak Factories*

Higgs factory proposals generally aim at improving the precision of coupling measurements of Higgs boson, top quark, W and Z by an order of magnitude or more compared with previous studies. Two proposals for ∼100 km circumference circular e^+e^- colliders have recently gained momentum: the Future Circular Collider (FCC-ee) at CERN [33] and the Circular Electron-Positron Collider (CEPC) in China [46]. Design philosophy of these machines assumes use of the maximum RF power available to compensate O(100 MW) synchrotron radiation losses $P_{SR} = 2I \cdot \Delta E_{SR}$ and operation at the beam-beam limit ξ_y that yields peak luminosity:

$$\mathcal{L} = \frac{3}{16\pi r_0^2(m_e c^2)} \frac{P_{\mathrm{SR}}\xi_y\rho}{\beta_y^*\gamma^3}\,, \qquad (31.17)$$

that scales approximately as $1/E_{\mathrm{b}}^{3.5}$ for practical limits on P, ξ_y and β_y^*. The short beam lifetime at the high target luminosity, due to radiative Bhabha scattering, requires these machines to be constructed with a full-energy injector ring installed in the same tunnel to *top off* the electron and positron currents in the collider rings operating at constant energy. Beamstrahlung introduces an additional beam lifetime limitation depending on momentum acceptance (so that achieving sufficient off-momentum dynamic aperture becomes one of the design challenges), as well as some bunch lengthening.

These ambitious, large-scale projects based on well-established technologies are not extendable to TeV or multi-TeV energies, but they offer several important advantages that include the potential for much higher luminosities, and, thus, higher precision, the ability to operate multiple experiments simultaneously, and their ∼100 km circular tunnels that could later house O(100 TeV) hadron colliders. The high energy efficiency of circular e^+e^- colliders is further boosted by advances in RF power sources, by improved SC cavities, and by innovative low-power magnet systems including ones based on high-temperature superconductors (HTS) at moderate magnetic field.

For more than four decades, efforts have been devoted to developing high-gradient RF technology linear e^+e^- colliders in order to overcome the synchrotron radiation limitations of circular e^+e^- machines. The International Linear Collider (ILC), with a c.m.e. of 250 GeV in e^+e^- collisions, has been under consideration for more than two decades and could potentially be upgraded to $\sqrt{s}$=500 GeV and further to 1 TeV. CERN's Compact Linear Collider (CLIC) design, developed since the mid-1980s, also includes possible upgrades, from an initial 380 GeV c.m.e. to ultimately 3 TeV, which would enable searches for new particles of significantly higher masses.

The primary challenge confronting a high energy, high luminosity single pass collider design is the beam power requirement, so that measures must be taken to keep the demand within bounds as illustrated in a transformed Eq.(31.15):

$$\mathcal{L} = \frac{1}{8\pi\alpha r_0}\,\frac{P_{\mathrm{wall}}}{\sqrt{s}}\,\frac{\eta}{\sigma_y^*}\,N_\gamma\,H_{\mathrm{D}}\,. \qquad (31.18)$$

Here, P_{wall} is the total wall-plug power of the collider, to be converted into beam power $P_{\mathrm{b}} = 2f_0NE_{\mathrm{b}}$ with efficiency η, $N_\gamma \approx 2\alpha r_0 N/\sigma_x^*$ is the number of beamstrahlung photons emitted per $e^\pm$ ($\alpha \approx 1/137$ denotes the fine-structure constant), and the last factor H_{D}, typically between 1 and 2, represents the enhancement of luminosity due to the *pinch effect*, the additional focusing occurring during the collision of oppositely charged bunches. The management of P_{wall} leads to an upward push on the bunch population N with an attendant rise in the energy radiated due to the electromagnetic field of one bunch acting on the particles of the other (beamstrahlung). Keeping a significant fraction of the

Table 31.1: Tentative parameters of selected future e^+e^- high-energy colliders. Parameters associated with different beam energy scenarios are comma-separated; H and V indicate horizontal and vertical directions.

luminosity close to the nominal energy represents a design goal, which is met if N_γ does not exceed a value of about 1. A consequence is the use of flat beams, where N_γ is managed by the beam width, and luminosity adjusted by the beam height, thus the explicit appearance of the vertical beam size σ_y^*.

The ILC [47, 48] is based on 1.3 GHz standing-wave superconducting accelerating structures operating at 2 K with 31.5 MV/m average gradient, up to 8 nm vertical beam size at the IP, and luminosity comparable to the LHC. Progress toward higher field gradients and Q values continues to be made, with nitrogen-doping techniques being a recent example [49]. CLIC is based on a novel two-beam acceleration scheme [50]. Here, room-temperature NC copper high-gradient 12 GHz accelerating structures are powered by a high-current 1.9 GeV drive beam to efficiently enable accelerating gradients of up to 100 MV/m (though optimal G=70 MV/m for the first CLIC stage at $\sqrt{s}$=380 GeV, and for this stage an alternative RF power drive option with 12 GHz klystrons powering is also being considered). To reach their design luminosities, both CLIC and ILC require unprecedented rates of positron production about 40 times the world record set by the SLC positron source, and very tight control of imperfections, such as $O(10\ \mu\text{m})$ accuracy of pre-alignment of the main linac and beam delivery system components at the level, suppression of fast vibrations of the quadrupoles due to ground motion to $O(1$ nm) level at frequencies above 1 Hz, advanced beam-based trajectory tuning, and mitigation of the effect of wakefields [51].

Recent developments of the RF technologies show promise of more compact linear e^+e^- Higgs/Electroweak factories based on either ∼70 MV/m travelling-wave 1.3 GHz SRF structures [52] or on 70–120 MV/m high-efficiency, distributed RF coupling, normal-conducting cold copper 5.7 GHz accelerating cavities at liquid nitrogen temperature [53].

There are a number of alternative ideas proposed for studies of the Higgs/Electroweak physics, such as high-energy, high-luminosity e^+e^- collider in a 100 km tunnel using ERLs to accelerate particles to collision energy in 4 to 6 passes and return up to 81% of the energy back into the SRF cavities on deceleration turns, thus, lowering the required facility power several-fold [54]; similar power recovery in one pass can greatly improve efficiency of linear colliders [55–57]; an arrangement of $\gamma\gamma$ collision through near-IP conversion of high energy electron beams into intense photon beams by backward Compton scattering off a high-power laser [58, 59] or off an FEL photon pulse [60, 61]; $\mu\mu$ Higgs factory with unprecedented 0.004% energy resolution [62], and a high-energy lepton-hadron collider bringing into collision a 60-GeV electron beam from an ERL with the 7 TeV protons circulating in the LHC (LHeC) [63]. At lower energies, Super Tau-Charm Factory proposals aim at the production and precise study of charmonium states and of the tau lepton [64, 65].

31.5.3 *Energy Frontier Circular Colliders*

Several hadron and lepton colliders have been proposed to extend the energy reach beyond the LHC. As noted above, ambitious plans have been proposed to upgrade the FCC and CEPC to hadron colliders – FCC-hh at CERN and Super Proton Proton Collider (SPPC) in China, respectively – by means of next- or next-next generation SC magnets installed in the arc sections of the 100 km rings, so as to enable $\sqrt{s}$ of the order 100 TeV or above [66, 67]. Comparable discovery reach is expected for a circular 10–14 TeV muon collider [68], significantly beyond that of practical e^+e^- linear colliders.

The maximum beam energy Eq.(31.1) is directly proportional to the magnetic field and to the ring circumference, hence,future hadron colliders like FCC-hh and SppC rely on the development of the technology of 14–16 T Nb_3Sn dipole magnets [69] or dipole magnets based on high-temperature superconductors (HTS) with a field of up to 18-20 T, including iron-based HTS [70]. Though higher fields are possible with HTS, more cost-effective might be hybrid magnet designs incorporating Nb-Ti, Nb_3Sn, and an inner layer of HTS and providing fields of about 20 T. Another important technology is the cryogenic beam vacuum system, which has to cope with unusually high levels of synchrotron radiation (up to 15 MW in total, for FCC-hh) in a cold environment. The beam-screen intercepting the radiation inside the cold bore of the magnets should operate at or above 50 K — significantly higher temperature than in the LHC.

Design luminosities of these hadron colliders $O(10^{35}\ \text{cm}^{-2}\text{s}^{-1})$ will result in a pile-up of events per crossing $O(500)$ (from up to 50 in LHC) and fast intensity drop due to burn-off. Significant radiation damping of beam emittances will naturally level luminosity evolution, though the total beam-beam tune shift $n_{\rm IP}\xi \sim (0.01 - 0.03)$ might need a special control as it will increase during the store [71].

Future hadron colliders are characterized by record high stored beam energy, e.g. 6–9 GJ in FCC-hh, rendering machine protection a paramount concern. A very challenging multi-stage collimation system is needed to avoid local beam loss spikes near cold magnets, which would induce magnet quenches. The primary and secondary collimators of the LHC are based on carbon-carbon composite material. For the future hadron colliders, ever stronger materials are being developed and examined, which also feature higher conductivity and, hence, lower impedance. More advanced options include the use of short bent crystals as primary collimators [72] and the deployment of hollow electron-beam lenses as non-destructible collimators [73].

It is noteworthy that machines like FCC-hh or SPPC can additionally be used for ion-ion/ion-proton collisions; their high-energy proton beams can also be collided with high-intensity $O(60$ GeV) electrons from an ERL resulting in c.m.e. of 3.5 TeV.

The lifetime of the muon, $\gamma\tau_0$ where τ_0=2.2μs, is sufficient to allow fast acceleration to high energy before most, or all, of the muons decay, and storage for some $300B$ turns in a ring with an average bending magnets field of B (in units of Tesla). The muon to electron mass ratio of 210 implies removal of the synchrotron radiation barrier and possibility of a muon collider facility scale to a level compatible with on-site placement at existing accelerator laboratories. High-energy muon colliders, as presently conceived, are predicted to be more compact, more power-efficient and significantly less expensive than the equivalent energy-frontier hadron or e^+e^- machines [74], and a neutrino factory could potentially be realized in the course of their construction [75]. The Higgs production cross-section in the s-channel is enhanced by a factor of $(m_\mu/m_e)^2$ compared to that in e^+e^- collisions.

The average luminosity of a muon collider,

$$\langle\mathcal{L}\rangle = f_0\gamma^2\frac{c\tau_0}{2C}\frac{n_{\rm b}N^2}{4\pi\varepsilon_{\rm n}\beta^*}\mathcal{F} = BP_{\rm b}\frac{Nr_0}{4\pi\varepsilon_{\rm n}}\frac{\gamma}{\beta^*}\left(\frac{c\tau_0\mathcal{F}}{8\pi e}\right), \qquad (31.19)$$

scales with B, the total beam power $P_{\rm b}$, and the beam brightness – the third factor above is nothing but the muon beam-beam tune shift Eq. (31.16). There is an obvious incentive to have all the particles in just one bunch per beam. The beta-function at the two IPs $\beta^* \approx \sigma_z$ scales as $1/\gamma$ within certain range of energies, giving overall scaling $\langle\mathcal{L}\rangle \propto \gamma^2$ with other limiting parameters fixed. The main challenges to luminosity achievement with decaying particles are related to production and fast cooling and acceleration of $O(10^{12})$ muons per bunch without emittance degradation. A multi-TeV c.m.e. high luminosity $O(10^{34}\ \text{cm}^{-2}\text{s}^{-1})$ muon collider would consist of [76] : (i) a high power proton driver (e.g., 8 GeV 2-4 MW H^- SRF linac), (ii) pre-target accumulation and compressor rings, in which high intensity 1-3 ns long proton bunches are formed, (iii) a liquid-mercury or other high-power target for converting the proton beam into a tertiary muon beam with energy of about 200 MeV, (iv) a multi-stage ionization cooling section that reduces transverse and longitudinal emittances by several orders of magnitude and creates a low emittance beam, similarly to that recently demonstrated [77], (v) a multistage acceleration system, possibly employing either rapid cycling synchrotrons or RLAs to accelerate muons in a modest number of turns up to the final energy using superconducting RF technology, and, finally, (vi) a 3–14 km diameter collider ring, where counter-propagating muon beams are stored and collide over the roughly 3000 turns corresponding to the muon lifetime.

The intense neutrino flux originating from the multi-TeV muon beams decaying in the collider poses another challenge — the need to minimize the environmental impact. The collider complex is usually located underground and when the produced neutrinos emerge at the surface, a small fraction interacts with the rock (and

other material) and produces ionizing radiation dose scaling as γ^3. The impact of this neutrino-induced radiation can be mitigated, for example, by continually adjusting the orbits of the beams to spread them out on a wider area, by deeper collider tunnels or with a further reduced emittance of the muon beam so that the required luminosity could be obtained using a substantially smaller number of muons.

31.5.4 *Plasma Acceleration and Other Advanced Concepts*

Since about the mid-1950s, it has been understood that collective plasma-based accelerators promise extremely large accelerating gradients, approximately three orders of magnitude greater than ∼100 MV/m obtained in conventional breakdown limited RF structures [78]. Ionized plasmas can sustain electron plasma density waves with electric fields in excess of $E_0 = cm_e\omega_\mathrm{p}/e$ or

$$E_0 \approx 96\,[\mathrm{V/m}]\,\sqrt{n_0[\mathrm{cm}^{-3}]}, \tag{31.20}$$

where n_0 denotes the ambient electron number density and $\omega_\mathrm{p} = \sqrt{e^2 n_0/(m_e\varepsilon_0)}$ is the electron plasma frequency [79].

Such gradients can be effectively excited by either powerful external pulses of laser light or by electron bunches if they are shorter than the plasma wavelength $\lambda_\mathrm{p} = c/\omega_\mathrm{p} \approx 1\ \mathrm{mm}\times\sqrt{10^{15}\,\mathrm{cm}^{-3}/n_0}$, or by longer beams of protons if their charge density is modulated with the period of λ_p. In the past decade, we have seen impressive progress in the plasma wakefield acceleration of high-quality beams. Laser-driven electron energy gain of about 8 GeV over 20 cm of plasma with density $3\times10^{17}\mathrm{cm}^{-3}$ has been demonstrated at the BELLA facility at the Lawrence Berkeley National Laboratory (LBNL) [80]. Short electron bunches were used to boost the energy of externally injected electron bunches by 9 GeV over 1.3 m of $\sim10^{17}\mathrm{cm}^{-3}$ plasma at the FACET facility in SLAC [81]. The AWAKE experiment at CERN used self-modulating long 450 GeV proton bunches to accelerate electrons to 2 GeV over 10 m of 10^{15} cm^{-3} plasma [82].

Whether plasma acceleration will find application in an HEP facility is not yet clear, given the necessity of staging and phase-locking acceleration in multiple plasma chambers [83]. Another critical issue is the power efficiency η for a collider based on plasma acceleration, whose luminosity would still be described by Eq. (31.18). Positrons can be accelerated as well but, contrary to electrons, plasma-wakefields will naturally defocus positively charged particles. Such fundamental deficiency can be addressed, e.g., in more complicated plasma acceleration schemes for e^+ [84]; or by acceleration of electrons in both linacs with conversion into a $\gamma\gamma$ collider at the IP. In addition, many novel approaches have been proposed to extend the energy or physics reach of future particle colliders, reduce their cost, and improve their luminosity or energy efficiency. Those include: i) *dielectric wakefield accelerators* in which resonant dielectric accelerating structures are fed by ultra-short RF pulses of wakefields driven by either collinear or preceding high charge electron bunches and withstand 270 MV/m operational accelerating gradients [85]; ii) *dielectric laser accelerators* – micron-size dielectric accelerating structures driven by a laser and supporting O(1 GV/m) accelerating fields [86]; iii) compact *linear muon crystal colliders* with ultimate energies O(1–10 PeV) [87] based on 1–10 TeV/m wakefield acceleration of muons (instead of electrons or hadrons) channeling between the planes in crystals or inside carbon nanotubes (CNT) with charge carrier density $\sim10^{20-22}$ cm^{-3} [88]; iv) the *Gamma Factory* concept [89], where frequent bursts of gamma rays are generated by repeatedly colliding a partially stripped heavy-ion beam circulating in the LHC, or in a future higher-energy hadron storage ring like the FCC-hh, with a conventional laser pulse, profiting from two Lorentz boosts. Active R&D programs are presently underway worldwide to determine the suitability of novel technologies for use in future high-energy colliders.

32. High-Energy Collider Parameters

High-Energy Collider Parameters: e^+e^- Colliders (I)

Table 32.1: Updated in March 2024 with numbers received from representatives of the colliders (contact E. Pianori, LBNL). The table shows the parameter values achieved. Quantities are, where appropriate, r.m.s.; unless noted otherwise, energies refer to beam energy; H and V indicate horizontal and vertical directions; s.c. stands for superconducting. Parameters for the defunct SPEAR, DORIS, PETRA, PEP, TRISTAN, and VEPP-2M colliders may be found in our 1996 edition (Phys. Rev. **D54**, 1 July 1996, Part I).

*For HL-LHC. Conservative estimates.
†Highest value achieved in ALICE.
‡Initial value, increases (descreases) without (with) cooling.
§Negative or infinite decay time is effect of cooling.
¶luminosity leveled to flat after set to target value, with cooling.
‖for a typical good fill without luminosity levelling.
**measured minimum, not theoretical.
††1240 bunches per ring were also used, but with lower peak performance due to lower bunch intensity.

33. Neutrino Beam Lines at High-Energy Proton Synchrotrons

Revised August 2023 with numbers verified by representatives of the synchrotrons (contact C.-J. Lin, LBNL). For existing (future) neutrino beam lines the latest achieved (design) values are given.

The main source of neutrinos at proton synchrotrons is from the decay of pions and kaons produced by protons striking a nuclear target. There are different schemes to focus the secondary particles to enhance neutrino flux and/or tune the neutrino energy profile. In wide-band beams (WBB), the neutrino parent mesons are focused over a wide momentum range to obtain maximum neutrino intensity. In narrow-band beams (NBB), the secondary particles are first momentum-selected to produce a monochromatic parent beam. Another approach to generate a narrow-band neutrino spectrum is to select neutrinos that are emitted off-axis relative to the momentum of the parent mesons. For a comprehensive review of the topic, including other historical neutrino beam lines, see the article by S. E. Kopp, "Accelerator-based neutrino beams," Phys. Rept. **439**, 101 (2007).

34. Passage of Particles Through Matter

Revised August 2023 by D.E. Groom (LBNL) and S.R. Klein (NSD LBNL; UC Berkeley).

This review covers the interactions of photons and electrically charged particles in matter, concentrating on energies of interest for high-energy physics and astrophysics and processes of interest for particle detectors (ionization, Cherenkov radiation, transition radiation). Much of the focus is on particles heavier than electrons ($\pi^{\pm}$, p, etc.). Although the charge number z of the projectile is included in the equations, only $z = 1$ is discussed in detail. Muon radiative losses are discussed, as are photon/electron interactions at high to ultrahigh energies. Neutrons are not discussed.

34.1 Notation

The notation and important numerical values are shown in Table 34.1.

Table 34.1: Summary of variables used in this section. The kinematic variables β and γ have their usual relativistic meanings.

Symb.	Definition	Value or (usual) units
$m_e c^2$	electron mass $\times\ c^2$	0.510 998 950 00(15) MeV
r_e	classical electron radius $e^2/4\pi\epsilon_0 m_e c^2$	2.817 940 3227(19) fm
α	fine structure constant $e^2/4\pi\epsilon_0\hbar c$	1/137.035 999 139(31)
N_A	Avogadro's number	$6.022\,140\,76 \times 10^{23}$ mol^{-1}
ρ	density	g cm^{-3}
x	mass per unit area	g cm^{-2}
M	incident particle mass	MeV/c^2
E	incident part. energy γMc^2	MeV
T	kinetic energy, $(\gamma - 1)Mc^2$	MeV
W	energy transfer to an electron in a single collision	MeV
$W_{\rm max}$	Maximum possible energy transfer to an electron in a single collision	MeV
k	bremsstrahlung photon energy	MeV
z	charge number of incident particle	
Z	atomic number of absorber	
A	atomic mass of absorber	g mol^{-1}
K	$4\pi N_A r_e^2 m_e c^2$ (Coefficient for dE/dx)	0.307 075 MeV mol^{-1} cm^2
I	mean excitation energy	eV (*Nota bene!*)
$\delta(\beta\gamma)$	density effect correction to ionization energy loss	
$\hbar\omega_p$	plasma energy $\sqrt{4\pi N_e r_e^3}\ m_e c^2/\alpha$	$\sqrt{\rho\,\langle Z/A\rangle} \times 28.816$ eV; ρ in g cm^{-3}
N_e	electron density	(units of r_e)$^{-3}$
w_j	weight fraction of the jth element in a compound or mixt.	
n_j	$\propto$ number of jth kind of atoms in a compound or mixture	
X_0	radiation length	g cm^{-2}
E_c	critical energy for electrons	MeV
$E_{\mu c}$	critical energy for muons	GeV
E_s	scale energy $\sqrt{4\pi/\alpha}\ m_e c^2$	21.2052 MeV
R_M	Molière radius	g cm^{-2}

34.2 Electronic energy loss by heavy particles

34.2.1 *Moments and cross sections*

The electronic interactions of fast charged particles with speed $v = \beta c$ occur in *single collisions with energy losses* W [1], leading to ionization, atomic, or collective excitation. Most frequently the energy losses are small (for 90% of all collisions the energy losses are less than 100 eV). In thin absorbers few collisions will take place and the total energy loss will show a large variance [1]; also see Sec. 34.2.9 below. For particles with charge ze more massive than electrons ("heavy" particles), scattering from free electrons is adequately described by the Rutherford differential cross section [2, 3].

$$\frac{d\sigma_R(W;\beta)}{dW} = \frac{2\pi r_e^2 m_e c^2 z^2}{\beta^2}\,\frac{(1-\beta^2 W/W_{\rm max})}{W^2}\ , \qquad (34.1)$$

where $W_{\rm max}$, the maximum energy transfer possible in a single collision, is discussed below. It differs from the classical cross section by the factor $(1 - \beta^2 W/W\mathrm{max})$, which arises when the spin of the target electrons is taken into account.

Bethe's original theory applied only to energies above which atomic effects are not important. The free-electron cross section (Eq. (34.1)) was used to extend the cross section to $W_{\rm max}$. This free-electron approximation is not valid if W is not large compared to electron binding energies. For this energy regime Bethe [4, 5] used "Born Theorie" to obtain the differential cross section

$$\frac{d\sigma_B(W;\beta)}{dW} = \frac{d\sigma_R(W,\beta)}{dW} B(W)\ . \qquad (34.2)$$

Electronic binding is accounted for by the correction factor $B(W)$. Examples of $B(W)$ and $d\sigma_B/dW$ can be seen in Figs. 5 and 6 of Ref. [1]. For a given material, the correction results in introducing an *effective ionization energy* I "which is a geometric average of the excitation energies of the medium weighed by the corresponding oscillator strength." [6]. The nontrivial task of finding these values is discussed in Sec. 34.2.4.

At high energies the stopping power is further modified by polarization of the medium, and this "density effect," discussed in Sec. 34.2.5, must also be included.

The mean number of collisions with energy loss between W and $W + dW$ occurring in a distance δx is $N_e \delta x\,(d\sigma/dW)dW$, where $d\sigma(W;\beta)/dW$, where the cross section is the Rutherford formula if free electrons can be assumed and the Bethe form where binding energy is important. It is convenient to define the moments

$$M_j(\beta) = N_e\,\delta x \int W^j \frac{d\sigma(W;\beta)}{dW} dW\ , \qquad (34.3)$$

so that M_0 is the mean number of collisions in δx, M_1 is the

mean energy loss in δx, $(M_2 - M_1)^2$ is the variance, *etc.* The number of collisions is Poisson-distributed with mean M_0. N_e is either measured in electrons/g ($N_e = N_A Z/A$) or electrons/cm^3 ($N_e = N_A \rho Z/A$). The former is used throughout this chapter, since quantities of interest (dE/dx, X_0, *etc.*) vary smoothly with composition when there is no density dependence.

34.2.2 *Maximum energy transfer to an electron in a single collision*

For a point-like particle with mass $M >> m_e$,

$$W_{\rm max} = \frac{2m_e c^2\,\beta^2\gamma^2}{1 + 2\gamma m_e/M + (m_e/M)^2}\ . \qquad (34.4)$$

In older references [2, 9] the "low-energy" approximation $W_{\rm max} = 2m_e c^2\,\beta^2\gamma^2$, valid for $2\gamma m_e \ll M$, is often implicit. For a pion in copper, the error thus introduced into dE/dx is greater than 6% at 100 GeV. For $2\gamma m_e \gg M$, $W_{\rm max} = Mc^2\,\beta^2\gamma$.

At energies of order 100 GeV, the maximum 4-momentum transfer to the electron can exceed 1 GeV/c, where hadronic structure effects modify the cross sections. This problem has been investigated by J.D. Jackson [10], who concluded that for incident hadrons (but not for large nuclei) corrections to dE/dx are negligible below energies where radiative effects dominate. While the cross section for rare hard collisions is modified, the average stopping power, dominated by many softer collisions, is almost unchanged.

34.2.3 *Stopping power at intermediate energies*

The mean rate of energy loss by moderately relativistic charged heavy particles is well described by the "Bethe equation" [2,4,5,9],

$$\left\langle -\frac{dE}{dx} \right\rangle = Kz^2 \frac{Z}{A}\frac{1}{\beta^2}\left[\frac{1}{2}\ln\frac{2m_e c^2\beta^2\gamma^2 W_{\rm max}}{I^2} - \beta^2 - \frac{\delta(\beta\gamma)}{2}\right]. \qquad (34.5)$$

Eq. (34.5) is valid in the region $0.1 \lesssim \beta\gamma \lesssim 1000$ with an accuracy of a few percent. At $\beta\gamma \sim 0.1$ the projectile speed is comparable to atomic electron "speed," and at $\beta\gamma \sim 1000$ radiative effects begin to be important (Sec. 34.6). Both limits are Z dependent. A minor dependence on M at high energies is introduced through $W_{\rm max}$, but for all practical purposes the stopping power in a given material is a function of β alone. Small corrections are discussed in Sec. 34.2.6.[1,2]

This is the *mass stopping power*; with the symbol definitions and values given in Table 34.1, the units are MeV g^{-1}cm^2. As can be seen from Fig. 34.2, dE/dx defined in this way is about the same for most materials, decreasing slowly with Z. The *linear stopping power*, in MeV/cm, is $\rho\,dE/dx$, where ρ is the density in g/cm^3.

The stopping power at first falls as $1/\beta^\alpha$ where $\alpha \approx 1.7$–1.5, decreasing with increasing Z, and reaches a broad minimum at $\beta\gamma = 3.8$–3.0 as Z rises from 6 to 82. It then inexorably rises as the argument of the logarithmic term increases. Two independent mechanisms contribute. Two thirds of the rise is produced by the explicit $\beta^2\gamma^2$ dependence through the relativistic flattening and extension of the particle's electric field. Rather than producing ionization at greater and greater distances, the field polarizes the medium, cancelling the increase in the logarithmic term at high energies. This is taken into account by the density-effect correction $\delta(\beta\gamma)$. The other third is introduced by the $\beta^2\gamma$ dependence of $W_{\rm max}$, the maximum possible energy transfer to a recoil electron. "Hard collision" events increasingly extend the tail of the energy loss distribution, increasing the mean but with little effect on the position of the maximum, the most probable energy loss.

Few concepts in high-energy physics are as misused as dE/dx, since the mean is weighted by rare events with large single-collision energy losses. Even with samples of hundreds of events in a typical detector, the mean energy loss cannot be obtained dependably. Far better and more easily measured is the most probable energy loss, discussed in Sec. 34.2.9. The most probable energy loss in a typical detector is considerably smaller than the mean given by the Bethe equation. It does not continue to rise with the mean stopping power, but approaches a "Fermi plateau."

In analysing TPC data (Sec. 35.6.5), the same end is often accomplished by using a restricted energy loss, the mean of 50%–70% of the samples with the smallest signals as the estimator.

Although it must be used with cautions and caveats, dE/dx as described in Eq. (34.5) still forms the basis of much of our understanding of energy loss by charged particles. Extensive tables are available [6, 7] and `pdg.lbl.gov/current/AtomicNuclearProperties/`.

For heavy projectiles, like ions, additional terms are required to account for higher-order photon coupling to the target, and to account for the finite target radius. These can change dE/dx by a factor of two or more for the heaviest nuclei in certain kinematic regimes [11].

The function as computed for muons on copper is shown as the "Bethe" region of Fig. 34.1. Mean energy loss behavior below this region is discussed in Sec. 34.2.6, and the radiative effects at high energy are discussed in Sec. 34.6. Only in the Bethe region is it a function of β alone; the mass dependence is more complicated elsewhere. The stopping power in several other materials is shown in Fig. 34.2. Except in hydrogen, particles with the same speed have similar rates of energy loss in different materials, although there is a slow decrease in the rate of energy loss with increasing Z. The qualitative behavior difference at high energies between a gas (He in the figure) and the other materials shown in the figure is due to the density-effect correction, $\delta(\beta\gamma)$, discussed in Sec. 34.2.5. The stopping power functions are characterized by broad minima whose position drops from $\beta\gamma = 3.5$ to 3.0 as Z goes from 7 to 100. The values of minimum ionization as a function of atomic number are shown in Fig. 34.3.

In practical cases, most relativistic particles (*e.g.*, cosmic-ray muons) have mean energy loss rates close to the minimum; they are "minimum-ionizing particles," or mip's.

Eq. (34.5) may be integrated to find the total (or partial) "continuous slowing-down approximation" (CSDA) range R for a particle which loses energy only through ionization and atomic excitation. Since dE/dx depends only on β, R/M is a function of E/M or pc/M. In practice, range is a useful concept only for low-energy hadrons ($R \lesssim \lambda_I$, where λ_I is the nuclear interaction length), and for muons below a few hundred GeV (above which radiative effects dominate). Fig. 34.4 shows R/M as a function of $\beta\gamma$ ($= p/Mc$) for a variety of materials.

The mass scaling of dE/dx and range is valid for the electronic losses described by the Bethe equation, but not for radiative losses.

34.2.4 *Mean excitation energy*

"The determination of the mean excitation energy is the principal non-trivial task in the evaluation of the Bethe stopping-power formula" [15]. Recommended values have varied substantially with time. Estimates based on experimental stopping-power measurements for protons, deuterons, and alpha particles and on oscillator-strength distributions and dielectric-response functions were given in ICRU 49 [6]. See also ICRU 37 [12]. These values, shown in Fig. 34.5, have since been widely used. Machine-readable versions can also be found [16].

34.2.5 *Density effect*

As the particle energy increases, its electric field flattens and extends, so that the distant-collision contribution to the logarithmic term in Eq. (34.5) increases as $\beta^2\gamma^2$. However, real media become polarized, limiting the field extension and effectively truncating this part of the logarithmic rise [2,3,6,17,18]. At very high energies,

$$\delta(\beta\gamma)/2 \to \ln(\hbar\omega_p/I) + \ln\beta\gamma - 1/2\ , \qquad (34.6)$$

where $\delta(\beta\gamma)/2$ is the density effect correction introduced in Eq. (34.5) and $\hbar\omega_p$ is the plasma energy defined in Table 34.1. A comparison with Eq. (34.5) shows that dE/dx then grows as $\ln T_{\rm max}$ rather than $\ln\beta^2\gamma^2 T_{\rm max}$, and that the mean excitation

[1] For incident spin 1/2 particles, $(W_{\rm max}/E)^2/4$ is included in the square brackets. Although this correction is within the uncertainties in the total stopping power, its inclusion avoids a systematic bias.

[2] In this section, "dE/dx" will be understood to mean the mass stopping power "$\langle -dE/dx\rangle$."

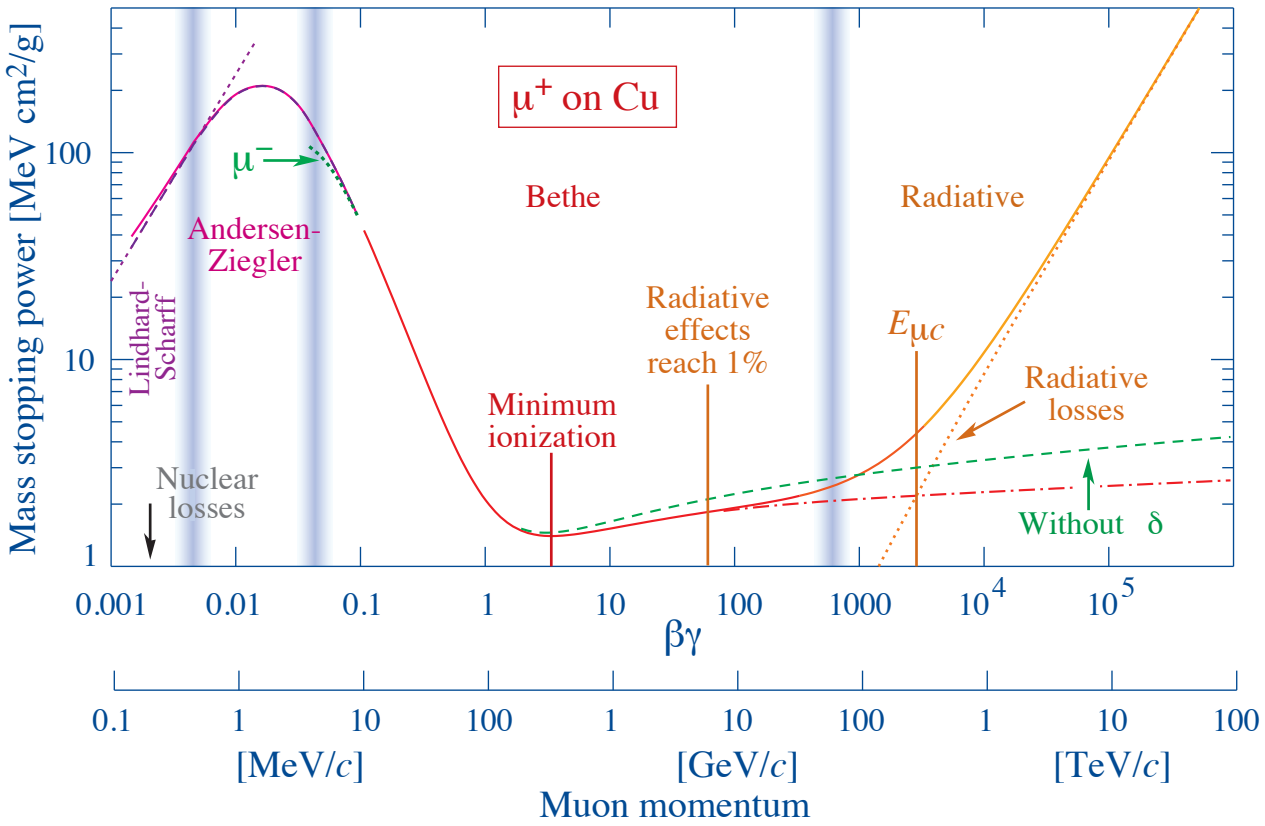

Figure 34.1: Mass stopping power (dE/dx) for positive muons in copper as a function of $\beta\gamma = p/Mc$ over nine orders of magnitude in momentum (12 orders of magnitude in kinetic energy). Solid curves indicate the total stopping power. Data below the break at $\beta\gamma \approx 0.1$ are taken from ICRU 49 [6] assuming only β dependence, and data at higher energies are from [7]. Vertical bands indicate boundaries between different approximations discussed in the text. The short dotted lines labeled "μ^-" illustrate the "Barkas effect," the dependence of stopping power on projectile charge at very low energies [8]. dE/dx in the radiative region is not simply a function of β.

energy I is replaced by the plasma energy $\hbar\omega_p$. An example of the ionization stopping power as calculated with and without the density effect correction is shown in Fig. 34.1. Since the plasma frequency scales as the square root of the electron density, the correction is much larger for a liquid or solid than for a gas, as is illustrated in Fig. 34.2.

The density effect correction is usually computed using Sternheimer's parameterization [17]:

$$\delta(\beta\gamma) = \begin{cases} 2(\ln 10)x - \overline{C} & \text{if } x \geq x_1; \\ 2(\ln 10)x - \overline{C} + a(x_1 - x)^k & \text{if } x_0 \leq x < x_1; \\ 0 & \text{if } x < x_0 \text{ (nonconductors)}; \\ \delta_0 10^{2(x-x_0)} & \text{if } x < x_0 \text{ (conductors)} \end{cases} \tag{34.7}$$

Here $x = \log_{10}\beta\gamma = \log_{10}(p/Mc)$. $\overline{C}$ (the negative of the C used in Ref. [17]) is obtained by equating the high-energy case of Eq. (34.7) with the limit given in Eq. (34.6). The other parameters are adjusted to give a best fit to the results of detailed calculations for momenta below $Mc\exp(x_1)$. For nonconductors the correction is 0 below $\beta\gamma = 10^{x_0}$, corresponding to 100–200 MeV for pions and 1–2 GeV for protons. For conductors it decreases rapidly below this point. Parameters for the elements and nearly 200 compounds and mixtures of interest are published in a variety of places, notably in Ref. [18]. A recipe for finding the coefficients for nontabulated materials is given by Sternheimer and Peierls [19] and is summarized in Ref. [7].

The remaining relativistic rise comes from the $\beta^2\gamma$ growth of $W_{\max}$, which in turn is due to (rare) large energy transfers to a few electrons. When these events are excluded, the energy deposit in an absorbing layer approaches a constant value, the Fermi plateau (see Sec. 34.2.8 below). At even higher energies (*e.g.*, > 332 GeV for muons in iron, and at a considerably higher energy for protons in iron), radiative effects are more important than ionization losses. These are especially relevant for high-energy muons, as discussed in Sec. 34.6.

34.2.6 *Energy loss at low energies*

The theory of energy loss by ionization and excitation as given by Bethe is based on a first-order Born approximation. It assumes free electrons, and should be valid when the projectile's speed is large compared to that of the atomic electrons. This presents a problem at low energies, where $W_{\max}$ is less than the K shell binding energy. However, Mott showed that the Born approximation can be applied at energies much smaller than atomic binding energies [20]; the incident particle can be treated by classical mechanics since its wavelength is shorter than atomic dimensions. The Born method is actually better justified when its speed is not large compared to the K electron speed [5].

Higher-order corrections must still be made to extend the Bethe equation (Eq. (34.5)) to low energies. An improved approximation for the terms in the square brackets of Eq. (34.5) at low energies is obtained with

$$L(\beta) = L_a(\beta) - \frac{C(\beta)}{Z} + zL_1(\beta) + z^2L_2(\beta)\ . \tag{34.8}$$

Here L_a is the square-bracketed terms of Eq. (34.5), C/Z is the sum of shell corrections and zL_1 and z^2L_2 are Barkas and Bloch correction terms [6, 21]. With these corrections, the Bethe treatment is accurate to about 1% down to $\beta \approx 0.05$, or about 1 MeV for protons (0.13 MeV for muons). Values of L_a, C/Z, L_1, and L_2 in the range T = 0.3–30 MeV for a proton traversing aluminum can be found in Table I of Ref. [21].

Shell correction $-C/Z$. As the speed of the projectile decreases, the contribution to the stopping power from K shell electrons decreases, and at even lower velocities contributions from L and

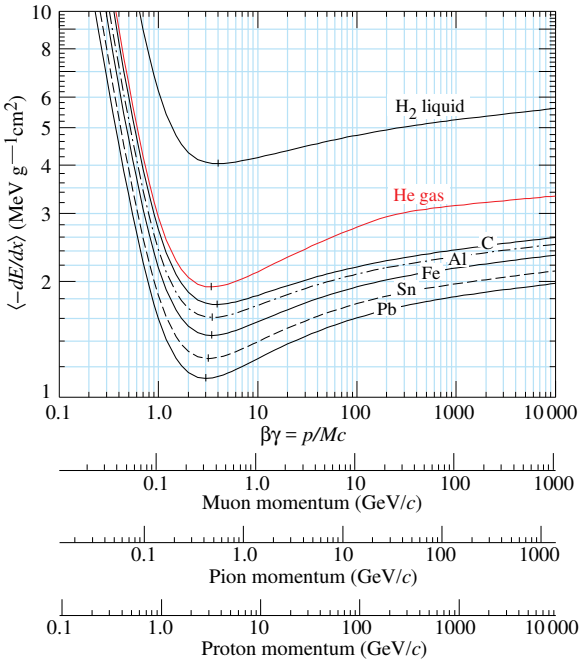

Figure 34.2: Mean energy loss rate in liquid (bubble chamber) hydrogen, gaseous helium, carbon, aluminum, iron, tin, and lead. Radiative effects, relevant for muons and pions, are not included. These become significant for muons in iron for $\beta\gamma \gtrsim 1000$, and at lower momenta for muons in higher-Z absorbers. See Fig. 34.23.

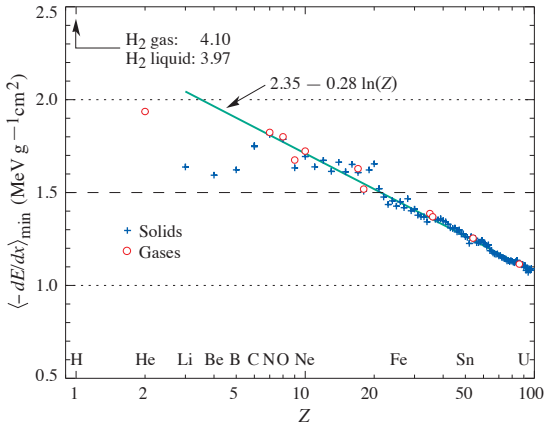

Figure 34.3: Mass stopping power at minimum ionization for the chemical elements. The straight line is fitted for $Z > 6$. A simple functional dependence on Z is not to be expected, since dE/dx also depends on other variables.

higher shells further reduce it. The correction $(C_{\rm K} + C_{\rm L} + \ldots)/Z$ is should be included in the square brackets of Eq. (34.5). It is calculated and tabulated (for a few common materials) in a number of places; Refs. [6, 12, 21] are especially useful. As an example, the shell correction for a 30 MeV proton traversing aluminum is 0.6%, increasing to 9.9% as the proton's energy decreases to 0.3 MeV.

Barkas correction zL_1. Qualitatively, one might imagine an atom's electron cloud slightly recoiling at the approach of a negative projectile and being attracted toward an approaching positive projectile. Hence the stopping power for negative particles should be slightly smaller than the stopping power for positive particles. In a 1956 paper, Barkas *et al.* noted that negative pions possibly had a longer range than positive pions [8]. The effect has been measured for a number of negative/positive particle pairs, and more recently in detailed studies with antiprotons at the CERN LEAR facility [22]. Since no complete theory exists, an empirical approach is necessary. A 1972 harmonic-oscillator model by Ashley *et al.* [23] is often used; it has two parameters determined by experimental data. For protons in aluminum, L_1/L_a is less than 0.1% at 30 MeV, but increases to 17% as T decreases to 0.3 MeV. This correction is indicated in Fig. 34.1.

Bloch correction z^2L_2. Bloch's extension of Bethe's theory introduced a low-energy correction that takes account of perturbations of the atomic wave functions. The form obtained by Lindhard and Sørensen [11] is used *e.g.* in Refs. [6, 21]. For protons in aluminum, $-L_2/L_|$ is less than 0.3% at 3.0 MeV, but rises to 7% when the energy has fallen to 0.3 MeV.

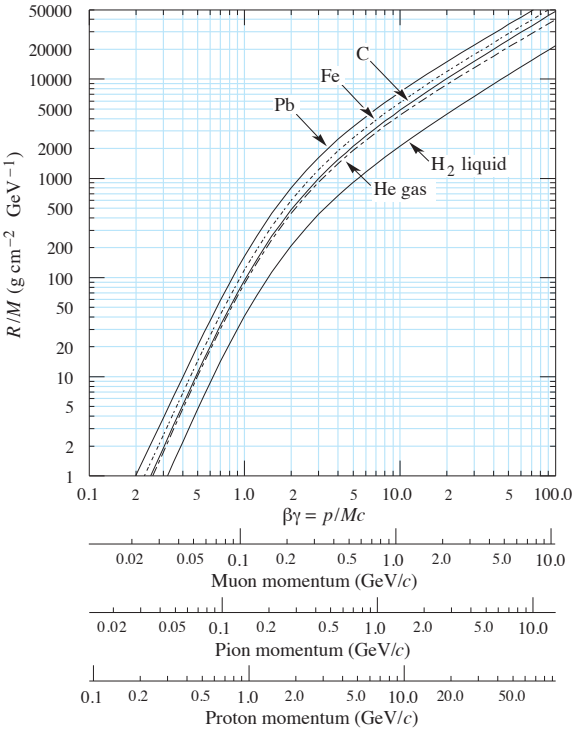

Figure 34.4: Range of heavy charged particles in liquid (bubble chamber) hydrogen, helium gas, carbon, iron, and lead. For example: For a K^+ whose momentum is 700 MeV/c, $\beta\gamma = 1.42$. For lead we read $R/M \approx 396$, and so the range is 195 g cm^{-2} (17 cm).

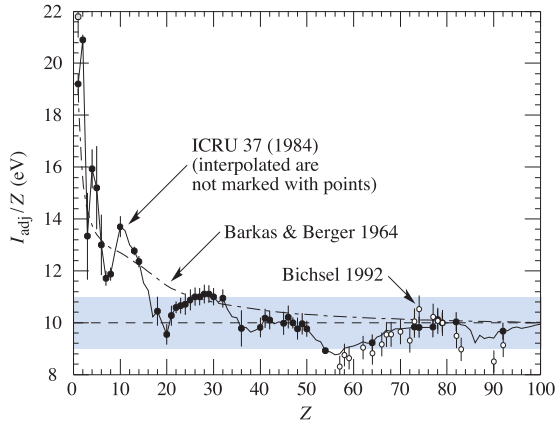

Figure 34.5: Mean excitation energies (divided by Z) as adopted by the ICRU [12]. Those based on experimental measurements are shown by symbols with error flags; the interpolated values are simply joined. The grey point is for liquid H_2; the black point at 19.2 eV is for H_2 gas. The open circles show more recent determinations by Bichsel [13]. The dash-dotted curve is from the approximate formula of Barkas [14] used in early editions of this *Review*.

For the interval $0.01 < \beta < 0.05$ there is no satisfactory theory. For protons, one usually relies on the phenomenological fitting formulae developed by Andersen and Ziegler [6,24]. As tabulated in ICRU 49 [6], the nuclear plus electronic proton stopping power in copper is 113 MeV cm^2 g^{-1} at $T = 10$ keV ($\beta\gamma = 0.005$), rises to a maximum of 210 MeV cm^2 g^{-1} at $T \approx 120$ keV ($\beta\gamma = 0.016$), then falls to 118 MeV cm^2 g^{-1} at $T = 1$ MeV ($\beta\gamma = 0.046$). Above 0.5–1.0 MeV the corrected Bethe theory is adequate.

For particles moving more slowly than $\approx 0.01c$ (more or less the speed of the outer atomic electrons), Lindhard has been quite successful in describing electronic stopping power, which is proportional to β [25]. Finally, we note that at even lower energies, *e.g.*, for protons of less than several hundred eV, non-ionizing nuclear recoil energy loss dominates the total energy loss [6, 25, 26].

34.2.7 *Energetic knock-on electrons (δ rays)*

The distribution of secondary electrons with kinetic energies $T \gg I$ is [2]

$$\frac{d^2N}{dTdx} = \frac{1}{2}\,Kz^2\frac{Z}{A}\frac{1}{\beta^2}\frac{F(T)}{T^2} \tag{34.9}$$

for $I \ll T \leq W_{\rm max}$, where $W_{\rm max}$ is given by Eq. (34.4). Here β is the speed of the primary particle. The factor F is spin-dependent, but is about unity for $T \ll W_{\rm max}$. For spin-0 particles $F(T) = (1-\beta^2 T/W_{\rm max})$; forms for spins 1/2 and 1 are also given by Rossi [2] (Sec. 2.3, Eqs. 7 and 8). Additional formulae are given in [27]. Equation Eq. (34.9) is inaccurate for T close to I [28].

δ rays of even modest energy are rare. For a $\beta \approx 1$ particle, for example, on average only one collision with $T_e > 10$ keV will occur along a path length of 90 cm of argon gas [1].

A δ ray with kinetic energy T_e and corresponding momentum p_e is produced at an angle θ given by

$$\cos\theta = (T_e/p_e)(p_{\rm max}/W_{\rm max})\ , \tag{34.10}$$

where $p_{\rm max}$ is the momentum of an electron with the maximum possible energy transfer $W_{\rm max}$.

34.2.8 *Restricted energy loss rates for relativistic ionizing particles*

Further insight can be obtained by examining the mean energy deposit by an ionizing particle when energy transfers are restricted to $T \leq W_{\rm cut} \leq W_{\rm max}$. The restricted energy loss rate is

$$-\left.\frac{dE}{dx}\right|_{T<W_{\rm cut}} = Kz^2\frac{Z}{A}\frac{1}{\beta^2}\left[\frac{1}{2}\ln\frac{2m_ec^2\beta^2\gamma^2W_{\rm cut}}{I^2} - \frac{\beta^2}{2}\left(1+\frac{W_{\rm cut}}{W_{\rm max}}\right) - \frac{\delta}{2}\right]. \tag{34.11}$$

This form approaches the normal Bethe function (Eq. (34.5)) as $W_{\rm cut} \to W_{\rm max}$. It can be verified that the difference between Eq. (34.5) and Eq. (34.11) is equal to $\int_{W_{\rm cut}}^{W_{\rm max}} T(d^2N/dTdx)dT$, where $d^2N/dTdx$ is given by Eq. (34.9).

Since $W_{\rm cut}$ replaces $W_{\rm max}$ in the argument of the logarithmic term of Eq. (34.5), the $\beta\gamma$ term producing the relativistic rise in the close-collision part of dE/dx is replaced by a constant, and $|dE/dx|_{T<W_{\rm cut}}$ approaches the constant "Fermi plateau." (The density effect correction δ eliminates the explicit $\beta\gamma$ dependence produced by the distant-collision contribution.) This behavior is illustrated in Fig. 34.6, where restricted loss rates for two examples of $W_{\rm cut}$ are shown in comparison with the full Bethe dE/dx and the Landau-Vavilov most probable energy loss (to be discussed in Sec. 34.2.9 below).

"Restricted energy loss" is cut at the total mean energy, not the single-collision energy above $W_{\rm cut}$ It is of limited use. The most probable energy loss, discussed in the next Section, is far more useful in situations where single-particle energy loss is observed.

34.2.9 *Fluctuations in energy loss*

For detectors of moderate thickness x (*e.g.* scintillators or LAr cells),[3] the energy loss probability distribution $f(\Delta;\beta\gamma,x)$ is adequately described by the highly-skewed Landau (or Landau-Vavilov) distribution [29,30].

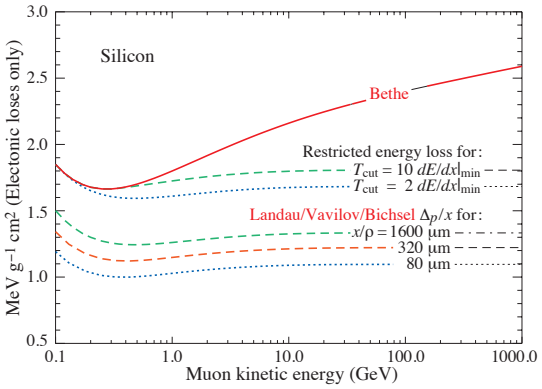

Figure 34.6: Bethe dE/dx, two examples of restricted energy loss, and the Landau most probable energy per unit thickness in silicon. The change of $\Delta_{\rm p}$/x with thickness x illustrates its $a\ln x + b$ dependence. Minimum ionization ($dE/dx|_{\rm min}$) is 1.664 MeV g^{-1} cm^2. Radiative losses are excluded. The incident particles are muons.

The most probable energy loss is [31][4]

$$\Delta_p = \xi\left[\ln\frac{2m_ec^2\beta^2\gamma^2}{I} + \ln\frac{\xi}{I} + j - \beta^2 - \delta(\beta\gamma)\right]\ , \tag{34.12}$$

where $\xi = (K/2)\langle Z/A\rangle\, z^2(x/\beta^2)$ MeV for a detector with a thickness x in g cm^{-2}, and $j = 0.200$ [31].[5] While dE/dx is independent of thickness, Δ_p/x scales as $a\ln x + b$. The density correction $\delta(\beta\gamma)$ was not included in Landau's or Vavilov's work, but it was later included by Bichsel [31]. The high-energy behavior of $\delta(\beta\gamma)$ (Eq. (34.6)) is such that

$$\Delta_p \underset{\beta\gamma\gtrsim 100}{\longrightarrow} \xi\left[\ln\frac{2m_ec^2\xi}{(\hbar\omega_p)^2} + j\right]\ . \tag{34.13}$$

Thus the Landau-Vavilov most probable energy loss, like the restricted energy loss, reaches a Fermi plateau. The Bethe dE/dx and Landau-Vavilov-Bichsel Δ_p/x in silicon are shown as a function of muon energy in Fig. 34.6. The energy deposit in the 1600 μm case is roughly the same as in a 3 mm thick plastic scintillator.

The distribution function for the energy deposit by a 10 GeV muon going through a detector of about this thickness is shown in Fig. 34.7. In this case the most probable energy loss is 62% of the mean ($M_1(\langle\Delta\rangle)/M_1(\infty)$). Folding in experimental resolution displaces the peak of the distribution, usually toward a higher value. 90% of the collisions ($M_1(\langle\Delta\rangle)/M_1(\infty)$) contribute to energy deposits below the mean. It is the very rare high-energy-transfer collisions, extending to $W_{\rm max}$ at several GeV, that drives the mean into the tail of the distribution. The large weight of these rare events makes the mean of an experimental distribution consisting of a few hundred events subject to large fluctuations and sensitive to cuts. *The mean of the energy loss given by the Bethe equation, Eq. (34.5), is thus ill-defined experimentally and is not useful for describing energy loss by single particles.*[6] It rises as $\ln\gamma$ because $W_{\rm max}$ increases as γ at high energies. *The most probable energy loss should be used.*

A practical example: For muons traversing 0.25 inches (0.64 cm) of PVT (polyvinyltolulene) based plastic scintillator,

[3] "Moderate thickness" means $G \lesssim 0.05$–0.1, where G is given by Rossi Ref. [2], Eq. 2.7(10). It is Vavilov's κ [29]. G is proportional to the absorber's thickness, and as such parameterizes the constants describing the Landau distribution. These are fairly insensitive to thickness for $G \lesssim 0.1$, the case for most detectors.

[4] Practical calculations can be expedited by using the tables of δ and β from the text versions of the muon energy loss tables to be found at pdg.lbl.gov/curremt/AtomicNuclearProperties.

[5] Rossi [2], Talman [32], and others give somewhat different values for j. The most probable loss is not sensitive to its value.

[6] It does find application in dosimetry, where only bulk deposit is relevant.

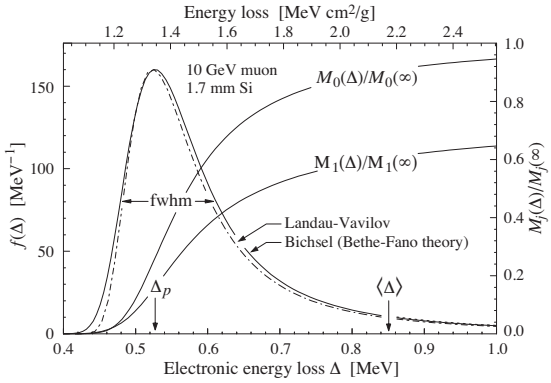

Figure 34.7: Electronic energy deposit distribution for a 10 GeV muon traversing 1.7 mm of silicon, the stopping power equivalent of about 0.3 cm of PVT-based scintillator [1, 13, 33]. The Landau-Vavilov function (dot-dashed) uses a Rutherford cross section without atomic binding corrections but with a kinetic energy transfer limit of $W_{\max}$. The solid curve was calculated using Bethe-Fano theory. $M_0(\Delta)$ and $M_1(\Delta)$ are the cumulative 0th moment (mean number of collisions) and 1st moment (mean energy loss) in crossing the silicon. (See Sec. 34.2.1). The fwhm of the Landau-Vavilov function is about 4ξ for detectors of moderate thickness. Δ_p is the most probable energy loss, and $\langle\Delta\rangle$ divided by the thickness is the Bethe dE/dx.

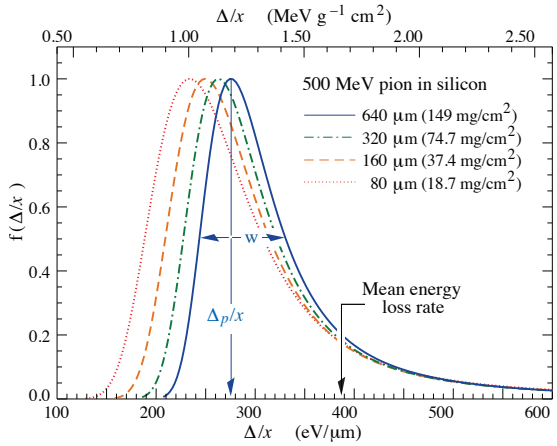

Figure 34.8: Straggling functions in silicon for 500 MeV pions, normalized to unity at the most probable value Δ_p/x. The width w is the full width at half maximum.

the ratio of the most probable E loss rate to the mean loss rate via the Bethe equation is $[0.69, 0.57, 0.49, 0.42, 0.38]$ for $T_\mu = [0.01, 0.1, 1, 10, 100]$ GeV. Radiative losses add less than 0.5% to the total mean energy deposit at 10 GeV, but add 7% at 100 GeV. The most probable E loss rate rises slightly beyond the minimum ionization energy, then is essentially constant.

The Landau distribution fails to describe energy loss in thin absorbers such as gas TPC cells [1] and Si detectors [31], as can be seen *e.g.* in Fig. 1 of Ref. [1] for an argon-filled TPC cell. Also see Talman [32]. While Δ_p/x may be calculated adequately with Eq. (34.12), the distributions are significantly wider than the Landau width $w = 4\xi$ Ref. [31], Fig. 15. Examples for 500 MeV pions incident on thin silicon detectors are shown in Fig. 34.8. For very thick absorbers the distribution is less skewed but never approaches a Gaussian.

The most probable energy loss, scaled to the mean loss at minimum ionization, is shown in Fig. 34.9 for several silicon detector thicknesses.

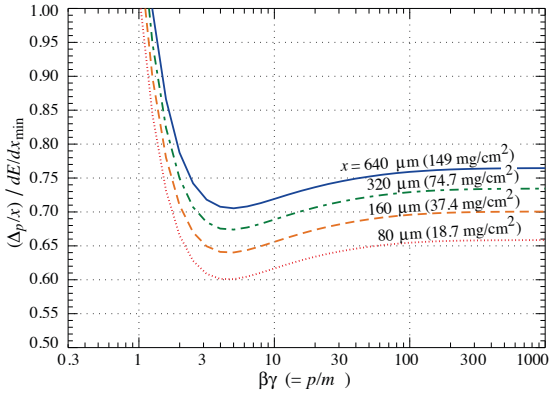

Figure 34.9: Most probable energy loss in silicon, scaled to the mean loss of a minimum ionizing particle, 388 eV/μm (1.66 MeV g^{-1}cm^2).

34.2.10 *Energy loss in mixtures and compounds*

A mixture or compound can be thought of as made up of thin layers of pure elements in the right proportion (Bragg additivity). In this case,

$$\left\langle \frac{dE}{dx} \right\rangle = \sum w_j \left\langle \frac{dE}{dx} \right\rangle_j , \qquad (34.14)$$

where $dE/dx|_j$ is the mean rate of energy loss (in MeV g cm^{-2}) in the jth element. Eq. (34.5) can be inserted into Eq. (34.14) to find expressions for $\langle Z/A\rangle$, $\langle I\rangle$, and $\langle\delta\rangle$; for example, $\langle Z/A\rangle = \sum w_j Z_j/A_j = \sum n_j Z_j / \sum n_j A_j$. However, $\langle I\rangle$ as defined this way is an underestimate, because in a compound electrons are more tightly bound than in the free elements, and $\langle\delta\rangle$ as calculated this way has little relevance, because it is the electron density that matters. If possible, one uses the tables given in Refs. [18, 34], or the recipes given in [19] (repeated in Ref. [7]), that include effective excitation energies and interpolation coefficients for calculating the density effect correction for the chemical elements and nearly 200 mixtures and compounds. Otherwise, use the recipe for δ given in Refs. [7, 19], and calculate $\langle I\rangle$ following the discussion in Ref. [15]. (Note the "13%" rule!)

34.2.11 *Ionization yields*

The Bethe equation describes energy loss via excitation and ionization. Many gaseous detectors (proportional counters or TPCs) or liquid ionization detectors count the number of electrons or positive ions from ionization, rather than the ionization energy. As a further complication, the electron liberated in the initial ionization often has enough energy to ionize other atoms or molecules; this process can happen several times. The number of electron-ion pairs per unit length is typically three or more times the original number. Ion or electron counting is a proxy for a direct dE/dx measurement. Calibrations link the number of observed ions to the traversing particle's dE/dx.

The details depend on the gases (or liquids) and the particular detector involved. A useful discussion of the physics is provided in Sec.35.6 of this Review.

34.3 Multiple scattering through small angles

A charged particle traversing a medium is deflected by many small-angle scatters. Most of this deflection is due to Coulomb scattering from nuclei as described by the Rutherford cross section. (However, for hadronic projectiles, the strong interactions also contribute to multiple scattering.) For many small-angle scatters the net scattering and displacement distributions are Gaussian via the central limit theorem. Less frequent "hard" scatters produce non-Gaussian tails. These Coulomb scattering distributions are well-represented by the theory of Molière [35]. Accessible discussions are given by Rossi [2] and Jackson [3], and exhaustive reviews have been published by Scott [36] and Motz *et al.* [37]. Experimental measurements have been published by Bichsel [38] (low energy protons) and by Shen *et al.* [39] (relativistic pions,

kaons, and protons).[7]

If we define

$$\theta_0 = \theta^{\rm rms}_{\rm plane} = \frac{1}{\sqrt{2}}\,\theta^{\rm rms}_{\rm space}\ , \tag{34.15}$$

then it is sufficient for many applications to use a Gaussian approximation for the central 98% of the projected angular distribution, with an rms width given by Lynch & Dahl [40]:

$$\begin{aligned}\theta_0 &= \frac{13.6\ {\rm MeV}}{\beta cp}\ z\ \sqrt{\frac{x}{X_0}}\left[1 + 0.088\log_{10}(\frac{x\,z^2}{X_0\beta^2})\right] \\ &= \frac{13.6\ {\rm MeV}}{\beta cp}\ z\ \sqrt{\frac{x}{X_0}}\left[1 + 0.038\ln(\frac{x\,z^2}{X_0\beta^2})\right]\end{aligned} \tag{34.16}$$

Here p, βc, and z are the momentum, speed, and charge number of the incident particle, and x/X_0 is the thickness of the scattering medium in radiation lengths (defined below). This takes into account the p and z dependence quite well at small Z, but for large Z and small x the β-dependence is not well represented. Further improvements are discussed in Ref. [40].

Eq. (34.16) describes scattering from a single material, while the usual problem involves the multiple scattering of a particle traversing many different layers and mixtures. Since it is from a fit to a Molière distribution, it is incorrect to add the individual θ_0 contributions in quadrature; the result is systematically too small. It is much more accurate to apply Eq. (34.16) once, after finding x and X_0 for the combined scatterer.

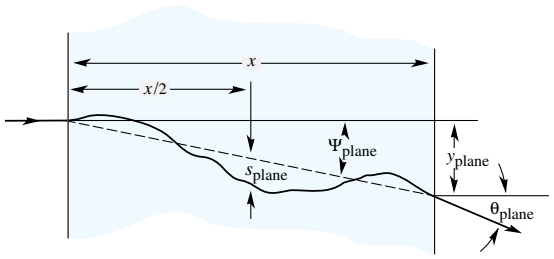

Figure 34.10: Quantities used to describe multiple Coulomb scattering. The particle is incident in the plane of the figure.

The nonprojected (space) and projected (plane) angular distributions are given approximately by [35]

$$\frac{1}{2\pi\,\theta_0^2}\ \exp\left(-\frac{\theta^2_{\rm space}}{2\theta_0^2}\right)\ d\Omega, \tag{34.17}$$

$$\frac{1}{\sqrt{2\pi}\,\theta_0}\ \exp\left(-\frac{\theta^2_{\rm plane}}{2\theta_0^2}\right)\ d\theta_{\rm plane}, \tag{34.18}$$

where θ is the deflection angle. In this approximation, $\theta^2_{\rm space} \approx (\theta^2_{{\rm plane},x} + \theta^2_{{\rm plane},y})$, where the x and y axes are orthogonal to the direction of motion, and $d\Omega \approx d\theta_{{\rm plane},x}\,d\theta_{{\rm plane},y}$. Deflections into $\theta_{{\rm plane},x}$ and $\theta_{{\rm plane},y}$ are independent and identically distributed. Fig. 34.10 shows these and other quantities sometimes used to describe multiple Coulomb scattering. They are

$$\psi^{\rm rms}_{\rm plane} = \frac{1}{\sqrt{3}}\,\theta^{\rm rms}_{\rm plane} = \frac{1}{\sqrt{3}}\,\theta_0, \tag{34.19}$$

$$y^{\rm rms}_{\rm plane} = \frac{1}{\sqrt{3}}\,x\,\theta^{\rm rms}_{\rm plane} = \frac{1}{\sqrt{3}}\,x\,\theta_0, \tag{34.20}$$

$$s^{\rm rms}_{\rm plane} = \frac{1}{4\sqrt{3}}\,x\,\theta^{\rm rms}_{\rm plane} = \frac{1}{4\sqrt{3}}\,x\,\theta_0. \tag{34.21}$$

All the quantitative estimates in this section apply only in the limit of small $\theta^{\rm rms}_{\rm plane}$ and in the absence of large-angle scatters. The random variables s, ψ, y, and θ in a given plane are correlated. Obviously, $y \approx x\psi$. In addition, y and θ have the correlation coefficient $\rho_{y\theta} = \sqrt{3}/2 \approx 0.87$. For Monte Carlo generation of a joint $(y_{\rm plane}, \theta_{\rm plane})$ distribution, or for other calculations, it may be most convenient to work with independent Gaussian random variables (z_1, z_2) with mean zero and variance one, and then set

$$y_{\rm plane} = z_1\,x\,\theta_0(1-\rho_{y\theta}^2)^{1/2}/\sqrt{3} + z_2\,\rho_{y\theta}x\,\theta_0/\sqrt{3} \tag{34.22a}$$

$$= z_1\,x\,\theta_0/\sqrt{12} + z_2\,x\,\theta_0/2; \tag{34.22b}$$

$$\theta_{\rm plane} = z_2\,\theta_0. \tag{34.22c}$$

Note that the second term for $y_{\rm plane}$ equals $x\,\theta_{\rm plane}/2$ and represents the displacement that would have occurred had the deflection $\theta_{\rm plane}$ all occurred at the single point $x/2$.

For heavy ions the multiple Coulomb scattering has been measured and compared with various theoretical distributions [41].

34.4 Photon and electron interactions in matter

At low energies electrons and positrons primarily lose energy by ionization, although other processes (Møller scattering, Bhabha scattering, e^+ annihilation) contribute, as shown in Fig. 34.11. While ionization loss rates rise logarithmically with energy, bremsstrahlung losses rise nearly linearly (fractional loss is nearly independent of energy), and dominates above the critical energy (Sec. 34.4.4 below), a few tens of MeV in most materials.

34.4.1 *Collision energy losses by* $e^\pm$

Stopping power differs somewhat for electrons and positrons, and both differ from stopping power for heavy particles because of the kinematics, spin, charge, and the identity of the incident electron with the electrons that it ionizes. Complete discussions and tables can be found in Refs. [12, 15, 34].

For electrons, large energy transfers to atomic electrons (taken as free) are described by the Møller cross section. From Eq. (34.4), the maximum energy transfer in a single collision should be the entire kinetic energy, $W_{\rm max} = m_e c^2(\gamma-1)$, but because the particles are identical, the maximum is half this, $W_{\rm max}/2$. (The results are the same if the transferred energy is ϵ or if the transferred energy is $W_{\rm max} - \epsilon$. The stopping power is by convention calculated for the faster of the two emerging electrons.) The first moment of the Møller cross section [27] (divided by dx) is the stopping power:

$$\begin{aligned}\left\langle -\frac{dE}{dx}\right\rangle = \frac{1}{2}K\frac{Z}{A}\frac{1}{\beta^2}\left[\ln\frac{m_e c^2\beta^2\gamma^2\{m_e c^2(\gamma-1)/2\}}{I^2} + (1-\beta^2)\right. \\ \left. -\ \frac{2\gamma-1}{\gamma^2}\ln 2 + \frac{1}{8}\left(\frac{\gamma-1}{\gamma}\right)^2 - \delta\right]\end{aligned} \tag{34.23}$$

The logarithmic term can be compared with the logarithmic term in the Bethe equation (Eq. (34.2)) by substituting $W_{\rm max} = m_e c^2(\gamma-1)/2$. Electron-positron scattering is described by the fairly complicated Bhabha cross section [27]. There is no identical particle problem, so $W_{\rm max} = m_e c^2(\gamma-1)$. The first moment of the Bhabha equation yields

$$\begin{aligned}\left\langle -\frac{dE}{dx}\right\rangle = \frac{1}{2}K\frac{Z}{A}\frac{1}{\beta^2}\left[\ln\frac{m_e c^2\beta^2\gamma^2\{m_e c^2(\gamma-1)\}}{2I^2} + 2\ln 2\right. \\ \left. -\frac{\beta^2}{12}\left(23 + \frac{14}{\gamma+1} + \frac{10}{(\gamma+1)^2} + \frac{4}{(\gamma+1)^3}\right) - \delta\right]\ .\end{aligned} \tag{34.24}$$

Following ICRU 37 [12], the density effect correction δ has been added to Uehling's equations [27] in both cases.

For heavy particles, shell corrections were developed assuming that the projectile is equivalent to a perturbing potential whose center moves with constant speed. This assumption has no sound theoretical basis for electrons. The authors of ICRU 37 [12] estimated the possible error in omitting it by assuming the correction was twice as great as for a proton of the same speed. At $T = 10$ keV, the error was estimated to be ≈2% for water, ≈9% for Cu, and ≈21% for Au.

[7] Shen *et al.*'s measurements show that Bethe's simpler methods of including atomic electron effects agrees better with experiment than does Scott's treatment.

As shown in Fig. 34.11, stopping powers for e^-, e^+, and heavy particles are not dramatically different. In silicon, the minimum value for electrons is 1.50 MeV cm^2/g (at $\gamma = 3.3$); for positrons, 1.46 MeV cm^2/g (at $\gamma = 3.7$), and for muons, 1.66 MeV cm^2/g (at $\gamma = 3.58$).

34.4.2 *Radiation length*

High-energy electrons predominantly lose energy in matter by bremsstrahlung, and high-energy photons by e^+e^- pair production. The characteristic amount of matter traversed for these related interactions is called the radiation length X_0, usually measured in g cm^{-2}. It is the mean distance over which a high-energy electron loses all but $1/e$ of its energy by bremsstrahlung. It is also the appropriate scale length for describing high-energy electromagnetic cascades. X_0 has been calculated and tabulated by Y.S. Tsai [42]:

$$\frac{1}{X_0} = 4\alpha r_e^2 \frac{N_A}{A}\left\{Z^2\left[L_{\rm rad} - f(Z)\right] + Z\,L'_{\rm rad}\right\}. \qquad (34.25)$$

For $A = 1$ g mol^{-1}, $4\alpha r_e^2 N_A/A = (716.408\ \text{g cm}^{-2})^{-1}$. $L_{\rm rad}$ and $L'_{\rm rad}$ are given in Table 34.2. The function $f(Z)$ is an infinite sum, but for elements up to uranium can be represented to 4-place accuracy by

$$f(Z) = a^2\left[(1+a^2)^{-1} + 0.20206 - 0.0369\,a^2 + 0.0083\,a^4 - 0.002\,a^6\right], \qquad (34.26)$$

where $a = \alpha Z$ [43].

Table 34.2: Tsai's $L_{\rm rad}$ and $L'_{\rm rad}$, for use in calculating the radiation length in an element using Eq. (34.25).

Element	Z	$L_{\rm rad}$	$L'_{\rm rad}$
H	1	5.31	6.144
He	2	4.79	5.621
Li	3	4.74	5.805
Be	4	4.71	5.924
Others	> 4	$\ln(184.15\,Z^{-1/3})$	$\ln(1194\,Z^{-2/3})$

The radiation length in a mixture or compound may be approximated by

$$1/X_0 = \sum w_j/X_j, \qquad (34.27)$$

where w_j and X_j are the fraction by weight and the radiation length for the jth element.

34.4.3 *Bremsstrahlung energy loss by* $e^\pm$

At very high energies and except at the high-energy tip of the bremsstrahlung spectrum, the cross section can be approximated in the "complete screening case" as [42]

$$d\sigma/dk = (1/k)4\alpha r_e^2\left\{(\tfrac{4}{3} - \tfrac{4}{3}y + y^2)[Z^2(L_{\rm rad} - f(Z)) + Z\,L'_{\rm rad}] + \tfrac{1}{9}(1-y)(Z^2+Z)\right\}, \qquad (34.28)$$

where $y = k/E$ is the fraction of the electron's energy transferred to the radiated photon. At small y (the "infrared limit") the term on the second line ranges from 1.7% (low Z) to 2.5% (high Z) of the total. If it is ignored and the first line simplified with the definition of X_0 given in Eq. (34.25), we have

$$\frac{d\sigma}{dk} = \frac{A}{X_0 N_A k}\left(\tfrac{4}{3} - \tfrac{4}{3}y + y^2\right). \qquad (34.29)$$

This cross section (times k) is shown by the top curve in Fig. 34.12.

This formula is accurate except near $y = 1$, where screening may become incomplete, and near $y = 0$, where the infrared divergence is removed by the interference of bremsstrahlung amplitudes from nearby scattering centers (the LPM effect) [44, 45] and dielectric suppression [46, 47]. These and other suppression effects in bulk media are discussed in Sec. 34.4.6.

With decreasing energy ($E \lesssim 10$ GeV) the high-y cross section drops and the curves become rounded as $y \to 1$. Curves of this familar shape can be seen in Rossi [2] (Figs. 2.11.2,3); see also the review by Koch & Motz [48].

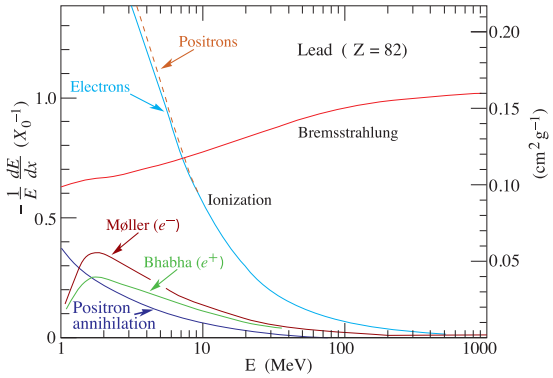

Figure 34.11: Fractional energy loss per radiation length in lead as a function of electron or positron energy. Electron (positron) scattering is considered as ionization when the energy loss per collision is below 0.255 MeV, and as Møller (Bhabha) scattering when it is above. Adapted from Fig. 3.2 from Messel and Crawford, *Electron-Photon Shower Distribution Function Tables for Lead, Copper, and Air Absorbers*, Pergamon Press, 1970. Messel and Crawford use X_0(Pb) = 5.82 g/cm^2, but we have modified the figures to reflect the value given in the Table of Atomic and Nuclear Properties of Materials (X_0(Pb) = 6.37 g/cm^2).

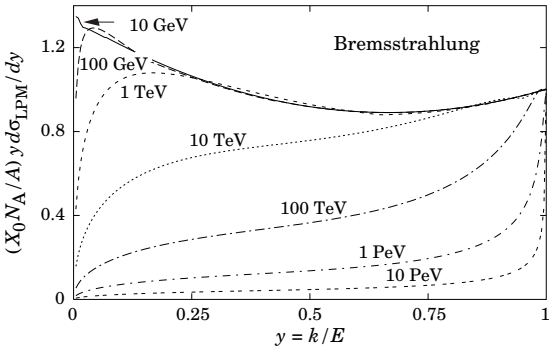

Figure 34.12: The normalized bremsstrahlung cross section $k\,d\sigma_{LPM}/dk$ in lead versus the fractional photon energy $y = k/E$. The vertical axis has units of photons per radiation length.

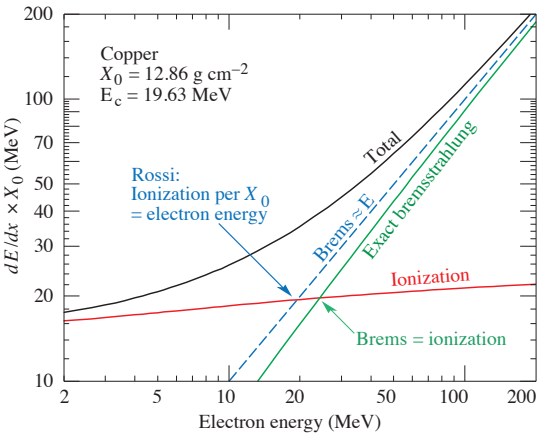

Figure 34.13: Two definitions of the critical energy E_c.

Except at these extremes, and still in the complete-screening approximation, the number of photons with energies between $k_{\min}$ and $k_{\max}$ emitted by an electron travelling a distance $d \ll X_0$ is

$$N_\gamma = \frac{d}{X_0}\left[\frac{4}{3}\ln\left(\frac{k_{\max}}{k_{\min}}\right) - \frac{4(k_{\max}-k_{\min})}{3E} + \frac{k_{\max}^2 - k_{\min}^2}{2E^2}\right]. \quad (34.30)$$

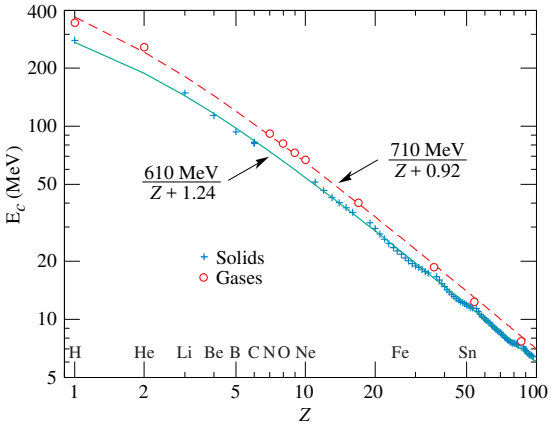

Figure 34.14: Electron critical energy for the chemical elements, using Rossi's definition [2]. The fits shown are for solids and liquids (solid line) and gases (dashed line). The rms deviation is 2.2% for the solids and 4.0% for the gases.

34.4.4 *Critical energy*

An electron loses energy by bremsstrahlung at a rate nearly proportional to its energy, while the ionization loss rate varies only logarithmically with the electron energy. The *critical energy* E_c is sometimes defined as the energy at which the two loss rates are equal [49]. Among alternate definitions is that of Rossi [2], who defines the critical energy as the energy at which the ionization loss per radiation length is equal to the electron energy. Equivalently, it is the same as the first definition with the approximation $|dE/dx|_{\rm brems} \approx E/X_0$. This form has been found to describe transverse electromagnetic shower development more accurately (see below). These definitions are illustrated in the case of copper in Fig. 34.13.

The accuracy of approximate forms for E_c has been limited by the failure to distinguish between gases and solid or liquids, where there is a substantial difference in ionization at the relevant energy because of the density effect. We distinguish these two cases in Fig. 34.14. Fits were also made with functions of the form $a/(Z+b)^\alpha$, but α was found to be essentially unity. Since E_c also depends on A, I, and other factors, such forms are at best approximate.

Values of E_c for both electrons and positrons in more than 300 materials at
`pdg.lbl.gov/current/AtomicNuclearProperties.`

34.4.5 *Energy loss by photons*

Contributions to the photon cross section in a light element (carbon) and a heavy element (lead) are shown in Fig. 34.15. At low energies it is seen that the photoelectric effect dominates, although Compton scattering, Rayleigh scattering, and photonuclear absorption also contribute. The photoelectric cross section is characterized by discontinuities (absorption edges) as thresholds for photoionization of various atomic levels are reached. Photon attenuation lengths for a variety of elements are shown in Fig. 34.16, and data for 30 eV< k <100 GeV for all elements are available from the web pages given in the caption. Here k is the photon energy.

The increasing domination of pair production as the energy increases is shown in Fig. 34.17. Using approximations similar to those used to obtain Eq. (34.29), Tsai's formula for the differential

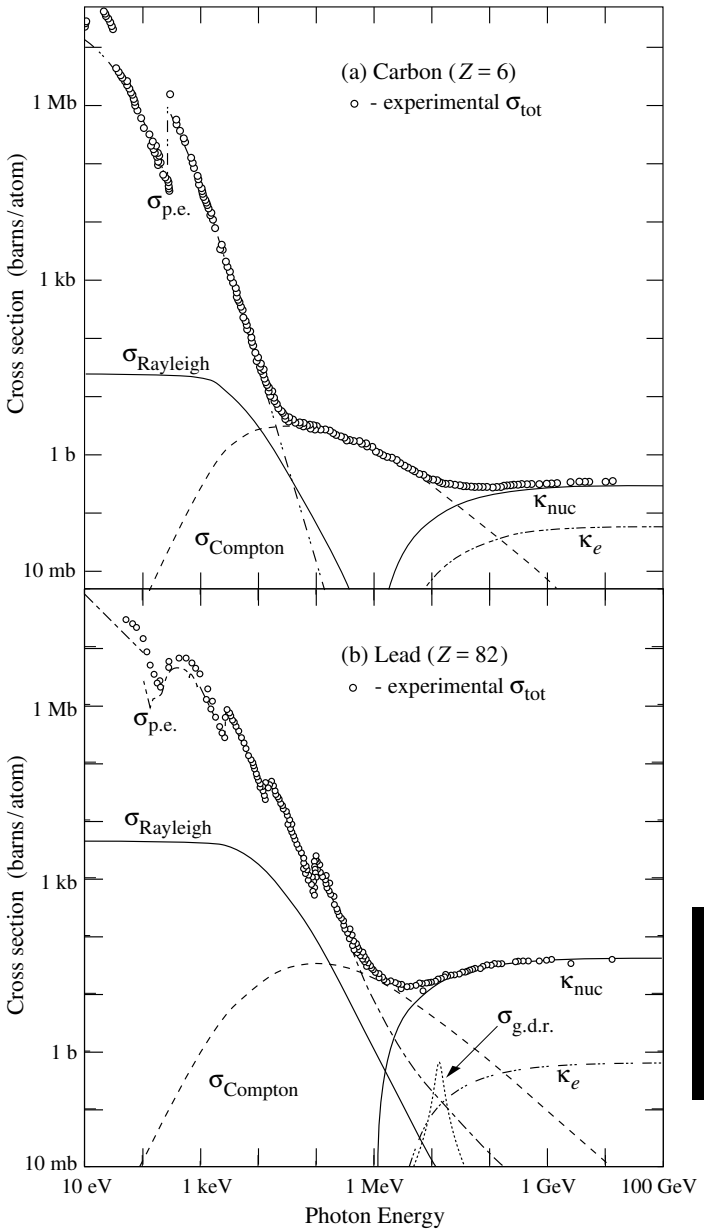

Figure 34.15: Photon total cross sections as a function of energy in carbon and lead, showing the contributions of different processes [50]:

$\sigma_{\rm p.e.}$ = Atomic photoelectric effect (electron ejection, photon absorption)
$\sigma_{\rm Rayleigh}$ = Rayleigh (coherent) scattering–atom neither ionized nor excited
$\sigma_{\rm Compton}$ = Incoherent scattering (Compton scattering off an electron)
$\kappa_{\rm nuc}$ = Pair production, nuclear field
κ_e = Pair production, electron field
$\sigma_{\rm g.d.r.}$ = Photonuclear interactions, most notably the Giant Dipole Resonance [51]. In these interactions, the target nucleus is usually broken up.

Original figures through the courtesy of John H. Hubbell (NIST).

cross section [42] reduces to

$$\frac{d\sigma}{dx} = \frac{A}{X_0 N_A}\left[1 - \tfrac{4}{3}x(1-x)\right] \quad (34.31)$$

in the complete-screening limit valid at high energies. Here $x = E/k$ is the fractional energy transfer to the pair-produced electron (or positron), and k is the incident photon energy. The cross

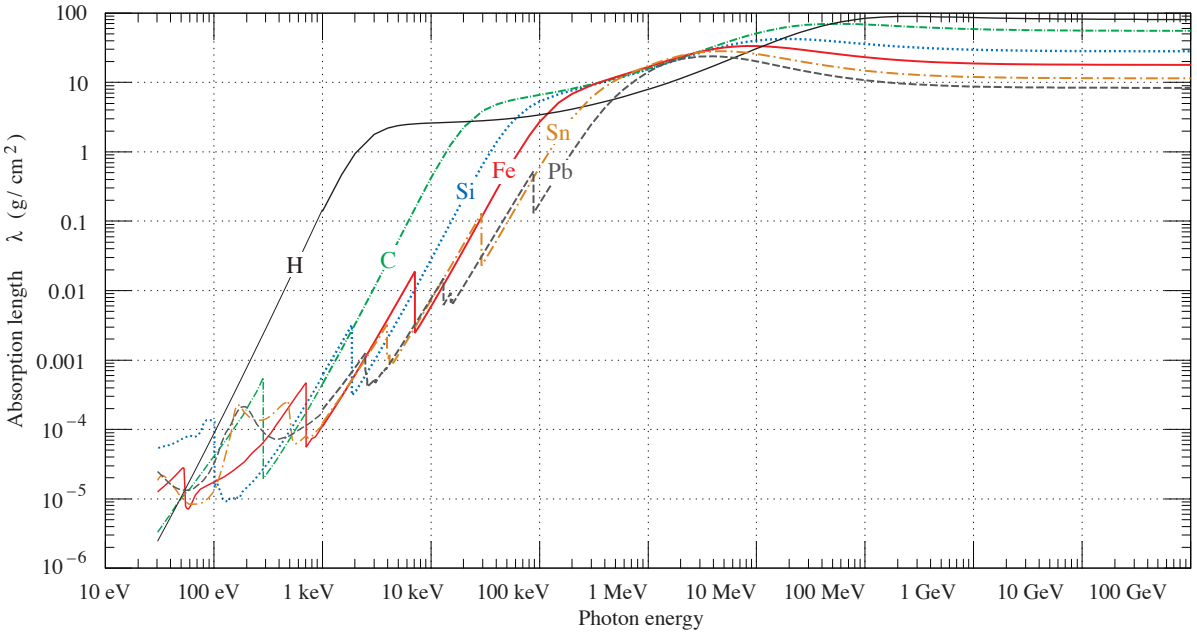

Figure 34.16: The photon mass attenuation length (or mean free path) $\lambda = 1/(\mu/\rho)$ for various elemental absorbers as a function of photon energy. The mass attenuation coefficient is μ/ρ, where ρ is the density. The intensity I remaining after traversal of thickness t (in mass/unit area) is given by $I = I_0 \exp(-t/\lambda)$. The accuracy is a few percent. For a chemical compound or mixture, $1/\lambda_{\rm eff} \approx \sum_{\rm elements} w_Z/\lambda_Z$, where w_Z is the proportion by weight of the element with atomic number Z. The processes responsible for attenuation are given in Fig. 34.11. Since coherent processes are included, not all these processes result in energy deposition. The data for 30 eV $< E <$ 1 keV are from Ref. [52], those for 1 keV $< E <$ 100 GeV from Ref. [53].

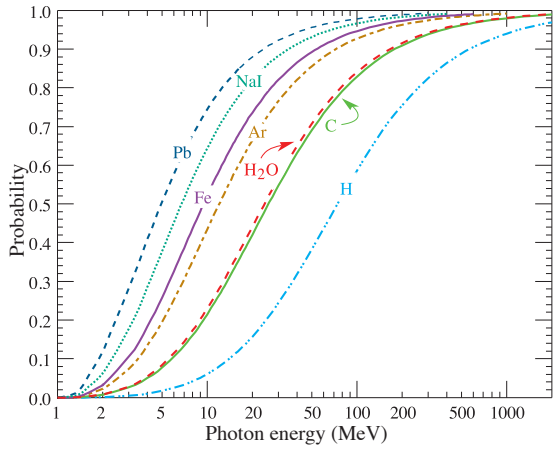

Figure 34.17: Probability P that a photon interaction will result in conversion to an e^+e^- pair. Except for a few-percent contribution from photonuclear absorption around 10 or 20 MeV, essentially all other interactions in this energy range result in Compton scattering off an atomic electron. For a photon attenuation length λ (Fig. 34.16), the probability that a given photon will produce an electron pair (without first Compton scattering) in thickness t of absorber is $P[1 - \exp(-t/\lambda)]$.

section is very closely related to that for bremsstrahlung, since the Feynman diagrams are variants of one another. The cross section is of necessity symmetric between x and $1 - x$, as can be seen by the solid curve in Fig. 34.18. See the review by Motz, Olsen, & Koch for a more detailed treatment [54]. Eq. (34.31) may be integrated to find the high-energy limit for the total e^+e^- pair-production cross section:

$$\sigma = \tfrac{7}{9}(A/X_0 N_A). \qquad (34.32)$$

Equation Eq. (34.32) is accurate to within a few percent down to energies as low as 1 GeV, particularly for high-Z materials.

34.4.6 *Bremsstrahlung and pair production at very high energies*

At ultrahigh energies, Eqns. 34.28–34.32 will fail because of quantum mechanical interference between amplitudes from different scattering centers. Since the longitudinal momentum transfer to a given center is small ($\propto k/E(E-k)$, in the case of bremsstrahlung), the interaction is spread over a comparatively long distance called the formation length ($\propto E(E-k)/k$) via the uncertainty principle. In alternate language, the formation length is the distance over which the highly relativistic electron and the photon "split apart." The interference is usually destructive. Calculations of the "Landau-Pomeranchuk-Migdal" (LPM) effect may be made semi-classically based on the average multiple scattering, or more rigorously using a quantum transport approach [44, 45].

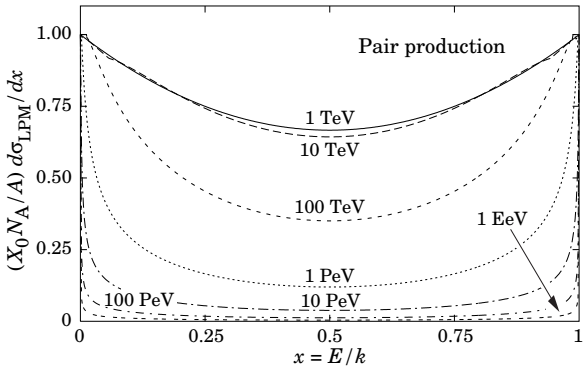

Figure 34.18: The normalized pair production cross section $d\sigma_{LPM}/dx$, versus fractional electron energy $x = E/k$.

In amorphous media, bremsstrahlung is suppressed if the pho-

ton energy k is less than $E^2/(E + E_{LPM})$ [45], where[8]

$$E_{LPM} = (m_e c^2)^2 \alpha \frac{X_0}{4\pi\hbar c\rho} = (7.7 \text{ TeV/cm}) \times \frac{X_0}{\rho} \,. \qquad (34.33)$$

Since physical distances are involved, X_0/ρ, in cm, appears. The energy-weighted bremsstrahlung spectrum for lead, $k\, d\sigma_{LPM}/dk$, is shown in Fig. 34.12. With appropriate scaling by X_0/ρ, other materials behave similarly.

For photons, pair production is reduced for $E(k - E) > k\, E_{LPM}$. The pair-production cross sections for different photon energies are shown in Fig. 34.18.

If $k \ll E$, several additional mechanisms can also produce suppression. When the formation length is long, even weak factors can perturb the interaction. For example, the emitted photon can coherently forward scatter off of the electrons in the media. Because of this, for $k < \omega_p E/m_e \sim 10^{-4}$, bremsstrahlung is suppressed by a factor $(k m_e/\omega_p E)^2$ [47]. Magnetic fields can also suppress bremsstrahlung.

In crystalline media, the situation is more complicated, with coherent enhancement or suppression possible. The cross section depends on the electron and photon energies and the angles between the particle direction and the crystalline axes [56].

34.4.7 *Photonuclear and electronuclear interactions at still higher energies*

At still higher photon and electron energies, where the bremsstrahlung and pair production cross-sections are heavily suppressed by the LPM effect, photonuclear and electronuclear interactions predominate over electromagnetic interactions.

At photon energies above about 10^{20} eV, for example, photons usually interact hadronically. The exact cross-over energy depends on the model used for the photonuclear interactions. These processes are illustrated in Fig. 34.19. At still higher energies ($\gtrsim 10^{23}$ eV), photonuclear interactions can become coherent, with the photon interaction spread over multiple nuclei. Essentially, the photon coherently converts to a ρ^0, in a process that is somewhat similar to kaon regeneration [57].

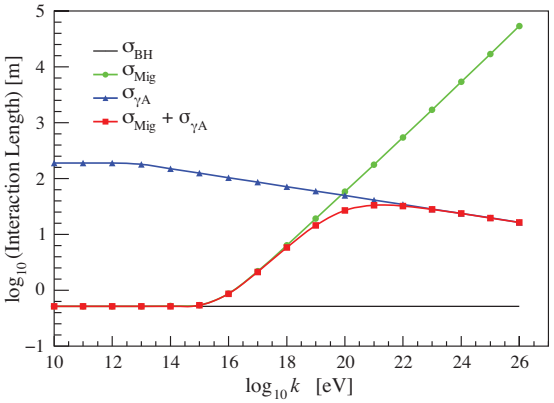

Figure 34.19: Interaction length for a photon in ice as a function of photon energy for the Bethe-Heitler (BH), LPM (Mig) and photonuclear (γA) cross sections [57]. The Bethe-Heitler interaction length is $9X_0/7$, and X_0 is 0.393 m in ice.

Similar processes occur for electrons. As electron energies increase and the LPM effect suppresses bremsstrahlung, electronuclear interactions become more important. At energies above 10^{21}eV, these electronuclear interactions dominate electron energy loss [57].

34.5 Electromagnetic cascades

When a high-energy electron or photon is incident on a thick absorber, it initiates an electromagnetic cascade as pair production and bremsstrahlung generate more electrons and photons with lower energy. The longitudinal development is governed by the high-energy part of the cascade, and therefore scales as the radiation length in the material. Electron energies eventually fall below the critical energy, and then dissipate their energy by ionization and excitation rather than by the generation of more shower particles. In describing shower behavior, it is therefore convenient to introduce the scale variables

$$t = x/X_0, \qquad y = E/E_c, \qquad (34.34)$$

so that distance is measured in units of radiation length and energy in units of critical energy.

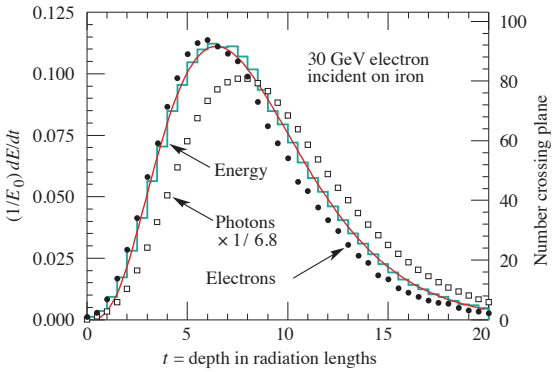

Figure 34.20: An EGS4 simulation of a 30 GeV electron-induced cascade in iron. The histogram shows fractional energy deposition per radiation length, and the curve is a gamma-function fit to the distribution. Circles indicate the number of electrons with total energy greater than 1.5 MeV crossing planes at $X_0/2$ intervals (scale on right) and the squares the number of photons with $E \geq$ 1.5 MeV crossing the planes (scaled down to have same area as the electron distribution).

Longitudinal profiles from an EGS4 [58] simulation of a 30 GeV electron-induced cascade in iron are shown in Fig. 34.20. The number of particles crossing a plane (very close to Rossi's Π function [2]) is sensitive to the cutoff energy, here chosen as a total energy of 1.5 MeV for both electrons and photons. The electron number falls off more quickly than energy deposition. This is because, with increasing depth, a larger fraction of the cascade energy is carried by photons. Exactly what a calorimeter measures depends on the device, but it is not likely to be exactly any of the profiles shown. In gas counters it may be very close to the electron number, but in glass Cherenkov detectors and other devices with "thick" sensitive regions it is closer to the energy deposition (total track length). In such detectors the signal is proportional to the "detectable" track length T_d, which is in general less than the total track length T. Practical devices are sensitive to electrons with energy above some detection threshold E_d, and $T_d = T\, F(E_d/E_c)$. An analytic form for $F(E_d/E_c)$ obtained by Rossi [2] is given by Fabjan in Ref. [59]; see also Amaldi [60].

The mean longitudinal profile of the energy deposition in an electromagnetic cascade is reasonably well described by a gamma distribution [61]:

$$\frac{dE}{dt} = E_0\, b\, \frac{(bt)^{a-1} e^{-bt}}{\Gamma(a)} \qquad (34.35)$$

The maximum $t_{\max}$ occurs at $(a-1)/b$. We have made fits to shower profiles in elements ranging from carbon to uranium, at energies from 1 GeV to 100 GeV. The energy deposition profiles are well described by Eq. (34.35) with

$$t_{\max} = (a-1)/b = 1.0 \times (\ln y + C_j), \qquad j = e, \gamma, \qquad (34.36)$$

where $C_e = -0.5$ for electron-induced cascades and $C_\gamma = +0.5$ for photon-induced cascades. To use Eq. (34.35), one finds $(a-1)/b$ from Eq. (34.36) and Eq. (34.34), then finds a either by assuming $b \approx 0.5$ or by finding a more accurate value from Fig. 34.21. The results are very similar for the electron number profiles, but there

[8] This definition differs from that of Ref. [55] by a factor of two. E_{LPM} scales as the 4th power of the mass of the incident particle, so that $E_{LPM} = (1.4 \times 10^{10} \text{ TeV/cm}) \times X_0/\rho$ for a muon.

is some dependence on the atomic number of the medium. A similar form for the electron number maximum was obtained by Rossi in the context of his "Approximation B," [2] (see Fabjan's review in Ref. [59]), but with $C_e = -1.0$ and $C_\gamma = -0.5$; we regard this as superseded by the EGS4 result.

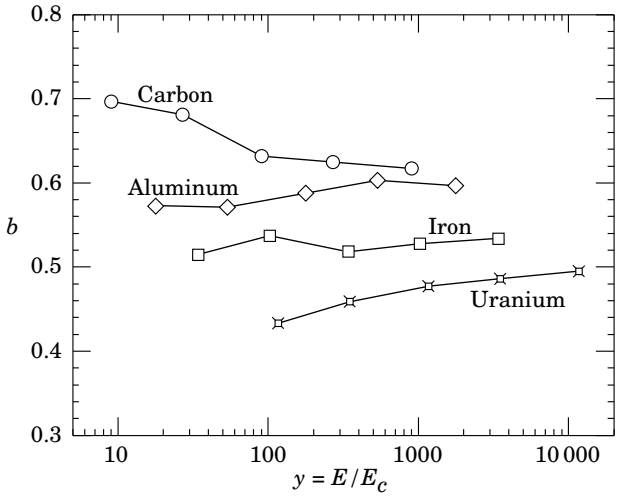

Figure 34.21: Fitted values of the scale factor b for energy deposition profiles obtained with EGS4 for a variety of elements for incident electrons with $1 \leq E_0 \leq 100$ GeV. Values obtained for incident photons are essentially the same.

The "shower length" $X_s = X_0/b$ is less conveniently parameterized, since b depends upon both Z and incident energy, as shown in Fig. 34.21. As a corollary of this Z dependence, the number of electrons crossing a plane near shower maximum is underestimated using Rossi's approximation for carbon and seriously overestimated for uranium. Essentially the same b values are obtained for incident electrons and photons. For many purposes it is sufficient to take $b \approx 0.5$.

The length of showers initiated by ultra-high energy photons and electrons is somewhat greater than at lower energies since the first or first few interaction lengths are increased via the mechanisms discussed above.

The gamma function distribution is very flat near the origin, while the EGS4 cascade (or a real cascade) increases more rapidly. As a result Eq. (34.35) fails badly for about the first two radiation lengths; it was necessary to exclude this region in making fits.

Because fluctuations are important, Eq. (34.35) should be used only in applications where average behavior is adequate. Grindhammer *et al.* have developed fast simulation algorithms in which the variance and correlation of a and b are obtained by fitting Eq. (34.35) to individually simulated cascades, then generating profiles for cascades using a and b chosen from the correlated distributions [62].

The transverse development of electromagnetic showers in different materials scales fairly accurately with the *Molière radius* R_M, given by [63, 64]

$$R_M = X_0\, E_s/E_c, \tag{34.37}$$

where $E_s \approx 21$ MeV (Table 34.1), and the Rossi definition of E_c is used.

In a material containing a weight fraction w_j of the element with critical energy E_{cj} and radiation length X_j, the Molière radius is given by

$$\frac{1}{R_M} = \frac{1}{E_s} \sum \frac{w_j\, E_{cj}}{X_j}\ . \tag{34.38}$$

Measurements of the lateral distribution in electromagnetic cascades are shown in Refs. [63, 64]. On the average, only 10% of the energy lies outside the cylinder with radius R_M. About 99% is contained inside of $3.5R_M$, but at this radius and beyond composition effects become important and the scaling with R_M fails. The distributions are characterized by a narrow core, and broaden as the shower develops. They are often represented as the sum of two Gaussians.

At high enough energies, the LPM effect (Sec. 34.4.6) reduces the cross sections for bremsstrahlung and pair production, and hence can cause significant elongation of electromagnetic cascades [45].

34.6 Muon energy loss at high energy

At sufficiently high energies, radiative processes become more important than ionization for all charged particles. For muons and pions in materials such as iron, this "critical energy" occurs at several hundred GeV. (There is no simple scaling with particle mass, but for protons the "critical energy" is much, much higher.) Radiative effects dominate the energy loss of energetic muons found in cosmic rays or produced at the newest accelerators. These processes are characterized by small cross sections, hard spectra, large energy fluctuations, and the associated generation of electromagnetic and (in the case of photonuclear interactions) hadronic showers [65–73] As a consequence, at these energies the treatment of energy loss as a uniform and continuous process is for many purposes inadequate.

It is convenient to write the average rate of muon energy loss as [74]

$$\langle -dE/dx \rangle = a(E) + b(E)\, E. \tag{34.39}$$

Here $a(E)$ is the ionization energy loss given by Eq. (34.5), and $b(E)$ is the sum of e^+e^- pair production, bremsstrahlung, and photonuclear contributions. To the approximation that these slowly-varying functions are constant, the mean range x_0 of a muon with initial energy E_0 is given by

$$x_0 \approx (1/b) \ln(1 + E_0/E_{\mu c}), \tag{34.40}$$

where $E_{\mu c} = a/b$.

Fig. 34.22 shows contributions to $b(E)$ for iron. Since $a(E) \approx 0.002$ GeV g^{-1} cm^2, $b(E)E$ dominates the energy loss above several hundred GeV, where $b(E)$ is nearly constant. The rates of energy loss for muons in hydrogen, uranium, and iron are shown in Fig. 34.23 [7].

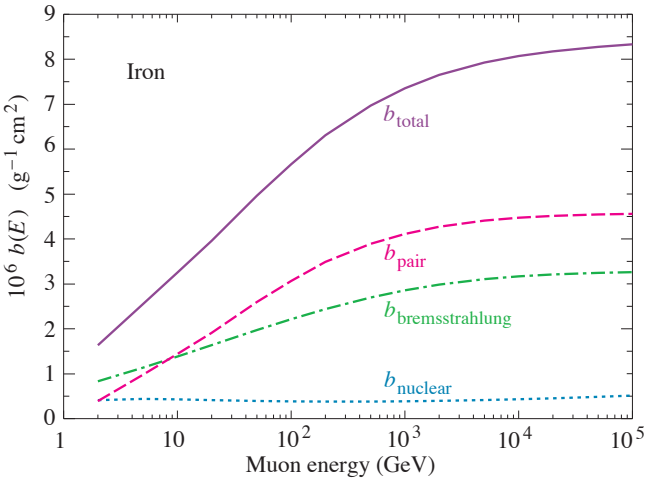

Figure 34.22: Contributions to the fractional energy loss by muons in iron due to e^+e^- pair production, bremsstrahlung, and photonuclear interactions, as obtained from Groom *et al.* [7] except for post-Born corrections to the cross section for direct pair production from atomic electrons.

The "muon critical energy" $E_{\mu c}$ can be defined more exactly as the energy at which radiative and ionization losses are equal, and can be found by solving $E_{\mu c} = a(E_{\mu c})/b(E_{\mu c})$. This definition corresponds to the solid-line intersection in Fig. 34.13, and is different from the Rossi definition we used for electrons. It serves the same function: below $E_{\mu c}$ ionization losses dominate, and above $E_{\mu c}$ radiative effects dominate. The dependence of $E_{\mu c}$ on atomic number Z is shown in Fig. 34.24.

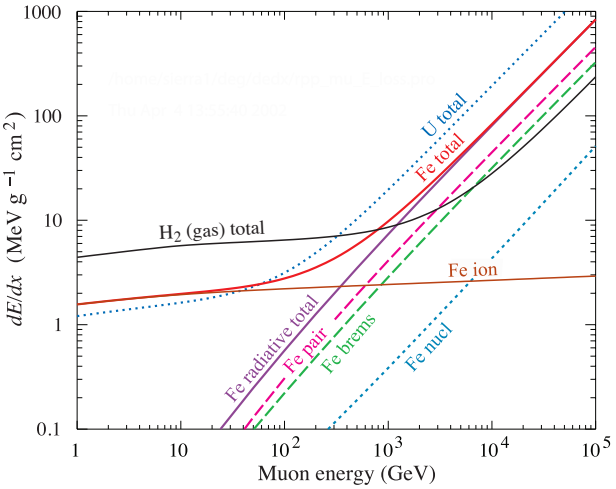

Figure 34.23: The average energy loss of a muon in hydrogen, iron, and uranium as a function of muon energy. Contributions to dE/dx in iron from ionization and pair production, bremsstrahlung and photonuclear interactions are also shown.

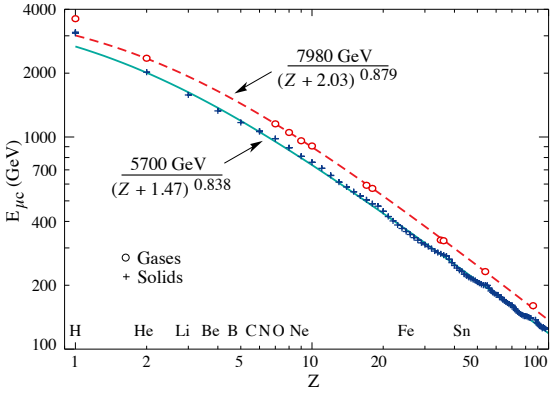

Figure 34.24: Muon critical energy for the chemical elements, defined as the energy at which radiative and ionization energy loss rates are equal [7]. The equality comes at a higher energy for gases than for solids or liquids with the same atomic number because of a smaller density effect reduction of the ionization losses. The fits shown in the figure exclude hydrogen. Alkali metals fall 3–4% above the fitted function, while most other solids are within 2% of the function. Among the gases the worst fit is for radon (2.7% high).

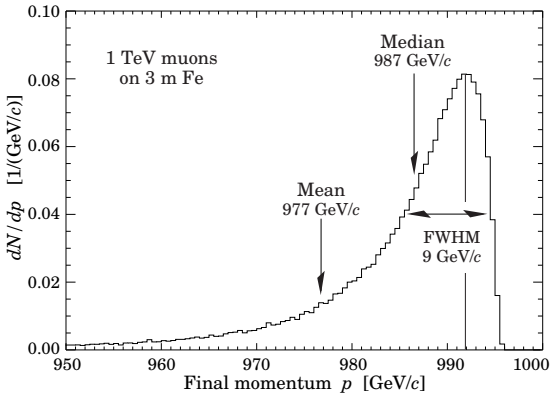

Figure 34.25: The momentum distribution of 1 TeV/c muons after traversing 3 m of iron as calculated by S.I. Striganov [7].

The radiative cross sections are expressed as functions of the fractional energy loss ν. The bremsstrahlung cross section goes roughly as $1/\nu$ over most of the range, while for the pair production case the distribution goes as ν^{-3} to ν^{-2} [75]. "Hard" losses are therefore more probable in bremsstrahlung, and in fact energy losses due to pair production may very nearly be treated as continuous. The simulated momentum distribution of an incident 1 TeV/c muon beam after it crosses 3 m of iron is shown in Fig. 34.25 [7]. The most probable loss is 8 GeV, or 3.4 MeV g^{-1}cm^2. The full width at half maximum is 9 GeV/c, or 0.9%. The radiative tail is almost entirely due to bremsstrahlung, although most of the events in which more than 10% of the incident energy lost experienced relatively hard photonuclear interactions. The latter can exceed detector resolution [76], necessitating the reconstruction of lost energy. Tables in Ref. [7] list the stopping power as 9.82 MeV g^{-1}cm^2 for a 1 TeV muon, so that the mean loss should be 23 GeV ($\approx$ 23 GeV/c), for a final momentum of 977 GeV/c, far below the peak. This agrees with the indicated mean calculated from the simulation. Electromagnetic and hadronic cascades in detector materials can obscure muon tracks in detector planes and reduce tracking efficiency [77].

34.7 Cherenkov and transition radiation [3, 78, 79]

A charged particle radiates if its speed is greater than the local phase speed of light (Cherenkov radiation) or if it crosses suddenly from one medium to another with different optical properties (transition radiation). Neither process is important for energy loss, but both are used in high-energy and cosmic-ray physics detectors.

34.7.1 *Optical Cherenkov radiation*

The angle θ_c of Cherenkov radiation, relative to the particle's direction, for a particle with speed βc in a medium with index of refraction n is

$$\cos\theta_c = (1/n\beta)$$
$$\text{or} \quad \tan\theta_c = \sqrt{\beta^2 n^2 - 1}$$
$$\approx \sqrt{2(1 - 1/n\beta)} \quad \text{for small } \theta_c, \textit{e.g.} \text{ in gases.} \quad (34.41)$$

The threshold speed β_t is $1/n$, and $\gamma_t = 1/(1-\beta_t^2)^{1/2}$. Therefore, $\beta_t\gamma_t = 1/(2\delta + \delta^2)^{1/2}$, where $\delta = n - 1$. Values of δ for various commonly used gases are given as a function of pressure and wavelength in Ref. [80]. See its Table 6.1 for values at atmospheric pressure. Data for other commonly used materials are given in Ref. [81].

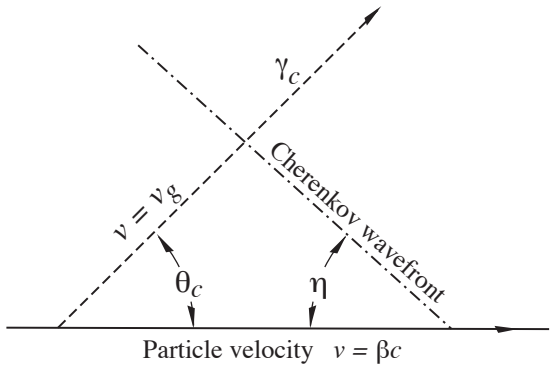

Figure 34.26: Cherenkov light emission and wavefront angles. In a dispersive medium, $\theta_c + \eta \neq 90^0$.

Practical Cherenkov radiator materials are dispersive. Let ω be the photon's frequency, and let $k = 2\pi/\lambda$ be its wavenumber. The photons propage at the group speed $v_g = d\omega/dk = c/[n(\omega) + \omega(dn/d\omega)]$. In a non-dispersive medium, this simplies to $v_g = c/n$.

In his classical paper, Tamm [82] showed that for dispersive media the radiation is concentrated in a thin conical shell whose

vertex is at the moving charge, and whose opening half-angle η is

$$\cot\eta = \left[\frac{d}{d\omega}(\omega\tan\theta_c)\right]_{\omega_0} = \left[\tan\theta_c + \beta^2\omega\, n(\omega)\,\frac{dn}{d\omega}\cot\theta_c\right]_{\omega_0}, \qquad (34.42)$$

where ω_0 is the central value of the small frequency range under consideration. (See Fig. 34.26.) This cone has a opening half-angle η, and, unless the medium is non-dispersive ($dn/d\omega = 0$), $\theta_c + \eta \neq 90^0$. The Cherenkov wavefront 'sideslips' along with the particle [83]. This effect has timing implications for ring imaging Cherenkov counters [84], but it is probably unimportant for most applications.

The number of photons produced per unit path length of a particle with charge ze and per unit energy interval of the photons is

$$\frac{d^2N}{dEdx} = \frac{\alpha z^2}{\hbar c}\sin^2\theta_c = \frac{\alpha^2 z^2}{r_e\, m_e c^2}\left(1 - \frac{1}{\beta^2 n^2(E)}\right) \approx 370\,\sin^2\theta_c(E)\ \mathrm{eV}^{-1}\mathrm{cm}^{-1} \qquad (z=1), \qquad (34.43)$$

or, equivalently,

$$\frac{d^2N}{dxd\lambda} = \frac{2\pi\alpha z^2}{\lambda^2}\left(1 - \frac{1}{\beta^2 n^2(\lambda)}\right). \qquad (34.44)$$

The index of refraction n is a function of photon energy $E = \hbar\omega$, as is the sensitivity of the transducer used to detect the light. For practical use, Eq. (34.43) must be multiplied by the the transducer response function and integrated over the region for which $\beta\, n(\omega) > 1$. Further details are given in the discussion of Cherenkov detectors in the Particle Detectors section (Sec. 35.5 of this *Review*).

When two particles are close together (lateral separation $\lesssim 1$ wavelength), the electromagnetic fields from the particles may add coherently, affecting the Cherenkov radiation. Because of their opposite charges, the radiation from an e^+e^- pair at close separation is suppressed compared to two independent leptons [85].

34.7.2 *Coherent radio Cherenkov radiation*

Coherent Cherenkov radiation is produced by many charged particles with a non-zero net charge moving through matter on an approximately common "wavefront"—for example, the electrons and positrons in a high-energy electromagnetic cascade. The signals can be visible for energies above 10^{16} eV; see Sec. 36.3.3 for more details. The phenomenon is called the Askaryan effect [86]. Near the end of a shower, when typical particle energies are below E_c (but still relativistic), a charge imbalance develops. Photons can Compton-scatter atomic electrons, and positrons can annihilate with atomic electrons to contribute even more photons which can in turn Compton scatter. These processes result in a roughly 20% excess of electrons over positrons in a shower. The net negative charge leads to coherent radio Cherenkov emission. The radiation includes a component from the decelerating charges (as in bremsstrahlung). Because the emission is coherent, the electric field strength is proportional to the shower energy, and the signal power increases as its square. The electric field strength also increases linearly with frequency, up to a maximum frequency determined by the lateral spread of the shower. This cutoff occurs at about 1 GHz in ice, and scales inversely with the Moliere radius. At low frequencies, the radiation is roughly isotropic, but, as the frequency rises toward the cutoff frequency, the radiation becomes increasingly peaked around the Cherenkov angle. The radiation is linearly polarized in the plane containing the shower axis and the photon direction. A measurement of the signal polarization can be used to help determine the shower direction. The characteristics of this radiation have been nicely demonstrated in a series of experiments at SLAC [87]. A detailed discussion of the radiation can be found in Ref. [88].

34.7.3 *Transition radiation*

The energy radiated when a particle with charge ze crosses the boundary between vacuum and a medium with plasma frequency ω_p is

$$I = \alpha z^2\gamma\hbar\omega_p/3, \qquad (34.45)$$

where

$$\hbar\omega_p = \sqrt{4\pi N_e r_e^3}\; m_e c^2/\alpha = \sqrt{\rho\ (\text{in g/cm}^3)\ \langle Z/A\rangle} \times 28.81\ \text{eV}. \qquad (34.46)$$

For styrene and similar materials, $\hbar\omega_p \approx 20$ eV; for air it is 0.7 eV.

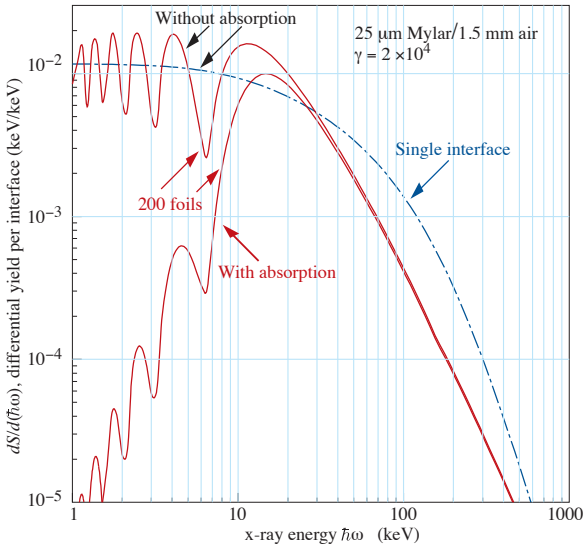

Figure 34.27: X-ray photon energy spectra for a radiator consisting of 200 25 μm thick foils of Mylar with 1.5 mm spacing in air (solid lines) and for a single surface (dashed line). Curves are shown with and without absorption. Adapted from Ref. [89].

The number spectrum $dN_\gamma/d(\hbar\omega$ diverges logarithmically at low energies and decreases rapidly for $\hbar\omega/\gamma\hbar\omega_p > 1$. About half the energy is emitted in the range $0.1 \leq \hbar\omega/\gamma\hbar\omega_p \leq 1$. Inevitable absorption in a practical detector removes the divergence. For a particle with $\gamma = 10^3$, the radiated photons are in the soft x-ray range 2 to 40 keV. The γ dependence of the emitted energy thus comes from the hardening of the spectrum rather than from an increased quantum yield.

The number of photons with energy $\hbar\omega > \hbar\omega_0$ is given by the answer to problem 13.15 in Ref. [3],

$$N_\gamma(\hbar\omega > \hbar\omega_0) = \frac{\alpha z^2}{\pi}\left[\left(\ln\frac{\gamma\hbar\omega_p}{\hbar\omega_0} - 1\right)^2 + \frac{\pi^2}{12}\right], \qquad (34.47)$$

within corrections of order $(\hbar\omega_0/\gamma\hbar\omega_p)^2$. The number of photons above a fixed energy $\hbar\omega_0 \ll \gamma\hbar\omega_p$ thus grows as $(\ln\gamma)^2$, but the number above a fixed fraction of $\gamma\hbar\omega_p$ (as in the example above) is constant. For example, for $\hbar\omega > \gamma\hbar\omega_p/10$, $N_\gamma = 2.519\,\alpha z^2/\pi = 0.59\% \times z^2$.

The particle stays "in phase" with the x ray over a distance called the formation length, $d(\omega) = (2c/\omega)(1/\gamma^2 + \theta^2 + \omega_p^2/\omega^2)^{-1}$. Most of the radiation is produced in this distance. Here θ is the x-ray emission angle, characteristically $1/\gamma$. For $\theta = 1/\gamma$ the formation length has a maximum at $d(\gamma\omega_p/\sqrt{2}) = \gamma c/\sqrt{2}\,\omega_p$. In practical situations it is tens of μm.

Since the useful x-ray yield from a single interface is low, in practical detectors it is enhanced by using a stack of N foil radiators—foils L thick, where L is typically several formation lengths—separated by gas-filled gaps. The amplitudes at successive interfaces interfere to cause oscillations about the single-interface spectrum. At increasing frequencies above the position of the last interference maximum ($L/d(w) = \pi/2$), the formation zones, which have opposite phase, overlap more and more and the

spectrum saturates, $dI/d\omega$ approaching zero as $L/d(\omega) \to 0$. This is illustrated in Fig. 34.27 for a realistic detector configuration.

For regular spacing of the layers fairly complicated analytic solutions for the intensity have been obtained [89, 90]. Although one might expect the intensity of coherent radiation from the stack of foils to be proportional to N^2, the angular dependence of the formation length conspires to make the intensity $\propto N$.

35. Particle Detectors at Accelerators

Revised 2024. See the various sections for authors.

35.1 Introduction

This review summarizes the detector technologies employed at accelerator particle physics experiments. Several of these detectors are also used in a non-accelerator context and examples of such applications will be provided. The detector techniques which are specific to non-accelerator particle physics experiments are the subject of Chap. 36. More detailed discussions of detectors and their underlying physics can be found in books by Kolanoski & Wermes [1], Ferbel [2], Kleinknecht [3], Knoll [4], Green [5], Leroy & Rancoita [6], and Grupen [7].

In Table 35.1 are given typical resolutions and deadtimes of common charged particle detectors. The quoted numbers are usually based on typical devices, and should be regarded only as rough approximations for new designs. The spatial resolution refers to the intrinsic detector resolution, i.e. without multiple scattering. We note that analog detector readout can provide better spatial resolution than digital readout by measuring and averaging the deposited charge in neighboring channels. Quoted ranges attempt to be representative of both possibilities. The time resolution is defined by how accurately the time at which a particle crossed the detector can be determined. The deadtime is the minimum separation in time between two resolved hits on the same channel. Typical performance of calorimetry and particle identification are provided in the relevant sections below.

Table 35.1: Typical resolutions and deadtimes of common charged particle detectors. Revised September 2023.

Detector Type	Intrinsinc Spatial Resolution (rms)	Time Resolution	Dead Time
Resistive plate chamber	50 μm	50–1000 ps*	10 ns†
Liquid argon TPC	0.5–1 mm‡	0.01-1 μs§	—¶
Scintillation tracker	$\sim$100 μm	100 ps/n‖	10 ns
Bubble chamber	10–150 μm	1 ms	50 ms**
Wire chambers (proportional and drift chambers)	50–100 μm	5–10 ns††	20–200 ns‡‡
Micro-pattern gas detector	30–40 μm	5–10 ns††	20–200 ns‡‡
Silicon strips/pixels	$\lesssim$ 10 μm§§	few ns¶¶ ‡‡	$\lesssim$ 50 ns‡‡

*LHC: $\sim$2 mm gap, $\sim$1 ns. HL-LHC: $\sim$1 mm gap, $\sim$350 ps. Timing RPC: $\sim$50 ps

†Limited by amplifier and discriminator bandwidth, usually around 100 MHz

‡Detector geometry dependent

§Using the scintillation signal

¶No deadtime for medium

‖n = index of refraction.

**Multiple pulsing time.

††For fast particles

‡‡Depending/limited by the amplifying electronics [8]

§§Depending on electrode pitch, best values around 2–4 μm have been achieved

¶¶Resolutions $<$ 100 ps are reached in dedicated pixel developments

35.2 Photon detectors

Revised August 2023 by P. Križan (Ljubljana U; Jozef Stefan Inst.).

Most detectors in high-energy, nuclear, and astrophysics rely on the detection of photons in or near the visible range, 100 nm $\lesssim \lambda \lesssim$ 1000 nm, or 1 eV $\lesssim E \lesssim$ 10 eV. This range covers scintillation and Cherenkov radiation as well as the light detected in many astronomical observations.

Generally, photodetection involves generating a detectable electrical signal proportional to the (usually very small) number of incident photons. The process involves three distinct steps:

1. generation of a primary photoelectron or electron-hole (e-h) pair by an incident photon by the photoelectric or photoconductive effect,
2. multiplication of the photoelectron or electron-hole pair signal to detectable levels, usually by one or more multiplicative bombardment steps and/or an avalanche process, and,
3. detection of charges induced by secondary electrons.

The important characteristics of a photodetector include the following:

1. quantum efficiency (QE or ϵ_Q): the average number of primary photoelectrons generated per incident photon ($0 \leq \epsilon_Q \leq 1$; in silicon more than one e-h pair per incident photon can be generated for $\lambda \lesssim 165$ nm),
2. collection efficiency (CE or ϵ_C): the overall acceptance factor other than the generation of photoelectrons ($0 \leq \epsilon_C \leq 1$),
3. gain (G): the number of electrons collected for each photoelectron generated,
4. dark current or dark noise: the electrical signal when there is no incident photon,
5. precision of measuring the intensity I of the incoming light: electronic noise (ENC or N_e) and statistical fluctuations in the amplification process compound the Poisson distribution of n_γ photons from a given source:

$$\frac{\sigma(I)}{\langle I \rangle} = \sqrt{\frac{f_N}{n_\gamma \epsilon_Q \epsilon_C} + \left(\frac{N_e}{G n_\gamma \epsilon_Q \epsilon_C} \right)^2}, \qquad (35.1)$$

   where f_N, or the excess noise factor (ENF), is the contribution to the intensity distribution variance due to multiplication statistics [9],
6. dynamic range, linearity and saturation: relation between the number of incident photons and the sensor output in the pulsed mode,
7. time dependence of the response: this includes the transit time, which is the time between the arrival of the photon and the electrical pulse, and the transit time spread, and
8. rate capability: maximal rate of light pulses at which detection is still possible.

The QE is a strong function of the photon wavelength (λ), and is usually quoted at maximum, together with a range of λ where the QE is comparable to its maximum. Spatial uniformity and linearity with respect to the number of photons are highly desirable in a photodetector response.

Optimization of these factors involves many trade-offs and varies widely between applications. For example, while a large gain is desirable, attempts to increase the gain for a given device also increases the ENF and after-pulsing ("echos" of the main pulse). In solid-state devices, a higher QE often requires a compromise in the timing properties. In other types, coverage of large areas by focusing photoelectrons increases the transit time spread.

Other important considerations also are highly application-specific. These include the photon flux and wavelength range, the total area to be covered, and the efficiency required, the volume available to accommodate the detectors, characteristics of the environment such as chemical composition, temperature, magnetic field, ambient background, as well as ambient radiation of different types, mode of operation (continuous or triggered), bias (high-voltage) requirements, power consumption, calibration needs, aging, cost, and so on. Several technologies employing different phenomena for the three steps described above, and many variants within each, offer a wide range of solutions to choose from. The salient features of the main technologies and the common variants are described below. Some key characteristics are summarized in Table 35.2.

35.2.1 *Vacuum photodetectors*

Vacuum photodetectors can be broadly subdivided into three types: photomultiplier tubes, microchannel plate photomultiplier tubes, and hybrid photodetectors.

35.2.1.1 *Photomultiplier tubes*

A versatile class of photon detectors, vacuum photomultiplier tube (PMT) has been employed by a vast majority of all particle physics experiments to date [9]. Both "transmission-" and "reflection-type" PMTs are widely used. In the former, the photocathode material is deposited on the inside of a transparent window through which the photons enter, while in the latter, the photocathode material rests on a separate surface that the incident photons strike. The cathode material has a low work function, chosen for the wavelength band of interest. When a photon hits the cathode and liberates an electron (the photoelectric effect), the latter is accelerated and guided by electric fields to impinge on a secondary-emission electrode, or dynode, which then emits several($\sim$ 5) secondary electrons. The multiplication process is repeated typically about 10 times in series to generate a sufficient number of electrons, which are collected at the anode for delivery to the external circuit. The total gain of a PMT depends on the applied high voltage V as $G = AV^{kn}$, where $k \approx 0.7$–0.8 (depending on the dynode material), n is the number of dynodes in the chain, and A a constant (which also depends on n). Typically, G is in the range of 10^5–10^7; time resolution is $O(1ns)$ but can be as good as ≈ 100 ps for certain PMT types.

A large variety of PMTs covers a wide span of wavelength ranges from infrared (IR) to extreme ultraviolet (XUV) [10]. They are categorized by the window materials, photocathode materials, dynode structures, and anode configurations. Common window materials are borosilicate glass for IR to near-UV, fused quartz and sapphire (Al_2O_3) for UV, and MgF_2 or LiF for XUV. The choice of photocathode materials include a variety of mostly Cs- and/or Sb-based compounds such as CsI, CsTe, bi-alkali (SbRbCs, SbKCs), multi-alkali (SbNaKCs), GaAs(Cs), GaAsP(Cs), *etc.* Sensitive wavelengths and peak quantum efficiencies for these materials are summarized in Table-35.3. Typical dynode structures used in PMTs are circular cage, line focusing, box-and-grid, venetian blind, and fine mesh.

Multianode PMTs (MaPMTs) of up to 5×5 cm^2 in size are based on the parallel (side-by-side) arrangement of several dynode channels and anodes in the same tube, requiring advanced micro-machining and processing techniques. Fast PMTs with very large windows—measuring up to 508 mm across—have been developed for detection of Cherenkov radiation in neutrino experiments such as Super-Kamiokande and KamLAND among many others. Specially prepared low-radioactivity glass is used to make these PMTs, and they are also able to withstand the high pressure of the surrounding liquid.

PMTs are vulnerable to magnetic fields—sometimes even the geomagnetic field causes large orientation-dependent gain changes. A high-permeability metal shield is often necessary. However, proximity-focused PMTs, *e.g.* the fine-mesh types, can be used even in a high magnetic field ($\geq$ 1 T) if the direction of electric field of the tube is close to the direction of the external magnetic field. CMS uses custom-made vacuum phototriodes (VPT) mounted on the back face of projective lead tungstate crystals to detect scintillation light in the endcap sections of its electromagnetic calorimeters, which are inside a 3.8 T superconducting solenoid. A VPT employs a single dynode (thus, $G \approx 10$) placed close to the photocathode, and a mesh anode plane between the two, to help it cope with the strong magnetic field, which is not too unfavorably oriented with respect to the photodetector axis in the endcaps (within 25°), but where the radiation level is too high for Avalanche Photodiodes (APDs) like those used in the barrel section.

35.2.1.2 *Microchannel plate photomultiplier tubes*

A typical microchannel plate photomultiplier tube (MCP-PMT) consists of two or more $\sim$1 mm thick glass plates with densely packed $O(10\ \mu$m)-diameter cylindrical holes, or "microchannels", sitting between the transmission-type photocathode and anode planes, separated by $O(1$ mm) gaps. Instead of discrete dynodes, the inner surface of each cylindrical hole with a length-to-diameter ratio of 40-100 serves as a continuous dynode for the entire cascade of multiplicative bombardments initiated by a photoelectron. Gain fluctuations are reduced by operating each of the MCPs in the saturation mode. MCPs are stacked in a "chevron" configuration that alternates their bias angle; this reduces ion and photon feed-back effects and optimizes the overall amplification gain.

MCP-PMTs are thin, offer good spatial resolution, have excellent time resolution ($\sim$20 ps), and can tolerate magnetic fields up to 0.1 T and axial fields up to $1-2$ T. The technology has significantly evolved over the past 10 years [11]. A main breakthrough was the introduction of the atomic layer deposition (ALD) coatings on the MCP surfaces to increase the lifetime (>20 C/cm^2 of charge accumulated on the anode) and gain. The Large Area Pi-

Table 35.2: Representative characteristics of some photodetectors commonly used in particle physics.

Type	λ (nm)	$\epsilon_Q\,\epsilon_C$	Gain	Risetime (ns)	Single photon time resol. (ps)	Area (mm^2)	1-p.e noise * (Hz/mm^2)	HV (V)
PMT †	115–1700	0.15–0.25	10^5–10^7	0.7–10	∼200	10–10^5	10^{-2}–10^2	500–3000

APD	300–1700	∼0.7	10–10^8	$O(1)$	- ‡	1–10^3	$O(10^7)$ §	400–1400
SiPM	125–1000	0.15–0.4	10^5–10^6	∼ 1	∼50	1–36	10^4–10^5	30–60

*Normalized to photocathode/sensor area; room temperature operation assumed.
†These devices often come in multi-anode configurations. In such cases, the area is to be considered on a "per readout-channel" basis.
‡No single photon detection possible.
§Since in an APD no single photon detection is possible, dark current is usually quoted instead of the dark count rate; here we assumed a gain of 50 to convert from the dark current to the dark count rate.

cosecond Photo-Detector (LAPPD) project [12] is an important attempt to produce at a reasonable cost large (20 by 20 cm^2) sensors with a transit time spread of 50-70 ps.

35.2.1.3 *Hybrid photon detectors*

Hybrid photon detectors (HPD) combine the sensitivity of a vacuum PMT with the excellent spatial and energy resolutions of a silicon sensor [13]. A single photoelectron ejected from the photocathode is accelerated through a large potential difference of ∼20 kV before it impinges on the silicon sensor/anode. The gain nearly equals the maximum number of *e-h* pairs that could be created from the entire kinetic energy of the accelerated electron: $G \approx \mathrm{eV}/w$, where e is the electronic charge, V is the applied potential difference, and $w \approx 3.7$ eV is the mean energy required to create an *e-h* pair in Si at room temperature. Since the gain is achieved in a single step, one can expect to have the excellent resolution of a simple Poisson statistic with large mean, but in fact it is even better, thanks to the Fano effect discussed in Sec. 35.8.

Low-noise electronics must be used to read out HPDs if one intends to take advantage of the low fluctuations in gain, *e.g.* when counting small numbers of photons. HPDs can have the same $\epsilon_Q\,\epsilon_C$ and window geometries as PMTs and can be segmented down to ∼50 μm. However, they require rather high biases and will not function in a magnetic field. The exception is proximity-focused devices (⇒ no (de)magnification) in an axial field. With time resolutions of ∼10 ps and superior rate capability, proximity-focused HPDs can be an alternative to MCP-PMTs. Applications of HPDs include the CMS hadronic calorimeter and the RICH detector in LHCb. Large-size HPDs with sophisticated focusing may be suitable for future water Cherenkov experiments.

Hybrid APDs (HAPDs) add an avalanche multiplication step following the electron bombardment to boost the gain by a factor of ∼50. This affords a higher gain and/or a lower bias voltage, but also increases the detector capacitance and fluctuations in multiplication. The forward RICH detector of Belle II uses a 144-channel device of this type [14].

Table 35.3: Properties of photocathode and window materials commonly used in vacuum photodetectors. [10]

Photocathode material	λ (nm)	Window material	Peak ϵ_Q (λ/nm)
CsI	115–200	MgF_2	0.13 (130)
CsTe	115–320	MgF_2	0.17 (200)
Bi-alkali	300–650	Borosilicate	0.27 (390)
	160-650	Synthetic Silica	0.27 (390)
"Ultra Bi-alkali"	300–650	Borosilicate	0.43 (350)
	160-650	Synthetic Silica	0.43 (350)
Multi-alkali	300–850	Borosilicate	0.20 (375)
	160-850	Synthetic Silica	0.25 (380)
GaAsP(Cs)	280-720	Borosilicate	0.40 (480-530)

35.2.2 *Gaseous photon detectors*

In a gaseous photon detector (GPD) a photoelectron in a suitable gas mixture initiates an avalanche in a high-field region, producing a large number of secondary impact-ionization electrons. In principle the charge multiplication and collection processes are identical to those employed in gaseous tracking detectors such as multiwire proportional chambers (MWPC), micromesh gaseous detectors (Micromegas), or gas electron multipliers (GEM). These are discussed in Sec. 35.6.4.

The devices can be divided into two types depending on the photosensitive material. One type uses solid photocathode materials much in the same way as PMTs. Since it is resistant to gas mixtures typically used in tracking chambers, CsI is a common choice. In the other type, photoionization occurs on suitable molecules vaporized and mixed in the drift volume. Most gases have photoionization work functions in excess of 10 eV, which would limit their sensitivity to wavelengths far too short. However, vapors of tetrakis dimethyl-amine ethylene (TMAE) or triethyl-amine (TEA), which have smaller work functions (5.3 eV for TMAE and 7.5 eV for TEA), are suited for XUV photon detection [15]. Since devices like GEMs offer sub-mm spatial resolution, GPDs are often used as position-sensitive photon detectors. They can be made into flat panels to cover large areas ($O(1\ \mathrm{m}^2)$), can operate in high magnetic fields, and are relatively inexpensive. Many of the ring imaging Cherenkov (RICH) detectors have used GPDs for the detection of Cherenkov light [16–19]. Special care must be taken to suppress the ion-feedback and photon-feedback processes in GPDs. It is also important to maintain high purity of the gas as minute traces of O_2 or H_2O can significantly degrade the detection efficiency.

35.2.3 *Solid-state photon detectors*

In a phase of rapid development, solid-state photodetectors are competing with vacuum- or gas-based devices for many existing applications and making way for a multitude of new ones. Compared to traditional vacuum- and gaseous photodetectors, solid-state devices are more compact, lightweight, rugged, tolerant to magnetic fields, and often cheaper. They also allow fine pixelization, are easy to integrate into large systems, and can operate at low electric potentials, while matching or exceeding most performance criteria.

Silicon photodiodes (PD) are widely used in high-energy physics as particle detectors and in a large number of applications as photon detectors. The structure is discussed in some detail in Sec. 35.8. In its simplest form, the PD is a reverse-biased *p-n* junction. Photons with energies above the indirect bandgap energy (wavelengths shorter than about 1050 nm, depending on the temperature) can create *e-h* pairs (the photoconductive effect), which are collected on the p and n sides, respectively. Often, as in the PDs used for crystal scintillator readout in CLEO, L3, Belle, BaBar, and GLAST, intrinsic silicon is doped to create a *p-i-n* structure. The reverse bias increases the thickness of the depleted region; in the case of these particular detectors, to full

depletion at a depth of about 100 μm. Increasing the depletion depth decreases the capacitance (and hence electronic noise) and extends the red response. Quantum efficiency can exceed 90%, but falls toward the red because of the decrease of the light absorption probability in silicon; the absorption length reaches 100 μm at 985 nm. However, since $G = 1$, electronic signal amplification is necessary. Optimal low-noise amplifiers are slow, but, even so, noise limits the minimum detectable signal in room-temperature devices to several hundred photons.

In APDs, an exponential cascade of impact ionizations initiated by the original photogenerated e-h pair under a large reverse-bias voltage leads to an avalanche multiplication [20–23], and eventually to breakdown in Geiger-mode APDs. As a result, detectable electrical response can be obtained from low-intensity optical signals down to single photons. Excellent junction uniformity is critical, and a guard ring is generally used as a protection against edge breakdown. Well-designed APDs, such as those used in CMS crystal-based electromagnetic calorimeter, have achieved $\epsilon_Q\,\epsilon_C \approx 0.7$ with sub-ns response time. The sensitive wavelength window and gain depend on the semiconductor used. The gain is typically 10–200 in linear and up to 10^8 in Geiger mode of operation. Stability and close monitoring of the operating temperature are important for linear-mode operation, and substantial cooling is often necessary.

One of the most promising recent developments in the field is SiPMs ("Silicon Photomultiplier"), a device consisting of large arrays ($O(10^3)$) of tiny APDs packed over a small area ($O(1\ \mathrm{mm}^2)$) and operated in a limited Geiger mode [24–26]. Although each cell only offers a binary output, linearity with respect to the number of photons is achieved by summing the cell outputs. The sum of all cells is proportional to the number of photons received so long as the probability of an individual cell receiving multiple photons during a single time gate is negligible. SiPMs are being adopted as the preferred solution for various purposes including medical imaging, *e.g.* positron emission tomography (PET). These compact, rugged, and economical devices allow auto-calibration through decent separation of photoelectron peaks and offer gains of $O(10^6)$ at a moderate bias voltage (∼30 V). However, the single-photoelectron noise of a SiPM, being the logical "or" of $O(10^3)$ Geiger APDs, is rather large: O(10-100 kHz/mm^2) at room temperature. Intensive R&D in recent years [27] led to a substantial reduction in dark count rates and in correlated noise levels, resulting in coverage of larger areas and in a wider range of applications. One way to further improve the signal-to-noise ratio in SiPMs is by using dedicated light collectors, either as quartz Winston cone like arrays [28] or suitably designed meta-materials [29]. In this way, photons propagate from a larger entry window to a considerably smaller semiconductor sensor, resulting in an improved signal photon to dark-count ratio. Intense R&D is expected to improve radiation hardness of these sensors. The fabrication of the sensors and the front-end electronics combined in the same process with the goal of making SiPMs extremely easy to use has already been successful (digital SiPMs) [30], and remains a topic of intense R&D.

More solid-state light sensors have either been developed or are potentially interesting for use in HEP experiments. The Run 2 DØ detector used 86000 Visible-light photon counters (VLPC) to read the optical signal from its scintillating-fiber tracker and scintillator-strip preshower detectors. These light sensors utilize the formation of an impurity band only 50 meV below the conduction band in As-doped Si to generate strong ($G \approx 5 \times 10^4$) yet sharp response to single photons with $\epsilon_Q \approx 0.9$ [31–33]. Only a very small bias (∼7 V) is needed, but high sensitivity to infrared photons requires cooling below 10 K. Another interesting light sensor that has not yet found its use in HEP instrumentation are quantum dots, realized by nanometer-sized semiconductor 'particles' embedded in a semiconductor bulk.

35.2.4 *Superconducting photon detectors*

In this rapidly developing technology field, three most established technologies are the superconducting nano-wire single photon detector (SNSPD), the transition edge sensor (TES), and the microwave kinetic inductance detector (MKID). An SNSPD consists of a thin (4 nm) and narrow (100-250 nm) superconducting nanostrip that is current-biased just below its critical current. Absorption of a photon generates a resistive domain in the superconducting nanostrip, which leads to a transient voltage signal that can be detected. SNSPDs offer a unique combination of speed, both in terms of count rate (∼GHz) and low timing jitter ($<$ 3 ps [34]), large range of wavelength sensitivity from VUV (120 nm) to mid-IR (10 μm), high detection efficiencies (approaching 100% for UV to near-IR), and low dark count rates (∼5-10 Hz), making them appealing for a wide variety of demanding applications.

Examples of present use in particle physics are small nanowire detectors for dark matter and dark photons. Work is in progress that could make these sensors relevant to HEP applications by increasing the area (using 300 mm wafers and larger) and pixel size, coupling via windows to cryogenic stages, and readout of arrays (superconducting electronics for data processing). While the performance of these sensors is impressive, an application in large accelerator-based detectors would require an extensive R&D program because of the severe cryogenic requirements.

35.3 Organic scintillators

Revised August 2023 by S. C. Eno (U. Maryland) and Matthieu Hamel (Paris-Saclay U. CEA, LIST).

Organic scintillators produce light when transversed by a charged particle. They can be broadly categorized into four types: single crystal, liquid, plastic, and a recently emerged glass [35]. The most useful scintillators produce photons with wavelengths between 370-750 nm (ultraviolet to red), typically peaking at 425 nm [36] via a series of processes that are initialized when charged particles interact with the material via both excitation and ionization/recombination (see Sec. 34.2 of this *Review*). Typical photon yields are about 1 photon per 100 eV of energy deposit [37], although the collected and transduced signal can be much lower. Methods to guide the light towards the photon-electron converter, such as diffusive paint, reflectors, photonic crystals, or light guides, may be required to optimize light yield.

Organic scintillators have found use in a wide variety of detectors [38]. Plastics are mostly used in collider detectors, and liquids in neutrino experiments. Ease of fabrication into desired shapes and low cost has made plastic scintillator ideal for large detectors. In the form of scintillating fiber, it has found widespread use in tracking and calorimetry. Demand for large volume detectors (e.g. neutrino detectors: MiniBooNE, NOvA) has led to increased use of liquid scintillator, which can be very low cost.

35.3.1 *Scintillation mechanism*

Plastic and liquid scintillators are based on an aromatic "matrix" such as benzene. The p electrons form both "pi" and "sigma" bonds between the atoms; the pi bonds are responsible for scintillation. Scintillation is produced via standard photophysical interactions, shown schematically in Fig. 35.1. While there have been claims of delayed light production on long time scales (labeled "phosphorescence" in the figure), this is still a subject of active debate in the community. As aromatic molecules scintillate in the ultraviolet (UV), useful scintillators have one or several fluorophores dissolved into the matrix as dopants. Common fluorophores include 2,5-diphenyloxazole, *p*-terphenyl, 9,10-diphenylanthracene (9,10-DPA), 1,4-bis(2-methylstyryl)benzene (bis-MSB) and 1,4-bis(5-phenyl-2-oxazolyl)benzene (POPOP). Each molecule has its own role: the matrix (whether liquid or plastic) is where most of the radiation/matter interaction occurs. After radiation interaction, ions may recombine giving birth to excited molecules (excitons). Excitons in the matrix are transferred to a "primary fluorophore", whose concentration is typically 1-3 weight % in commercial plastic and liquid scintillators. This concentration is large enough to ensure exciton transfer – primarily via the Förster mechanism, a resonant dipole-dipole interaction which decreases at sixth the power of the distance between molecules. The concentration, however, can be up to the solubility limit. Transfer via the Förster mechanism increases both speed and light output

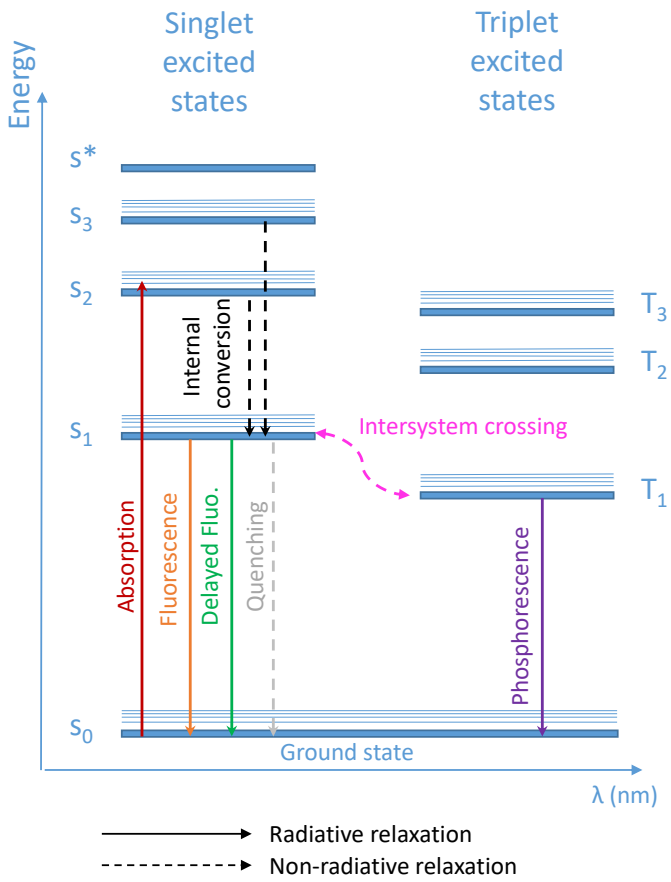

Figure 35.1: Schematic of scintillation mechanism. Schematic of typical excitation and de-excitation of matrix modules.

of the organic scintillator. To reduce reabsorption of the emitted light by the matrix or the primary fluorophore, and the resulting shortened attenuation length, a "secondary fluorophore" is also used to shift the light to longer wavelengths. Transfer from the primary to the secondary is generally radiative. Typical secondary concentrations in plastic and liquids are 0.01-0.2 weight %. The chain of emission and absorption from the matrix to the subsequent fluorophores is shown in Fig. 35.2. Scintillators with

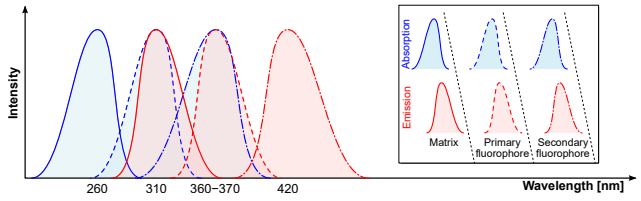

Figure 35.2: Schematic of scintillation mechanism. Typical emission and absorption spectra for the matrix, the primary, and the secondary fluorophore.

two fluorophores typically have absorption lengths of several meters. The longest attenuation lengths require a third fluorophore: when the matrix is transparent up to 1 cm, adding a primary fluorophore increases the light transmission up to ≈ 10 cm, whereas the ternary cocktail is transparent up to 2 m and longer [39].

For most scintillators, decay times are in the ns range; rise times are much faster. Sub-ns timing resolutions have been achieved [40].

Organic scintillators do not respond linearly to the ionization density. Very dense ionization tracks, with large dE/dx, emit less light than expected compared to minimum-ionizing particles. A widely used semi-empirical model by Birks posits that recombination and quenching effects between the excited molecules reduce the light yield [41]. These effects are more pronounced the greater the density of the excited molecules. Birks' formula is

$$\frac{d\mathcal{L}}{dx} = \mathcal{L}_0 \frac{dE/dx}{1 + kB\, dE/dx}, \tag{35.2}$$

where $\mathcal{L}$ is the luminescence, $\mathcal{L}_0$ is the luminescence at low specific ionization density, and the product kB is known as Birks' constant, which must be determined for each scintillator by measurement. The value of kB for polystyrene is 0.126 mm/MeV, which is large enough to play an important role in compensation in scintillator-based calorimetry. The high hydrogen content of plastic, which enhances the neutron interaction cross section, as well as the its large mass stopping power, also contributes to calorimetry compensation. In the case of large dE/dx values (e.g. with alpha particles), ion recombination may lead to the creation of triplet excited states instead of singlet excited states. If two triplet states are close enough (typically in the order of 10Å), then triplet-triplet annihilation may occur following the Dexter process [42], leading to delayed fluorescence. This phenomenon is useful for α/β or neutron/γ discrimination and is more efficient in liquid scintillators than in plastics due to the molecular motion.

Extensive research searching for new efficient molecules that can act as matrix, primary, or secondary fluorophores, is ongoing [43]. Other chemical modifications can affect the scintillator emission wavelength and decay time, or be used *e.g.* as stabilizers or to enhance thermal neutron sensitivity. Other parameters that can be modified are the density and the effective atomic number.

35.3.2 *Plastic scintillator practicalities*

Most commercial plastic scintillators use either polystyrene (PS) or poly(vinyltoluene) (PVT) as matrix. A variety of manufacturing techniques [43] are used in the production of plastic scintillator. Cast plastic has the highest light yield, while extruded scintillator is less expensive and allows creation of the scintillator and coating with a diffusive reflector in a single process. In the last couple of years, 3D printing of plastic scintillator has emerged as a reliable production method. The technique has been applied towards plastics for pulse-shape discrimination (PSD) [44]. However, large-scale production (10+ liters) has not yet been achieved. Plastic scintillator is also used to produce scintillating, wavelength-shifting, and clear fibers. These fibers can be useful to guide light to photodetectors, and as the active element in the type of calorimeter pioneered by the RD52/DREAM collaboration [45]. They have even been used in the construction of trackers [46, 47].

Plastic scintillators are reliable, robust, and convenient. However, exposure to solvent vapors, high temperatures, mechanical flexing, irradiation, or rough handling will cause degradation. The surface is a particularly fragile region and can "craze" – develop microcracks which degrade transmission of light by total internal reflection. Crazing is particularly likely where oils, solvents, or fingerprints have contacted the surface or when mechanical stresses are present. The light yield is influenced by several environmental factors: it decreases with the partial pressure of oxygen [48] and increases with increasing magnetic field. In particular, the combination of elevated temperature with relative humidity accelerates aging. This apparent fogging is typically observed in radiation portal monitors, which are exposed to harsh environmental conditions. The aging can become irreversible after multiple cycles. Recently the T2K collaboration reported a 10-year light-yield measurement showing damage due to aging [49].

Plastics are susceptible to radiation damage [50]. At high enough dose, the visible color of the plastic can change to yellow or (at high enough dose) even brown. During irradiation, broken atomic bonds ("radicals") absorb light, generally strongly in the UV, with tails to longer wavelengths. Because of this, shifting the light to longer wavelengths reduces the decrease in light output and in attenuation length due to radiation effects. Radicals produce mostly temporary damage that "anneals" when the irradiation ends, as the bonds can reform. Radicals can also polymerize via cross linking, and this leads to a permanent reduction in light yield [51]. In an inert atmosphere at room temperature, the bond reformation timescale is on the order of a month. Oxygen, which

diffuses into the plastic during radiation to a depth that scales as the inverse square root of dose rate, can quickly bind to the radicals, reducing but not eliminating temporary damage at the price of a small increased permanent damage [52–54]. After irradiation, oxygen, if present, will diffuse through the entire sample, leading to oxide formation and speeding the annealing process. The decrease in light output due to permanent damage depends on the dose rate. Lower dose rates show large light losses for the same dose. The ratio of the light output to the unirradiated light output can roughly be parameterized as an exponential. For dose rates typical of current collider detectors at the Large Hadron Collider (from a few 10^{-3} to 10 Gy/hr), an exponential dose constant of tens of kGy is observed.

35.3.3 *Organic glass scintillators*

Starting in 2016, extensive research by Sandia National Laboratories lead to a new organic scintillator family: organic glasses (OGSs) [55]. Whereas polymers are long-chain molecules built from a standard unit called a monomer, OGSs consist of small organic molecules. In addition, polymers such as PS or PVT require dopants, when OGSs are intrinsically good scintillators. This new material has the useful properties present in inorganic single crystals (light yield, PSD properties, along with fast-timing properties), without the poor mechanical characteristics seen in single crystals. The maintenance of the amorphous state of these bulk optical materials was achieved mainly either by using molecules with high configurational disorder or by introducing compositional disorder. OGSs can be prepared in medium to large scales when they are blended with polymers, or pixelated for neutron detection systems, and they can eventually be loaded with heavy elements.

35.3.4 *Liquid scintillator practicalities*

Liquid scintillators have been used in large scale neutrino experiments 36.3.1.1 due to their low cost. They can hermetically fill any vessel shape. Liquid scintillators are also, due to the mobility of the molecules, much less susceptible to radiation damage.

Care must be taken to avoid dissolved water, solvents such as isopropyl alcohol, and oxygen, which reduce light yield. As they can dissolve many materials (e.g. plastics, adhesives, paints..) care must be taken in their handling. Flammability concerns limit their use in practical experiments in intense radiation fields.

35.4 Inorganic scintillators

Revised August 2023 by C.L. Woody (BNL) and R.-Y. Zhu (HEP California Inst. of Technology).

Inorganic crystals form a class of scintillating materials with much higher densities than organic plastic scintillators (typically $\sim$ 4–8 g/cm^3) with a variety of different properties for use as scintillation detectors. Due to their high density and high effective atomic number, they can be used in applications where high stopping power or a high conversion efficiency for electrons or photons is required. These include total absorption electromagnetic calorimeters (see Sec. 35.10.2), which consist of a totally active absorber (as opposed to a sampling calorimeter), as well as serving as gamma ray detectors over a wide range of energies. Many of these crystals also have very high light output, and can therefore provide excellent energy resolution down to very low energies ($\sim$ few hundred keV).

Some crystals are intrinsic scintillators in which the luminescence is produced by a part of the crystal lattice itself. However, other crystals require the addition of a dopant, typically fluorescent ions such as thallium (Tl) or cerium (Ce) which is responsible for producing the scintillation light. However, in both cases, the scintillation mechanism is the same. Energy is deposited in the crystal by ionization, either directly by charged particles, or by the conversion of photons into electrons or positrons which subsequently produce ionization. This energy is transferred to the luminescent centers which then radiate scintillation photons. The light yield LY in terms of the number of scintillation photons produced per MeV of energy deposit in the crystal can be expressed as [56]

$$LY = 10^6 \; S \cdot Q/(\beta \cdot E_g), \tag{35.3}$$

where $\beta \cdot E_g$ is the energy required to create an e-h pair expressed as a multiple of the band gap energy Eg (eV), S is the efficiency of energy transfer to the luminescent center and Q is the quantum efficiency of the luminescent center. The values of β, S and Q are crystal dependent and are the main factors in determining the intrinsic light yield of the scintillator. The decay time of the scintillator is mainly dominated by the decay time of the luminescent center.

Table-35.4 lists the basic properties of some commonly used inorganic crystals. NaI(Tl) is one of the most common and widely used scintillators, with an emission that is well matched to a bialkali photomultiplier tube, but it is highly hygroscopic and difficult to work with, and has a rather low density. CsI(Tl) and CsI(Na) have high light yield, low cost, and are mechanically robust (high plasticity and resistance to cracking). However, they need careful surface treatment and are slightly and highly hygroscopic respectively. Pure CsI has identical mechanical properties as CsI(Tl), but a faster emission at shorter wavelength and a much lower light yield.

Undoped BaF_2 has a fast component with a less than 0.6 ns decay time, and is the fastest known scintillator. However, it also has a slow component with a much longer decay time ($\sim$ 630 ns). Bismuth gemanate ($Bi_4Ge_3O_{12}$ or BGO) has a high density, and consequently a short radiation length X_0 and Molière radius R_M. Similar to CsI(Tl), BGO's emission is well-matched to the spectral sensitivity of silicon photodiodes, and it is easy to handle and not hygroscopic. Lead tungstate ($PbWO_4$ or PWO) has a very high density, with a very short X_0 and R_M, but its intrinsic light yield is rather low.

Cerium doped lutetium oxyorthosilicate (Lu_2SiO_5:Ce, or LSO:Ce) [57] and cerium doped lutetium-yttrium oxyorthosilicate ($Lu_{2(1-x)}Y_{2x}SiO_5$, LYSO:Ce) [58] are dense crystal scintillators which have a high light yield and a fast decay time. Only the properties of LSO:Ce are listed in Table-35.4 since the properties of LYSO:Ce are similar to that of LSO:Ce except a slightly lower density than LSO:Ce depending on the yttrium fraction (typically 5 to 10%) in LYSO:Ce. This material is also featured with excellent radiation hardness [59, 60], so is expected to be used where extraordinary radiation hardness is required.

Also listed in Table-35.4 are other fluoride crystals such as PbF_2 as a Cherenkov material and CeF_3, which have been shown to provide excellent energy resolution in calorimeter applications. Table-35.4 also includes cerium doped lanthanum tri-halides, such as $LaBr_3$ [61] and $CeBr_3$ [62], which are brighter and faster than LSO:Ce, but they are highly hygroscopic and have a lower density. The FWHM energy resolution measured for these materials coupled to a PMT with bi-alkali photocathode for 0.662 MeV γ-rays from a ^{137}Cs source is about 3%, and has recently been improved to 2% by co-doping with cerium and strontium [63], which is the best among all inorganic crystal scintillators. For this reason, $LaBr_3$ and $CeBr_3$ are expected to be used in applications where a good energy resolution for low energy photons are required, such as homeland security.

Beside the crystals listed in Table-35.4, a number of new crystals are being developed that may have potential applications in high energy or nuclear physics. Of particular interest is the family of yttrium and lutetium perovskites and garnet, which include YAP ($YAlO_3$:Ce), LuAP ($LuAlO_3$:Ce), YAG ($Y_3Al_5O_{12}$:Ce) and LuAG ($Lu_3Al_5O_{12}$:Ce) and their mixed compositions. These have been shown to be linear over a large energy range [64], and have the potential for providing good intrinsic energy resolution.

Aiming at the best jet-mass resolution inorganic scintillators are being investigated for HEP calorimeters with dual readout for both Cherenkov and scintillation light to be used at future lepton colliders. These materials may be used for an electromagnetic calorimeter [65] or a homogeneous hadronic calorimetry (HHCAL) detector concept, including both electromagnetic and hadronic parts [66, 67]. Because of the unprecedented volume (70 to 100 m^3) foreseen for the HHCAL detector concept the materials must be (1) dense (to minimize the leakage) and (2) cost-effective. It should also be UV transparent (for effective collection of the Cherenkov light) and allow for a clear discrimination between the Cherenkov and scintillation light. The preferred scintillation light

‡Relative light yield measured for samples of 1.5 X_0 cube with a Tyvek paper wrapping and a full end face coupled to a photodetector. The quantum efficiencies of the photodetector are taken out.

§Variation of light yield with temperature evaluated at the room temperature.

f = fast component, s = slow component

is thus at a longer wavelength, and not necessarily bright or fast. Dense crystals, scintillating glasses and ceramics offer a very attractive implementation for this detector concept [68].

The fast scintillation light provides timing information about electromagnetic interactions and showers, which may be used to mitigate pile-up effects and/or for particle identification since the time development of electromagnetic and hadronic showers, as well as minimum ionizing particles, are different. The timing information is primarily determined by the scintillator rise time and decay time, and the number of photons produced. For fast timing, it is important to have a large number of photons emitted in the initial part of the scintillation pulse, e.g. in the first ns, since one is often measuring the arrival time of the particle in the crystal using the leading edge of the light pulse. A good example of this is BaF_2, which has $\sim 10\%$ of its light in its fast component with a decay time of less than 0.6 ns. Recent investigation shows that doping with yttrium in BaF_2 reduces its slow component significantly, while keeping its ultrafast scintillation component unchanged [69, 70]. The light propagation can spread out the arrival time of the scintillation photons at the photodetector due to time dispersion [71]. The time response of the photodetector also plays a major role in achieving good time resolution with fast scintillating crystals.

Table-35.4 gives the light yield of other crystals relative to NaI(Tl) and their dependence to the temperature variations. The light output was measured for 1.5 X_0 cube crystal samples with a Tyvek paper wrapping and a full end face coupled to a photodetector [72]. The quantum efficiency of the photodetector is taken out to facilitate a direct comparison of crystal's light yield. However, the measured light output produced by a scintillator is usually quoted in terms of the number of photoelectrons per MeV produced by a given photodetector. The relationship between the light yield (LY) in number of photons/MeV produced ($N_{\rm photons}$/MeV) and the light output (LO) in number of photoelectrons/MeV detected involves the factors for the light collection efficiency (LCE) and the quantum efficiency (QE) of the photodetector:

$$LO = LY \cdot LCE \cdot QE. \tag{35.4}$$

LCE depends on the size and shape of the crystal sample, and includes effects such as the transmission of scintillation light within the crystal (i.e., the bulk attenuation length of the material), scattering from within the crystal, reflections and scattering from the crystal surfaces, and re-bouncing back into the crystal by wrapping materials. These factors can vary considerably depending on the sample, but can be in the range of ∼10–60%. The internal light transmission depends on the intrinsic properties of the material, e.g. the density and type of the scattering centers and defects that can produce internal absorption within the crystal, and can be highly affected by factors such as radiation damage, as discussed below.

The quantum efficiency depends on the type of photodetector used to detect the scintillation light, which is typically ∼15–30% for photomultiplier tubes and higher for silicon photodetectors for visible wavelengths. The response of the detector is usually highly wavelength dependent and should be matched to the particular crystal of interest to give the highest quantum yield at the wavelength corresponding to the peak of the scintillation emission. Fig. 35.3 shows the quantum efficiency for a Hamamatsu R2059 PMT with bi-alkali cathode and quartz window, and the particle detection efficiency (PDE) for a Hamamatsu S14160-3015ps multi-pixel photon counter (MPPC), which is also called silicon photomultiplier (SiPM), as a function of wavelength. Also shown in the figure are emission spectra of three crystal scintillators, BGO, LSO:Ce/LYSO:Ce and CsI(Tl), and the numerical values of the emission weighted quantum efficiency. The area under each emission spectrum is proportional to crystal's light yield, as shown in Table-35.4, where the quantum efficiencies of the photodetector has been taken out. Results with different photodetectors can be significantly different. For example, the response of CsI(Tl) relative to NaI(Tl) with a standard photomultiplier tube with a bi-alkali photo-cathode, e.g. Hamamatsu R2059, would be 45 rather than 165 because of the photomultiplier's low quantum efficiency at longer wavelengths. For scintillators which emit in the UV, a detector with a quartz window should be used.

For very low energy applications (typically below 1 MeV), non-proportionality of the scintillation light yield may be important. It has been known for a long time that the conversion factor between the energy deposited in a crystal scintillator and the number of photons produced is not constant. It is also known that the energy resolution measured by all crystal scintillators for low energy γ-rays is significantly worse than the contribution from photo-electron statistics alone, indicating an intrinsic contribution from the scintillator itself. Precision measurement using low energy electron beam shows that this non-proportionality is crystal dependent [73]. Recent study on this issue also shows that this effect is also sample dependent even for the same crystal [74]. Further work is therefore needed to fully understand this subject.

One important issue related to the application of a crystal scintillator is its radiation hardness. Stability of its light output, or the ability to track and monitor the variation of its light output

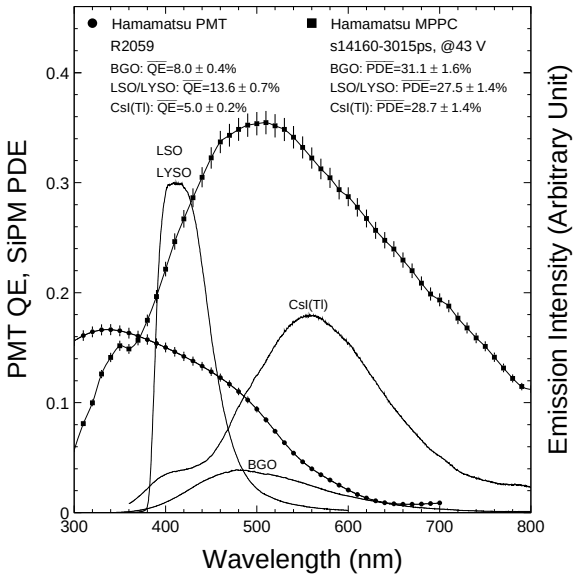

Figure 35.3: The quantum efficiency for a Hamamatsu R2059 PMT with bi-alkali cathode and quartz window and the particle detection efficiency (PDE) for a Hamamatsu S14160-3015ps multi-pixel photon counter (MPPC), which is also called silicon photomultiplier (SiPM), are shown as a function of wavelength. Also shown in the figure are emission spectra of three crystal scintillators, BGO, LSO and CsI(Tl), and the numerical values of the emission weighted quantum efficiencies. The area under each emission spectrum is proportional to crystal's light yield.

in a radiation environment, is required for high resolution and precision calibration [75]. All known crystal scintillators suffer from ionization dose induced radiation damage [76], where a common damage phenomenon is the appearance of radiation induced absorption caused by the formation of color centers originated from the impurities or point defects in the crystal. This radiation induced absorption reduces the light attenuation length in the crystal, and hence its light output. For crystals with high defect density, a severe reduction of light attenuation length may cause a distortion of the light response uniformity, leading to a degradation of the energy resolution. Additional radiation damage effects may include a reduced intrinsic scintillation light yield (damage to the luminescent centers) and an increased phosphorescence (afterglow). For crystals to be used in a high precision calorimeter in a radiation environment, its scintillation mechanism must not be damaged and its light attenuation length in the expected radiation environment must be long enough so that its light response uniformity, and thus its energy resolution, does not change.

While radiation damage induced by ionization dose is well understood [77], investigation is on-going to understand radiation damage caused by hadrons, including both charged hadrons [78] and neutrons [79]. Two additional fundamental processes may cause defects by hadrons: displacement damage and nuclear breakup. While charged hadrons can produce all three types of damage (and it's often difficult to separate them), neutrons can produce only the last two, and electrons and photons only produce ionization damage. Studies on hadron induced radiation damage to lead tungstate [80] show a proton-specific damage component caused by fragments from fission induced in lead and tungsten by particles in the hadronic shower. The fragments cause a severe, local damage to the crystalline lattice due to their extremely high energy loss over a short distance [80]. Recent investigation also sees evidence of neutron-specfic damage in various crystals [79].

Most of the crystals listed in Table-35.4 have been used in high energy or nuclear physics experiments when the ultimate energy resolution for electrons and photons is desired. Examples are the Crystal Ball NaI(Tl) calorimeter at SPEAR, the L3 BGO calorimeter at LEP, the CLEO CsI(Tl) calorimeter at CESR, the KTeV CsI calorimeter at the Tevatron, and the BaBar, BELLE and BES III CsI(Tl) calorimeters at PEP-II, KEK and BEPC II, respectively. Because of their high density and relative low cost, PWO calorimeters are used by CMS and ALICE at LHC, by CLAS and PrimEx at CEBAF and by PANDA at GSI, and is planned to be used for the Backward Endcap Calorimeter for the ePIC experiment at the EIC. Similarly, PbF_2 calorimeters are used by the A4 experiment at MAINZ and by the g-2 experiment at Fermilab. A CsI calorimeter is being built for the Mu2e experiment at Fermilab. An LYSO:Ce calorimeter is being built for the COMET experiment at J-PARC, and an LYSO:Ce crystal-based precision timing layer is being built for the CMS experiment for the HL-LHC.

35.5 Cherenkov detectors

Revised August 2023 by J. Schwiening (GSI Darmstadt).

Although devices using Cherenkov radiation are often thought of as only particle identification (PID) detectors, in practice they are used over a much broader range of applications including; (1) fast particle counters; (2) hadronic PID; (3) electromagnetic calorimeters (EMC); and (4) tracking detectors performing complete event reconstruction. Examples of applications from each category include; (1) the BaBar luminosity detector [81] and the Quartic fast timing counter for the ATLAS Forward Proton Detector, designed to measure small angle scatters at the LHC [82]; (2) the hadronic PID detectors at the B factory detectors—DIRC in BaBar [83], and the modern Imaging Aerogel and TOP counters at Belle II [84]; (3) the CMS Hadron Forward calorimeter based on Cherenkov light emitted in quartz fibers embedded in a steel absorber [85]; and (4) large water Cherenkov counters such as Super-Kamiokande [86].

Cherenkov counters contain two main elements; (1) a radiator through which the charged particle passes, and (2) a photodetector. As Cherenkov radiation is a weak source of photons, light collection and detection must be as efficient as possible. The refractive index n and the particle's path length through the radiator L appear in the Cherenkov relations allowing the tuning of these quantities for particular applications. One or more of the properties of Cherenkov radiation discussed in the Passages of Particles through Matter section (Sec. 34 of this *Review*) are utilized in Cherenkov detectors: the prompt emission of a light pulse; the existence of a velocity threshold for radiation; and the dependence of the Cherenkov cone half-angle θ_c and the number of emitted photons on the velocity of the particle v_p and the refractive index n of the medium. The Cherenkov angle can be calculated as

$$\cos\theta_c = \frac{1}{n(E)\beta}, \tag{35.5}$$

where $\beta = v_p/c$ with c being the speed of light, and E the photon energy. The number of photoelectrons ($N_{\rm p.e.}$) detected in a given device with radiator of length L is

$$N_{\rm p.e.} = L\frac{\alpha^2 z^2}{r_e\, m_e c^2}\int \epsilon(E)\,\sin^2\theta_c(E)dE, \tag{35.6}$$

where $\epsilon(E)$ is the efficiency for collecting the Cherenkov light and transducing it into photoelectrons, and $\alpha^2/(r_e\, m_e c^2) = 370\ \mathrm{cm}^{-1}\mathrm{eV}^{-1}$. The quantities ϵ and θ_c are functions of the photon energy. As the typical energy dependent variation of the index of refraction is modest, a quantity called the *Cherenkov detector quality factor* N_0 can be defined as

$$N_0 = \frac{\alpha^2 z^2}{r_e\, m_e c^2}\int \epsilon\, dE, \tag{35.7}$$

so that, taking the charge number $z = 1$ (the usual case in high-energy physics),

$$N_{\rm p.e.} \approx L N_0 \langle\sin^2\theta_c\rangle. \tag{35.8}$$

This definition of the quality factor N_0 is not universal, nor, indeed, very useful for those common situations where ϵ factorizes as $\epsilon = \epsilon_{\rm coll}\epsilon_{\rm det}$ with the geometrical photon collection efficiency

($\epsilon_{\rm coll}$) varying substantially for different tracks while the photon detector efficiency ($\epsilon_{\rm det}$) remains nearly track independent. In this case, it can be useful to explicitly remove ($\epsilon_{\rm coll}$) from the definition of N_0. A typical value of N_0 for a photomultiplier (PMT) detection system working in the visible and near UV, and collecting most of the Cherenkov light, is about 100 cm^{-1}. Practical counters, utilizing a variety of different photodetectors, have values ranging between about 30 and 180 cm^{-1}. Radiators can be chosen from a variety of transparent materials (Sec. 34 of this *Review* and Table 6). In addition to refractive index, the choice requires consideration of factors such as material density, radiation length and radiation hardness, transmission bandwidth, absorption length, chromatic dispersion, optical workability (for solids), availability, environmental impact, and cost. When the momenta of particles to be identified is high, the refractive index must be set close to one, so that the photon yield per unit length is low and a long particle path in the radiator is required. In recent years, the gap in refractive index that has traditionally existed between gases and liquid or solid materials has been partially closed with transparent *silica aerogels* with indices that range between about 1.003 and 1.26. Due to the potential ability to tune the refractive index to the exact requirements of an experiment, metamaterials, including photonic crystals, are being investigated as radiators for future Cherenkov counters [87].

Cherenkov counters may be classified as either *imaging* or *threshold* types, depending on whether they do or do not make use of Cherenkov angle (θ_c) information. Imaging counters may be used to track particles as well as identify them. The recent development of very fast photodetectors such as micro-channel plate PMTs (MCP-PMT) (see 35.2 of this *Review*) also potentially allows very fast Cherenkov based time of flight (TOF) detectors of either class [87]. The track timing resolution of imaging detectors can be extremely good as it scales approximately as $\frac{1}{\sqrt{N_{\rm p.e.}}}$.

Threshold Cherenkov detectors [88], in their simplest form, make a yes/no decision based on whether the particle is above or below the Cherenkov threshold velocity $\beta_t = 1/n$. A straightforward enhancement of such detectors uses the number of observed photoelectrons (or a calibrated pulse height) to discriminate between species or to set probabilities for each particle species [89]. This strategy can increase the momentum range of particle separation by a modest amount (to a momentum some 20% above the threshold momentum of the heavier particle in a typical case).

Careful designs give $\langle\epsilon_{\rm coll}\rangle \gtrsim 90\%$. For a photomultiplier with a typical bialkali cathode, $\int \epsilon_{\rm det} dE \approx 0.27$ eV, so that

$$N_{\rm p.e.}/L \approx 90\ {\rm cm}^{-1}\,\langle\sin^2\theta_c\rangle \qquad (i.e.,\ N_0 = 90\ {\rm cm}^{-1}). \quad (35.9)$$

Suppose, for example, that n is chosen so that the threshold for species a is p_t; that is, at this momentum species a has velocity $\beta_a = 1/n$. A second, lighter, species b with the same momentum has velocity β_b, so $\cos\theta_c = \beta_a/\beta_b$, and

$$N_{\rm p.e.}/L \approx 90\ {\rm cm}^{-1}\,\frac{m_a^2 - m_b^2}{p_t^2 + m_a^2}. \quad (35.10)$$

For K/π separation at $p = p_t = 1(5)$ GeV/c, $N_{\rm p.e.}/L \approx 16(0.8)$ cm^{-1} for π's and (by design) 0 for K's.

For limited path lengths $N_{\rm p.e.}$ will usually be small. The overall efficiency of the device is controlled by Poisson fluctuations, which can be especially critical for separation of species where one particle type is dominant. Moreover, the effective number of photoelectrons is often less than the average number calculated above due to additional equivalent noise from the photodetector (see the discussion of the excess noise factor in 35.2 of this *Review*). It is common to design for at least 10 photoelectrons for the high velocity particle in order to obtain a robust counter. As rejection of the particle that is below threshold depends on *not* seeing a signal, electronic and other background noise, especially overlapping tracks, can be important. Physics sources of light production for the below threshold particle, such as decay to an above threshold particle, scintillation light, or the production of delta rays in the radiator, often limit the separation attainable, and need to be carefully considered. Well designed, modern multi-channel counters, such as the ACC at Belle [90], can attain adequate particle separation performance over a substantial momentum range.

Imaging counters make the most powerful use of the information available by measuring the ring-correlated angles of emission of the individual Cherenkov photons. They typically provide positive ID information both for the "wanted" and the "unwanted" particles, thus reducing mis-identification substantially. Since low-energy photon detectors can measure only the position (and, perhaps, a precise detection time) of the individual Cherenkov photons (not the angles directly), the photons must be "imaged" onto a detector so that their angles can be derived [91]. Typically the optics map the Cherenkov cone onto (a portion of) a distorted "circle" at the photodetector. Though the imaging process is directly analogous to familiar imaging techniques used in telescopes and other optical instruments, there is a somewhat bewildering variety of methods used in a wide variety of counter types with different names. Some of the imaging methods used include (1) focusing by a lens or mirror; (2) proximity focusing (i.e., focusing by limiting the emission region of the radiation); and (3) focusing through an aperture (a pinhole). In addition, the prompt Cherenkov emission coupled with the speed of some modern photon detectors allows the use of (4) time imaging, a method which is little used in conventional imaging technology, and may allow some separation with particle TOF. Finally, (5) correlated tracking (and event reconstruction) can be performed in large water counters by combining the individual space position and time of each photon together with the constraint that Cherenkov photons are emitted from each track at the same polar angle (Sec. 36.3.1of this *Review*).

In a simple model of an imaging PID counter, the fractional error on the particle velocity (δ_β) is given by

$$\delta_\beta = \frac{\sigma_\beta}{\beta} = \tan\theta_c \sigma(\theta_c)\ , \quad (35.11)$$

where

$$\sigma(\theta_c) = \frac{\langle\sigma(\theta_i)\rangle}{\sqrt{N_{\rm p.e.}}} \oplus C, \quad (35.12)$$

and $\langle\sigma(\theta_i)\rangle$ is the average single photoelectron resolution, as defined by the optics, detector resolution and the intrinsic chromaticity spread of the radiator index of refraction averaged over the photon detection bandwidth. C combines a number of other contributions to resolution including, (1) correlated terms such as tracking, alignment, and multiple scattering, (2) hit ambiguities, (3) background hits from random sources, and (4) hits coming from other tracks. The actual separation performance is also limited by physics effects such as decays in flight and particle interactions in the material of the detector. In many practical cases, the performance is limited by these effects.

For a $\beta \approx 1$ particle of momentum (p) well above threshold entering a radiator with index of refraction (n), the number of σ separation (N_σ) between particles of mass m_1 and m_2 is approximately

$$N_\sigma \approx \frac{|m_1^2 - m_2^2|}{2p^2\sigma(\theta_c)\sqrt{n^2-1}}. \quad (35.13)$$

In practical counters, the angular resolution term $\sigma(\theta_c)$ varies between about 0.1 and 5 mrad depending on the size, radiator, and photodetector type of the particular counter. The range of momenta over which a particular counter can separate particle species extends from the point at which the number of photons emitted becomes sufficient for the counter to operate efficiently as a threshold device (∼20% above the threshold for the lighter species) to the value in the imaging region given by the equation above. For example, for $\sigma(\theta_c)$ =2 mrad, a fused silica radiator ($n = 1.474$), or a fluorocarbon gas radiator (C_5F_{12}, $n = 1.0017$), would separate π/K's from the threshold region starting around 0.15(3) GeV/c through the imaging region up to about 4.2(18) GeV/c at better than 3σ.

Many different imaging counters have been built during the last several decades [87]. Among the earliest examples of this class of counters are the very limited acceptance *Differential Cherenkov*

detectors, designed for particle selection in high momentum beam lines. These devices use optical focusing and/or geometrical masking to select particles having velocities in a specified region. With careful design, a velocity resolution of $\sigma_\beta/\beta \approx 10^{-4}$–$10^{-5}$ can be obtained [88].

Practical multi-track *Ring-Imaging Cherenkov detectors* (generically called RICH counters) are a more recent development. RICH counters are sometimes further classified by 'generations' that differ based on historical timing, performance, design, and photodetection techniques. Prototypical examples of first generation RICH counters are those used in the DELPHI and SLD detectors at the LEP and SLC Z factory e^+e^- colliders [87]. They have both liquid (C_6F_{14}, $n = 1.276$) and gas (C_5F_{12}, $n = 1.0017$) radiators, the former being proximity imaged with the latter using mirrors. The phototransducers are a TPC/wire-chamber combination. They are made sensitive to photons by doping the TPC gas (usually, ethane/methane) with $\sim 0.05\%$ TMAE (tetrakis(dimethylamino)ethylene). Great attention to detail is required, (1) to avoid absorbing the UV photons to which TMAE is sensitive, (2) to avoid absorbing the single photoelectrons as they drift in the long TPC, and (3) to keep the chemically active TMAE vapor from interacting with materials in the system. In spite of their unforgiving operational characteristics, these counters attained good $e/\pi/K/p$ separation over wide momentum ranges (from about 0.25 to 20 GeV/c) during several years of operation at LEP and SLC. Related but smaller acceptance devices include the OMEGA RICH at the CERN SPS, and the RICH in the balloon-borne CAPRICE detector [87]. Despite their excellent match to the radiator requirement for gaseous RICHes, saturated fluorocarbons may soon need to be replaced due to their high global warming impact. Possible alternatives for a similar refractive index include hydrofluoroolefins or Argon, pressurized at a few bar [87].

Later generation counters [87] generally operate at much higher rates, with more detection channels, than the first generation detectors just described. They also utilize faster, more forgiving photon detectors, covering different photon detection bandwidths. Radiator choices have broadened to include materials such as lithium fluoride, fused silica, and aerogel.

Vacuum-based photodetection systems (*e.g.*, single or multi anode PMTs, MCP-PMTs, or hybrid photodiodes (HPD)) have become increasingly common (see 35.2 of this *Review*). They handle high rates, and can be used with a wide choice of radiators. Examples include (1) the SELEX RICH at Fermilab, which mirror focuses the Cherenkov photons from a neon radiator onto a camera array made of ~ 2000 PMTs to separate hadrons over a wide momentum range (to well above 200 GeV/c for heavy hadrons);(2) the NA62 RICH at CERN, which uses a 17 m long tank filled with neon gas as radiator and spherical mirrors to focus the photons on two arrays of 2 000 PMTs to separate pions from muons for momenta between 15 and 35 GeV/c; (3) the CBM RICH under construction at FAIR where the Cherenkov photons, produced in about 30 m^3 of CO_2 radiator gas, are mirror-focused on arrays of multi-anode PMTs (MaPMTs) with a total of about 55,000 pixels, to identify electrons with momenta up to 10 GeV/c; and (4) the LHCb detector now running at the LHC. It uses two separate counters. One volume contains C_4F_{10} (originally in combination with aerogel, which was removed in 2015) while the second volume contains CF_4. Photons are mirror-focused onto arrays of photon detectors to cover a π/K separation momentum range between 1 and 150 GeV/c. Additional upgrades, including the replacement of the HPDs by MaPMTs and improved readout electronics, were performed to deal with increases in luminosity.

Other fast detection systems that use solid cesium iodide (CsI) photocathodes or triethylamine (TEA) doping in proportional chambers are useful with certain radiator types and geometries. Examples include (1) the CLEO-III RICH at CESR that uses a LiF radiator with TEA doped proportional chambers; (2) the ALICE detector at the LHC that uses proximity focused liquid (C_6F_{14} radiators and solid CsI photocathodes (similar photodectors have been used for several years by the HADES and COMPASS detectors), and the hadron blind detector (HBD) in the PHENIX detector at RHIC that couples a low index CF_4 radiator to a photodetector based on electron multiplier (GEM) chambers with reflective CsI photocathodes [87].

Recent technological advances in the production of aerogel with improved transparency in the UV range and finely tuned refractive indices enable several new RICH designs. The innovative hybrid geometry of the CLAS12 RICH, with complex photon paths that feature multiple passes through the aerogel tiles, is only possible due to the improved scattering length of the aerogel. It minimizes the material inside of the detector acceptance as well as the size and cost of the photon sensor array. Beam tests have demonstrated that the counter will be able to provide clean π/K separation up to 8 GeV/c. The forward endcap Aerogel RICH (ARICH) for the Belle II upgrade at KEKB, designed to provide clean π/K separation for momenta up to 3.5 GeV/c, is an example of the so-called focusing aerogel approach [92]. The radiator is a dual-layer aerogel, with a thickness of 20 mm for each layer and increasing refractive indices of $n = 1.045$ and $n = 1.055$ along the particle path. The Cherenkov ring images from the two layers overlap on the array of Hybrid Avalanche Photo Detectors (HAPDs), which provide efficient single photon detection in the 1.5 T magnetic field.

A DIRC (Detection [of] Internally Reflected Cherenkov [light]) is a distinctive, compact RICH subtype first used in the BaBar detector [83]. A DIRC "inverts" the usual RICH principle for use of light from the radiator by collecting and imaging the total internally reflected light rather than the transmitted light. It utilizes the optical material of the radiator in two ways, simultaneously: as a Cherenkov radiator and as a light pipe. The magnitudes of the photon angles are preserved during transport by the flat, rectangular cross section radiators, allowing the photons to be efficiently transported to a detector outside the path of the particle where they may be imaged in up to three independent dimensions (the usual two in space and, due to the long photon paths lengths, one in time). Because the index of refraction in the radiator is large ($n \sim 1.47$ for fused silica), the momentum range with good π/K separation goes up to 4–5 GeV/c. It is plausible, but difficult, to extend it up to about 10 GeV/c with an improved design.

The BaBar experiment at the asymmetric PEP-II e^+e^- collider studied CP violation in $\Upsilon(4S)$ decays. Excellent pion/kaon separation for particle momenta up to 4 GeV/c was required. The BaBar DIRC used 4.9 m long, rectangular bars made from synthetic fused silica as radiator and light guide. The photons were imaged via a "pin-hole" through an expansion region filled with 6 000 liters of purified water onto an array of 10 752 densely packed photomultiplier tubes placed at a distance of about 1.2 m from the bar end. During more than 8 years of operation, the BaBar DIRC achieved π/K separation of 2.5 standard deviations or more up to 4 GeV/c momentum. For a pion identification rate around 85% the DIRC provided a kaon misidentification rate well below 1% up to 3 GeV/c.

The next generation of DIRC detectors [93] takes advantage of the new, very fast, pixelated photodetectors becoming available, such as MaPMTs and MCP-PMTs. They typically utilize either time imaging or lens/mirror-focused optics, or both, leading not only to a precision measurement of the Cherenkov angle, but in some cases, to a precise measurement of the particle time of flight, and/or to correction of the chromatic dispersion in the radiator. Examples [87] include (1) the Belle II Time of Propagation (TOP) counter that emphasizes precision timing for both Cherenkov imaging and TOF to perform π/K separation of at least 3 standard deviations up to 4 GeV/c; (2) the DIRC upgrade of the GlueX experiment at Jefferson Lab that places four decommissioned BaBar DIRC modules, coupled to upgraded optics and readout, perpendicular to the beamline, the first application of a DIRC in a detector endcap; (3) the high-performance DIRC for the ePIC detector at the EIC, to be installed in 2030, that will combine lens focusing with fast photon time imaging and is expected to provide more than 3 standard deviations π/K separation up to 6 GeV/c; and (4) the TORCH counter being developed for an LHCb upgrade in 2033 which uses DIRC imaging for individual photons with fast photon detectors to provide π/K separation up to 10 GeV/c via particle TOF with a precision of

10-15 ps per track over a flight path length of 9.5 m.

35.6 Gaseous detectors

35.6.1 *Energy loss and charge transport in gases*

Revised November 2021 by F. Sauli (CERN) and M. Titov (IRFU, CEA, Université Paris-Saclay).

Gas-filled detectors use the localized ionization produced by charged particles, generally after charge multiplication. The statistics of ionization processes, having asymmetries in the ionization trails, affect the coordinate determination deduced from the measurement of drift time, or of the center of gravity of the collected charge. For thin gas layers, the width of the energy loss distribution can be larger than its average, requiring multi-sampling devices or truncated mean analysis to achieve good particle identification. In the truncated mean method for calculating $\langle dE/dx \rangle$, the ionization measurements along the track length are broken into many samples and then a fixed fraction of high-side (and sometimes also low-side) values are rejected [94].

Table 35.5: Properties of noble and molecular gases at normal temperature and pressure (NTP: 20° C, one atm). E_X, E_I: first excitation, ionization energy; W_I: average energy for creation of ion pair; $dE/dx|_{\rm min}$, N_P, N_T: differential energy loss, primary and total number of electron-ion pairs per cm, for unit charge minimum ionizing particles. Values often differ, depending on the source, and those in the table should be taken only as approximate.

Gas	Density, mg cm^{-3}	E_x eV	E_I eV	W_I eV	$dE/dx\|_{\rm min}$ keV cm^{-1}	N_P cm^{-1}	N_T cm^{-1}
H_2	0.084	10.8	13.6	37	0.34	5.2	9.2
He	0.179	19.8	24.6	41.3	0.32	3.5	8
Ne	0.839	16.7	21.6	37	1.45	13	40
Ar	1.66	11.6	15.7	26	2.53	25	97
Xe	5.495	8.4	12.1	22	6.87	41	312
CH_4	0.667	8.8	12.6	30	1.61	28	54
C_2H_6	1.26	8.2	11.5	26	2.91	48	112
iC_4H_{10}	2.49	6.5	10.6	26	5.67	90	220
CO_2	1.84	7.0	13.8	34	3.35	35	100
CF_4	3.78	10.0	16.0	35-52	6.38	52-63	120

The energy loss of charged particles and photons in matter is discussed in Sec. 34. Every ionization process is a quantum mechanical transition initiated by the Coulomb field of the particle and the field created by neighbouring polarizable atoms; the average energy losses are described by the Bethe-Bloch formula with Sternheimer's density effect corrections. The fluctuations caused by Rutherford scattering on quasi-free electrons follow a Landau distribution and the influence of atomic shells is described by the photoabsorption ionization (PAI) model, which allows simulation of each energy transfer [95], with relaxation cascades and simulation of delta-electrons [96]. Table 35.5 provides values of relevant parameters in some commonly used gases at NTP for unit-charge minimum-ionizing particles (MIPs) [97] [98]. When an ionizing particle passes through the gas it creates electron-ion pairs; often the ejected electrons have sufficient energy to further ionize the medium. The number of pairs is known as cluster-size distribution, because the secondary electrons are created in the immediate vicinity of the primary encounter and, together with the primary electrons, form clusters of one, several, or sometimes many, electron-ion pairs. As shown in Table 35.5, the total number of pairs (N_T) is a few times larger than the number of primaries (N_P). For different conditions and for mixtures, and neglecting energy transfer processes (*e.g.* Penning effect), one can scale the density, N_P, and N_T with temperature and pressure assuming a perfect gas law.

The probability for a released electron to have an energy E or larger follows an approximate $1/E^2$ dependence (Rutherford law), shown in Fig. 35.4 for Ar at NTP (dotted line, left scale). More detailed estimates taking into account the electronic structure of the medium are shown in the figure, for three values of the particle velocity factor $\beta\gamma$ [99]. The dot-dashed line provides, on the right scale, the practical range of electrons (including scattering) of energy E. As an example, about 0.6% of released electrons have 1 keV or more energy, substantially increasing the total ionization loss. The practical range of 1 keV electrons in argon (dot-dashed line, right scale) is 70 μm and this can contribute to the error in the coordinate determination.

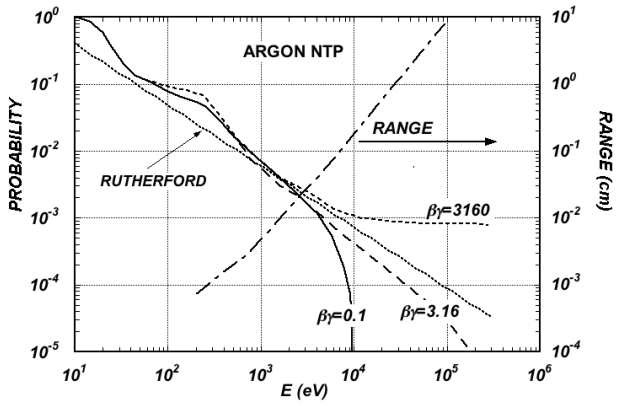

Figure 35.4: Probability of single collisions in which released electrons have an energy E or larger (left scale) and practical range of electrons in Ar at NTP (dot-dashed curve, right scale) [99].

Garfield^{++} [100], together with HEED [96], Degrad [101], Magboltz [102, 103], SRIM, ANSYS, COMSOL, and neBEM [104] software packages represent the core simulation tools for microscopic modelling of gaseous detector response. The number of electron-ion pairs per primary ionization, or cluster size depends little on the medium; it can be computed with the programs mentioned above or experimentally measured. For example, there is about 1% probability for primary clusters to contain ten or more electron-ion pairs in argon [105].

Once released in the gas, and under the influence of an applied electric field, electrons and ions drift in opposite directions and diffuse towards the electrodes. The electron-molecule collision cross sections are determined by the details of atomic and molecular structure and depends strongly on the electron energy and therefore on the electric field **E** for most gases. High values of the total electron scattering cross section reduce the electron diffusion and increase the drift velocity; a large inelasticity implies that high fields are required to raise the electron energy. For noble gases, the inelastic cross section is zero until the electrons reach the first excitation and ionization energies $\mathcal{O}(10\ eV)$; on the contrary, for molecular gases, like CH_4, inelastic channels, involving rotational and vibrational levels, open up at energies above ~ 0.1 eV. Large drift velocities are achieved by adding polyatomic gases (usually hydrocarbons C_xH_y, CO_2, CF_4) having large inelastic component at moderate energies of a few eV; this results in the electron "cooling" into the energy range of the Ramsauer-Townsend minimum (at $\sim$0.5 eV) of the elastic ("momentum-transfer") cross-section in Ar [98]. Under these circumstances, it is not surprising that the addition of very small quantities of one gas to another can dramatically modify the average electron energy and alter the dependence of the drift velocity (v_d) on **E/P** and temperature; this has a particularly strong effect for noble gases, as illustrated in Fig. 35.5 for Ar. Carbon tetrafluoride (CF_4) has the largest drift velocity and the lowest electron diffusion among known gases due to the sizeable Ramsauer-Townsend dip in the elastic cross-section which coincides with a very large vibrational modes. Another principal role of the polyatomic gas is to absorb the ultraviolet photons emitted by the excited noble gas atoms. Addition of molecular gases (hydrocarbons or CO_2 are widely used in the proportional counters as a quencher) to noble gas allows to dissipate a good fraction of energy through rotational and vibrational radiationless transitions without the creation of photons or ions. On the

contrary, CF_4 has a small quenching cross-section of excited Ar states and light emission in CF_4 (from the far UV to the visible light) is a complex process, involving the creation of CF_3^+ excited states [106].

Extensive collections of experimental data [107] and theoretical calculations based on transport theory permit evaluation of drift and diffusion properties in pure gases and their mixtures; modern compilations of the electron-molecule cross sections are available at the open-access website LXCAT [108]. Fig. 35.5 and Fig. 35.6 show drift velocity and transverse diffusion for some commonly used gases at NTP, computed with the Magboltz program [102, 103]. For different conditions, the horizontal axis must be scaled inversely with the gas density. Standard deviations for longitudinal (σ_L) and transverse diffusion (σ_T) are given for one cm of drift, and scale with the the square root of the drift distance.

In a simple approximation, gas kinetic theory provides the drift velocity v_d as a function of the mean collision time τ and the electric field $\mathbf{E}$: $v_d = eE\tau/m_e$ (Townsend's expression). In the presence of an external magnetic field, the Lorentz force acting on electrons between collisions deflects the drifting electrons and modifies the drift properties. The electron trajectories, velocities and diffusion parameters can be computed with Magboltz. The friction force model provides an approximate expression for the vector drift velocity $\boldsymbol{v}$ as a function of electric and magnetic field vectors $\boldsymbol{E}$ and $\boldsymbol{B}$, of the Larmor frequency $\omega = eB/m_e$, and of the mean collision time τ (more precise calculation is available in Magboltz, which computes drift velocity by tracing electrons at the microscopic level through numerous collisions with gas molecules):

$$\boldsymbol{v} = \frac{e}{m_e}\,\frac{\tau}{1+\omega^2\tau^2}\left(\boldsymbol{E} + \frac{\omega\tau}{B}(\boldsymbol{E}\times\boldsymbol{B}) + \frac{\omega^2\tau^2}{B^2}(\boldsymbol{E}\cdot\boldsymbol{B})\boldsymbol{B}\right) \quad (35.14)$$

To a good approximation, and for moderate fields, one can assume that the energy of the electrons is not affected by B, and use for τ the values deduced from the drift velocity at $B = 0$ (the Townsend expression). For $\boldsymbol{E}$ perpendicular to $\boldsymbol{B}$, the drift angle relative to the electric field vector is $\tan\theta_B = \omega\tau$ and $v = (E/B)(\omega\tau/\sqrt{1+\omega^2\tau^2})$. For parallel electric and magnetic fields, drift velocity and longitudinal diffusion are not affected, while the transverse diffusion can be strongly reduced: $\sigma_T(B) = \sigma_T(B=0)/\sqrt{1+\omega^2\tau^2}$. As an example, the dotted line in Fig. 35.6 represents σ_T for the classic Ar/CH_4 (90:10) mixture at 4 T. Large values of $\omega\tau \sim 20$ at 5 T are consistent with the measurement of diffusion coefficient in $Ar/CF_4/iC_4H_{10}$ (95:3:2). This reduction is exploited to substantially improve spatial resolution in the Drift (Sec. 35.6.2) and Time Projection Chambers (Sec. 35.6.5).

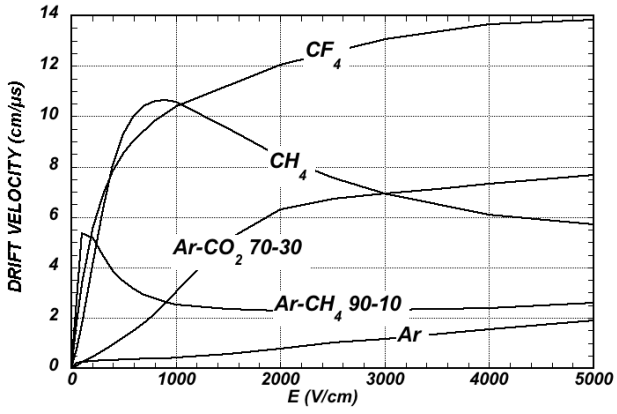

Figure 35.5: Computed electron drift velocity as a function of electric field in several gases at NTP and $B = 0$ [102, 103].

In some mixtures containing molecules with electronic affinity, electrons can be captured to form negative ions. Capture cross sections vary considerably with an energy and, hence, the electric field; as a consequence, the three-body electron attachment coefficients may differ significantly for the same additive in different mixtures. As an example, at moderate fields (up to 1 kV/cm) the addition of 0.1% of oxygen to an Ar/CO_2 mixture results in an electron capture probability about twenty times larger than in Ar/CH_4. Among common molecules, the largest electron affinities are found for the halogenides, O_2 and H_2O. The attachment probability in O_2 or H_2O is large at low fields and electron energies close to thermal, but decreases at increasing fields. On the contrary, CF_4 is not electronegative at low and moderate fields, but has a large electron capture cross section at fields above ~ 8 kV/cm, before reaching the avalanche field strengths. Depending on the mixture and detector geometry, some signal reduction and energy resolution loss is expected in this gas.

If the electric field is increased sufficiently, electrons gain enough energy between collisions to excite and ionize molecules. Above a gas-dependent threshold, the mean free path for ionization, λ_i, decreases exponentially with the field; its inverse, $\alpha = 1/\lambda_i$, is named the first Townsend coefficient. In wire chambers, most of the increase of avalanche particle density occurs very close to the anode wires, and a simple electrostatic consideration shows that the largest fraction of the detected signal is due to the motion of positive ions receding from the wires. The electron component, although very fast, contributes very little to the signal. This determines the characteristic shape of the detected signals in the proportional mode: a fast rise followed by a gradual increase. The slow component, the so-called "ion tail" that limits the time resolution of the detector, is usually removed by differentiation of the signal. In uniform fields, N_0 initial electrons multiply over a length x forming an electron avalanche of size $N = N_0\, e^{\alpha x}$; N/N_0 is the gain of the detector. Fig. 35.7 shows examples of Townsend coefficients for several gas mixtures, computed with Magboltz [102, 103].

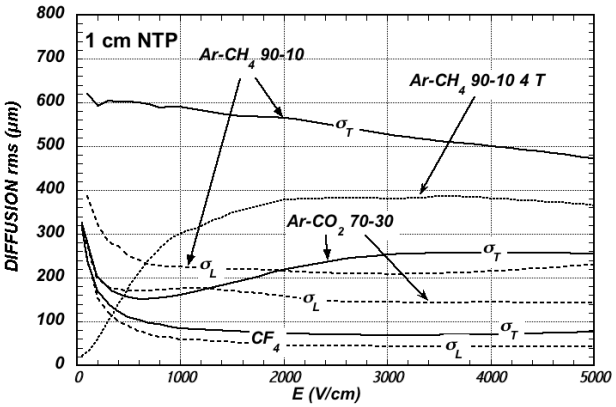

Figure 35.6: Electron longitudinal diffusion (σ_L) (dashed lines) and transverse diffusion (σ_T) (full lines) for 1 cm of drift at NTP and $B = 0$. The dotted line shows σ_T for the P10 mixture at 4 T [102, 103].

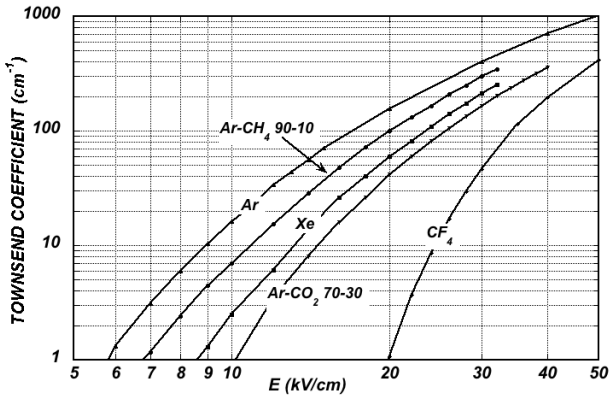

Figure 35.7: Computed first Townsend coefficient α as a function of electric field in several gases at NTP [102, 103].

Additional ionizing energy transfer mechanisms due to the excited noble gas atoms, called collisional Penning energy transfers, occur when the excitation energy of a noble gas is higher than the ionization potential of an admixture gas. The energy transfer rate, probability that an excited atom ionizes a quenching agent, is a priori not known for a mixture but can be extracted from the fits of the experimental gas gain data [109] using the Magboltz simulations [102, 103]. In the gain calculations, the Penning adjusted Townsend coefficient is defined in terms of the total production frequencies of the noble gas excitations and direct ionizations of the mixture. Systematic gas gain measurements for varying mixing ratios and pressures are critical for determining the efficiency of the different mechanisms involved in the transfers. Collisional energy transfer mostly scales linearly with the gas pressure and the fraction of quenching gas in the mixture, while ionization by photons emitted from excitations is independent of the medium [110]. In addition, collisional Penning transfers of some higher excited states can occur before they decay at atmospheric pressure and are not restricted to metastable states of the excited noble gas. For example, the impact of the Penning effect on gas gain is roughly a factor 10 in Ar-CO_2 mixtures and exceeding a factor of 100 in Ar-C_2H_2 mixtures [110].

Positive ions released by the primary ionization or produced in the avalanches drift and diffuse under the influence of the electric field. Negative ions may also be produced by electron attachment to gas molecules. The drift velocity of ions in the fields encountered in gaseous detectors (up to few kV/cm) is typically about three orders of magnitude smaller than for electrons. The ion mobility μ, the ratio of drift velocity to electric field, is constant for a given ion type up to very high fields. Values of ions mobility at NTP are given in Table 35.6 [111]. For different temperatures and pressures, the mobility can be scaled inversely with the density assuming an ideal gas law. Both the longitudinal and transverse diffusion of ions are proportional to the square root of the drift time, with a coefficient that depends on temperature but not on the ion mass. It has been historically assumed that, due to a very effective charge transfer mechanism, only ions with the lowest ionization potential survive after a short path in the mixture. However, recent experimental data suggests that the signal ions, in e.g. CO_2-quenched mixtures of Ar and Ne are $CO_2^+ \cdot (CO2)_n$ cluster ions, and not CO_2^+ or noble gas ions [112]. Since the cluster ions are slower than the initial ions, the signals induced by ion motion are altered. The effect can be present in constant-field detectors and TPCs (see Sec. 35.6.5), and might affect devices such as Micromegas (see Sec. 35.6.4) and drift tubes. A negative-ion TPC can be used to expand the reach of directional dark matters searches [113].

Table 35.6: Mobility of ions in gases and mixtures at NTP [111].

Gas	Mobility μ ($cm^2\ V^{-1}\ s^{-1}$)
He	10.4
Ne	4.7
Ar	1.54
Ar/CH_4	1.87
Ar/CO_2	1.72
CH_4	2.26
CO_2	1.09

35.6.2 *Multi-Wire Proportional and Drift Chambers*

Revised November 2021 by F. Sauli (CERN) and M. Titov (IRFU, CEA, Université Paris-Saclay).

Single-wire counters that detect the ionization produced in a gas by a charged particle, followed by charge multiplication and collection around a thin (typically 20 – 50 μm diameter) wire, have been used for decades. Good energy resolution is obtained in the proportional amplification mode, while very large saturated pulses can be detected in the streamer and Geiger modes [114].

Modern fully electronic devices, multiwire proportional chambers (MWPCs) [115,116] introduced in the late 1960's, detect, localize and measure energy deposit by charged particles over large areas. A mesh of parallel anode wires at a suitable potential, inserted between two cathodes, acts almost as a set of independent proportional counters (see Fig. 35.8a). Electrons released in the gas volume drift towards the anodes and produce avalanches in the increasing field. Analytic expressions for the electric field can be found in many textbooks. The fields close to the wires $E(r)$, in the drift region E_D, and the capacitance C per unit length of anode wire are approximately given by

$$E(r) = \frac{CV_0}{2\pi\epsilon_0}\,\frac{1}{r} \qquad E_D = \frac{CV_0}{2\epsilon_0 s} \qquad C = \frac{2\pi\epsilon_0}{\pi(\ell/s) - \ln(2\pi a/s)}\ , \tag{35.15}$$

where r is the distance from the center of the anode, s the wire spacing, ℓ and V_0 the distance and potential difference between anode and cathode, and a the anode wire radius.

Because of electrostatic forces, anode wires are in equilibrium only for a perfect geometry. Small deviations result in forces displacing the wires alternatively below and above the symmetry plane, sometimes with catastrophic results [117]. These displacement forces are countered by the mechanical tension of the wire, up to a maximum unsupported stable length, L_M [118], above which the wire displaces:

$$L_M = \frac{s}{CV_0}\sqrt{4\pi\epsilon_0 T_M} \tag{35.16}$$

The maximum tension T_M depends on the wire diameter and modulus of elasticity. Table 35.7 gives approximate values for tungsten and the corresponding maximum stable wire length under reasonable assumptions for the operating voltage ($V_0 = 5\,\text{kV}$) [119]. Internal supports and spacers can be used in the construction of longer detectors to overcome limits on the wire length imposed by Eq. (35.16).

Table 35.7: Maximum tension T_M and stable unsupported length L_M for tungsten wires with spacing s, operated at $V_0 = 5$ kV. No safety factor is included.

Wire diameter (μm)	T_M (newton)	s (mm)	L_M (cm)
10	0.16	1	25
20	0.65	2	85

Traditionally, several simplifying assumptions are made in such analytical calculations: electrostatic force acting on the wire does not change during wire movements, or varies linearly with the displacement, the wire shape is parabolic; only one wire moves at a time. Therefore, for complicated electrode geometries the approximations listed above are not applicable. The advantage of numerical integrations using Garfield^{++} program is to simulate the collective movement of all wires, which are difficult analytically, and to consider all forces acting on a wire: forces between anode wire and other electrodes (wires, cathode) and a gravitational force [120].

Detection of charge on the wires over a predefined threshold provides the transverse coordinate to the wire with an accuracy comparable to that of the wire spacing. The coordinate along each wire can be obtained by measuring the ratio of collected charge at the two ends of resistive wires. The cathode planes can be fabricated in the form of group of wires or isolated strips, which are often patterned in orthogonal directions. Making use of the charge profile induced by avalanches on segmented cathodes, the so-called electronic center-of-gravity (COG) method allows localization of tracks to sub-mm accuracy. Due to the statistics of energy loss and asymmetric ionization clusters, the position accuracy is $\sim$ 50 μm rms for fast particles perpendicular to the wire plane, but degrades to $\sim$ 250 μm at 30° to the normal [121].

Drift chambers, developed in the early '70's, can be used to estimate the space coordinate perpendicular to the wires by exploiting the arrival time of electrons at the anodes if the time of interaction is known [122]. The distance between anode wires (e.g.

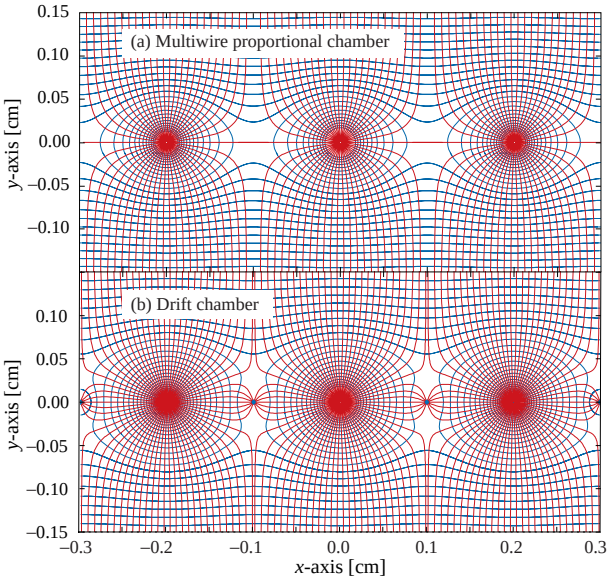

Figure 35.8: Electric field lines and equipotentials in (a) a multiwire proportional chamber and (b) a drift chamber.

Au-plated W) is usually several cm, allowing coverage of large areas at reduced cost. In the original design, a thicker wire (the field wire, often from Cu-Be or Al) at the proper voltage, placed between the anode wires, removes the low-field region at the midpoint between anodes and improves charge collection (Fig. 35.8b). In some drift chamber designs, and with the help of suitable voltages applied to field-shaping electrodes, the electric field structure is adjusted to improve the linearity of space-to-drift-time relation, resulting in better spatial resolution [123].

Drift chambers can reach a longitudinal spatial resolution from timing measurement of order 100 μm (rms) or better for minimum ionizing particles, depending on the geometry and operating conditions. However, a degradation of resolution is observed [124] due to primary ionization statistics for tracks close to the anode wires, caused by the spread in arrival time of the nearest ionization clusters. The effect can be reduced by operating the detector at higher pressures. Sampling the drift time on rows of anodes led to the concept of multiple arrays such as the multi-drift module [125] and the JET chamber [126]. A measurement of drift time, together with the recording of charge sharing from the two ends of the anode wires provides the coordinates of segments of tracks. An ultimate drift chamber design is the Time Projection Chamber (TPC) concept [127], which provides 3D precision tracking with low material budget and enables particle identification through differential energy loss dE/dx measurement or cluster counting dN_{cl}/dx techniques. In all cases, a good knowledge of electron drift velocity and diffusion properties is required. This has to be combined with the knowledge of the electric fields in the structures [103]. Accumulation of ions in the gas volume may induce gain reduction and field distortions, especially for long drift distances in TPC (see Sec. 35.6.5). An important major innovation is related to the replacement of MWPC with Micro-Pattern Gaseous Detectors (MPGD) (see Sec. 35.6.4) for the TPC endplate readout, which offers many advantages: reduced track-angle, and negligible E × B track distortion effects, narrower pad response function (PRF), and intrinsic suppression of Ion Back Flow (IBF). For an overview of detectors exploiting the drift time for coordinate measurement see Refs. [118, 128].

Multiwire and drift chambers have been operated with a variety of gas fillings and operating modes, depending on experimental requirements. The so-called "Magic Gas," a mixture of argon, isobutane and Freon [116], permits very high and saturated gains ($\sim 10^6$). This gas mixture was used in early wire chambers, but was found to be susceptible to severe aging processes. DAFNE's KLOE Drift Chamber and the recent version of it developed for the MEG2 experiment [129] are the precursors of the next generation of ultralight central trackers for future colliders. Since the main contribution in terms of radiation length is related to tungsten wires, high transparency can be achieved thanks to the development of new wire materials (e.g. carbon monofilaments) and novel approaches for the wiring and assembly procedures. Drift chambers have been operated with a light helium/hydrocarbon mixtures, which are not reliable for long-term, high-rate operation [130]. Dedicated R&D is necessary to find an alternative hydrocarbon-free mixture adapted to the desired performance at future colliders.

Although very powerful in terms of performance, multi-wire structures have reliability problems when used in harsh or hard-to-access environments, since a single broken wire can disable the entire detector. Introduced in the 1980s, straw and drift tube systems make use of large arrays of proportional counters encased in individual enclosures, each acting as an independent wire counter [131]. Techniques for low-cost mass production of these detectors have been developed for large experiments, such as the Transition Radiation Tracker and the Drift Tubes arrays for CERN's LHC experiments [132]. The state-of-the-art NA62 straw tracker utilizes new construction techniques of ultrasonic welding to close the straw and to keep them straight and withstand the vacuum pressure without breaking [133]. Future efforts for straw detectors, e.g. COMET Phase-II at JPARC or Mu2e-II at Fermilab, will focus on ultra-thin wall development, long and thin wire handling, precise mechanics and innovative designs.

35.6.3 *High Rate Effects*

Revised November 2021 by F. Sauli (CERN) and M. Titov (IRFU, CEA, Université Paris-Saclay).

The production of positive ions in the avalanches and their slow drift before neutralization result in a rate-dependent accumulation of positive charge in the detector. This may result in significant field distortion, gain reduction and degradation of spatial resolution. As shown in Fig. 35.9 [134], the proportional gain drops above a charge production rate around 10^9 electrons per second and mm of wire, independently of the avalanche size. For a proportional gain of 10^4 and 100 electrons per track, this corresponds to a particle flux of $10^3\,s^{-1}mm^{-1}$ (1 kHz/mm^2 for 1 mm wire spacing). For the description of rate effects in MPGD, see Sec. 35.6.4.

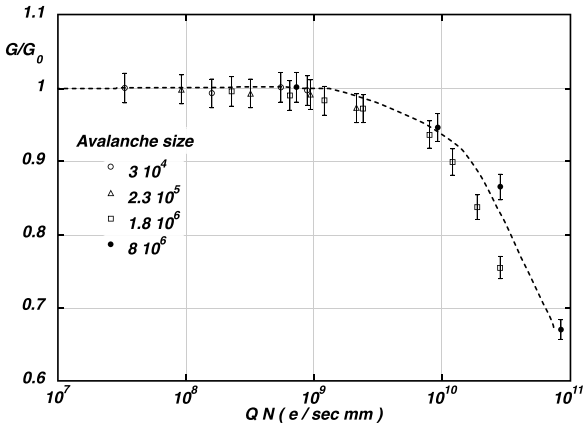

Figure 35.9: Charge rate dependence of normalized gas gain G/G_0 (relative to zero counting rate) in proportional thin-wire detectors [134]. Q is the total charge in single avalanche; N is the particle rate per wire length.

Although almost any gas can be used to operate wire chambers, CF_4-based mixtures have been preferred due to their properties. Their main advantage for the use in large volume detectors are high drift velocity, low diffusion, non-flammability and low sensitivity to neutrons; also they do not form polymers in avalanches.

However, the problem of greenhouse gases, such as CF_4, could become a fundamental limitation for their future applications in

gaseous detectors; due to the EU regulations their prices might go up and future availability is unknown. Performance studies of several eco-friendly mixtures have been initiated, together with a better understanding of their long-term ageing effects [135] (see also Sec. 35.6.4).

Ageing phenomena (formation of polymer deposits on the electrodes) constitute one of the most complex and serious potential problems which could limit or severely impair the use of gaseous detectors in unprecedented harsh radiation environments and lead to operational instabilities [136] [130]. The process has been extensively investigated, often with conflicting results. Several causes have been identified, including organic pollutants and silicone oils. Addition of small amounts of water in many (but not all) cases has been shown to extend the lifetime of the detectors. Addition of fluorinated gases (*e.g.*, CF_4) or oxygen may result in an etching action that can overcome polymer formation, or even eliminate already existing deposits. However, the issue of long-term survival of gas detectors with these gases is controversial. Under optimum operating conditions, a total collected charge of a few coulombs per cm of wire can usually be reached before noticeable degradation occurs. This corresponds, for one mm spacing and at a gain of 10^4, to a total particle flux of $\sim 10^{14}$ MIPs/cm^2.

35.6.4 *Micro-Pattern Gas Detectors*

Revised November 2021 by F. Sauli (CERN) and M. Titov (IRFU, CEA, Université Paris-Saclay).

Despite various improvements, position-sensitive detectors based on wire structures are limited by basic diffusion processes and space charge effects to localization accuracies of 50–100 μm [137]. Industrial advances in microelectronics and photolithographic technology on flexible and standard PCB substrates has favored the invention, in the last years of the 20th century, of novel Micro-Pattern Gaseous Detectors (MPGD) [138–140]. Since the very beginning, the goal was the development of novel devices with high rate capability (up to 10^6 Hz/mm^2) and excellent spatial resolution (down to 30 μm), single photo-electron time resolution in the ns-range, large sensitive area and dynamic range, superior radiation hardness and low-cost for large area coverage. Nowadays, a broad family of MPGD technologies are being developed and optimized for numerous applications, such as [141,142]: Micro-Strip Gas Chamber (MSGC), Gas Electron Multiplier (GEM), Micro-Mesh Gaseous Structure (Micromegas), THick GEMs (THGEM), also referred to in the literature as Large Electron Multipliers (LEM), Resistive Plate WELL (RPWELL), GEM-derived architecture (μ-RWELL), Micro-Pixel Gas Chamber (μ-PIC), and an integrated readout of gaseous detectors (Gridpix) using solid-state pixel chips (e.g. Medipix or Timepix).

The MSGC concept, invented in 1988, was the first of the microstructure gas chambers [138]. It consists of a set of tiny parallel metal strips laid on a thin resistive support, alternatively connected as anodes and cathodes and resembles a multi-anode proportional counter. Through an accurate and simple photolithography process, the anode strips can be made very narrow (~ 10 μm) with a typical pitch (distance between strips) of ~ 100 μm. When appropriate potentials are applied to the electrodes, electrons released in the drift volume move toward the strips and multiply in the high-field region. Owing to the small anode-to-cathode distance, the fast removal of positive ions by nearby cathode strips reduces space charge build-up, and improves siginicantly the rate capability, compared to wire counter. Despite their promising performance, experience with MSGCs has raised serious concerns about their long-term behavior. There are several major processes, particularly at high rates, leading to the MSGC operational instabilities: substrate charging-up and time-dependent distortions of the electric field, surface deposition of polymers ("aging") during sustained irradiation, and destructive micro-discharges under exposure to heavily ionizing particles [143]. The physical parameters used to manufacture and operate these detectors (substrate material, metal of strips, type and purity of the gas mixture) appeared to play dominant roles in determining the medium- and long-term stability. The problems encountered inspired the development of novel structures, using modern photolithographic processes: GEM, Micromegas and others, having increased reliability and radiation hardness.

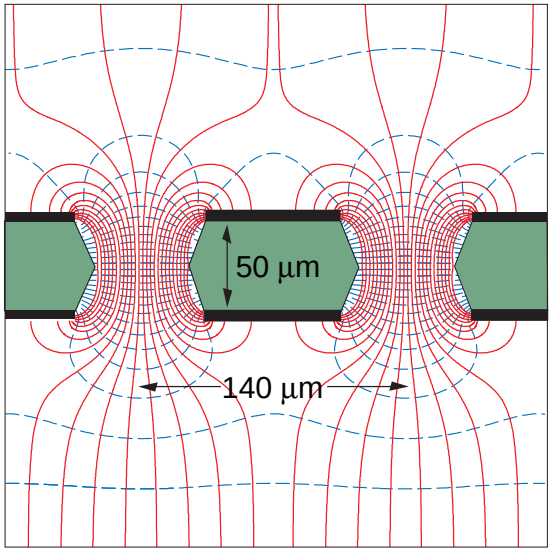

Figure 35.10: Schematic view and typical dimensions of the hole structure in the GEM amplification cell. Electric field lines (solid) and equipotentials (dashed) are shown. Electron trajectories do not strictly follow the field lines as drifting electrons scatter isotropically with gas molecules and diffuse transversally.

A GEM detector consists of a thin-foil copper-insulator-copper sandwich chemically perforated to obtain a high density of holes in which avalanches occur [139, 144]. The hole diameter is typically between 25 μm and 150 μm, while the corresponding distance between holes varies between 50 μm and 200 μm. The central insulator is usually (in the original design) a polyimid foil, with a thickness of 50 μm. Application of a potential difference between the two metal sides of the GEM generates the electric fields indicated in Fig. 35.10. Each hole acts as an independent proportional counter. Electrons released by the primary ionization particle in the upper conversion region (above the GEM foil) drift into the holes, where charge multiplication occurs in the high electric field (50–70 kV/cm), and are transferred into the gap below the GEM. Systematic measurements with cascaded multi-GEM structures confirm that the gains and charge transfer processes are predictable from electrostatic considerations and avalanche development models; an overall gas gain well above 10^4 can be reached in the presence of highly ionizing particles, while strongly reducing the risk of discharges [145]. Other important parameters such as attachment, diffusion depend on the gas mixture composition and E/P. The majority of the charges created in the avalanche process follow the field lines and are collected by the metallic electrodes; owing however to diffusion, some may deposit on the dielectric surfaces, modifying the field and affecting gain and transparency of the structures [146]. This effect is known as "charging-up" effect; its time constant and amplitude depend largely on the shape of the holes.

The micro-mesh gaseous structure (Micromegas) is a thin parallel-plate avalanche counter, as shown in Fig. 35.11 [140]. It consists of a drift region and a narrow multiplication gap (25–150 μm) between a thin metal grid (micromesh) and the readout electrode (strips or pads of conductor printed on an insulator board). Electrons from the primary ionization drift through the mesh into the narrow multiplication gap, where they are amplified. The electric field is mostly homogeneous in both the drift (electric field ~ 1 kV/cm) and amplification (50–70 kV/cm) regions and exhibits a funnel-like shape close to the openings of the micromesh: field lines are compressed into a small diameter of the order of a few microns, depending on the electric field ratio between the two gaps. In the narrow multiplication region, small variations of the amplification gap are approximately compensated by an inverse variation of the Townsend coefficient from

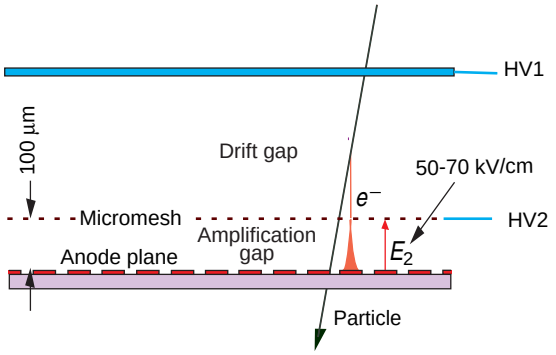

Figure 35.11: Schematic drawing of the Micromegas detector.

the electric field, resulting in a more uniform gain. The transverse size of the electron avalanche due to diffusion is of the order of 10–15 μm, depending on the gas mixture, the electric field, and the gap width, giving rise to excellent spatial resolution (12 μm for MIPs) [147]. Most positive ions are quickly removed by the micromesh; this prevents space-charge accumulation and induces very fast signals ($\sim$ 100 ns length) due to electrons with a (fast) tail due to ions. Efforts have been also focused on producing Micromegas detector using innovative manufacturing techniques - the "Bulk" and "'MicroBulk" technologies [148].

The absence of space-charge effects in GEMs at the highest rates reached so far, thanks to its fine-pitch structure of a few hundred microns, improves the maximum rate capability by more than two orders of magnitude compared to MWPC (see Fig.35.12) [149] [150]. Even larger rate capability has been reported for Micromegas [151].

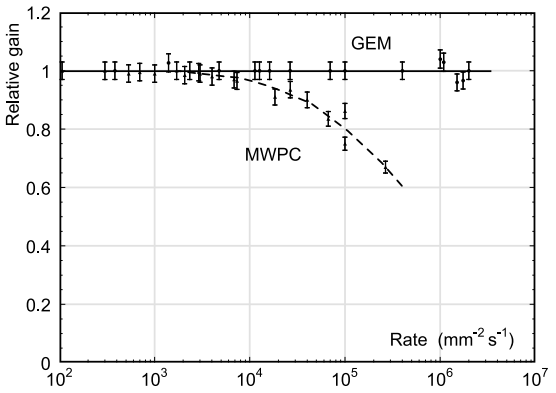

Figure 35.12: Normalized gas gain as a function of particle rate for MWPC [149] and GEM [150].

The fine granularity and high-rate capability of GEM and Micromegas can be fully exploited by using high-density pixel readout with a size corresponding to the intrinsic width of the detected avalanche charge. An elegant solution is the use of a CMOS pixel ASIC, assembled directly below the GEM or Micromegas amplification structure. Modern wafer post-processing technology allows an integration of a small-scale micromesh grid directly on top of a Timepix chip, thus forming an integrated MPGD readout, called GridPix concept (see Fig.35.13) [152]. With this arrangement, avalanche electrons are collected on the metalized input pads, exposed to the gas and signals are induced at the input gate of a charge-sensitive preamplifier. Every pixel is then directly connected to the amplification and digitization circuits, integrated in the underlying CMOS layers. A thin insulating layer, e.g. a few μm of silicon nitride, is usually deposited on top of CMOS ASIC to protect against destructive discharges across the $\mathcal{O}(50$ $\mu m)$ amplification gap. The GridPix concept provides the high granularity needed to resolve individual electron clusters (separated by an average distance of a few hundred microns) and to determine energy loss by the cluster counting technique, rather than by the charge measurement, with a precision of better than 3 %. Despite the enormous challenges, real breakthrough was the development of the TPC readout endplate with a 160 GridPix ASICs, each 2 cm^2, corresponding to 10.5 million pixels, demonstrating for the first time the feasibility of large-area MPGD with CMOS pixel readout [153]. New structures, where a GEM foil is facing the Medipix chip, forming the GEMpix detector, are in use for medical applications [154] as well as for monitoring the radioactive waste [155].

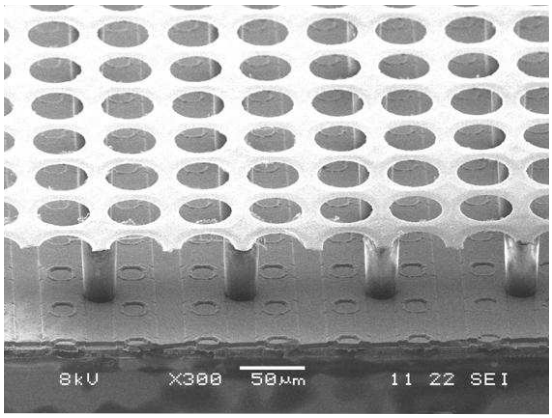

Figure 35.13: Photo of the Micromegas ('GridPix") detector. The grid holes can be accurately aligned with readout pixels of Timepix CMOS chip. The insulating pillars are centered between the grid holes, thus avoiding dead regions.

Gaseous detectors represent the most cost-effective solution to cover very large areas with photosensitive elements. MPGD-based gaseous photomultipliers, conceived with the aim to overcome the limitations of MWPCs, with semi-transparent or reflective photocathodes (PC), allow to minimize PC aging due to the ion and photon feedback and to avoid secondary effects causing electrical instability. For RICH applications requiring large-area coverage and moderate spatial resolution, coarser macro-patterned structures (e.g. THGEM with typical thickness of 0.4–1 mm and hole spacing of 0.7–1.2 mm) offer an interesting cheaper solution [156]. These are derived from the GEM design, scaling up $\sim$ 10-fold geometrical parameters, and can be mass-produced with standard PCB technology and mechanical drilling of large number of holes: some millions per square meter. Systematic studies to find the optimal electrostatic configuration revealed that the presence of a rim, a circular region around the holes where metal is etched away, plays a major role in THGEM performance. A small or zero rim allows to achieve better gain stability in time and under irradiation, while large rims permit to attain larger maximum gain and to reduce discharges, at the cost of significant charging up of the insulating surface, which modify the electric field. Therefore, in spite of the enhanced gain performance, the use of large rim THGEMs must be avoided to guarantee stable detector performance [157]. MPGDs are now in operation for single photon detection in the COMPASS RICH where a hybrid architecture formed by two THGEM layers (one covered by CsI-PC) and a Micromegas, acting as a third amplification stage, has been adopted.

Lately, closed geometry THGEM-based structures (RPWELL) [158], in common with some MPGDs invented at the end of the last century – C.A.T. and WELL, with resistive anodes have been developed, combining THGEM and RPC properties. This concept consists of a single-faced THGEM, copper-clad on its top side only, mounted directly on top of a resistive film deposited on a thin insulating sheet. Compared to THGEM with an induction gap, higher gains could be achieved in RPWELL for lower applied voltage across the THGEM electrode, due to the larger electric field within the closed holes. Another promising GEM-derived architecture is that of the μ-RWELL [159], with its $\sim$ seven-fold smaller pitch with respect to the RPWELL. Two different layouts for resistive stage have been studied: the simplest one is based on

a single-resistive Diamong-Like Carbon (DLC) layer, and grounding by edges (2D charge evacuation for low-rates $\mathcal{O}(\mathrm{kHz/cm^2})$) and a more sophisticated scheme using double-resistive layer with a through-vias between them and the grounding done by means of the readout electrodes (3D charge evacuation for high-rate $\mathcal{O}(\mathrm{MHz/cm^2})$ applications) [160]. The μ-PIC structure is an industrially produced PCB including anode strips on one side and orthogonal cathode strips on the other one. A regular pattern of uncoated regions is present along the cathode strips; an electric conductor buried in the thin PCB substrate transfers the anode voltage to a "dot" at the center of each of the uncoated cathode zones. Electron avalanches occur under the high-electric field around the point-like anodes; the electric field near cathode edges is weaker than in MSGCs, resulting in a lower discharge probability. A resistive coating of the cathode strips (e.g. using DLC layers) ensures tolerance to occasional discharges [161].

A big step in the direction of large-size applications has been obtained both with conceptual consolidation and industrial and cost-effective manufacturing of MPGDs by developing new fabrication techniques: resistive Micromegas (to suppress destructive sparks in hadron environments) [162] and single-mask and self-stretching GEM techniques (to enable production of large-size foils and significantly reduce detector assembly time) [163]. Scaling up of MPGDs to very large single unit detectors of $\mathcal{O}(\mathrm{m^2})$, has facilitated their use in the High Luminosity LHC upgrades: Micromegas will instrument an area of $\mathcal{O}(1000\,\mathrm{m^2})$ in the New Small Wheel of the ATLAS Muon endcaps, while GEMs be used in the CMS Muon system and for the ALICE TPC readout. Exploiting the Micromegas, GEM, and μ-RWELL ability to measure both position and arrival time of the charge released in the drift gap, a novel μ-TPC concept has been developed; it permits achieving nearly constant spatial resolution over a wide range of particle incident angles and allows 3D track reconstruction with a single MPGD layer [164]. Although normally used as planar detectors, GEM, Micromegas, and μ-RWELL can be bent to form cylindrically curved ultra-light inner tracking systems, without support and cooling structures [165].

The consolidation of the better-established technologies has been accompanied with flourishing of novel ones, often specific to well-defined applications. Modern technologies have been also derived from Micromegas and GEM concepts, hybrid approaches combining different elements in a single device, gaseous with non-gaseous detectors, as is the case for optical read-out. MPGD hybridization, a strategy aiming to strengthen the detector performance, remains a valid asset for addressing future experimental challenges such as high granularity and picosecond-precision timing (e.g. PICOSEC-Micromegas concept [166]). A clear direction for future developments is that of resistive materials and related detector architectures. Their usage improves detector stability, making possible a higher gain in a single multiplication layer. Recent DLC resistive layers studies are the key ingredients for increasing the rate capability of MPGDs [167]. Future developments call for novel materials as well as for new fabrication techniques. Contributions to the detector concepts are required in several domains: resistive materials, solid-state photon and neutron converters, innovative nanotechnology components. Material studies can contribute to requirements related to low out-gassing, radiation hardness, radio-purity, converter robustness, and eco-friendly gases. The development of the next generation of MPGDs can largely profit from emerging technologies as those related to MicroElectroMechanical Systems (MEMS), sputtering, novel photoconverters, 3D printing of amplifying structures and cooling circuits, etc. Nowadays, many intensive MPGD R&D activities and their diversified applications are pursued within the world-wide CERN-RD51 collaboration [168].

35.6.5 *Time-projection chambers*

Revised August 2023 by C. Lippmann (GSI Darmstadt).

The Time Projection Chamber (TPC) concept was invented by David Nygren in the 1970's [169]. It consists of a cylindrical or square field cage that is filled with a gaseous (or liquid) detection medium. Charged particles produce tracks of ionization electrons that drift in a uniform electric field towards a position-sensitive amplification stage which provides a 2D projection of the particle trajectories. The third coordinate can be calculated from the arrival times of the drifted electrons. The start for this drift time measurement is usually derived from an external detector, e.g. a fast interaction trigger detector.

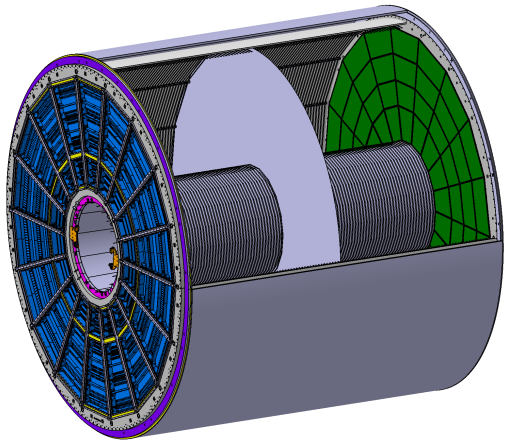

Figure 35.14: Schematic view of the ALICE TPC [170, 171]. The drift volume with 5 m diameter is divided into two halves, each providing 2.5 m drift length. The amplification stage has recently been upgraded from wire planes to GEMs.

This section focuses on the gas-filled TPCs that are often used in particle or nuclear physics experiments at accelerators on account of their low material budget. For neutrino physics (Sec. 35.11) or for detecting rare events (Sec. 36.4), on the contrary, usually high density and large active mass are required, and a liquid detection medium is favored.

The TPC enables full 3D measurements of charged particle tracks, which gives it a distinct advantage over other tracking detector designs which record information only in two-dimensional detector planes and have less overall segmentation. The track points recorded in a TPC are basically adjacent, which facilitates the track finding enormously. This advantage is often exploited for pattern recognition in events with large numbers of particles, e.g. heavy-ion collisions. Two examples of modern large-volume gaseous TPCs are shown in (Figure 35.14) and (Figure 35.15).

Identification of the charged particles crossing the TPC is possible by simultaneously measuring their momentum and specific energy deposit through ionisation ($\mathrm{d}E/\mathrm{d}x$). The momentum, as well as the charge sign, are calculated from a helix fit to the particle trajectory in the presence of a magnetic field (typically parallel to the drift field). For this application, precise spatial measurements in the plane transverse to the magnetic field are most important. The specific energy deposit is estimated from many charge measurements along the particle trajectory (e.g. one measurement per anode wire or per row of readout pads). As the charge collected per readout segment depends on the track angle and on the ambient conditions, the measured values are corrected for the effective length of the track segments and for variations of the gas temperature and pressure. The most probable value of the corrected signal amplitudes for a given track provides the best estimator for the specific energy deposit (see Sec. 34.2.3); it is usually approximated by the truncated mean, i.e. the average of the 50%–70% smallest values. The resulting particle identification performance is illustrated in (Figure 35.16), for the ALICE TPC.

The dependence of the achievable energy resolution on the number of measurements N, on the thickness of the sampling layers t, and on the gas pressure P can be estimated using an empirical formula [173]:

$$\sigma_{dE/dx} = 0.41\ N^{-0.43}(t\,P)^{-0.32}. \qquad (35.17)$$

Typical values at nominal pressure are $\sigma_{dE/dx} = 4.5$ to 7.5%, with $t = 0.4$ to 1.5 cm and $N = 40$ up to more than 300. The

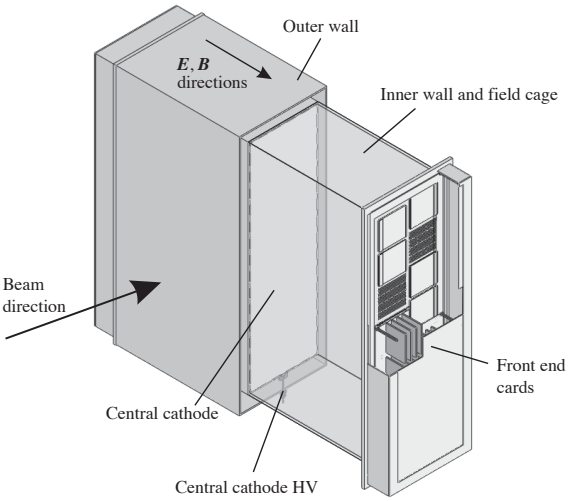

Figure 35.15: One of the 3 TPC modules for the near detector of the T2K experiment [172]. The size is $2 \times 2 \times 0.8\,\mathrm{m}^3$. Micromegas devices are used for gas amplification and readout.

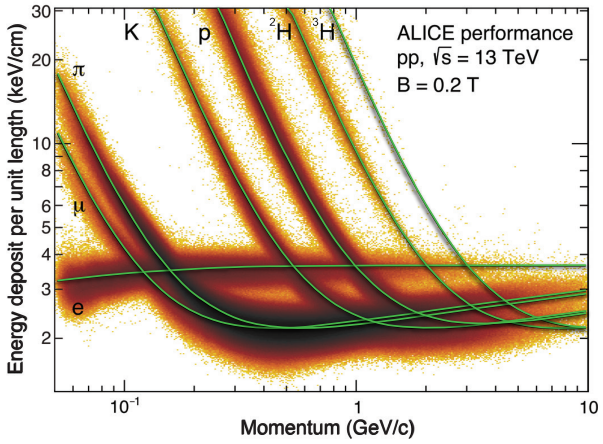

Figure 35.16: Energy deposit versus momentum measured in the ALICE TPC.

record, with an unprecedented energy resolution of 3%, is held by the PEP-4/9 TPC [174], due to the high gas pressure of 8.5 bar.

The greatest challenges for a large TPC are due to the length of the drift of up to a few meters. In particular, it can make the device sensitive to small distortions in the electric field. Such distortions can arise from a number of sources, e.g. imperfections in the field cage construction or the presence of ions in the drift volume. The electron drift in a TPC in the presence of a magnetic field is defined by Eq. (35.14). The $E \times B$ term of Eq. (35.14) vanishes for perfectly aligned electric and magnetic fields, which can however be difficult to achieve in practice. Furthermore, the electron drift depends on the $\omega\tau$ factor, which is defined by the gas mixture and the magnetic field strength. The electrons will tend to follow the magnetic field lines for $\omega\tau > 1$, or the electric field lines for $\omega\tau < 1$. The former mode of operation makes the TPC less sensitive to non-uniformities of the electric field, which is usually desirable.

The drift of the ionization electrons is superposed with a random diffusion motion which degrades their position information. The ultimate resolution of a single position measurement is limited to around

$$\sigma_x = \frac{\sigma_D \sqrt{L}}{\sqrt{n}}\,, \tag{35.18}$$

where σ_D is the transverse diffusion coefficient for 1 cm drift, L is the drift length in cm and n is the effective number of electrons collected. Without a magnetic field, $\sigma_{D,B=0}\sqrt{L}$ is typically a few mm after a drift of $L = 100\,\mathrm{cm}$. However, in a strong magnetic field parallel to the drift field, a large value of $\omega\tau$ can significantly reduce diffusion:

$$\frac{\sigma_{D,B>0}}{\sigma_{D,B=0}} = \frac{1}{\sqrt{1+\omega^2\tau^2}}\,. \tag{35.19}$$

This factor can reach values of up to 10. In practice, the final resolution limit due to diffusion typically lies around $\sigma_x = 100\,\mu\mathrm{m}$.

The drift and diffusion of electrons depend strongly on the gas mixture. The optimal gas mixture varies according to the environment in which the TPC operates. In all cases, the oxygen concentration must be kept very low (few ten parts per million in a large TPC) in order to avoid electron loss through attachment.

Ideally, the drift velocity should depend only weakly on the electric field at the nominal operating condition. The classic Ar/CH_4 (90:10) mixture, known as P10, has a drift velocity maximum of $5\,\mathrm{cm}/\mu\mathrm{s}$ at an electric field of only $125\,\mathrm{V/cm}$ (Figure 35.5). In this regime, the electron arrival time is not affected by small variations in the ambient conditions. Moreover, low electric fields simplify the design and operation of the field cage. The mixture has a large transverse diffusion at $B = 0$, but this can be reduced significantly in a strong magnetic field due to the relatively large value of $\omega\tau$.

For some applications organic gases like CH_4 are not desirable since they may cause aging. An alternative is to replace CH_4 with CO_2. An Ar/CO_2 (90:10) mixture has a low transverse diffusion at all magnetic field strengths, but does not provide a saturated drift velocity for the typical electric fields used in TPCs (up to a few 100 V/cm). As a consequence, it is quite sensitive to the ambient conditions. Freon admixtures like CF_4 can be an attractive option for a TPC as well, since the resulting gas mixtures provide high drift velocities at low electric fields. However, the use of CF_4 always needs to be thoroughly validated for compatibility with all materials of the detector and the gas system.

Historically, the amplification stages used in gaseous TPCs have been planes of anode wires operated in proportional mode. The performance is limited by effects related to the feature size (wire spacing) of a few mm. Since near the wires the electric and magnetic fields are not parallel, the incoming ionisation electrons are displaced in the direction of the wires ("wire $E \times B$ effect"), which degrades the resolution. The smaller feature sizes of Micro-Pattern Gas Detectors (MPGDs) like GEMs and Micromegas lead to many advantages as compared to wire planes (see Sec. 35.6.4). In particular, $E \times B$ effects in the amplification stage are much smaller. Moreover, the signal induction process in MPGDs leads to a very narrow pad response, allowing for a much finer segmentation, which improves the separation for two very close tracks. Combinations of MPGDs with silicon sensors have resulted in the highest granularity readout systems so far (see Sec. 35.6.4). These devices make it possible to count the number of ionization clusters along the length of a track, which can, in principle, improve the particle identification capability. However, the big challenge for such a system is the huge number of readout channels for a TPC of a typical size.

The accumulation of the positive ions created by the ionization from the particle tracks can lead to time-dependent distortions of the drift field. Due to their low drift velocity, ions from many events may coexist in the drift volume. To reduce the effect of such a build-up of space charge, Argon can be replaced by Neon as the main component of the gas mixture. Neon features a lower number of ionisation electrons per unit of track length (see 35.5) and a higher ion mobility (see 35.6).

Of greater concern are the ions produced in the gas amplification stage. In order to prevent them from entering the drift volume, large TPCs built until now have a gating grid. The gating

grid can be switched to transparent mode (usually in the presence of an interaction trigger) to allow the ionization electrons to pass into the amplification region. After all electrons have reached the amplification region, it is usually closed such that it is rendered opaque to electrons and ions. For triggered operation, a combination of a MPGD and a gating structure may be an attractive solution. However, a gating grid implies a principal rate limitation to a few kHz.

A next generation of TPCs (e.g. ALICE [171], sPHENIX [175]) has been developed for applications where a triggered operation would lead to inacceptable data loss. The employed readout schemes are based on MPGDs, as these can be optimised in order to drastically reduce the ion back-flow. Extensive work has been carried out during the 2010's to design such readout structures. In ALICE and sPHENIX ion back-flow values below 1 % are achieved with a thorough adjustment of the various fields in a quadruple GEM system. Similar levels of ion back-flow can be reached with Micromegas detectors [176].

35.6.6 *Transition radiation detectors (TRD's)*

Revised July 2021 by P. Nevski (BNL) and A. Romaniouk (Innsbruck U.; MEPhI Moscow).

Transition radiation (TR) x-rays are produced when a highly relativistic particle ($\gamma \gtrsim 10^3$) crosses a refractive index interface, as discussed in Sec. 34.7. Since the TR yield is about a few % per boundary crossing, radiation from multiple surface crossings (e.g., a stack of foils) is used in practical detectors. The x-rays, ranging from a few keV to a few dozen keV or more, are emitted in a forward direction at small angles (within few mrad) to the particle trajectory. The TR intensity for a single boundary crossing always increases with γ, but, for multiple boundary crossings, interference leads to saturation above a Lorentz factor $\gamma_{\,\mathrm{sat}} = 0.6\ \omega_1\sqrt{\ell_1\ell_2}/c$ [177], where ω_1 is the radiator material plasma frequency, ℓ_1 is its thickness, and ℓ_2 the spacing between material elements. The probability density function of TR is a fairly complex function of γ, radiator parameters, photon energy (ω) and its emission angle (θ). For well defined radiator parameters a measured two-dimensional distribution of photon energy vs its reconstructed emission angle is in very good agreement with the theory predictions [178].

Integration over the angle yields the TR spectrum, which typically features many maxima (see Sec. 34.7). Most of the TR energy is emitted near the last maximum of the spectra determined by radiator material parameters at $\omega_{max} = \ell_1\omega_1^2/2\pi c$. The effective TR photon emission starts at about $\gamma_{thr} = \ell_1\omega_1/c$. By varying radiator parameters one may optimize the particle separation for a given range of the γ-factor. The angular distribution of TR photons has a few maxima and extends up to $\theta_{max} = (1/\gamma^2 + \omega_1^2/\omega^2)^{1/2}$ [179]. For a single foil the largest part of the TR energy is emitted around the most probable angle $\theta = (1/\gamma^2 + \omega_2^2/\omega^2)^{1/2}$, where ω_2 is the plasma frequency of the gas surrounding the radiator material elements. However, in case of multiple interfaces, interference effects may significantly change this angle and more realistic expression for the angle which corresponds to the last interference maximum of the energy spectra is $\theta \approx \sqrt{1.4\pi^2/\gamma_{\,\mathrm{sat}}^{\,2} - 1/\gamma^2}$ [178]. The higher is the gamma-factor, the larger is the angle of the first interference maximum. It reaches almost its asymptotic limit at $\gamma = \gamma_{sat}$. This effect is illustrated in Fig. 35.17 [178] which shows two-dimensional distribution of the TR photon energy versus the reconstructed production angle obtained in 20 GeV electron beam with the radiator containing a stack of foils of 15.5 μm thickness spaced by 210 μm (the left plot) using a Si-pixel detector. TR produced by 20 GeV electrons is emitted mostly around $\theta \sim 0.9$ mrad. All features of this distribution are well reproduced with MC simulations (the right plot).

The simplified numerical expressions can be used for practical estimation of the main TR production parameters [178]: $\theta \sim 1.2/\omega_1\sqrt{l_1 l_2}$, $\gamma_{thr} \sim 3\times10^3\ \omega_1\ell_1$, $\gamma_{\,\mathrm{sat}} \sim 3\times10^3\ \omega_1\sqrt{\ell_1\ell_2}$ and $\omega_{max} = 0.65\ \ell_1\omega_1^2$, where θ in mrad, ω_1 in eV, ω_{max} in keV and l_1 and l_2 in mm.

In the simplest concept, a detector module might consist of a low-Z TR radiator followed by a high-Z active layer made of proportional counters filled with a Xe-rich gas mixture. The atomic number considerations follow from the dominant photoelectric absorption cross section per atom going roughly as $Z^{\,n}/\omega^3$, where n varies between 4 and 5 over the region of interest.[1] To minimize self-absorption, materials such as polypropylene, Mylar, carbon, and (rarely) lithium in the form of foils, fibers or foams are used as radiators. The TR signal in the active regions is in most cases superimposed upon the particle ionization losses, which are proportional to Z. In most of the detectors used in particle physics the radiator parameters are chosen to provide $\gamma_{\,\mathrm{sat}} \approx 3000$. Those detectors normally work as threshold devices, ensuring the best electron/pion separation in the momentum range 1 GeV/$c \lesssim p \lesssim$ 150 GeV/c.

One can distinguish two design concepts—"thick" and "thin" detectors. In "thick" detectors the radiator, optimized for a fixed total radiation length at maximum TR yield and maximum TR absorption in the detector, consists of few hundred foils (for instance 300 20 μm thick polypropylene foils). Most of the TR photons are absorbed in the radiator itself. To maximise the number of TR photons reaching the detector, part of the radiator far from the active layers is often made of thicker foils, which shifts the x-ray spectrum to higher energies. The detector thickness, about 2-4 cm for Xe-filled gas chambers, is optimized to absorb most of the incoming x-ray spectrum. A classical detector is composed of several similar modules which respond nearly independently. Such detectors were used in the UA2, NA34 and other experiments [180], are being used in the ALICE experiment [181, 182] and are built for the CBM experiment [183]. In another TRD concept a fine granular radiator/detector structure exploits the soft part of the TR spectrum more efficiently. This can be achieved, for instance, by distributing small-diameter straw-tube detectors uniformly or in thin layers throughout the radiator material. This approach allows to realise a TRD as an integral part of a tracking detector providing many points of measurements on the particle track. Even with a relatively thin radiator stack, radiation below 4 keV is mostly lost in the radiators themselves. However, for photon energies above this value, the absorption is reduced and the radiation can be registered by several consecutive detector layers, thus creating a strong TR build-up effect. Descriptions of detectors using this approach in both accelerator and space experiments can be found in [181, 184–187]. For example, in the ATLAS TR tracker (TRT), charged particles on average cross about 35 straw tube layers embedded in the radiator material [184]. The effective thickness of the Xe gas per straw is about 2.5 mm and the average number of foils per straw is about 40 with an effective foil thickness of about 18 μm. In this approach straw walls also act as radiator and make some contribution to the TR spectrum.

Although the values mentioned above are typical for most of the plastic radiators used with Xe-based detectors, they vary significantly depending on the detector requirements. Careful simulations are usually needed to build a detector optimized for a particular application. For TRD simulations the codes are based on well understood TR emission formulas (see for instance [179] for regular radiators and [188] for irregular radiators). They are realised as the stand-alone simulation programs [178,189,190] or GEANT4 based ones [191] and give both a good agreement of the TR energy spectra and of the angular distributions with data [178, 192, 193].

The discrimination between electrons and pions can be based on the charge deposition measured in each detection module, on the number of clusters – energy depositions observed above an optimal threshold (usually it is 5–7 keV), or on more sophisticated methods such as analyzing the pulse shape as a function of time. The total energy measurement technique is more suitable for thick gas volumes, which absorb most of the TR radiation and where the ionization loss fluctuations are relatively small. The cluster-counting method works better for detectors with thin gas layers, where the fluctuations of the ionization losses are bigger. Cluster-counting replaces the Landau-Vavilov distribution of background ionization energy losses with the Poisson statistics of

[1] Photon absorption coefficients for the elements (via a NIST link), and $dE/dx|_{\mathrm{min}}$ and plasma energies for many materials are given in https://pdg.lbl.gov/current/AtomicNuclearProperties.

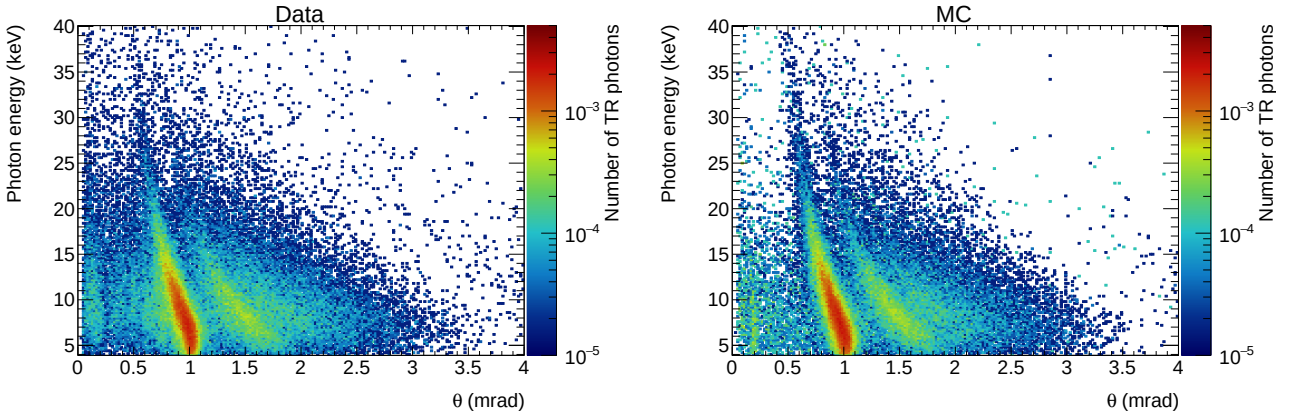

Figure 35.17: Two dimensional distributions of photon energy versus reconstructed production angle obtained with the polypropylene radiator with 20 GeV/c electron beam. Data - the left plot, MC - the right plot. Z-axis is a number of photons per particle [178]

δ-electrons, responsible for the distribution tails. The latter distribution is narrower than the Landau-Vavilov distribution. In practice, most of the experiments use a likelihood method, which exploits detailed knowledge of the detector response for different particles and gives the best separation. The more parameters are considered, the better achievable separation power. The neural network method is the most powerful tool. When it used by the ALICE TRD (ALICE point in Fig. 35.18) it lead to an increase of the rejection power by another factor of 2–3 with respect to the likelihood method [181].

The major factor in the performance of any TRD is its overall length. This is illustrated in Fig. 35.18, which shows, for a variety of detectors, the pion efficiency at a fixed electron efficiency of 90% as a function of the overall detector length. As TRD performance depends on particle energy, the experimental data in this figure covering a range of particle energies from 1 GeV to 40 GeV, are rescaled to an energy of 10 GeV when possible. Phenomenologically, the rejection power against pions increases as $5 \cdot 10^{L/38}$, where the range of validity is $L \approx$ 20–100 cm. Apart from the beam energy variations, the observed scattering of the points in the plot reflects how effectively the detector space is used and how well the exact response to different particles is taken into account in the analysis. For instance, the ATLAS TRT was built as a compromise between TR and tracking requirements; that is why the test-beam prototype result (lower point) is better than the real End-Cap TRT performance at the LHC shown in Fig. 35.18 for different regions in the detector (in agreement with MC).

In most cases, recent TRDs combine particle identification with charged-track measurement in the same detector [181, 183, 186]. This is particularly important for collider experiments, where the available space for the inner detector is very limited. For a modest increase of the radiation length due to the radiator (∼4% X0), a significant enhancement of the electron identification was obtained in the case of the ATLAS TRT. Here, the combination of the two detector functions provides a powerful tool for electron identification even at very high particle densities.

In addition to the enhancement of the electron identification during offline data analysis, TRD signatures are often used in the trigger algorithms at collider experiments. The ALICE experiment [182] is a good example for the use of the TRD in a First Level Trigger. In the ATLAS experiment, the TRT information is used in the High Level Trigger (HLT) algorithms. At increasing luminosities, the electron trigger output rate becomes so high, that a significant increase of the calorimeter energy threshold is required to keep it at an acceptable level. This may affect the trigger efficiency of very important physics channels (e.g. $W \to e\nu$ inclusive decay). Even a very soft TR cut at the HLT level, which preserves high electron efficiency (98%), allows to suppress a significant part of fake triggers and enhance the purity for physics events with electrons in a final state. The TRT also plays a crucial role in the studies where an electron suppression is required (e.g.

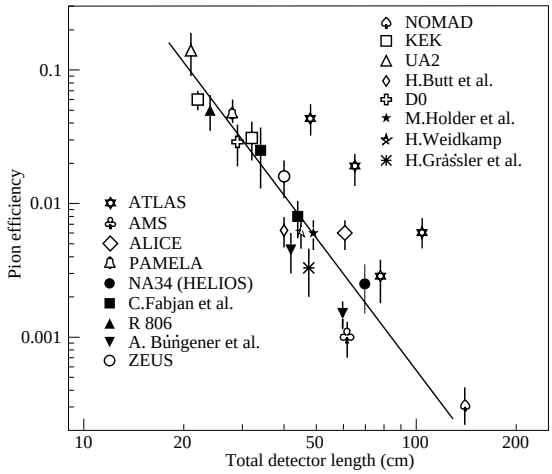

Figure 35.18: Pion efficiency measured (or predicted) for different TRDs as a function of the detector length for a fixed electron efficiency of 90%. The plot is based on the table given in [180]. Results from more recent detectors are added from [181, 185–187, 194].

hadronic mode of τ–decays). TR information is a completely independent tool for electron identification and allows to study systematic uncertainties of other electron reconstruction methods.

Electron identification is not the only TRD application. Some TRDs for particle astrophysics are designed to directly measure the Lorentz factor of high-energy nuclei by using the quadratic dependence of the TR yield on nuclear charge; see, for instance, in [195]. The radiator configuration (ℓ_1, ℓ_2) is tuned to extend the TR yield rise up to $\gamma \approx 10^5$ using the more energetic part of the TR spectrum (up to 100 keV). High density radiator materials (such as Al) are the best for this purpose. Direct absorption of the TR-photons of these energies with thin detectors becomes problematic and TR detection methods based on Compton scattering have been proposed, see in [196].

The high granularity of the semiconductor pixel or microstrip detectors provides spatial separation of the TR photons and dE/dx losses at relatively modest distances between radiator and detector. These detectors may be the basis for novel devices which combine precise tracking and PID properties [178, 190, 197]. Use of the TR production angle in addition to its energy can help to improve PID properties of the TRD. The presence of a magnetic field could enhance the separation between TR photons and dE/dx losses [198]. New detector techniques for TRDs are also under consideration. GasPixel detectors allow to reconstruct a track segment with a space point accuracy of < 30 μm and ex-

ploit all details of the particle tracks to highlight individual TR clusters in the gas, see in [199]. Thin films of heavy scintillators might be a very attractive option for non-gas based TRD [200].

35.6.7 *Resistive-plate chambers*

Revised August 2023 by G. Aielli (Rome U. Tor Vergata).

The resistive-plate chamber (RPC) is a gaseous detector working at atmospheric pressure developed by R. Santonico and R. Cardarelli in the early 1980's [201]. A precursor of the RPC was the Pestov spark chamber [202] [203], which had a metallic plate cathode and a thick glass plate anode, designed to work at 12 bar to obtain an outstanding 0.1 ns time resolution. Although the original purpose of RPCs was to provide a competitive alternative to large scintillator counters, the RPC's potential for timing tracker systems was quickly recognized given its high detection efficiency (>95%), excellent temporal and spatial resolutions and ease of constructing large-format single frame detectors. The RPC, as sketched in Fig. 35.19, is a large planar capacitor with two parallel high bulk resistivity electrode plates (10^9–10^{13} Ω·cm) separated by a set of insulating spacers. The spacers define a gap in the range from a few millimeters down to 0.1 mm with a precision of a few μm. The gap is filled with a suitable atmospheric-pressure gas mixture which serves as a target for ionizing radiation. The gas gap thickness practically determines the time resolution of the RPC. On the other hand, the limit for reaching full detection efficiency at atmospheric pressure is typically 1 mm (also influenced by the gas molecular weight). Since the primary ionization released in sub-millimeter gas gaps is limited, multiple gaps can be combined to effectively obtain a very high detection efficiency [204]. The electrodes are most commonly made of high pressure phenolic-melaminic laminate (HPL), commonly referred to as "bakelite", or soda-lime glass (glass from

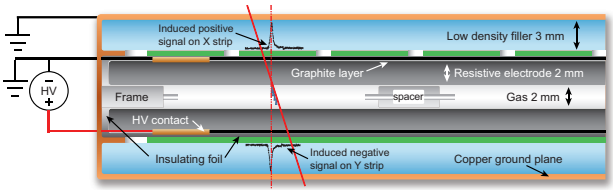

Figure 35.19: Schematic cross section of a generic single gap RPC.

now on), having a lower resistivity than borosilicate glass. An uniform electric field of several kV/mm is established on the gas gap, sufficient to promptly start an avalanche multiplication of the primary electrons. The electric field is typically applied through a moderately conductive ($\sim 10^5 to 10^8$ $\Omega/\square$) graphite varnish, forming an ohmic contact with the external faces of the electrodes. Its conductivity is sufficiently low to be transparent to the fast avalanche signal transients, and high enough to suppress surface voltage gradients arising from the working current flowing in it. Due to the high electrode resistivity in RPCs, the time constant of the equivalent RC circuit ($\tau = \rho\epsilon_r$ being ρ the electrode resistivity and ϵ_r its dielectric constant) is much longer than the discharge processes duration. Therefore only the locally-stored electrostatic energy contributes to the discharge, preventing the formation of sparks and leaving the rest of the detector field unaffected. The gas-facing surface of HPL electrodes are commonly coated with a few μm-thick layer of polymerized linseed oil [205] with the function of smoothing the electrode surface, improving the electric field uniformity. Glass-based RPCs don't require such treatment. It also has the function of protecting the electrode from the being eventually etched by free radicals generated in the discharge e.g. in presence of fluorocarbons. In RPCs the gaseous target and the multiplication region coincide. In the early stage of the avalanche multiplication the uniform electric field exponentially amplifies each primary ionization cluster, as the avalanche progresses away from the location of the primary ionization. Since the ionization clusters generated by the incident MIP are randomly distributed along the ionizing particle track, for low gains the observed RPC charge spectrum is broad and approximately exponentially distributed[2] with the mode close to zero. Because of this, it is difficult to separate noise from signals using a discrimination threshold. This is not the case in gaseous detectors where ionization and amplification occur in separate regions.

For increasingly larger avalanches, the space-charge progressively saturates the avalanche growth from exponential to almost linear, producing a peaked charge spectrum, essential to efficiently separate the signal from the noise [207]. For large gains[3] the avalanche, with increasing probability, onsets a transition to "streamer" [208], a plasma filament connecting the electrodes, depleting all the locally-available energy [209], and generating an almost fixed amplitude signal. This prevents any further evolution of the discharge. This streamer mode was the first ever used by RPCs, until the introduction of very electronegative gases and more sensitive front end electronics made it possible to detect the precursor avalanche independently on the streamer [210,211] Any of this operating regimes can be used in RPC detectors, depending on the application.

As with other gaseous detectors, the gas mixture is optimized for each specific application. In general it needs to contain a UV photons quencher suppressing the photon-mediated feedback that can lead to self generated after-pulse discharges, and one or more electronegative components, to extend the avalanche growth, free from streamers, to as high as possible electric fields [212]. The addition of small fractions of electronegative molecules with a very high capture cross section for slow electrons, such as SF_6, was proven to inhibit the transition to streamer over a wide electric field range. Even though there is not yet an accepted and robust avalanche-to-streamer-transition model, this effect is commonly explained as a delay in the growth of the electron density of the avalanche front, which perturbates the electric field driving the transition to streamer. As a reference, the mixture for stable avalanche operation in ATLAS and CMS is $C_2H_2F_4$/i-C_4H_10/SF_6=94.5%/5%/0.3%.

The avalanche induces a fast electron signal on a set of metallic readout electrodes (e.g. pads or strips) commonly placed externally and insulated from the resistive electrodes. The signal is isotropically distributed with respect to the field direction and present with equal but opposite amplitude on both electrodes. Thanks to these features, performances of the readout electrodes on both RPC sides are equivalent. The induced charge density distribution can be ideally calculated for a simplified RPC model [213] [214] as: $\sigma(x) = A/\cosh[(r)/\delta]$ where A is a normalization constant, r is the distance from the center of the avalanche axis and $\delta = (g+2d)/\pi$ depends on the gap and electrode width (g and d, respectively). Depending on the specific RPC layout and geometry, the interplay between conductive coating and pick-up electrodes typically broadens, by means of a diffusion-like process (see [214] [215]). This effect mostly preserves the information on the avalanche position, which can be obtained using the charge centroid method, with the drawback of increasing the signal space occupancy. Sensitivity to the high-frequency spectrum of electron avalanche signals over large RPC areas requires a correspondingly adequate Faraday cage and readout design. At the same time, to preserve the excellent timing features of the RPC signal, the front end electronics should have a short rise time (ideally $\ll$ than the signal rise time) and low noise, although these requirements could be in competition [216].

35.6.7.1 *RPC types and applications*

RPCs are generally classified in two categories depending on the gas gap structure: single gap RPCs (described above) and multiple gap RPCs [204] (typically referred as MRPCs). While they are both based on the same principle they have different construction techniques, performance and limitations, making them suitable for different applications. Due to its simplicity and robustness, the single gap RPC is ideal for covering very large surfaces. Typical detector systems can have sensitive surface areas

[2] An analytic treatment of the low gain avalanche process shows that the charge distribution is well described by the Γ function [206]

[3] A multiplicity of the order of 10^8 electrons is classically referred as Raether/Meek limit for on-setting a streamer

up to $\sim 10^4$ m^2, with single module areas of a few m^2, and a space-time resolution down to $\sim$0.4 ns $\times$ 100 μm [217] [218]. Representative examples are the muon systems of ATLAS [219] and CMS [220] or ground and underground based cosmic rays [221] and neutrino arrays [222]. It is interesting to note that CMS implemented a bi-gap structure, i.e. the pickup signal is sandwiched by 2 single gas gaps, both contributing to the signal induction, improving efficiency and time resolution with respect to the single gas gap. Relevant new trends for single gap RPC applications are represented by new Dark Matter search experiments such as CODEX-B [223] and ANUBIS [224], in both cases exploiting RPCs to enclose and instrument large detection volumes with a good space-time tracker. Single gap RPCs have also recently demonstrated good candidates for application in tracking calorimetry [225].

The MRPC [226], as sketched in Fig. 35.20, segments the gaseous target by means of a stack of floating glass electrodes separated by a monofilament (i.e. fishing line) sandwiched between two external electrodes providing the high-voltage bias. Since the current flowing in between the gas gaps must be in average equal, the difference of potential between each couple of adjacent floating electrodes will tend to be the same. An extensive description can be found in [227]. It has been observed that higher time resolution is inversely correlated to the gas gap size, so this configuration allows for smaller gas thicknesses while maintaining a sufficient total gas thickness. This tends to separate primary clusters avalanches in different gas gaps, treating them independently, and determines a shorter avalanche growth time, increasing time resolution by one order of magnitude with respect to the classic RPCs [228]. The mechanical fragility of sub-mm-gap structures makes this technique less suitable for very large detector areas. Moreover the only material nowadays practically suitable for building such structures is soda-lime glass with resistivity above 10^{12} Ω·cm, limiting the rate capability to about 500 Hz/cm^2 [229].

MRPCs have been largely used in Time Of Flight systems such as ALICE [230], HADES [231], FOPI [232] and BESSIII [233], and in applications such as timing PET [234]. In perspective MRPC will be used for upgraded and new nuclear physics experiments such as CBM@FAIR [235] and SoLID [236].

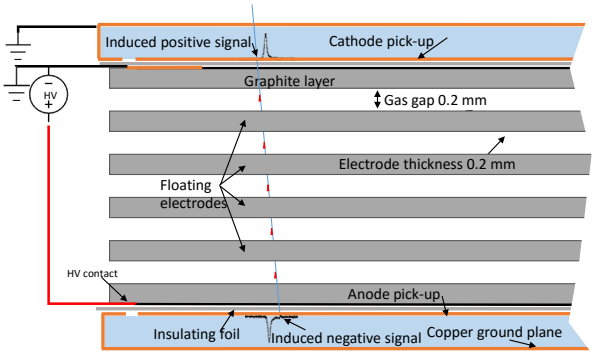

Figure 35.20: Schematic cross section of a generic multi gap RPC.

35.6.7.2 *Time and space resolution*

Space-time uncertainties in RPCs are determined by the statistical fluctuations of the primary and secondary ionization, the avalanche multiplication rate, which is a function of the electric field, and on the Signal/Noise ratio of the front end electronics. The intrinsic signal latency is commonly in a few ns range (avalanche growth time to produce a detectable signal), making the RPC suitable for applications where a low latency is essential.

The gas gap size is a crucial feature for the RPC timing performance: producing the same total charge (for a detectable signal) in a smaller gas gap implies the necessity of increasing the first Townsend coefficient by increasing the electric field, reducing at the same time the total signal duration and the related time fluctuations; moreover the chance of having multiple clusters in the same gas gap decreases with the gap size, suppressing the charge collection fluctuations [237], due to the unknown distance in between the clusters. This chance becomes necessarily higher along with the intrinsic efficiency of the single gas gap. Typical timing performances range from around 1 ns with a 2 mm gas gap, down to 20 ps for a stack of several 0.1 mm gaps [238].

The intrinsic position sensitivity of an RPC is in the range of tens of μm depending on the lateral spread of the avalanche induced charge distribution, influenced also by the gap size. In typical RPC applications the pick up electrodes pitch L ($\sim$1 cm) is much broader than the intrinsic resolution, and being readout via a discriminator, the spatial resolution is geometrically limited in the range of L/$\sqrt{12}$. A much better result is obtained by using a finer electrodes granularity and measuring the charge in each strip collecting the avalanche charge, so to reconstruct the charge centroid. It has been demonstrated, through charge centroid techniques, that the RPC avalanche space-time localization can be as good as $\sim$50 ps $\times$ 40 μm [239] [240].

35.6.7.3 *Rate capability and ageing*

RPC rate capability is limited by the voltage drop on resistive electrodes, $\Delta V = V_a - V_{gas} = I \cdot R$ [241]. Here V_a is the applied voltage, V_{gas} is the effective voltage on the gas, $R = \rho \cdot d/S$ is the total electrode resistance, ρ being the resistivity and d,S the sample thickness and surface respectively, and I is the working current. Assuming uniform irradiation we can express $I = \phi \cdot S \cdot \langle Q \rangle$ where ϕ is the particle fluence and $\langle Q \rangle$ is average charge per avalanche. So we obtain a state equation for the RPC rate capability:

$$\Delta V/\phi = \rho \cdot d \cdot \langle Q \rangle$$

A large I not only limits the rate capability but also affects the long term performance of the detector since the working current, associated to discharges, depletes the conductive properties of HPL electrodes [242]. In presence of fluorocarbons and water, discharges generate hydrofluoric acid (HF) and other fluorinated compounds, which damage internal detector surfaces, especially if made of glass, known to be not resistant to HF [243]. The practical way to suppress HF formation in glass RPCs is preventing water vapor contamination. Conversely, HPL electrodes, coated with linseed oil, are relatively resistant to HF, but the presence of water can not be avoided since it mediates the HPL conduction. In this case the HF damage is mitigated by removing it with a forced flow of gas through the gas gap.

Operating in the streamer regime places low requirements on the front end electronics sensitivity, but generally limits the counting rate capability to $\sim$100 Hz/cm^2. Higher-rate operation can be achieved by reducing gas gain in favor of electronic amplification, operating the detector in avalanche mode. Increasing concentrations of electronegative gases, such as $C_2H_2F_4$ and SF_6 [212], shifts the streamer transition to higher gains, thus the avalanche signal can access an higher dynamic range, which puts further stress on the performance request on the front end electronics. By further lowering the avalanche mode gas gain compatibly with the front end performance, efficient and stable performance at high rates (e.g. 10 kHz/cm^2) has been achieved for large area single gap RPCs [216]. Two complementary strategies rely either on the natural redundancy and higher signal yield of multiple micro gap structures [244] or on electrodes made with lower resistivity materials [245]. Lowering the electrode resistivity in presence of high uniform field is increasingly difficult, since high resistivity limits the appearance of larger discharge events and increase of spurious counts, favoured by the effect of local electrode defects on the field gradient. In this case, to safely lower the electrode resistivity, a safety margin would be given by operating with a lower electric field, and a correspondingly lower average charge per count.

35.6.7.4 *Alternative gas mixtures*

The standard gas mixture mentioned above is based on Hydrofluorocarbon (HFC), specifically the R134A, extensively used in the refrigeration industry. R134A features matches very well the RPCs performance requirements. It has high density that results in high primary ionization. It is electronegative, which limits secondary discharge phenomena. It is not flammable, and it has a

limited degradation if exposed to UV photons due to the absence of saturated bonds. This last feature permits high rate operation, limiting the ageing effects due to the byproducts of the avalanche discharges. However, this gas has a Global Warming Potential (GWP) of 1450 thus it is not considered anymore a viable option for future industrial applications. Therefore, since a few years the RPC community is researching alternative gases [246, 247] to replace R134A, focusing on the Hydro-Fluoro-Olefins, a category of gases recently proposed for industrial applications. HFOs exhibit important limitations with respect to HFCs, if used in high concentrations. In particular its much higher electronegativity implies an impractically high applied electric field for the existing RPC systems, and a much higher charge per count due to a large fraction of negative ions produced by electron capture, which do not contribute to the prompt signal. A further side effect is a larger production of fluoride ions by UV decomposition of the gas. To contrast the ageing acceleration drive represented by the phenomena stated above, the proposed strategy was to largely dilute HFO whih a neutral gas, such as CO_2, compatibly with keeping an enough dense gaseous target, and whenever possible, operate at a lower gain by using very performing front end electronics. A representative example of the several variants tested [248] is $CO_2/C_3H_2F_4$/i-C_4H_{10}/SF_6=59%/35%/5%/1%. This mixture with a large fraction of CO_2 is suitable for thicker (2mm) gas gap. The presence of CO_2 in 1 mm gas gaps lower the amount of primary electrons thus practically limiting its fraction to no more than 30%. Thus for a safe operation a reduction of the charge per count by an order of magnitude is necessary to compensate the stronger ageing phenomena. It has to be noted that the research in this field is recent and very intensive [249, 250], so relevant updates are expected in future.

35.6.7.5 *A new detector: the **R**esistive **C**ylindrical **C**ounter*

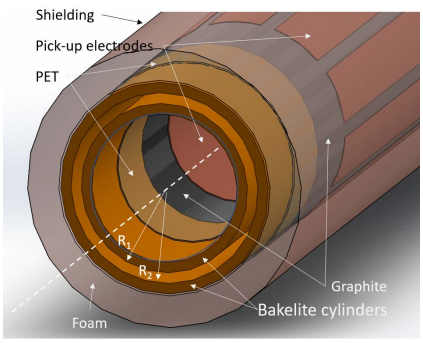

Figure 35.21: Schematic drawing of an RCC.

The RCC, illustrated in fig. 35.20, has been recently proposed as an evolution of the RPC [251] and is essentially an RPC warped to a cylindrical shape. The idea is to combine the advantages of parallel plate geometry and high pressure drift tubes in a single detector. The electric field $E(r)$, which is uniform in RPCs, here depends instead on the distance from the axis r, according to $E(r) = -\frac{V}{r \ln(R_1/R_2)}$. By choosing appropriate values for R_1, R_2, V and its polarization (the innermost cylinder is the cathode), it is possible to virtually segment the cylindrical gap in a innermost sensitive layer, where the field is sufficiently high to start the avalanche multiplication, and an outermost layer where the drift happens, increasing the induced signal with lower or no multiplication at all. This effect is called geometrical quenching and limits the avalanche growth without the necessity of electronegative gases. Moreover a geometrically quenched avalanche would have a much better prompt to total charge ratio, lowering the total operative current, hence increasing the rate capability. The cylindrical structure has a further major advantage with respect to the planar one, it can be easily pressurized overcoming the RPC limitation of working at atmospheric pressure only. Pressurization on one side increases the gaseous target density, thus increasing the efficiency of narrow gaps, on the other, it could largely improve RPC time resolution since the Townsend coefficient $\alpha = A\ p \cdot \exp(-Bp/E)$ (where p is the pressure, E the electric field and A,B are constants), as we learn from the RPC precursor, the Pestov spark chamber [203]. The performance of the RCC concept in terms of time resolution and counting rates are yet to be demonstrated. On the other side, being insensitive to the environmental pressure, potentially extends its range to space and under water applications.

35.7 LAr Time Projection Chamber

Written in October 2021 by F. Pietropaolo (CERN; INFN, Padova) and S. Pordes (FNAL). Revised in August 2023 by A. Fava (FNAL) and F. Pietropaolo (CERN; INFN, Padova).

35.7.1 *Introduction*

Liquid argon is an attractive material for particle detection. Some properties of argon are given in table 35.8; for many more see [252]. Energy deposition in the argon produces scintillation light and ionization electrons; in the presence of a moderate electric field, a significant fraction of the electrons escape recombination, making them available for detection as a charge signal. Typical values for a minimum ionizing particle are ∼ 40,000 photons/MeV at zero field (lower at finite fields) and ∼ 30,000 electrons/MeV at a field of 500 V/cm. That the liquid has a relative density of 1.4, that the free electrons can be drifted many meters with minimal dispersion and that it is abundant in the atmosphere and commercially available as a by-product in the distillation of air to produce nitrogen and oxygen, makes it particularly attractive for use in massive time-projection chambers (TPC) to study rare processes, as realized in [254] and [255]. Since that time, the liquid argon TPC (LAr TPC) has been developed into a detector that combines mm^3 resolution with particle identification, calorimetry, and 100% live time. Detectors with masses up to 600 tons have been built and operated and detectors of 10's of kilotons are being planned.

Table 35.8: Some physical properties of liquid argon from [253].

Property	Unit	Value
Boiling Point *(BP)* at 1013 hPa	K	87.3
Density (ρ) at 1013 hPa	kg m^{-3}	1395
d*(BP)*/dP	K hPa^{-1}	9×10^{-3}
dρ/dT	kg m^{-3} K^{-1}	−6.2
Latent Heat of Evaporation	kJ kg^{-1}	161
Freezing Point (1013 hPa)	K	83.8

The operation of a liquid argon time projection chamber requires

1. a cryostat and cryogenic system to maintain ultra-pure liquid argon clean and stable,
2. an electric field that permeates the liquid argon volume and allows ionization electrons to escape recombination, and drifts them to the charge sensors,
3. an array of charge sensors and associated electronics to amplify and digitize the charge signals,
4. sensors to detect the scintillation light and associated electronics,
5. a data-acquisition system to read out and record the data,
6. software to reconstruct and interpret the data.

Surveys of previous, present and proposed detectors are described in the literature [271] [272] and in detailed descriptions of detectors which have operated in experiments [273–279]. This article provides a description of the challenges in achieving items 1 to 4 with some of the solutions presently adopted. Topics 5 and 6, crucial to the successful exploitation of the LAr TPC technology and subject of intense activity, are also introduced [280–282]. References are also given for a number of ancillary devices - cameras that can operate in the liquid argon [279], monitors to provide a rapid measurement of the purity of the argon [283,284], ionization lasers to measure distortions of the drift field due to space charge

Table 35.9: Some Detector Relevant Properties of liquid argon.

Property	Unit	Value
Stopping Power (m.i.p.)	MeV g^{-1} cm^2	1.51
Radiation Length	g cm^{-2}	19.6
Nuclear Interaction / Collision Length	g cm^{-2}	120 / 76
W_{el}, Energy to form one electron-ion pair	eV	23.6 (±0.3) [256, 257]
Ion mobility	cm^2 V^{-1} s^{-1}	1.6 $\times 10^{-3}$ [258]
Temperature dependence of drift velocity	% K^{-1}	-1.7 [259]
Longitudinal diffusion coefficient, D_L	mm^2 ms^{-1}	0.4 (see text)
W_{ph}, Energy to produce one scint. photon	eV	25 [260, 261]
Scintillation photon wavelength (vacuum)	nm	128 ±8 (FWHM) [262]
Scintillation light inverse velocity	ns m^{-1}	7.46 (±0.08) [263]
Rayleigh scattering length (predicted)	m	0.9 (±0.2) [263–265]
Scintillation Decay times fast/slow	ns	6 (±1)/1500 (±100) [266–268]
Dielectric strength	kV cm^{-1}	>40 [269, 270]

or electrical problems [285] - that have been developed to improve performance. A list of experiments with their masses is also given in 35.14.

35.7.2 *A Mass of ultra-pure Liquid Argon*

Argon is commercially available in large quantities as a by-product in the distillation of air to produce liquid nitrogen and oxygen. Critical to any LAr TPC are the cryostat and the cryogenic and purification system to maintain the argon liquid, ultra-clean and stable in temperature and pressure. Evacuable double-walled vacuum cryostats are practical for detectors with a mass of O(100) t. Based on the demonstration that ultra-clean argon can be achieved without initial evacuation [284], current and proposed larger detectors are hosted in foam-insulated non-evacuable cryostats based on a technology used in liquefied natural gas transport [279]. A convenient feature of these cryostats is that their components (inner walls, insulation, outer structures) are modular and of a size suited to assembly in underground environment. In addition, passive insulation is intrinsically safer than vacuum insulation because the heat input cannot rapidly increase as in the case of vacuum degradation.

The absence of electronegative contaminants, mainly environmental oxygen and water, from the liquid argon is crucial to ensure the ionization electrons drift from their point of production to the charge sensors without being captured (the drift motion of the produced negative ions is too slow to be detectable). The 'electron lifetime', τ, is the parameter describing the purity level of argon. To set a scale, the electron capture time in liquid argon with a concentration of oxygen of 0.1 ppb (part per billion by volume - all concentrations here are by volume) is $\sim$ 3 ms [286, 287], largely independent of electric field in our range of interest. For detectors with electron drift times in the milliseconds, the oxygen level must be well below 0.1 ppb to avoid losing most of the signal. In order to achieve this goal, first the air is removed from the cryostat volume mostly by controlled purging with argon [288], allowing to reach ppm purity levels; a purification system is then required during filling, to purify the commercial argon delivered from its typical ppm oxygen and water levels. Molecular sieve and activated copper on alumina [289] are commonly used to remove water and oxygen, respectively. This purification is performed in the liquid phase and the discovery that purification with standard materials is effective at cryogenic temperatures [290] allowed for an enormous gain in throughput compared to purification in the gas phase. The purification system delivers essentially pure argon - which then mixes with contaminants from outgassing or residual leaks. To avoid the build-up of contaminants, both the boil-off gas and the liquid are continuously recirculated through the purification system. Schematics of experiment cryogenics systems are shown in [274, 276, 279]. While reconstructed tracks eventually determine the argon quality, so-called 'purity monitors', double-gridded ionization chambers, are often installed to give rapid feedback on the purity of the liquid [279].

Another potential contaminant is environmental nitrogen. This does not affect the free electron lifetime at levels up to many ppm but it does affect light production [267] and transmission [291] at the few ppm level.

35.7.3 *Charge and Light Signals*

Figure 35.22 (left) shows how the electron and scintillation yields for a minimum ionizing particle (m.i.p.) change with electric field. The free electron yield from the passage of a charged particle can be calculated from 'W_{el}' = 23.6 eV [256], the energy deposit that generates one ion-electron pair, the dE/dx of the particle, and 'R' the (unfortunately labeled) fraction of electrons that escape recombination - see figure 35.22 (left). Measurements of electron yield have been made at various electric fields and at different ionization densities [292–296] and show good consistency. Of the models proposed to predict recombination [297, 298], none is fully successful; the so-called 'box model' [299] which considers the situation of mobile electrons and stationary ions makes more realistic assumptions than other models and it is commonly used [300]. The data from [295] which are some of the most comprehensive are described by the form $R = \frac{0.8}{(1+0.049(dE/dx)/\mathcal{E})}$ where dE/dx is in MeV/cm and $\mathcal{E}$ in kV/cm. At a drift field of 500 V/cm, The recombination factor R for a minimum ionizing particle is 70%. A comprehensive summary and analysis of charge yield is given in [301].

The movement of the free electron charge towards the charge sensors is characterized by the drift velocity, the charge loss due to impurities, and the diffusion. The drift velocity depends on the strength of the electric field and slightly on the argon temperature (see table 35.9); a measurement of drift velocity vs electric field from [302] with a fit from [259] is shown in 35.22 (right). At an electric field of 500 V/cm, the drift velocity is 1.55 m/ms at 89 K. The charge loss depends on the purity of the liquid. For a drift of duration, t, the fraction of charge that survives to the sense electrodes is $e^{-t/\tau}$ where τ is the electron lifetime. Values of τ exceeding tens of ms have been achieved [303–305]. Diffusion broadens the charge distribution as it travels to the sensor. The diffusion coefficient, D, defines the contribution to the spatial distribution of the charge at the sensor from diffusion after a drift of time, t, via $\sigma_D^2 = 2Dt$. Several measurements of the longitudinal diffusion component, D_L, have been made with a typical value around 0.4 mm^2/ms [294, 306–308]. For a 3 ms drift, this gives a contribution of $(0.4 \cdot 6)^{1/2}$ mm, $\sim$ 1.5 mm, to the spread of the charge.

The scintillation light comes from the decay of excited argon dimers, Ar_2^*, (excimers) produced through direct excitation and through recombination of ionized argon ions and electrons [309]. The contribution of the latter process is reduced in the presence of an electric field as shown in figure 35.22, (left). The excimer is produced either in a singlet ('allowed' decay) or in a triplet spin state ('forbidden' (spin-flip) decay), with lifetimes of 6 ns and 1.5 μs respectively. The states are almost degenerate and photons are emitted, somewhat inconveniently [310], in the VUV with a spectrum peaked at 128 nm with a ±8 nm (FWHM) spread [262]. The relative populations of the two states depends on the ionization density; typically 1:3 (singlet:triplet) for minimum ionizing and 3:1 for highly ionizing nuclear fragments [266]. The long life-

time of the triplet state makes it sensitive to quenching impurities such as nitrogen or oxygen to which the excitation energy of the dimer can be transferred without the subsequent emission of a visible photon [267, 311].

The propagation of the scintillation is affected by two processes: absorption and Rayleigh scattering. While the large Stokes shift [312] makes pure LAr transparent to its own scintillation light, methane at the few ppb level [313] and nitrogen at the few ppm [291] level lead to light absorption. Rayleigh scattering increases the effective travel distance of photons between their production point and their detection and for detectors where the distance between origin and detection covers a range of many meters, the short Rayleigh scattering length for argon scintillation has a serious effect on the uniformity of detection. In this situation, the long lifetime of the triplet state can be exploited by the use of dopants to which the argon dimers can transfer their excitation energy with subsequent photon emission. Xenon, where almost complete transfer of the long-lived state energy is achieved at a concentration of 10's of ppm (mass), is a leading candidate. [314, 315].

35.7.4 *LAr TPC topologies*

Currently operating LAr-TPC detectors come in a range of sizes but the basic form of a cathode and field cage generating a field which drives the ionization electrons to planes of charge sensors at ground potential is universal. A standard criterion is to make the TPC drift as long as considered possible to maximize the detector mass for a given channel count; this can result in a single drift volume; two drift volumes with a common cathode, or multiple drift volumes with multiple common cathodes. An exception is the DUNE near detector TPC; it is segmented into many small TPCs to help resolve the large interaction rate [316].

The drift field is produced by a planar cathode at -HV, a graded field-cage surrounding the active volume, and the sensing electrodes at a potential near ground which form the anode. The field cage is designed to produce a uniform electric field throughout the drift region although for detectors at surface, the slow-moving positive ions generated by the flux of cosmic rays distort the field, particularly for TPCs with long drift [301, 305, 317–319]. Particular challenges in the drift field system are the feed-through [274, 320] that brings the voltage from the HV supply outside the cryostat to the cathode (the cathode can sit at negative voltages up to 300 kV), avoiding damage to the electronics from a potential cathode discharge [279], and ensuring the integrity of the field-cage resistor chain [321]. Avoiding discharge and current draw in a medium chosen because it allows electron flow is possibly the hardest challenge in the technology.

The schematics in figure 35.23 shows the sensor arrangement using vertical planes of wires as sense electrodes and a horizontal electric field. The sense planes are perpendicular to the drift direction and can be arranged in a stack with the wires in each plane oriented at a different angle. While the schematic shows three planes, in principle only two are needed; however three views are useful in the 3D reconstruction procedures to remove ambiguities in the hit associations and in case of dead or noisy channels. The wire-pitch, p, is a few mm and the plane spacing is similar. As indicated in figure 35.23, the planes are biased such that all field lines from the drift region pass through the intermediate planes and terminate on the final plane as shown in 35.23. (The condition for transparency across one plane is derived in [322].) The drift electrons follow the field lines, inducing bi-polar current pulses on the first two planes, and terminate on the last one, the collection plane, producing a unipolar signal [323].

The raw signal rise and fall times are a few μs as determined by the electron drift velocity and the plane spacing, and any geometric effects from the track angles. The signals from each wire are recorded as wave-forms spanning the maximum drift time at typically 2 or 2.5 MHz sampling rate. The intersection of wires on different planes which record signals at the same time, and the drift time converted to a distance knowing the drift velocity give the position of the charge source.

The design of large (> kiloton) detectors faces an intrinsic electrical challenge in that long (> few m) cables from the sense electrodes to the first-stage amplifier will introduce an unacceptable amount of noise through their capacitance, and attempts to avoid such cables leads to impractical constraints on the charge sensor geometry; both of these are emphasized in [323]. To address this problem, CMOS based ASIC amplifiers that operate in the cold and can be placed next to the charge sensor (wire or strip or pixel) have been developed, their design rules and robustness validated, and successfully deployed [324,325]. The subsequent problem that individual feed-throughs for each signal in a detector with hundreds of thousands of channels complicate the cryostat structure and raise the specter of leaks has been resolved by the development of flash-ADC and signal multiplexers [326] that also operate in the liquid. These implementations have resulted in equivalent noise charge levels of a few hundred electrons [305, 327] to be compared with a charge yield for a m.i.p of 30000 e/MeV or, equivalently, 60000 e/cm. With such low noise, energy depositions well below 1 MeV on wires/pixels with 0.5 cm pitch or less are quite accessible.

Large LAr detectors usually contain a system to detect the primary scintillation light. These provide an event time for drift time measurement [328], a trigger [329, 330], calorimetry that can be independent of and complementary to the charge [305], and event position information [280]. Given the VUV nature of the scintillation, a wavelength shifter is typically used to move the light into the visible [310]. Photo-multiplier tubes that operate in liquid argon were developed under the ICARUS program [331], while some recent systems are based on Silicon Photo-Multipliers. This latter approach separates the light collection from the light-to-electrical signal transducer, and many designs for the first task are being pursued [279, 332, 333].

35.7.5 *Data Acquisition and event reconstruction*

For the operation of large mass LAr-TPCs, the recording and storage of large volumes of data from the digitised charge waveforms and scintillation light channels is a critical issue. For instance, in the DUNE experiment, the throughput will amount to 1.5 TB/s per detector module (10 kt fiducial mass). To cope with, data reduction strategies are typically applied [334], [335]: (1) channel by channel zero suppression applied to the digitised wave forms, (2) fast signals from photon detectors or from external sources (for instance a neutrino beam), to trigger the readout of the TPC over a limited, predefined time window. The trigger rate is tuned to match the throughput capabilities of the Data AcQuisition (DAQ). Recent advances in communication and computing technologies have reshaped the approach to DAQ for LAr-TPCs. It is now possible to readout the complete digitised data and process them online [336], [337], allowing to identify space-time Regions of Interest (RoI) where charge or light activity is detected. For the DUNE experiment, the data reduction could be in the order of 10^5. With this architecture, charge and photon detectors become truly complementary and their information can be combined online for high efficiency data filtering even for energy depositions at a few MeV scale.

The goals of LArTPC event reconstruction are to provide the building blocks necessary to perform physics analyses: reconstruct the event topology, particle identification and calorimetry. Generally, this proceeds in subsequent stages. (1) Signal Processing: the waveforms providing a measure of the charge deposited in the TPC as a function of time are conditioned to mitigate detector issues, suppress noise, deconvolve the detector/electronic response; this allows to produce hit objects - measurements of the drift time and charge deposited by tracks in the LAr active volume on any readout channel [338] [339] [340]. (2) Wire readout LArTPCs produce 2D images in drift time and coordinate transverse to the wire direction with, generally, 3 planes allowing for stereo imaging for 3D reconstruction. Pattern Recognition (PR) approaches are distinguished between those acting of the 2D images with matching of objects to build the 3D picture and those working in the 3D space directly. The common goal is to find and reconstruct tracks and showers, their common vertices and identify the event topology. An example of 2D to 3D PR is the Pandora package [341]. An example of a pure 3D approach is the WireCell package [342]. Recent efforts in PR aim at employing sophisticated machine learning (ML) techniques. In

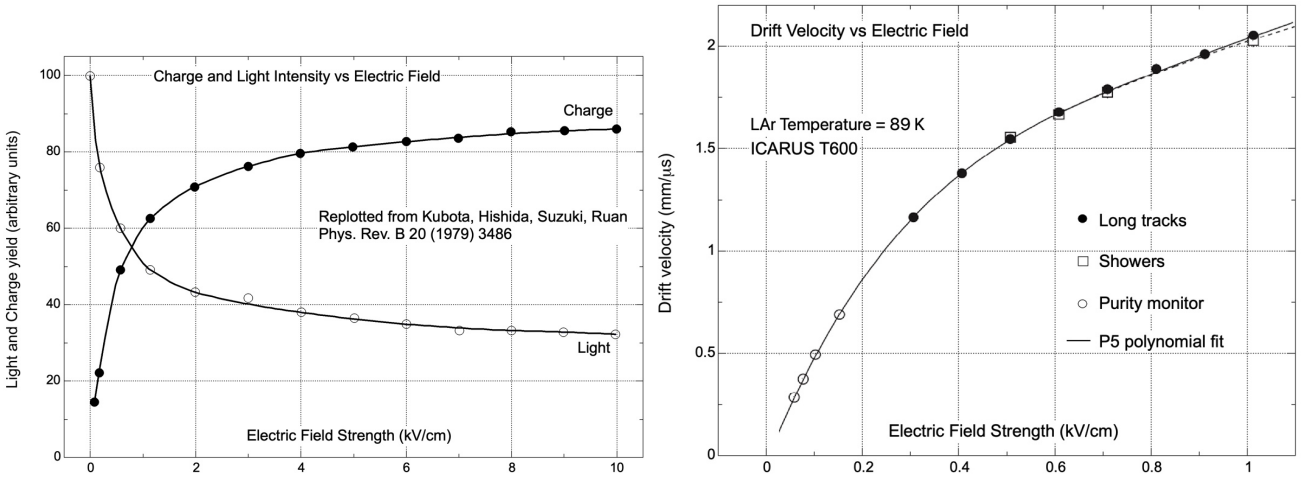

Figure 35.22: (*left*) the form of the light yield and the charge yield vs electric field redrawn from [309]; (*right*) electron drift velocity vs electric field redrawn from [302].

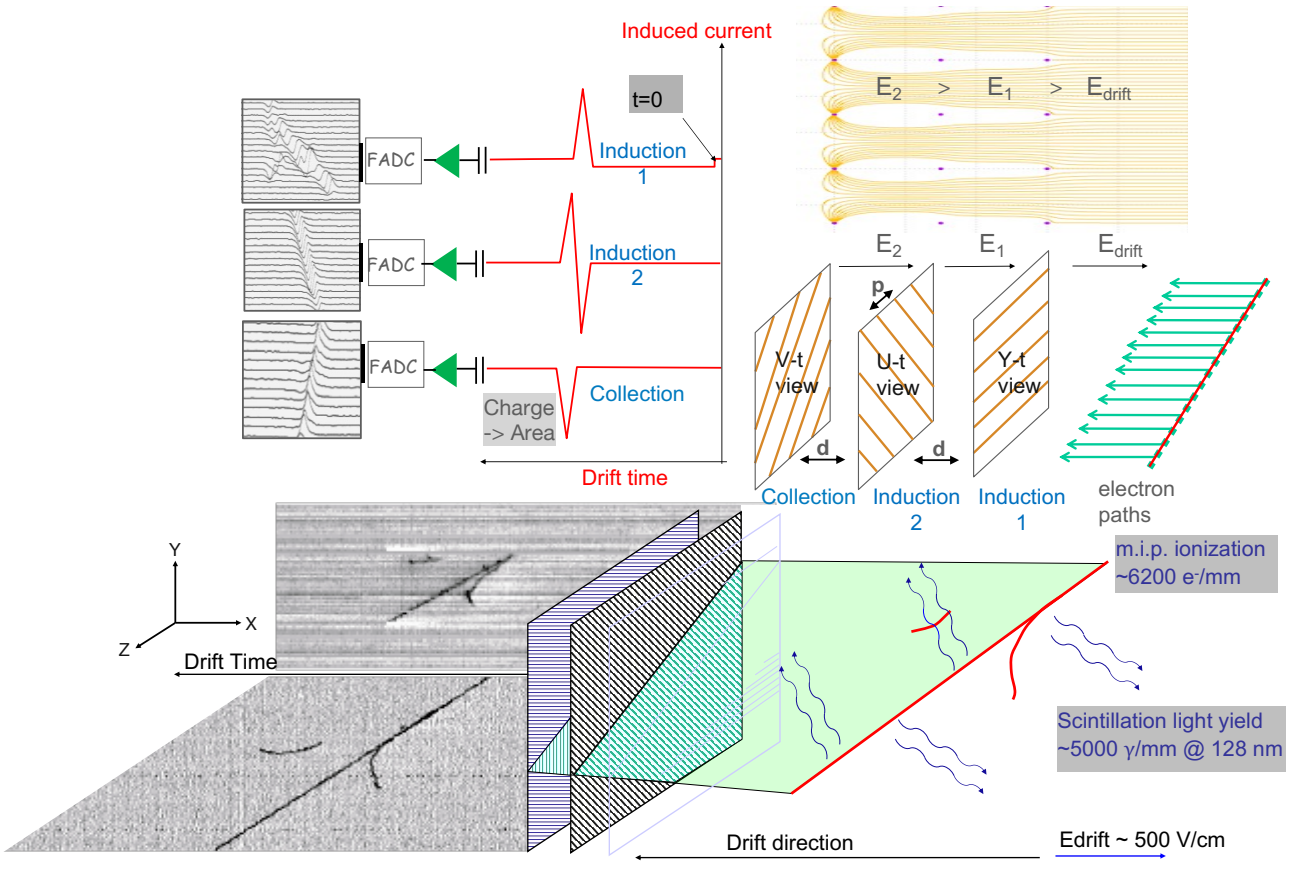

Figure 35.23: Schematic of an event in the ICARUS 3 t LAr TPC; *Top (from right to left)*: field lines from drift region to collection wires, electron flow & arrangement of wire-planes, signal shapes on the wires, and wave-forms from the continuous readout and digitization; *Bottom*: the passage of a muon. The gray scale on the track indicates the ionization density.

the 2D-to-3D approach convolution neural networks (CNNs) are applied on 2D images to identify objects which can be matched across planes [343] [344]. In the 3D approach CNNs, graph neural networks (GNNs), etc., are used in several steps to de-ghost the original 3D image and perform full event reconstruction including calorimetry, particle ID, etc. [345]. (3) The reconstructed tracks and showers are then passed to the calorimetry and particle ID modules. These modules utilize the charge deposition per unit length, after calibrations, to compute track and/or shower energy and particle identification [346].

35.7.6 *Developments*

The successful operation [347] of the ICARUS T600 TPC served as clear demonstration of the feasibility of the liquid argon TPC technology on a massive scale. Since this milestone, the liquid argon TPC community has expanded and the technology has continued to evolve. Notable developments include in-liquid electronics, the adoption of Silicon Photo-Multipliers and new light collection technologies, the use of dopants in the argon to improve the light performance, improved techniques for wavelength shifting, the adoption of a cryostat technology which permits detector masses of tens of kilotons and, in a major change to the standard single-phase topology, the implementation of pixelated readout to replace projective geometry in busy environments [348]. Technical R&D is continuing; as examples, the vertical-drift single-phase design for the second DUNE far-detector that uses strips on perforated printed circuit boards as charge sensors [349], a dual-phase TPC readout [350] using fast cameras to read out the scintillation light produced in the gas region in place of a charge readout; a light detection system powered and readout using optical fiber allowing the readout to operate at any potential and therefore anywhere in the TPC, and efforts to build up the HV directly in the liquid argon with a voltage multiplier (Greinacher design) [351].

An abundance of data from recent experiments is encouraging insights into the liquid argon medium as in [301,352] and revealing new phenomena. For a taste, see [353]. The ground is fertile, busy, and full of opportunity.

35.8 Semiconductor detectors

Revised August 2023 by N. Wermes (Bonn U.).

Semiconductor detectors provide outstanding detection opportunities in terms of position, energy and also time resolution, often in combination. In accelerator experiments, they are most widely used as position-sensing devices, *e.g.* in tracking detectors, or as photodetectors (Sec. 35.2), for example in calorimeters (Sec. 35.10) or in imaging Cherenkov detectors (Sec. 35.5). In recent years also precise time measurement ($\mathcal{O}$(10–30 ps)) with silicon detectors has come into the focus of development. When comparing semiconductor detectors particularly with gaseous detectors, the main features are high density and low ionisation threshold, providing in high resistivity substrates comparatively large signals even without intrinsic amplification. Silicon detectors with active layers only 100–300 µm thick provide adequately large and fast signals on a typical time scale[4] of 10–50 ns. Challenges are the purity of the semiconductor material, characterised by its mobility-lifetime ($\mu\tau$) product, and its radiation resistance. The development of modern semiconductor detectors is strongly interconnected with integrated circuit technology. Microprocessing and micro-electronics technologies enable fabrication of high-density micron-scale electrodes on large wafers (6–8 in ≈ 15–20 cm diameter for sensor wafers) and allow for high-density amplification and readout circuits connected to them (chip wafer sizes are up to 12 in ≈ 30 cm with typical reticles of 26×33 mm^2).

Some important material properties of common semiconductors used as detectors are summarised in Tab. 35.10. While for particle tracking the excellent position resolution is the main (but not the only) interest, high stopping power and high energy resolution are key parameters in X-ray, gamma-ray, and β spectroscopy, for example in neutrinoless double-beta decay searches. Due to its small bandgap, germanium excels in energy resolution but needs to be operated at very low temperatures (liq. N_2) to reduce thermally generated reverse bias current. Besides Ge, also GaAs, CdTe and CdZnTe (CZT) feature high atomic numbers and hence much higher stopping power and shorter absorption length which is important, especially for X-ray detection. Diamond, fabricated by chemical vapour deposition (CVD) and strictly speaking classified as an insulator with a large bandgap (Tab. 35.10), features low Z and large radiation length X_0. Thanks to its radiation hardness (Sec. 35.8.5) it is used for particle detection in dedicated applications, especially in zones with high particle flux (see *e.g.* [354] and references therein).

Materials R&D for radiation sensors extends to other bulk semiconductors as well, for example, ZnS, SiC, GaN or InP, and also to new material structures and metamaterials. Examples are semiconductor Quantum Dots, realised by nanometer-sized semiconductor "particles" embedded in a semiconductor bulk, or graphene, which – as a zero bandgap 2D material – features extraordinarily high conductivity (electrical and thermal) as well as outstanding photonic properties. A bandgap can be introduced by employing doped bi- or multi-layer graphene structures, thus rendering transistor and sensor realisations possible. The interested reader is referred to references [355] or [356], for example.

Operating usually without intrinsic amplification, semiconductor detectors crucially depend on low-noise electronics (see Sec. 35.9), so the detection sensitivity is determined largely by signal charge and input capacitance. Reviews of semiconductor detectors and electronics can be found for example in Refs. [1, 8, 357–359]

35.8.1 *Signal generation in semiconductors*

35.8.1.1 *Creation of charges*

Semiconductor detectors are solid-state ionisation chambers. Absorbed energy forms electron-hole (e-h) pairs, *i.e.* negative and positive charge carriers which—when moving in an applied electric field—generate a signal current on the electrodes by electrostatic induction (see Sec. 35.8.1.2). For the signal charge carriers to (freely) drift in the electric field and to become detectable, semiconductors must feature small intrinsic charge-carrier densities (as existing for example in diamond and to some extent also in GaAs and CZT) or they must be depleted by reverse-bias junction configurations (as for Si, Ge or CdTe). In addition, they should feature low intrinsic density of defects which can act as trapping or generation/recombination centers (see Sec. 35.8.5).

The minimum energy required to form an e-h pair is the bandgap energy (1.12 eV in Si, 0.66 eV in Ge, 5.5 eV in diamond). However, impinging radiation or particles also release energy to lattice vibrations (phonons) such that the average energy for e-h pair creation is higher. In an "indirect" semiconductor like Si, the valence-band maximum is not at the same position in k-space (crystal-momentum space) as the conduction-band minimum and additional momentum transfer is required for a band transition to occur. Since the "direct" bandgap energy without k-transfer in Si is 3.4 eV, fewer-eV photons must receive momentum from lattice phonons. Because phonons are Bose-Einstein distributed the needed momentum kick causes a steep rise in photon absorption probability between 1.12 eV and about 3.4 eV. For larger energy deposits the average energy w_i needed to produce an e-h pair assumes a constant value of 3.65 eV at room temperature. For other semiconductors consult Tab. 35.10.

For minimum-ionising particles, the most probable charge deposition in a 300 µm thick silicon detector is about 3.7 fC (∼23 000 electrons). In tracking detectors, a particle's energy loss and scattering in the detector material should be minimal (large X_0), whereas, for energy spectroscopy, *e.g.* of X-ray photons, the stopping power should be maximised by choosing high-Z semiconductors[5]. A smaller bandgap (in fact a smaller w_i) leads to a larger signal per deposited energy and improves the energy resolution, but also (exponentially) increases thermally excited carrier generation. To cope with excessive leakage currents at room temperature, Ge diodes are typically operated at liquid nitrogen temperature (77 K). In pure Si at 300 K, the intrinsic carrier concentration

Table 35.10: Properties of some detector-relevant semiconductors; temperature-dependent quantities given at 300 K (from [1] and references therein).

Property	Si	Ge	GaAs	CdTe (CZT*)	Diamond
atomic number (Z)	14	32	31/33	48/(30)/52	6
density ρ (g/cm^3)	2.328	5.327	5.32	5.85	3.51
dielectric constant ϵ	11.9	16.0	13.1	10.2	5.7
semiconductor type	indirect	indirect	direct	direct	indirect
bandgap E_G (eV)	1.12	0.66	1.424	1.44(1.44–2.2)	5.5
intr. carrier density (cm^{-3})	1.09×10^{10}	2.4×10^{13}	2.1×10^{6}	10^7	≈ 0
radiation length X_0 (cm)	9.36	2.30	2.29	1.52	12.15
average energy w_i for (e/h) creation (eV)	3.65	2.96	4.35	4.43	13.1
mobility (cm^2/Vs)					
electrons μ_n	1450	3900	8500	1050	$\approx$1800†
holes μ_h	500	1800	400	90	$\approx$2300†
lifetime					
electrons τ_e	>100 µs	∼ms	1–10 ns	0.1–2 µs	$\approx$100 ns
holes τ_h	>100 µs	∼ms	20 ns	0.1–1 µs	$\approx$ 50 ns

*CZT = CdZnTe with the bandgap depending on the Cd to Zn ratio.
†Approximate averages. Values quoted in the literature for the mobility in diamond vary strongly.

is $n_i \simeq 10^{10}\,\mathrm{cm}^{-3}$ (Tab. 35.10), corresponding to a resistivity in the order of $\rho \simeq (e\mu n)^{-1} \approx 400\,\mathrm{k\Omega\,cm}$. In reality, crystal imperfections and minute impurity concentrations limit Si carrier concentrations to about $10^{11}\,\mathrm{cm}^{-3}$ at 300 K ($\rho \approx 40\,\mathrm{k\Omega\,cm}$). In practice, wafer resistivities up to 20 $\mathrm{k\Omega\,cm}$ are available, with mass production ranging from 1 to 10 $\mathrm{k\Omega\,cm}$.

The energy released in a semiconductor is absorbed by electronic excitations (e/h) and lattice excitations (phonons) in an anti-correlated way. Therefore, for a fixed released energy E (for example of an X-ray photon), the variance in the number of charge carriers $N = E/w_i$ follows binomial statistics. Due to the energy constraint, this variance is reduced by the Fano factor F relative to Poisson statistics (F ≈ 0.1 in Si and Ge). Thus, $\sigma_N = \sqrt{FN}$ and the energy resolution is $\sigma_E/E = \sqrt{Fw_i/E}$. However, for semiconductors the measured fluctuations of a detected energy signal are usually dominated by electronic noise rather than by signal fluctuations. The electronic noise contribution depends much on the detector leakage current and the electrode capacitance as well as on pulse shaping (*i.e.* the shaping time) in the signal processing electronics (see Sec. 35.9).
